The formal definition of an integral and procedures for evaluating integrals are covered in classes on calculus. For our purposes here it is sufficient that you interpret an integral as simply the area under a curve. Appendix C provides some useful background information and analytic expressions for a few common integrals that we use in this book.

In this case, the ideal gas law is used to write this area as

$$w = -nRT \int_{V_1}^{V_2} \frac{1}{V} dV \quad [12.15]$$

since the temperature is constant. This integral is the area under a curve of  $1/V$  against  $V$  (a hyperbola) from  $V_1$  to  $V_2$ . The integral of  $1/x$  evaluated between the points  $x_1$  and  $x_2$  is equal to  $\ln(x_2/x_1)$ , where  $\ln$  is the natural logarithm function (see Table C.2). Because we know that  $\Delta U = 0$  for an isothermal process, we can find that  $q = -w$  for such a process. Combining this relation with the result of evaluating the integral in Eq. [12.15] leads us to conclude that  $\Delta H = 0$  for isothermal processes involving ideal gases.

$$\begin{aligned} w &= -nRT \ln \frac{V_2}{V_1} \\ q &= -w = nRT \ln \frac{V_2}{V_1} \\ \Delta U &= 0 \text{ because } \Delta T = 0 \\ \Delta H &= \Delta U + \Delta(PV) = \Delta U + \Delta(nRT) = 0 \end{aligned} \quad [12.16]$$

The enthalpy, like the internal energy, depends only on temperature for an ideal gas, so neither changes because the process was isothermal (constant temperature). Again, not that if a phase change or a chemical reaction occurs isothermally, you would *not* conclude that  $\Delta U = 0$ .

That  $V_2$  is greater than  $V_1$  implies that  $w < 0$  and  $q > 0$ ; in an isothermal expansion, the system does work against the surroundings and heat must be transferred into the system to maintain  $T$  constant. In an isothermal compression, the reverse is true: The surroundings do work on the system, and the system must then lose heat to the bath to maintain  $T$  constant.

**EXAMPLE 12.10**

Calculate the heat and the work associated with a process in which 5.00 mol of gas expands reversibly at constant temperature  $T = 298 \text{ K}$  from a pressure of 10.00 to 1.00 atm.

**Solution**

At constant  $T$  and  $n$ ,  $q$  and  $w$  are given by the equations just above Equation 12.16. Inserting the data for this example gives

$$\frac{V_2}{V_1} = \frac{P_1}{P_2} = \frac{10.0 \text{ atm}}{1.00 \text{ atm}} = 10.0$$

Thus,

$$\begin{aligned} w &= -(5.00 \text{ mol})(8.315 \text{ J K}^{-1} \text{ mol}^{-1})(298 \text{ K}) \ln 10.0 \\ &= -2.85 \times 10^4 \text{ J} = -28.5 \text{ kJ} \end{aligned}$$

$$q = -w = 28.5 \text{ kJ}$$

**Related Problems: 55, 56**

**12.7.2 Adiabatic Processes**

An **adiabatic process** is one in which there is no transfer of heat into or out of the system. This is accomplished by placing an adiabatic wall (thermal insulation) around the system to prevent heat flow.

$$q = 0$$

$$\Delta U = w$$

Consider a small adiabatic change. The volume changes by an amount  $dV$  and the temperature by an amount  $dT$ . Now  $U$  depends only on temperature for an ideal gas (no phase changes or chemical reactions), so

$$dU = n c_V dT$$

As always, the work is given by  $-P_{\text{ext}} dV$ . Setting these equal gives

$$n c_V dT = -P_{\text{ext}} dV$$

In other words, the temperature change  $dT$  is related to the volume change  $dV$  in such a process.

If the process is *reversible*, as well as adiabatic, so that  $P_{\text{ext}} \approx P$ , the ideal gas law can be used to write

$$n c_V dT = -P dV = -\frac{nRT}{V} dV$$

The equation is simplified by dividing both sides through by  $nT$ , making the left side depend only on  $T$  and the right side only on  $V$ :

$$\frac{c_V}{T} dT = -\frac{R}{V} dV$$

Suppose now that the change is not infinitesimal but large. How are temperature and volume related in this case? If a series of such infinitesimal changes is added together, the result is an integral of both sides of the equation from the initial state (specified by  $T_1$  and  $V_1$ ) to the final state (specified by  $T_2$  and  $V_2$ ):

$$c_V \int_{T_1}^{T_2} \frac{1}{T} dT = -R \int_{V_1}^{V_2} \frac{1}{V} dV$$

Here,  $c_V$  has been assumed to be approximately independent of  $T$  over the range from  $T_1$  to  $T_2$ . Evaluating the integrals gives

$$c_V \ln \frac{T_2}{T_1} = -R \ln \frac{V_2}{V_1} = R \ln \frac{V_1}{V_2}$$

A more useful form results from taking antilogarithms of both sides:

$$\left(\frac{T_2}{T_1}\right)^{c_V} = \left(\frac{V_1}{V_2}\right)^R = \left(\frac{V_1}{V_2}\right)^{c_P - c_V}$$

The last step used the fact that  $R = c_P - c_V$ . Thus,

$$\left(\frac{T_2}{T_1}\right) = \left(\frac{V_1}{V_2}\right)^{c_P/c_V - 1} = \left(\frac{V_1}{V_2}\right)^{\gamma - 1}$$

where  $\gamma = c_P/c_V$  is the ratio of specific heats. This can be rearranged to give

$$T_1 V_1^{\gamma - 1} = T_2 V_2^{\gamma - 1} \quad [12.17]$$

In many situations, the initial thermodynamic state and, therefore,  $T_1$  and  $V_1$  are known. If the final volume  $V_2$  is known,  $T_2$  can be calculated; if  $T_2$  is known,  $V_2$  can be calculated.

In some cases, only the final pressure,  $P_2$ , of an adiabatic process is known. In this case, the ideal gas law gives

$$\frac{P_1 V_1}{T_1} = \frac{P_2 V_2}{T_2}$$

Multiplying this by Equation 12.17 gives

$$P_1 V_1^\gamma = P_2 V_2^\gamma \quad [12.18]$$

This can be used to calculate  $V_2$  from a known  $P_2$ .

Once the pressure, temperature, and volume of the final state are known, the energy and enthalpy changes and the work done are straightforward to calculate:

$$\Delta U = n c_V (T_2 - T_1) = w \text{ (reversible adiabatic process for ideal gas)}$$

$$\Delta H = \Delta U + \Delta(PV) = \Delta U + (P_2 V_2 - P_1 V_1)$$

or more simply,

$$\Delta H = n c_P \Delta T$$

### EXAMPLE 12.11

Suppose 5.00 mol of an ideal monatomic gas at an initial temperature of 298 K and pressure of 10.0 atm is expanded adiabatically and reversibly until the pressure has decreased to 1.00 atm. Calculate the final volume and temperature, the energy and enthalpy changes, and the work done.

#### Solution

The initial volume is

$$V_1 = \frac{nRT_1}{P_1} = \frac{(5.00 \text{ mol})(0.08206 \text{ L atm K}^{-1} \text{ mol}^{-1})(298 \text{ K})}{(10.0 \text{ atm})} = 12.2 \text{ L}$$

and the heat capacity ratio for a monatomic gas is

$$\gamma = \frac{c_P}{c_V} = \frac{\frac{5}{2}R}{\frac{3}{2}R} = \frac{5}{3}$$

For a reversible adiabatic process,

$$\begin{aligned} \frac{P_1}{P_2} V_1^\gamma &= V_2^\gamma \\ (10.0)(12.2 \text{ L})^{5/3} &= V_2^{5/3} \\ V_2 &= (12.2 \text{ L})(10.0)^{3/5} = 48.7 \text{ L} \end{aligned}$$

(Continued)

The final temperature can now be calculated from the ideal gas law:

$$T_2 = \frac{P_2 V_2}{nR} = 119 \text{ K}$$

From this the work done and the energy change can be found,

$$\begin{aligned} w &= \Delta U = nc_V \Delta T \\ &= (5.00 \text{ mol})\left(\frac{5}{2} \times 8.315 \text{ J K}^{-1} \text{ mol}^{-1}\right)(119 \text{ K} - 298 \text{ K}) \\ &= -11,200 \text{ J} \end{aligned}$$

as well as the enthalpy change:

$$\begin{aligned} \Delta H &= nc_P \Delta T \\ &= (5.00 \text{ mol})\left(\frac{7}{2} \times 8.315 \text{ J K}^{-1} \text{ mol}^{-1}\right)(119 \text{ K} - 298 \text{ K}) \\ &= -18,600 \text{ J} \end{aligned}$$

**Related Problems: 57, 58**

**FIGURE 12.22** A comparison of reversible isothermal and adiabatic expansions. Using the technique shown in Figure 12.21, the adiabatic work is 40% of the isothermal work.

Figure 12.22 compares the adiabatic expansion of Example 12.11 to the isothermal expansion of Example 12.10. Note that the initial states were the same in the two cases, as were the final pressures. However, the final volume is larger by more than a factor of 2 for the isothermal expansion, and the work output for the adiabatic case is only 40% of the output from the isothermal expansion. Because  $\gamma > 1$ , the adiabatic line falls off more rapidly with increasing volume than the isothermal line. Because no heat is transferred in an adiabatic expansion, the work comes from the internal energy of the gas; thus, the temperature declines.

## 12.8 A DEEPER LOOK Distribution of Energy among Molecules

The kinetic molecular theory of gases (Section 9.5) relates the macroscopic properties of a gas to the structure of the constituent molecules, the forces between them, and their motions. Because the number of molecules in a sample

of gas is so incredibly large—28 g nitrogen contains  $6.02 \times 10^{23}$  molecules—we give up the idea of following the detailed motions of any one molecule and rely on a statistical description that gives the *probability* of finding a molecule in the gas at a certain position, with a certain speed, with a certain value of energy, and so on. Treating the molecules as point masses obeying classical mechanics and using simple statistical arguments, the kinetic theory shows that the temperature of the gas is proportional to the average kinetic energy per molecule. This relation not only provides a microscopic interpretation of the concept of temperature, but it also indicates the typical values of molecular kinetic energy that occur in a gas at a particular temperature.

Now we want to determine the relation between temperature and the energy involved in other kinds of molecular motions that depend on molecular structure, not just the translation of the molecule. This relation is provided by the *Boltzmann energy distribution*, which relies on the quantum description of molecular motions. This section defines the Boltzmann distribution and uses it to describe the vibrational energy of diatomic molecules in a gas at temperature  $T$ .

The Boltzmann energy distribution is one of the most widely used relations in the natural sciences, because it provides a reliable way to interpret experimental results in terms of molecular behavior. You should become skilled in its applications.

### 12.8.1 The Boltzmann Energy Distribution

We start with a model system in which gaseous molecules move around inside a container held at temperature  $T$ . The molecules collide with the container walls, but not with one another. We can achieve this condition by setting up the experiment with sufficiently low pressure in the system. But this time we assume that the molecules have quantum states described by a quantum number  $n$  and represented on an energy level diagram where the energy of each state is labeled  $\varepsilon_n$ . After the system has settled down to equilibrium, how many of the molecules are in their ground state? To what extent are the excited states populated? The answers depend on the probability that a molecule in the gas is in the quantum state  $n$ , which is given by the **Boltzmann energy distribution**:

$$P(n) = C \exp(-\varepsilon_n/k_B T) \quad [12.19]$$

where  $C$  is a normalization factor and  $k_B$  is Boltzmann's constant. This equation was derived for classical systems by Ludwig Boltzmann even before quantum mechanics had been invented. Max Planck used a version of the Boltzmann distribution in formulating his theory of blackbody radiation (see Section 4.2) to obtain the probability that his quantized oscillators would radiate energy when the blackbody was at temperature  $T$ . We do not derive the distribution, but illustrate its application and interpretation.

### 12.8.2 Vibrational Energy Distribution

We apply the Boltzmann distribution to describe the probability of finding molecules in each of the vibrational states in a sample of CO held at temperature  $T$ . We describe the vibrational motions using the harmonic oscillator model, for which the allowed energy levels are

$$\varepsilon_n = \left( n + \frac{1}{2} \right) h\nu$$

where  $n = 0, 1, 2, 3, \dots$  and the vibrational frequency is related to the force constant  $k$  by

$$\nu = \frac{1}{2\pi} \sqrt{\frac{k}{\mu}}$$

and  $\mu$  is the reduced mass. These equations define the energy level diagram, which has uniformly spaced levels separated by

$$h\nu = \frac{h}{2\pi} \sqrt{\frac{k}{\mu}} \quad [12.20]$$

We calculate the reduced mass of  $^{12}\text{C}^{16}\text{O}$  using the isotopic masses in Table 19.1 to be

$$\begin{aligned} \mu &= \frac{m_{\text{C}}m_{\text{O}}}{m_{\text{C}} + m_{\text{O}}} \\ &= \frac{(12.00)(15.99) \text{ amu}}{27.99} \left( \frac{1 \text{ g}}{6.02 \times 10^{23} \text{ amu}} \right) \left( \frac{1 \text{ kg}}{10^3 \text{ g}} \right) \\ \mu &= 1.14 \times 10^{-26} \text{ kg} \end{aligned}$$

The value of the force constant for CO is  $1902 \text{ N m}^{-1}$ , as measured in vibrational spectroscopy (see Section 20.3). The value of the energy level separation is then

$$\begin{aligned} h\nu &= \left( \frac{6.63 \times 10^{-34} \text{ J s}}{2\pi} \right) \left( \frac{1.902 \times 10^3 \text{ N m}^{-1}}{1.14 \times 10^{-26} \text{ kg}} \right)^{1/2} \\ h\nu &= 4.52 \times 10^{-20} \text{ J} \end{aligned}$$

The relative probability of finding molecules in the excited state  $n$  and in the ground state  $n = 0$  is given by

$$\frac{P(n)}{P(0)} = \frac{C \exp(-\varepsilon_n/k_{\text{B}}T)}{C \exp(-\varepsilon_0/k_{\text{B}}T)} = \exp(-[\varepsilon_n - \varepsilon_0]/k_{\text{B}}T) \quad [12.21]$$

Inserting the energy level expression for the harmonic oscillator gives

$$\frac{P(n)}{P(0)} = \exp\left(-\left[\left(n + \frac{1}{2}\right)h\nu - \frac{1}{2}h\nu\right]/k_{\text{B}}T\right) = \exp(-nh\nu/k_{\text{B}}T) \quad [12.22]$$

The relative populations of the first excited state  $n = 1$  and the ground state are determined by the ratio  $h\nu/k_{\text{B}}T$ . We know (Chapter 3, page 94) that  $h\nu$  is the quantum of vibrational energy needed to put a CO molecule in its first excited state, and we have calculated that value to be  $h\nu = 4.52 \times 10^{-20} \text{ J}$ . From Section 9.5 we know that the average kinetic energy of a molecule in the gas is  $(3/2)k_{\text{B}}T$ , which is  $(1/2)k_{\text{B}}T$  for each of the  $x$ ,  $y$ , and  $z$  directions of motion. Therefore, we interpret  $k_{\text{B}}T$  as a measure of the average energy available to each molecule in a gas at temperature  $T$ . So, the ratio  $h\nu/k_{\text{B}}T$  determines whether there is sufficient energy in the gas to put the molecules into excited states. At 300 K, the value of  $k_{\text{B}}T$  is  $4.14 \times 10^{-21} \text{ J}$ , which is a factor of 10 smaller than the vibrational quantum of CO. Inserting these numbers into Equation 12.22 gives the relative probability as  $3.03 \times 10^{-5}$ . This means that only 3 molecules in a group of 100,000 are in the first excited state at 300 K. (More precisely, the ratio between the number of molecules in the first excited state to the number of molecules in the ground vibrational state is 3/100,000.) At 1000 K, the value

of  $k_B T$  is  $1.38 \times 10^{-20}$  J, which is closer to the value of the CO vibrational quantum and gives a relative population of  $4.41 \times 10^{-2}$ .

This case study shows that CO molecules do not have significant vibrational energy unless the temperature is quite high. This happens because CO has a triple bond and, therefore, a large force constant ( $k = 1902 \text{ N m}^{-1}$ ). The correlation between force constant and bond order in diatomic molecules is explained by molecular orbital theory, and is summarized in Figure 6.21. Other diatomic molecules will have quantitatively different distributions, as determined by their structure.

### EXAMPLE 12.12

Calculate the population of the first and second vibrational excited states, relative to the ground state, for  $\text{Br}_2$  at  $T = 300$  K and 1000 K. For  $\text{Br}_2$ , the measured vibrational frequency is  $9.68 \times 10^{12} \text{ s}^{-1}$ . Interpret your results in relation to the chemical bond in  $\text{Br}_2$ .

#### Solution

Use Equation 12.22 with  $n = 1$  to obtain  $N_1/N_0$  and  $n = 2$  to obtain  $N_2/N_0$ . It is convenient to evaluate the important quantities before substituting into the equation.

Evaluate the vibrational energy of  $\text{Br}_2$ :

$$h\nu = (6.63 \times 10^{-34} \text{ J s})(9.68 \times 10^{12} \text{ s}^{-1}) = 6.42 \times 10^{-21} \text{ J}$$

Evaluate  $k_B T$  at 300 K and 1000 K:

$$k_B T = (300 \text{ K})(1.380 \times 10^{-23} \text{ J K}^{-1}) = 4.14 \times 10^{-21} \text{ J}$$

$$k_B T = (1000 \text{ K})(1.380 \times 10^{-23} \text{ J K}^{-1}) = 1.38 \times 10^{-20} \text{ J}$$

The population ratios at 300 K are:

$$\frac{P(1)}{P(0)} = \exp\left[-\frac{6.42 \times 10^{-21} \text{ J}}{4.14 \times 10^{-21} \text{ J}}\right] = 0.212$$

$$\frac{P(2)}{P(0)} = \exp\left[-\frac{2(6.42 \times 10^{-21} \text{ J})}{4.14 \times 10^{-21} \text{ J}}\right] = 0.045$$

The population ratios at 1000 K are:

$$\frac{P(1)}{P(0)} = \exp\left[-\frac{6.42 \times 10^{-21} \text{ J}}{1.38 \times 10^{-20} \text{ J}}\right] = 0.628$$

$$\frac{P(2)}{P(0)} = \exp\left[-\frac{2(6.42 \times 10^{-21} \text{ J})}{1.38 \times 10^{-20} \text{ J}}\right] = 0.395$$

The distribution for the first six states at 300 K and 1000 K is shown in Figure 12.23.

The quantized energy of vibration is much less for  $\text{Br}_2$  than for CO for two reasons: the single bond in  $\text{Br}_2$  has a much smaller force constant than the triple bond in CO, and the Br atoms are much more massive than C and O atoms.

**FIGURE 12.23** The potential energy curve and energy levels for the harmonic oscillator model for  $\text{Br}_2$ .

## CHAPTER SUMMARY

---

The central goal of this chapter is to define and measure the heat liberated or absorbed during a chemical reaction. We achieved that goal in Section 12.6 by introducing the enthalpy change of a reaction, which is measured by performing the reaction in a constant-pressure calorimeter. Tabulating data for reactions in which both products and reactants are in their standard states gives the standard enthalpy of reaction, which enables systematic comparison of the energy changes due to bond rearrangements in different reactions. The standard enthalpy change for a reaction is readily calculated from tables of the standard enthalpy of formation for the products and reactants. These basic tools of thermochemistry completely describe the energy transfers in chemical reactions.

The discussion of basic thermodynamics in Sections 12.1 through 12.4 can be viewed as background necessary for achieving the central goal. Sections 12.5 and 12.7 provide the molecular interpretation of these relations. Even so, this material is important in its own right and will be used repeatedly throughout the book. Similarly, the discussion of reversible isothermal and adiabatic processes in Section 12.6 provides background needed later in the book to calculate changes in state functions for irreversible processes.

## CONCEPTS AND SKILLS

---

### Section 12.1 – Systems, States, and Processes

*Give precise definitions for the terms thermodynamic system, open system, closed system, thermodynamic state, reversible process, irreversible process.*

- The system is that part of the universe of interest, for example, a chemical reaction, an engine, a human being.
- The surroundings are that part of the universe that exchanges matter and energy with the system during a process.
- The thermodynamic universe is the combination of the system and the surroundings for a particular process of interest; it is assumed to be closed and isolated.
- A closed system is one in which no exchange of matter between system and surroundings is permitted.
- An adiabatic system is one in which no exchange of heat between system and surroundings is permitted.
- A thermodynamic state is a condition in which all macroscopic properties of a system are determined by the external conditions imposed on the system (for example,  $n$ ,  $T$ , and  $P$ ).
- A thermodynamic system is in thermodynamic equilibrium if none of its macroscopic properties is changing over time. (**Note:** Some states that appear not to be changing may not be true equilibrium states because the changes are too slow to be observed, for example, diamond turning into graphite.)
- Properties of a system may either be independent of the amount of material present (intensive, like  $T$  and  $P$ ) or proportional to the quantity of material present (extensive, like internal energy and heat capacity).
- Processes can be either irreversible (a small change in the external condition will not reverse the course of the process) or reversible (a small change in the external condition will reverse the course of the process). The latter are idealizations, often called quasi-static, and would take an infinite amount of time to occur in a real sense.

Define and give examples of properties that are state functions of a system.

- A state function is a property whose value depends only on the current state of the system and not on the path by which that state was reached (examples include  $T$  and  $P$ ).
- A path-dependent quantity is one in which the value does depend on the details of the path taken, work and heat being the most common examples.

### Section 12.2 – The First Law of Thermodynamics: Internal Energy, Work, and Heat

Calculate the work done on an ideal gas when it is compressed reversibly (Problems 1–2).

- Work ( $w$ ) is force times displacement  $w = Fd$ . Perhaps the most important type of work in chemistry is pressure–volume work, in which a system either expands against or is compressed by the external pressure.
- We chose the sign convention so that if the work  $w = - \int_{i,\text{path}}^f P_{\text{ext}} dV$  is positive, work is done on the system.

Give a physical interpretation to the concept of heat, and calculate the change in temperature of a given quantity of a substance from its heat capacity and the amount of heat transferred to it (Problems 3–8).

- Heat transfer is measured by calorimetry.  $q_{\text{cal}} = mc_s\Delta T$  (if there are no phase changes or chemical reactions), where  $m$  is the mass of the heat-absorbing substance in the calorimeter (usually water) and  $c_s$  is the specific heat of the substance. The heat added to the system,  $q$ ,  $= -q_{\text{cal}}$  (treating the water in the calorimeter as the surroundings and using  $q_{\text{sys}} = -q_{\text{surr}}$ ).

State the first law of thermodynamics and give a physical interpretation (Problems 9–10).

- $\Delta U = q + w$ . The internal energy of a system is a state function. Although  $q$  and  $w$  are functions of the path, their sum is a state function. Heat transferred and work done must leave the energy of the thermodynamic universe unchanged.

$$q_{\text{sys}} = -q_{\text{surr}}$$

$$w_{\text{sys}} = -w_{\text{surr}}$$

$$\Delta U_{\text{sys}} = -\Delta U_{\text{surr}}$$

### Section 12.3 – Heat Capacity, Calorimetry, and Enthalpy

Calculate the final temperature reached when two substances of different mass, heat capacity, and temperature are placed in thermal contact (Problems 11–16).

- The heat  $q_2$  taken up by the cooler body is  $-q_1$ , the heat given up by the warmer body. This fact gives the equation

$$m_1c_{s1}(T_f - T_1) = -m_2c_{s2}(T_f - T_2)$$

which is solved for  $T_f$ .

### Section 12.4 – The First Law and Ideal Gas Processes

Calculate the amounts of heat and work and the change in the internal energy of an ideal gas during expansion and compression (Problems 17–22).

- Heat capacities of ideal monatomic gases

$$c_V (\text{ideal gas}) = (3/2)R$$

$$c_P = c_V + R = (5/2)R$$

- Heat and work for ideal gases: The calculations in section 12.4.2 associated with Figure 12.12 demonstrate that the values of  $q$  and  $w$  depend on the path over which a process occurs.

### Section 12.5 – Molecular Contributions to Internal Energy and Heat Capacity

Estimate the heat capacity for a gas based on its molecular structure (Problems 23–26).

- From the known structure of the gaseous molecule, we determine the number of degrees of freedom for rotational and vibrational motions, and add these to the three degrees of freedom for translation of the molecule. Assuming ideal gas behavior, we calculate  $c_V$  by adding up the contributions from all these degrees of freedom using the classical equipartition theorem. Each translation degree of freedom contributes  $R/2$ , each rotational degree of freedom contributes  $R/2$ , and each vibrational degree of freedom contributes  $R$ . We add one additional term  $R$  to convert  $c_V$  to  $c_P$ . The results are summarized and illustrated in Table 12.3.

### Section 12.6 – Thermochemistry

Calculate the energy and enthalpy changes for chemical reactions from the standard molar enthalpies of formation of reactants and products (Problems 39–46).

- The most useful thermochemical data are tables of the standard enthalpy of formation  $\Delta H_f^\circ$  for compounds, defined as the enthalpy of formation of a compound in its standard state from the elements in their standard states at 1 atm and 298.15 K.
- The change in standard state enthalpy for any reaction can be calculated from the standard state enthalpy of formation of its products and reactants as

$$\Delta H^\circ = \sum_{i=1}^{prod} n_i \Delta H_i^\circ - \sum_{j=1}^{react} n_j \Delta H_j^\circ$$

Use bond enthalpies to estimate enthalpies of formation of gaseous compounds (Problems 49–52).

- Bond enthalpy is the enthalpy change associated with breaking a chemical bond. It is based on the idea that bond enthalpy, like bond energy (see Chapter 3), is approximately independent of the rest of the molecule. Average bond enthalpies are tabulated from measurements over a broad range of molecules in which the same bond appears.

### Section 12.7 – Reversible Processes in Ideal Gases

Calculate the heat absorbed and work done by an ideal gas when it expands reversibly and either isothermally or adiabatically (Problems 55–58).

- **Isothermal processes:** In this case, heat will flow (in either direction) to offset the cost of  $PV$  work, whereas  $T$  remains constant.

$$dw = -PdV$$

$$w = -\int_{V_1}^{V_2} P dV$$

- For an ideal gas,  $P = nRT/V$ . Because  $T$  is constant it comes outside the integral to give

$$w = -nRT \int_{V_1}^{V_2} (1/V) dV$$

$$w = -nRT \ln(V_2/V_1)$$

$$q = +nRT \ln(V_2/V_1)$$

$$\Delta U = 0$$

$$\Delta H = 0$$

- Adiabatic processes:** No heat flows, so all of the energy comes from or goes into the internal energy of the system. The key steps are:

$$q = 0, \text{ so } \Delta U = w$$

$$nC_V dT = -P dV = -\frac{nRT}{V} dV \text{ rearranging, integrating, and "simplifying"}$$

gives  $P_1 V_1^\gamma = P_2 V_2^\gamma$ , where  $\gamma = c_P/c_V = 5/3$  for ideal gases.

- The important result is that the pressure decreases faster in an adiabatic expansion than in an isothermal expansion because there is no heat to enable the expansion work and keep the pressure higher.

### Section 12.8 – A Deeper Look . . . Distribution of Energy among Molecules

Use the Boltzmann distribution to determine the relative population of two quantum states in a gas at temperature  $T$  (Problems 59–64).

- The relative probability of finding molecules in the excited state  $n$  and in the ground state  $n = 0$  is given by

$$\frac{P(n)}{P(0)} = \frac{C \exp(-\epsilon_n/k_B T)}{C \exp(-\epsilon_0/k_B T)} = \exp(-[\epsilon_n - \epsilon_0]/k_B T)$$

FIGURE 12.25 A methanol-powered bus.

## CUMULATIVE EXERCISES

### Methanol as a Gasoline Substitute

Methanol ( $\text{CH}_3\text{OH}$ ) (Fig. 12.24) is used as a substitute for gasoline in certain high-performance vehicles (Fig. 12.25). To design engines that will run on methanol, we must understand its thermochemistry.

- The methanol in an automobile engine must be in the gas phase before it can react. Calculate the heat (in kilojoules) that must be added to 1.00 kg liquid methanol to increase its temperature from  $25.0^\circ\text{C}$  to its normal boiling point,  $65.0^\circ\text{C}$ . The molar heat capacity of liquid methanol is  $81.6 \text{ J K}^{-1} \text{ mol}^{-1}$ .
- Once the methanol has reached its boiling point, it must be vaporized. The molar enthalpy of vaporization for methanol is  $38 \text{ kJ mol}^{-1}$ . How much heat must be added to vaporize 1.00 kg methanol?
- Once it is in the vapor phase, the methanol can react with oxygen in the air according to

Use average bond enthalpies to estimate the enthalpy change in this reaction, for 1 mol of methanol reacting.

- (d) Use data from Appendix D to calculate the actual enthalpy change in this reaction, assuming it to be the same at 65°C as at 25°C.
- (e) Calculate the heat released when 1.00 kg gaseous methanol is burned in air at constant pressure. Use the more accurate result of part (d), rather than that of part (c).
- (f) Calculate the *difference* between the change in enthalpy and the change in internal energy when 1.00 kg gaseous methanol is oxidized to gaseous CO<sub>2</sub> and H<sub>2</sub>O at 65°C.
- (g) Suppose now that the methanol is burned inside the cylinder of an automobile. Taking the radius of the cylinder to be 4.0 cm and the distance moved by the piston during one stroke to be 12 cm, calculate the work done on the gas per stroke as it expands against an external pressure of 1.00 atm. Express your answer in liter-atmospheres and in joules.

### Answers

- (a) 102 kJ  
 (b)  $1.2 \times 10^3$  kJ  
 (c) -508 kJ  
 (d) -676.49 kJ  
 (e)  $2.11 \times 10^4$  kJ  
 (f)  $\Delta H - \Delta U = 43.9$  kJ  
 (g)  $-0.60$  L atm = -61 J

## PROBLEMS

Answers to problems whose numbers are red appear in Appendix G. Problems that are more challenging are indicated with asterisks.

### 12.2 The First Law of Thermodynamics: Internal Energy, Work, and Heat

- Some nitrogen for use in synthesizing ammonia is heated slowly, maintaining the external pressure close to the internal pressure of 50.0 atm, until its volume has increased from 542 to 974 L. Calculate the work done on the nitrogen as it is heated, and express it in joules.
- The gas mixture inside one of the cylinders of an automobile engine expands against a constant external pressure of 0.98 atm, from an initial volume of 150 mL (at the end of the compression stroke) to a final volume of 800 mL. Calculate the work done on the gas mixture during this process, and express it in joules.
- When a ball of mass  $m$  is dropped through a height difference  $\Delta b$ , its potential energy changes by the amount  $mg \Delta b$ , where  $g$  is the acceleration of gravity, equal to  $9.81 \text{ m s}^{-2}$ . Suppose that when the ball hits the ground, all that energy is converted to heat, increasing the temperature of the ball. If the specific heat capacity of the material in the ball is  $0.850 \text{ J K}^{-1} \text{ g}^{-1}$ , calculate the height from which the ball must be dropped to increase the temperature of the ball by  $1.00^\circ\text{C}$ .
- During his honeymoon in Switzerland, James Joule is said to have used a thermometer to measure the temperature difference between the water at the top and at the bottom of a waterfall. Take the height of the waterfall to be  $\Delta b$  and the acceleration of gravity,  $g$ , to be  $9.81 \text{ m s}^{-2}$ . Assuming that all the potential energy change  $mg \Delta b$  of a mass  $m$  of water is used to heat that water by the time it reaches the bottom, calculate the temperature difference between the top and the bottom of a waterfall 100 meters high. Take the specific heat capacity of water to be  $4.18 \text{ J K}^{-1} \text{ g}^{-1}$ .
- The specific heat capacities of Li(s), Na(s), K(s), Rb(s), and Cs(s) at 25°C are 3.57, 1.23, 0.756, 0.363, and  $0.242 \text{ J K}^{-1} \text{ g}^{-1}$ , respectively. Compute the molar heat capacities of these elements and identify any periodic trend. If there is a trend, use it to predict the molar heat capacity of francium, Fr(s).

- The specific heat capacities of  $F_2(g)$ ,  $Cl_2(g)$ ,  $Br_2(g)$ , and  $I_2(g)$  are 0.824, 0.478, 0.225, and  $0.145 \text{ J K}^{-1} \text{ g}^{-1}$ , respectively. Compute the molar heat capacities of these elements and identify any periodic trend. If there is a trend, use it to predict the molar heat capacity of astatine,  $At_2(g)$ .
- The specific heat capacities of the metals nickel, zinc, rhodium, tungsten, gold, and uranium at  $25^\circ\text{C}$  are 0.444, 0.388, 0.243, 0.132, 0.129, and  $0.116 \text{ J K}^{-1} \text{ g}^{-1}$ , respectively. Calculate the molar heat capacities of these six metals. Note how closely the molar heat capacities for these metals, which were selected at random, cluster about a value of  $25 \text{ J K}^{-1} \text{ mol}^{-1}$ . The rule of Dulong and Petit states that the molar heat capacities of the metallic elements are approximately  $25 \text{ J K}^{-1} \text{ mol}^{-1}$ .
- Use the empirical rule of Dulong and Petit stated in Problem 7 to estimate the specific heat capacities of vanadium, gallium, and silver.
- A chemical system is sealed in a strong, rigid container at room temperature, and then heated vigorously.
  - State whether  $\Delta U$ ,  $q$ , and  $w$  of the system are positive, negative, or zero during the heating process.
  - Next, the container is cooled to its original temperature. Determine the signs of  $\Delta U$ ,  $q$ , and  $w$  for the cooling process.
  - Designate heating as step 1 and cooling as step 2. Determine the signs of  $(\Delta U_1 + \Delta U_2)$ ,  $(q_1 + q_2)$ , and  $(w_1 + w_2)$ , if possible.
- A battery harnesses a chemical reaction to extract energy in the form of useful electrical work.
  - A certain battery runs a toy truck and becomes partially discharged. In the process, it performs a total of 117.0 J of work on its immediate surroundings. It also gives off 3.0 J of heat, which the surroundings absorb. No other work or heat is exchanged with the surroundings. Compute  $q$ ,  $w$ , and  $\Delta U$  of the battery, making sure each quantity has the proper sign.
  - The same battery is now recharged exactly to its original condition. This requires 210.0 J of electrical work from an outside generator. Determine  $q$  for the battery in this process. Explain why  $q$  has the sign that it does.
- Very early in the study of the nature of heat it was observed that if two bodies of equal mass but different temperatures are placed in thermal contact, their specific heat capacities depend inversely on the change in temperature each undergoes on reaching its final temperature. Write a mathematical equation in modern notation to express this fact.
- Iron pellets with total mass 17.0 g at a temperature of  $92.0^\circ\text{C}$  are mixed in an insulated container with 17.0 g water at a temperature of  $20.0^\circ\text{C}$ . The specific heat capacity of water is 10 times greater than that of iron. What is the final temperature inside the container?
- In their *Memoir on Heat*, published in 1783, Lavoisier and Laplace reported, "The heat necessary to melt ice is equal to three quarters of the heat that can raise the same mass of water from the temperature of the melting ice to that of boiling water" (English translation). Use this 18th-century observation to compute the amount of heat (in joules) needed to melt 1.00 g ice. Assume that heating 1.00 g water requires 4.18 J of heat for each  $1.00^\circ\text{C}$  throughout the range from  $0^\circ\text{C}$  to  $100^\circ\text{C}$ .
- Galen, the great physician of antiquity, suggested scaling temperature from a reference point defined by mixing equal masses of ice and boiling water in an insulated container. Imagine that this is done with the ice at  $0.00^\circ\text{C}$  and the water at  $100.0^\circ\text{C}$ . Assume that the heat capacity of the container is negligible, and that it takes 333.4 J of heat to melt 1.000 g ice at  $0.00^\circ\text{C}$  to water at  $0.00^\circ\text{C}$ . Compute Galen's reference temperature in degrees Celsius.

## 12.4 The First Law and Ideal Gas Processes

- If 0.500 mol neon at 1.00 atm and 273 K expands against a constant external pressure of 0.100 atm until the gas pressure reaches 0.200 atm and the temperature reaches 210 K, calculate the work done on the gas, the internal energy change, and the heat absorbed by the gas.
- Hydrogen behaves as an ideal gas at temperatures greater than 200 K and at pressures less than 50 atm. Suppose 6.00 mol hydrogen is initially contained in a 100-L vessel at a pressure of 2.00 atm. The average molar heat capacity of hydrogen at constant pressure,  $c_p$ , is  $29.3 \text{ J K}^{-1} \text{ mol}^{-1}$  in the temperature range of this problem. The gas is cooled reversibly at constant pressure from its initial state to a volume of 50.0 L. Calculate the following quantities for this process.
  - Temperature of the gas in the final state,  $T_2$
  - Work done on the gas,  $w$ , in joules
  - Internal energy change of the gas,  $\Delta U$ , in joules
  - Heat absorbed by the gas,  $q$ , in joules

## 12.3 Heat Capacity, Calorimetry, and Enthalpy

- Suppose 61.0 g hot metal, which is initially at  $120.0^\circ\text{C}$ , is plunged into 100.0 g water that is initially at  $20.00^\circ\text{C}$ . The metal cools down and the water heats up until they reach a common temperature of  $26.39^\circ\text{C}$ . Calculate the specific heat capacity of the metal, using  $4.18 \text{ J K}^{-1} \text{ g}^{-1}$  as the specific heat capacity of the water.
- A piece of zinc at  $20.0^\circ\text{C}$  that weighs 60.0 g is dropped into 200.0 g water at  $100.0^\circ\text{C}$ . The specific heat capacity of zinc is  $0.389 \text{ J K}^{-1} \text{ g}^{-1}$ , and that of water near  $100^\circ\text{C}$  is  $4.22 \text{ J K}^{-1} \text{ g}^{-1}$ . Calculate the final temperature reached by the zinc and the water.

19. Suppose 2.00 mol of an ideal, monatomic gas is initially at a pressure of 3.00 atm and a temperature  $T = 350$  K. It is expanded *irreversibly* and *adiabatically* ( $q = 0$ ) against a constant external pressure of 1.00 atm until the volume has doubled.
- Calculate the final volume.
  - Calculate  $w$ ,  $q$ , and  $\Delta U$  for this process, in joules.
  - Calculate the final temperature of the gas.
20. Consider the free, isothermal (constant  $T$ ) expansion of an ideal gas. “Free” means that the external force is zero, perhaps because a stopcock has been opened and the gas is allowed to expand into a vacuum. Calculate  $\Delta U$  for this irreversible process. Show that  $q = 0$ , so that the expansion is also adiabatic ( $q = 0$ ) for an ideal gas. This is analogous to a classic experiment first performed by Joule.
21. If 6.00 mol argon in a 100-L vessel initially at 300 K is compressed adiabatically ( $q = 0$ ) and irreversibly until a final temperature of 450 K is reached, calculate the energy change of the gas, the heat added to the gas, and the work done on the gas.
22. A gas expands against a constant external pressure of 2.00 atm until its volume has increased from 6.00 to 10.00 L. During this process, it absorbs 500 J of heat from the surroundings.
- Calculate the energy change of the gas,  $\Delta U$ .
  - Calculate the work,  $w$ , done on the gas in an irreversible adiabatic ( $q = 0$ ) process connecting the same initial and final states.

## 12.5 Molecular Contributions to Internal Energy and Heat Capacity

23. Calculate the value of  $c_p$  at 298 K and 1 atm pressure predicted for  $I_2(g)$  and  $HI(g)$  by the classical equipartition theorem. Compare the predicted results with the experimental results (see Appendix D) and calculate the percent of the measured value that arises from vibrational motions.
24. Calculate the value of  $c_p$  at 298 K and 1 atm pressure predicted for  $CH_4(g)$  and  $C_2H_4(g)$  by the classical equipartition theorem. Compare the predicted results with the experimental results (see Appendix D) and calculate the percent of the measured value that arises from vibrational motions.
25. (a) Calculate the change in enthalpy when 2.00 moles of argon is heated from 298 K to 573 K at constant pressure of 1 atmosphere.  
 (b) Calculate the change in enthalpy when 2.00 moles of ethylene  $C_2H_4$  is taken through the same process. In both cases assume the heat capacity values predicted by equipartition are valid through the temperature range stated.
26. (a) Calculate the change in enthalpy when 20.0 grams of aluminum metal is heated from 298 K to 573 K at constant pressure of 1 atm.  
 (b) Calculate the change in enthalpy when 20.0 grams of metallic lead is taken through the same process. In both cases assume the heat capacity values predicted by equipartition are valid through the temperature range stated.

## 12.6 Thermochemistry

27. For each of the following reactions, the enthalpy change written is that measured when the numbers of moles of reactants and products taking part in the reaction are as given by their coefficients in the equation. Calculate the enthalpy change when 1.00 *gram* of the underlined substance is consumed or produced.
- $4 \text{ Na}(s) + \text{O}_2(g) \longrightarrow 2 \underline{\text{Na}_2\text{O}}(s) \quad \Delta H = -828 \text{ kJ}$
  - $\text{CaMg}(\text{CO}_3)_2(s) \longrightarrow \text{CaO}(s) + \underline{\text{MgO}}(s) + 2 \text{ CO}_2(g) \quad \Delta H = +302 \text{ kJ}$
  - $\text{H}_2(g) + 2 \underline{\text{CO}}(g) \longrightarrow \text{H}_2\text{O}_2(\ell) + 2 \text{ C}(s) \quad \Delta H = +33.3 \text{ kJ}$
28. For each of the following reactions, the enthalpy change given is that measured when the numbers of moles of reactants and products taking part in the reaction are as given by their coefficients in the equation. Calculate the enthalpy change when 1.00 *gram* of the underlined substance is consumed or produced.
- $\text{Ca}(s) + \underline{\text{Br}_2}(\ell) \longrightarrow \text{CaBr}_2(s) \quad \Delta H = -683 \text{ kJ}$
  - $6 \text{ Fe}_2\text{O}_3(s) \longrightarrow 4 \underline{\text{Fe}_3\text{O}_4}(s) + \text{O}_2(g) \quad \Delta H = +472 \text{ kJ}$
  - $2 \underline{\text{NaHSO}_4}(s) \longrightarrow 2 \text{ NaOH}(s) + 2 \text{ SO}_2(g) + \text{O}_2(g) \quad \Delta H = +806 \text{ kJ}$
29. Liquid bromine dissolves readily in aqueous NaOH:
- $$\text{Br}_2(\ell) + 2 \text{ NaOH}(aq) \longrightarrow \text{NaBr}(aq) + \text{NaOBr}(aq) + \text{H}_2\text{O}(\ell)$$
- Suppose  $2.88 \times 10^{-3}$  mol of  $\text{Br}_2(\ell)$  is sealed in a glass capsule that is then immersed in a solution containing excess  $\text{NaOH}(aq)$ . The capsule is broken, the mixture is stirred, and a measured 121.3 J of heat evolves. In a separate experiment, simply breaking an empty capsule and stirring the solution in the same way evolves 2.34 J of heat. Compute the heat evolved as 1.00 mol  $\text{Br}_2(\ell)$  dissolves in excess  $\text{NaOH}(aq)$ .
30. A chemist mixes 1.00 g  $\text{CuCl}_2$  with an excess of  $(\text{NH}_4)_2\text{HPO}_4$  in dilute aqueous solution. He measures the evolution of 670 J of heat as the two substances react to give  $\text{Cu}_3(\text{PO}_4)_2(s)$ . Compute the  $\Delta H$  that would result from the reaction of 1.00 mol  $\text{CuCl}_2$  with an excess of  $(\text{NH}_4)_2\text{HPO}_4$ .
31. Calculate the enthalpy change when 2.38 g carbon monoxide (CO) vaporizes at its normal boiling point. Use data from Table 12.2.

32. Molten sodium chloride is used for making elemental sodium and chlorine. Suppose the electrical power to a vat containing 56.2 kg molten sodium chloride is cut off and the salt crystallizes (without changing its temperature). Calculate the enthalpy change, using data from Table 12.4.

33. Suppose an ice cube weighing 36.0 g at a temperature of  $-10^{\circ}\text{C}$  is placed in 360 g water at a temperature of  $20^{\circ}\text{C}$ . Calculate the temperature after thermal equilibrium is reached, assuming no heat loss to the surroundings. The enthalpy of fusion of ice is  $\Delta H_{\text{fus}} = 6.007 \text{ kJ mol}^{-1}$ , and the molar heat capacities  $c_p$  of ice and water are 38 and  $75 \text{ J K}^{-1} \text{ mol}^{-1}$ , respectively.

34. You have a supply of ice at  $0.0^{\circ}\text{C}$  and a glass containing 150 g water at  $25^{\circ}\text{C}$ . The enthalpy of fusion for ice is  $\Delta H_{\text{fus}} = 333 \text{ J g}^{-1}$ , and the specific heat capacity of water is  $4.18 \text{ J K}^{-1} \text{ g}^{-1}$ . How many grams of ice must be added to the glass (and melted) to reduce the temperature of the water to  $0^{\circ}\text{C}$ ?

35. The measured enthalpy change for burning ketene ( $\text{CH}_2\text{CO}$ )

is  $\Delta H_1 = -981.1 \text{ kJ}$  at  $25^{\circ}\text{C}$ . The enthalpy change for burning methane

is  $\Delta H_2 = -802.3 \text{ kJ}$  at  $25^{\circ}\text{C}$ . Calculate the enthalpy change at  $25^{\circ}\text{C}$  for the reaction

36. Given the following two reactions and corresponding enthalpy changes,

$$\Delta H = +520.9 \text{ kJ}$$

$$\Delta H = +461.05 \text{ kJ}$$

compute the  $\Delta H$  of the reaction

37. The enthalpy change to make diamond from graphite is  $1.88 \text{ kJ mol}^{-1}$ . Which gives off more heat when burned—a pound of diamonds or a pound of graphite? Explain.

38. The enthalpy change of combustion of monoclinic sulfur to  $\text{SO}_2(g)$  is  $-9.376 \text{ kJ g}^{-1}$ . Under the same conditions, the rhombic form of sulfur has an enthalpy change of combustion to  $\text{SO}_2(g)$  of  $-9.293 \text{ kJ g}^{-1}$ . Compute the  $\Delta H$  of the reaction

per gram of sulfur reacting.

39. Calculate the standard enthalpy change  $\Delta H^{\circ}$  at  $25^{\circ}\text{C}$  for the reaction

using the standard enthalpies of formation ( $\Delta H_f^{\circ}$ ) of reactants and products at  $25^{\circ}\text{C}$  from Appendix D.

40. Using the data in Appendix D, calculate  $\Delta H^{\circ}$  for each of the following processes:

41. Zinc is commonly found in nature in the form of the mineral sphalerite ( $\text{ZnS}$ ). A step in the smelting of zinc is the roasting of sphalerite with oxygen to produce zinc oxide:

(a) Calculate the standard enthalpy change  $\Delta H^{\circ}$  for this reaction, using data from Appendix D.

(b) Calculate the heat absorbed when 3.00 metric tons (1 metric ton =  $10^3 \text{ kg}$ ) of sphalerite is roasted under constant-pressure conditions.

42. The thermite process (see Fig. 12.16) is used for welding railway track together. In this reaction, aluminum reduces iron(III) oxide to metallic iron:

Igniting a small charge of barium peroxide mixed with aluminum triggers the reaction of a mixture of aluminum powder and iron(III) oxide; the molten iron produced flows into the space between the steel rails that are to be joined.

(a) Calculate the standard enthalpy change  $\Delta H^{\circ}$  for this reaction, using data from Appendix D.

(b) Calculate the heat given off when 3.21 g iron(III) oxide is reduced by aluminum at constant pressure.

43. The dissolution of calcium chloride in water

is used in first-aid hot packs. In these packs, an inner pouch containing the salt is broken, allowing the salt to dissolve in the surrounding water.

(a) Calculate the standard enthalpy change  $\Delta H^{\circ}$  for this reaction, using data from Appendix D.

(b) Suppose 20.0 g  $\text{CaCl}_2$  is dissolved in 0.100 L water at  $20.0^{\circ}\text{C}$ . Calculate the temperature reached by the solution, assuming it to be an ideal solution with a heat capacity close to that of 100 g pure water ( $418 \text{ J K}^{-1}$ ).

44. Ammonium nitrate dissolves in water according to the reaction

(a) Calculate the standard enthalpy change  $\Delta H^{\circ}$  for this reaction, using data from Appendix D.

(b) Suppose 15.0 g  $\text{NH}_4\text{NO}_3$  is dissolved in 0.100 L water at  $20.0^{\circ}\text{C}$ . Calculate the temperature reached by the solution, assuming it to be an ideal solution with a heat capacity close to that of 100 g pure water ( $418 \text{ J K}^{-1}$ ).

(c) From a comparison with the results of Problem 43, can you suggest a practical application of this dissolution reaction?

45. The standard enthalpy change of combustion [to  $\text{CO}_2(\text{g})$  and  $\text{H}_2\text{O}(\ell)$ ] at  $25^\circ\text{C}$  of the organic liquid cyclohexane,  $\text{C}_6\text{H}_{12}(\ell)$ , is  $-3923.7 \text{ kJ mol}^{-1}$ . Determine the  $\Delta H_f^\circ$  of  $\text{C}_6\text{H}_{12}(\ell)$ . Use data from Appendix D.
46. The standard enthalpy change of combustion [to  $\text{CO}_2(\text{g})$  and  $\text{H}_2\text{O}(\ell)$ ] at  $25^\circ\text{C}$  of the organic liquid cyclohexane,  $\text{C}_6\text{H}_{10}(\ell)$ , is  $-3731.7 \text{ kJ mol}^{-1}$ . Determine the  $\Delta H_f^\circ$  of  $\text{C}_6\text{H}_{10}(\ell)$ .
47. A sample of pure solid naphthalene ( $\text{C}_{10}\text{H}_8$ ) weighing  $0.6410 \text{ g}$  is burned completely with oxygen to  $\text{CO}_2(\text{g})$  and  $\text{H}_2\text{O}(\ell)$  in a constant-volume calorimeter at  $25^\circ\text{C}$ . The amount of heat evolved is observed to be  $25.79 \text{ kJ}$ .
- Write and balance the chemical equation for the combustion reaction.
  - Calculate the standard change in internal energy ( $\Delta U^\circ$ ) for the combustion of  $1.000 \text{ mol}$  naphthalene to  $\text{CO}_2(\text{g})$  and  $\text{H}_2\text{O}(\ell)$ .
  - Calculate the standard enthalpy change ( $\Delta H^\circ$ ) for the same reaction as in part (b).
  - Calculate the standard enthalpy of formation per mole of naphthalene, using data for the standard enthalpies of formation of  $\text{CO}_2(\text{g})$  and  $\text{H}_2\text{O}(\ell)$  from Appendix D.
48. A sample of solid benzoic acid ( $\text{C}_6\text{H}_5\text{COOH}$ ) that weighs  $0.800 \text{ g}$  is burned in an excess of oxygen to  $\text{CO}_2(\text{g})$  and  $\text{H}_2\text{O}(\ell)$  in a constant-volume calorimeter at  $25^\circ\text{C}$ . The temperature increase is observed to be  $2.15^\circ\text{C}$ . The heat capacity of the calorimeter and its contents is known to be  $9382 \text{ J K}^{-1}$ .
- Write and balance the equation for the combustion of benzoic acid.
  - Calculate the standard change in internal energy ( $\Delta U^\circ$ ) for the combustion of  $1.000 \text{ mol}$  benzoic acid to  $\text{CO}_2(\text{g})$  and  $\text{H}_2\text{O}(\ell)$  at  $25^\circ\text{C}$ .
  - Calculate the standard enthalpy change ( $\Delta H^\circ$ ) for the same reaction as in part (b).
  - Calculate the standard enthalpy of formation per mole of benzoic acid, using data for the standard enthalpies of formation of  $\text{CO}_2(\text{g})$  and  $\text{H}_2\text{O}(\ell)$  from Appendix D.
49. A second CFC used as a refrigerant and in aerosols (besides that discussed in Example 12.9) is  $\text{CCl}_3\text{F}$ . Use the atomization enthalpies and average bond enthalpies from Table 12.5 to estimate the standard enthalpy of formation ( $\Delta H_f^\circ$ ) of this compound in the gas phase.
50. The compound  $\text{CF}_3\text{CHCl}_2$  (with a  $\text{C}-\text{C}$  bond) has been proposed as a substitute for  $\text{CCl}_3\text{F}$  and  $\text{CCl}_2\text{F}_2$  because it decomposes more quickly in the atmosphere and is much less liable to reduce the concentration of ozone in the stratosphere. Use the atomization enthalpies and average bond enthalpies from Table 12.5 to estimate the standard enthalpy of formation ( $\Delta H_f^\circ$ ) of  $\text{CF}_3\text{CHCl}_2$  in the gas phase.

51. Propane has the structure  $\text{H}_3\text{C}-\text{CH}_2-\text{CH}_3$ . Use average bond enthalpies from Table 12.5 to estimate the change in enthalpy  $\Delta H^\circ$  for the reaction

52. Use average bond enthalpies from Table 12.5 to estimate the change in enthalpy  $\Delta H^\circ$  for the reaction

Refer to the molecular structures on page 109.

53. The following reaction

has a  $\Delta H$  close to zero. Sketch the Lewis structures of the four compounds, and explain why  $\Delta H$  is so small.

54. At  $381 \text{ K}$ , the following reaction takes place:

- (a) Offer an explanation for the very small  $\Delta H$  for this reaction for the known structures of the compounds

- (b) Explain why the small  $\Delta H$  in this reaction is evidence against

as the structure of  $\text{Hg}_2\text{Cl}_4(\text{g})$ .

## 12.7 Reversible Processes in Ideal Gases

55. If  $2.00 \text{ mol}$  of an ideal gas at  $25^\circ\text{C}$  expands isothermally and reversibly from  $9.00$  to  $36.00 \text{ L}$ , calculate the work done on the gas and the heat absorbed by the gas in the process. What are the changes in energy ( $\Delta U$ ) and in enthalpy ( $\Delta H$ ) of the gas in the process?
56. If  $54.0 \text{ g}$  argon at  $400 \text{ K}$  is compressed isothermally and reversibly from a pressure of  $1.50$  to  $4.00 \text{ atm}$ , calculate the work done on the gas and the heat absorbed by gas in the process. What are the changes in energy ( $\Delta U$ ) and in enthalpy ( $\Delta H$ ) of the gas?
57. Suppose  $2.00 \text{ mol}$  of a monatomic ideal gas ( $c_V = \frac{3}{2}R$ ) is expanded adiabatically and reversibly from a temperature  $T = 300 \text{ K}$ , where the volume of the system is  $20.0 \text{ L}$ , to a volume of  $60.0 \text{ L}$ . Calculate the final temperature of the gas, the work done on the gas, and the energy and enthalpy changes.
58. Suppose  $2.00 \text{ mol}$  of an ideal gas is contained in a heat-insulated cylinder with a moveable frictionless piston. Initially, the gas is at  $1.00 \text{ atm}$  and  $0^\circ\text{C}$ . The gas is compressed reversibly to  $2.00 \text{ atm}$ . The molar heat capacity at constant pressure,  $c_p$ , equals  $29.3 \text{ J K}^{-1} \text{ mol}^{-1}$ . Calculate the final temperature of the gas, the change in its internal energy,  $\Delta U$ , and the work done on the gas.

## 12.8 A Deeper Look . . . Distribution of Energy among Molecules

59. Calculate the relative populations of two quantum states separated by an energy of  $0.4 \times 10^{-21}$  J if the temperature is  $25^\circ\text{C}$ .
60. Calculate the relative populations of two quantum states separated by an energy of  $40 \times 10^{-21}$  J if the temperature is  $25^\circ\text{C}$ .
61. Estimate the ratio of the number of molecules in the first excited vibrational state of the molecule  $\text{N}_2$  to the number in the ground state, at a temperature of 450 K. The vibrational frequency of  $\text{N}_2$  is  $7.07 \times 10^{13} \text{ s}^{-1}$ .
62. The vibrational frequency of the  $\text{ICl}$  molecule is  $1.15 \times 10^{13} \text{ s}^{-1}$ . For every million ( $1.00 \times 10^6$ ) molecules in the ground vibrational state, how many will be in the first excited vibrational state at a temperature of 300 K?
63. The force constant for  $\text{HF}$  is  $966 \text{ N m}^{-1}$ . Using the harmonic oscillator model, calculate the relative population of the first excited state and the ground state at 300 K.
64. The force constant for  $\text{HBr}$  is  $412 \text{ N m}^{-1}$ . Using the harmonic oscillator model, calculate the relative population of the first excited state and the ground state at 300 K.

## ADDITIONAL PROBLEMS

65. At one time it was thought that the molar mass of indium was near  $76 \text{ g mol}^{-1}$ . By referring to the law of Dulong and Petit (see Problem 7), show how the measured specific heat of metallic indium,  $0.233 \text{ J K}^{-1} \text{ g}^{-1}$ , makes this value unlikely.
66. The following table shows how the specific heat at constant pressure of liquid helium changes with temperature. Note the sharp increase over this temperature range:
- | Temperature (K): |      |      |      |      |      |      |      |
|------------------|------|------|------|------|------|------|------|
| 1.80             | 1.85 | 1.90 | 1.95 | 2.00 | 2.05 | 2.10 | 2.15 |
- 
- | $c_p$ ( $\text{J K}^{-1} \text{ g}^{-1}$ ): |      |      |      |      |      |      |      |
|---|------|------|------|------|------|------|------|
| 2.81  | 3.26 | 3.79 | 4.42 | 5.18 | 6.16 | 7.51 | 9.35 |
- Estimate how much heat it takes at constant pressure to increase the temperature of  $1.00 \text{ g He}(\ell)$  from 1.8 to 2.15 K. (*Hint:* For each temperature interval of 0.05 K, take the average,  $c_p$ , as the sum of the values at the ends of the interval divided by 2.)
67. Imagine that  $2.00 \text{ mol}$  argon, confined by a moveable, frictionless piston in a cylinder at a pressure of  $1.00 \text{ atm}$  and a temperature of  $398 \text{ K}$ , is cooled to  $298 \text{ K}$ . Argon gas may be considered ideal, and its molar heat capacity at constant pressure is  $c_p = (5/2)R$ , where  $R = 8.315 \text{ J K}^{-1} \text{ mol}^{-1}$ . Calculate:
- The work done on the system,  $w$
  - The heat absorbed by the system,  $q$
  - The energy change of the system,  $\Delta U$
  - The enthalpy change of the system,  $\Delta H$
68. Suppose  $1.00 \text{ mol}$  ice at  $-30^\circ\text{C}$  is heated at atmospheric pressure until it is converted to steam at  $140^\circ\text{C}$ . Calculate  $q$ ,  $w$ ,  $\Delta H$ , and  $\Delta U$  for this process. For ice, water, and steam,  $c_p$  is 38, 75, and  $36 \text{ J K}^{-1} \text{ mol}^{-1}$ , respectively, and can be taken to be approximately independent of temperature.  $\Delta H_{\text{fus}}$  for ice is  $6.007 \text{ kJ mol}^{-1}$ , and  $\Delta H_{\text{vap}}$  for water is  $40.66 \text{ kJ mol}^{-1}$ . Use the ideal gas law for steam, and assume that the volume of  $1 \text{ mol}$  ice or water is negligible relative to that of  $1 \text{ mol}$  steam.
69. The gas inside a cylinder expands against a constant external pressure of  $1.00 \text{ atm}$  from a volume of  $5.00 \text{ L}$  to a volume of  $13.00 \text{ L}$ . In doing so, it turns a paddle immersed in  $1.00 \text{ L}$  water. Calculate the temperature increase of the water, assuming no loss of heat to the surroundings or frictional losses in the mechanism. Take the density of water to be  $1.00 \text{ g cm}^{-3}$  and its specific heat to be  $4.18 \text{ J K}^{-1} \text{ g}^{-1}$ .
70. Suppose  $1.000 \text{ mol}$  argon (assumed to be an ideal gas) is confined in a strong, rigid container of volume  $22.41 \text{ L}$  at  $273.15 \text{ K}$ . The system is heated until  $3.000 \text{ kJ}$  ( $3000 \text{ J}$ ) of heat has been added. The molar heat capacity of the gas does not change during the heating and equals  $12.47 \text{ J K}^{-1} \text{ mol}^{-1}$ .
- Calculate the original pressure inside the vessel (in atmospheres).
  - Determine  $q$  for the system during the heating process.
  - Determine  $w$  for the system during the heating process.
  - Compute the temperature of the gas after the heating, in degrees Celsius. Assume the container has zero heat capacity.
  - Compute the pressure (in atmospheres) inside the vessel after the heating.
  - Compute  $\Delta U$  of the gas during the heating process.
  - Compute  $\Delta H$  of the gas during the heating process.
  - The correct answer to part (g) exceeds  $3.000 \text{ kJ}$ . The increase in enthalpy (which at one time was misleadingly called the “heat content”) in this system exceeds the amount of heat actually added. Why is this not a violation of the law of conservation of energy?
71. When glucose, a sugar, reacts fully with oxygen, carbon dioxide and water are produced:
- $$\text{C}_6\text{H}_{12}\text{O}_6(\text{s}) + 6 \text{O}_2(\text{g}) \longrightarrow 6 \text{CO}_2(\text{g}) + 6 \text{H}_2\text{O}(\ell)$$
- $$\Delta H^\circ = -2820 \text{ kJ}$$
- Suppose a person weighing  $50 \text{ kg}$  (mostly water, with specific heat capacity  $4.18 \text{ J K}^{-1} \text{ g}^{-1}$ ) eats a candy bar containing  $14.3 \text{ g}$  glucose. If all the glucose reacted with oxygen and the heat produced were used entirely to increase the person’s body temperature, what temperature

increase would result? (In fact, most of the heat produced is lost to the surroundings before such a temperature increase occurs.)

72. In walking 1 km, you use about 100 kJ of energy. This energy comes from the oxidation of foods, which is about 30% efficient. How much energy do you save by walking 1 km instead of driving a car that gets 8.0 km L<sup>-1</sup> gasoline (19 miles/gal)? The density of gasoline is 0.68 g cm<sup>-3</sup> and its enthalpy of combustion is -48 kJ g<sup>-1</sup>.
73. Liquid helium and liquid nitrogen are both used as coolants; He(*l*) boils at 4.21 K, and N<sub>2</sub>(*l*) boils at 77.35 K. The specific heat of liquid helium near its boiling point is 4.25 J K<sup>-1</sup> g<sup>-1</sup>, and the specific heat of liquid nitrogen near its boiling point is 1.95 J K<sup>-1</sup> g<sup>-1</sup>. The enthalpy of vaporization of He(*l*) is 25.1 J g<sup>-1</sup>, and the enthalpy of vaporization of N<sub>2</sub>(*l*) is 200.3 J g<sup>-1</sup> (these data are calculated from the values in Appendix F). Discuss which liquid is the better coolant (on a per-gram basis) *near* its boiling point and which is better *at* its boiling point.
74. When 1.00 g potassium chlorate (KClO<sub>3</sub>) is dissolved in 50.0 g water in a Styrofoam calorimeter of negligible heat capacity, the temperature decreases from 25.00°C to 23.36°C. Calculate *q* for the water and Δ*H*<sup>o</sup> for the process.

The specific heat of water is 4.184 J K<sup>-1</sup> g<sup>-1</sup>.

75. The enthalpy of combustion and the standard enthalpy of formation of a fuel can be determined by measuring the temperature change in a calorimeter when a weighed amount of the fuel is burned in oxygen.
- (a) Write a balanced chemical equation for the combustion of isooctane, C<sub>8</sub>H<sub>18</sub>(*l*), to CO<sub>2</sub>(*g*) and H<sub>2</sub>O(*l*). Isooctane is a component of gasoline and is used as a reference standard in determining the “octane rating” of a fuel mixture.
- (b) Suppose 0.542 g isooctane is placed in a fixed-volume (bomb) calorimeter, which contains 750 g water, initially at 20.450°C, surrounding the reaction compartment. The heat capacity of the calorimeter itself (excluding the water) has been measured to be 48 J K<sup>-1</sup> in a separate calibration. After the combustion of the isooctane is complete, the water temperature is measured to be 28.670°C. Taking the specific heat of water to be 4.184 J K<sup>-1</sup> g<sup>-1</sup>, calculate Δ*U* for the combustion of 0.542 g isooctane.
- (c) Calculate Δ*U* for the combustion of 1 mol isooctane.
- (d) Calculate Δ*H* for the combustion of 1 mol isooctane.
- (e) Calculate Δ*H*<sub>f</sub><sup>o</sup> for the isooctane.
76. The enthalpy change to form 1 mol Hg<sub>2</sub>Br<sub>2</sub>(*s*) from the elements at 25°C is -206.77 kJ mol<sup>-1</sup>, and that of HgBr(*g*) is 96.23 kJ mol<sup>-1</sup>. Compute the enthalpy change for the decomposition of 1 mol Hg<sub>2</sub>Br<sub>2</sub>(*s*) to 2 mol HgBr(*g*):

- \*77. The gas most commonly used in welding is acetylene, C<sub>2</sub>H<sub>2</sub>(*g*). When acetylene is burned in oxygen, the reaction is

- (a) Using data from Appendix D, calculate Δ*H*<sup>o</sup> for this reaction.
- (b) Calculate the total heat capacity of 2.00 mol CO<sub>2</sub>(*g*) and 1.00 mol H<sub>2</sub>O(*g*), using *c*<sub>p</sub>(CO<sub>2</sub>(*g*)) = 37 J K<sup>-1</sup> mol<sup>-1</sup> and *c*<sub>p</sub>(H<sub>2</sub>O(*g*)) = 36 J K<sup>-1</sup> mol<sup>-1</sup>.
- (c) When this reaction is performed in an open flame, almost all the heat produced in part (a) goes to increase the temperature of the products. Calculate the maximum flame temperature that is attainable in an open flame burning acetylene in oxygen. The actual flame temperature would be lower than this because heat is lost to the surroundings.
- \*78. The enthalpy of reaction changes somewhat with temperature. Suppose we wish to calculate Δ*H* for a reaction at a temperature *T* that is different from 298 K. To do this, we can replace the direct reaction at *T* with a three-step process. In the first step, the temperature of the reactants is changed from *T* to 298 K. Δ*H* for this step can be calculated from the molar heat capacities of the reactants, which are assumed to be independent of temperature. In the second step, the reaction is conducted at 298 K with an enthalpy change Δ*H*<sup>o</sup>. In the third step, the temperature of the products is changed from 298 K to *T*. The sum of these three enthalpy changes is Δ*H* for the reaction at temperature *T*.

An important process contributing to air pollution is the following chemical reaction

For SO<sub>2</sub>(*g*), the heat capacity *c*<sub>p</sub> is 39.9, for O<sub>2</sub>(*g*) it is 29.4, and for SO<sub>3</sub>(*g*) it is 50.7 J K<sup>-1</sup> mol<sup>-1</sup>. Calculate Δ*H* for the preceding reaction at 500 K, using the enthalpies of formation at 298.15 K from Appendix D.

79. At the top of the compression stroke in one of the cylinders of an automobile engine (that is, at the minimum gas volume), the volume of the gas-air mixture is 150 mL, the temperature is 600 K, and the pressure is 12.0 atm. The ratio of the number of moles of octane vapor to the number of moles of air in the combustion mixture is 1.00:80.0. What is the maximum temperature attained in the gas if octane burns explosively before the power stroke of the piston (gas expansion) begins? The gases may be considered to be ideal, and their heat capacities at constant pressure (assumed to be temperature-independent) are

$$c_p(\text{C}_8\text{H}_{18}(g)) = 327 \text{ J K}^{-1} \text{ mol}^{-1}$$

$$c_p(\text{O}_2(g)) = 35.2 \text{ J K}^{-1} \text{ mol}^{-1}$$

$$c_p(\text{N}_2(g)) = 29.8 \text{ J K}^{-1} \text{ mol}^{-1}$$

$$c_p(\text{CO}_2(g)) = 45.5 \text{ J K}^{-1} \text{ mol}^{-1}$$

$$c_p(\text{H}_2\text{O}(g)) = 38.9 \text{ J K}^{-1} \text{ mol}^{-1}$$

The enthalpy of formation of C<sub>8</sub>H<sub>18</sub>(*g*) at 600 K is -57.4 kJ mol<sup>-1</sup>.

80. Initially, 46.0 g oxygen is at a pressure of 1.00 atm and a temperature of 400 K. It expands adiabatically and reversibly until the pressure is reduced to 0.60 atm, and it is then compressed isothermally and reversibly until the volume returns to its original value. Calculate the final pressure and temperature of the oxygen, the work done and heat added to the oxygen in this process, and the energy change  $\Delta U$ . Take  $c_p(\text{O}_2) = 29.4 \text{ J K}^{-1} \text{ mol}^{-1}$ .
81. A young chemist buys a “one-lung” motorcycle but, before learning how to drive it, wants to understand the processes that occur in its engine. The manual says the cylinder has a radius of 5.00 cm, a piston stroke of 12.00 cm, and a (volume) compression ratio of 8:1. If a mixture of gasoline vapor (taken to be  $\text{C}_8\text{H}_{18}$ ) and air in mole ratio 1:62.5 is drawn into the cylinder at 80°C and 1.00 atm, calculate:
- The temperature of the compressed gases just before the spark plug ignites them. (Assume that the gases are ideal, that the compression is adiabatic, and that the average heat capacity of the mixture of gasoline vapor and air is  $c_p = 35 \text{ J K}^{-1} \text{ mol}^{-1}$ .)
  - The volume of the compressed gases just before ignition.
  - The pressure of the compressed gases just before ignition.
  - The maximum temperature of the combustion products, assuming combustion is completed before the piston begins its downstroke. Take  $\Delta H_f^\circ(\text{C}_8\text{H}_{18}) = -57.4 \text{ kJ mol}^{-1}$ .
  - The temperature of the exhaust gases, assuming the expansion stroke to be adiabatic.
82. Nitromethane,  $\text{CH}_3\text{NO}_2$ , is a good fuel. It is a liquid at ordinary temperatures. When the liquid is burned, the reaction involved is chiefly
- $$2 \text{CH}_3\text{NO}_2(\ell) + \frac{3}{2} \text{O}_2(\text{g}) \longrightarrow 2 \text{CO}_2(\text{g}) + \text{N}_2(\text{g}) + 3 \text{H}_2\text{O}(\text{g})$$

The standard enthalpy of formation of liquid nitromethane at 25°C is  $-112 \text{ kJ mol}^{-1}$ ; other relevant values can be found in Appendix D.

## CUMULATIVE PROBLEMS

86. Suppose 32.1 g  $\text{ClF}_3(\text{g})$  and 17.3 g  $\text{Li}(\text{s})$  are mixed and allowed to react at atmospheric pressure and 25°C until one of the reactants is used up, producing  $\text{LiCl}(\text{s})$  and  $\text{LiF}(\text{s})$ . Calculate the amount of heat evolved.
87. Calculate  $\Delta H_f^\circ$  and  $\Delta U_f^\circ$  for the formation of silane,  $\text{SiH}_4(\text{g})$ , from its elements at 298 K, if 250  $\text{cm}^3$  of the gaseous compound at  $T = 298 \text{ K}$  and  $P = 0.658 \text{ atm}$  is burned in a constant-volume gas calorimeter in an excess of oxygen and causes the evolution of 9.757 kJ of heat. The combustion reaction is
- $$\text{SiH}_4(\text{g}) + 2 \text{O}_2(\text{g}) \longrightarrow \text{SiO}_2(\text{s, quartz}) + 2 \text{H}_2\text{O}(\ell)$$
- and the formation of silane from its elements is
- $$\text{Si}(\text{s}) + 2 \text{H}_2(\text{g}) \longrightarrow \text{SiH}_4(\text{g})$$
88. (a) Draw Lewis diagrams for  $\text{O}_2$ ,  $\text{CO}_2$ ,  $\text{H}_2\text{O}$ ,  $\text{CH}_4$ ,  $\text{C}_8\text{H}_{18}$ , and  $\text{C}_2\text{H}_5\text{OH}$ . In  $\text{C}_8\text{H}_{18}$ , the eight carbon atoms form a chain with single bonds; in  $\text{C}_2\text{H}_5\text{OH}$ , the two carbon atoms are bonded to one another. Using average bond enthalpies from Table 12.5, compute the enthalpy change in each of the following reactions, if 1 mol of each carbon compound is burned, and all reactants and products are in the gas phase.
- $\text{CH}_4 + 2 \text{O}_2 \longrightarrow \text{CO}_2 + 2 \text{H}_2\text{O}$  (burning methane, or natural gas)
  - $\text{C}_8\text{H}_{18} + \frac{25}{2} \text{O}_2 \longrightarrow 8 \text{CO}_2 + 9 \text{H}_2\text{O}$  (burning octane, in gasoline)
  - $\text{C}_2\text{H}_5\text{OH} + 3 \text{O}_2 \longrightarrow 2 \text{CO}_2 + 3 \text{H}_2\text{O}$  (burning ethanol, in gasohol)

89. By considering the nature of the intermolecular forces in each case, rank the following substances from smallest to largest enthalpy of vaporization: KBr, Ar, NH<sub>3</sub>, and He. Explain your reasoning.
90. A supersonic nozzle is a cone-shaped object with a small hole in the end through which a gas is forced. As it moves through the nozzle opening, the gas expands in a manner that can be approximated as reversible and adiabatic. Such nozzles are used in molecular beams (see Section 18.5) and in supersonic aircraft engines to provide thrust, because as the gas cools, its random thermal energy is converted into directed motion of the molecules with average velocity  $v$ . Little thermodynamic work is done because the external pressure is low; thus, the net effect is to convert thermal energy to net translational motion of the gas molecules. Suppose the gas in the nozzle is helium; its pressure is 50 atm and its temperature is 400 K before it begins its expansion.
- (a) What are the average speed and the average velocity of the molecules *before* the expansion?
- (b) What will be the temperature of the gas after its pressure has decreased to 1.0 atm in the expansion?
- (c) What is the average velocity of the molecules at this point in the expansion?
91. (a) Draw a Lewis diagram for carbonic acid, H<sub>2</sub>CO<sub>3</sub>, with a central carbon atom bonded to the three oxygen atoms.
- (b) Carbonic acid is unstable in aqueous solution and converts to dissolved carbon dioxide. Use bond enthalpies to estimate the enthalpy change for the following reaction:

© Cengage Learning/Charles D. Winters

The reaction between solid sodium and gaseous chlorine proceeds imperceptibly, if at all, until the addition of a drop of water sets it off.

In both fundamental research and practical applications of chemistry, chemical reactions are carried out by mixing the reactants and regulating external conditions such as temperature and pressure. Two questions arise immediately:

1. Is it possible for the reaction to occur at the selected conditions?
2. If the reaction is possible, what determines the ratio of products and reactants at equilibrium?

Predicting the equilibrium composition for a chemical reaction is the central goal of Unit 4, and in this chapter, we develop the conceptual basis for answering these two key questions.

Thermodynamics can tell us whether a proposed reaction is possible under particular conditions even before we attempt the reaction. We can find out

whether a proposed reaction is possible by determining whether it is a spontaneous thermodynamic process. In this context, “spontaneous” has a precise technical meaning (see later for definition) that should not be confused with its conversational meaning, such as describing the spontaneous behavior of people in social situations. If the reaction is spontaneous, thermodynamics can also predict the ratio of concentrations of products and reactants at equilibrium. This chapter develops the thermodynamic methods for predicting whether a reaction is spontaneous, and Chapter 14 uses these results to determine the equilibrium ratio of products and reactants.

But, we cannot use thermodynamics to predict the rate of a spontaneous reaction or how long it will take to reach equilibrium. These questions are the subject of chemical kinetics. To obtain a large amount of product from a spontaneous reaction in a short time, we need a reaction that is spontaneous and fast. Chapter 18 discusses the rates of chemical reactions. Manipulating conditions to optimize the yield of chemical reactions in practical applications requires the concepts from thermodynamics and kinetics from all three chapters.

The criteria for predicting spontaneity of physical and chemical processes are provided by the second law of thermodynamics, which is a brilliant abstraction and generalization from the observed facts of directionality in processes involving heat transfer. This is accomplished by introducing a new state function called *entropy*, which is denoted by  $S$ . We define the entropy function in such a way that the total entropy change of a thermodynamic universe (system and surroundings) is positive in the direction of spontaneous processes:  $\Delta S_{\text{tot}} > 0$ . Sections 13.1 through 13.5 develop the second law and demonstrate methods for calculating  $\Delta S_{\text{univ}}$  and predicting spontaneity.

When processes are conducted at constant  $T$  and  $P$ , the criteria for spontaneity and for equilibrium are stated more conveniently in terms of another state function called the *Gibbs free energy* (denoted by  $G$ ), which is derived from  $S$ . Because chemical reactions are usually conducted at constant  $T$  and constant  $P$ , their thermodynamic description is based on  $\Delta G$  rather than  $\Delta S$ . This chapter concludes by restating the criteria for spontaneity of chemical reactions in terms of  $\Delta G$ . Chapter 14 shows how to identify the equilibrium state of a reaction, and calculate the equilibrium constant from the standard Gibbs free energy change  $\Delta G^\circ$ .

For all these reasons,  $\Delta G$  is the most important thermodynamic concept in the entire field of chemical equilibrium. Your goals in this chapter should be to understand the meaning of the state function  $G$ , to become skilled in calculating its changes,  $\Delta G$ , and to interpret both the magnitude and the sign of these changes.

## 13.1 The Nature of Spontaneous Processes

In preparation for setting up the second law of thermodynamics, and stating precisely the criteria for spontaneity, we examine several familiar examples of spontaneous processes and describe their features in general terms. A spontaneous change is one that *will* occur by itself without outside intervention, once conditions have been established for its initiation. The change may be fast or slow, and we may have to wait a significant period to determine whether it *does* occur.

One of the most striking features of spontaneous change is that it follows a specific direction when starting from a particular initial condition. A dramatic example is shown in the series of photographs in Figure 13.1, which shows the freezing of supercooled distilled water poured from a water bottle. The liquid

**FIGURE 13.1** Supercooled water freezes spontaneously, set off when any small particle nucleates crystallization. (a) Distilled water is cooled to  $-8^{\circ}\text{C}$ , but is still liquid. (b) As the liquid water falls into a plastic bowl, ice crystals form spontaneously. (c) The spontaneous process is, in this case, rapid; the supercooled liquid water freezes during pouring, making a column of ice.

water, at a temperature of  $-8^{\circ}\text{C}$ , freezes instantly as it hits a particle of ice (the particle nucleates the reaction; so you see why water must be distilled before trying to get it that cold). The freezing of supercooled water at this temperature happens spontaneously in the forward direction, but the reverse reaction is impossible (ice held at  $-8^{\circ}\text{C}$ , 1 atm does not melt). One of the goals of thermodynamics is to account for this *directionality* of spontaneous change. The first law of thermodynamics provides no guidance in predicting or explaining directionality. Energy is conserved both in a forward process and in its reverse; nothing in the first law indicates a preference for one direction of change over the other.

Spontaneous processes familiar in chemical laboratories also follow specific directions:

1. We measure *heat transfer* from a hot body to a cold one when they are brought into thermal contact, but we never detect heat flowing spontaneously in the opposite direction.
2. We observe a gas *expanding* into a region of lower pressure, but we never see the reverse process, a gas compressing itself spontaneously into a small part of its container.
3. We place a drop of red ink into a beaker of water and watch the color spread by *diffusion* of the ink particles until the water is uniformly pink, but we never see the ink spontaneously reorganize as a small red drop in a volume of otherwise colorless water.
4. We place 10 g sucrose (ordinary table sugar) in a beaker and add 100 mL water at  $80^{\circ}\text{C}$ . The sucrose *dissolves* to form a uniform solution. We never observe the spontaneous reappearance of a mound of sucrose at the bottom of a beaker of water.
5. We open a container of acetone on the laboratory bench. We detect the aroma of acetone because some of the molecules have *evaporated* from the liquid and then diffused through the atmosphere to our position. We never observe the molecules to retreat spontaneously into the container.

All the previous examples are physical processes that are both spontaneous and rapid. We initiate the process and see the result quickly thereafter, with no further intervention.

Like the simple physical processes described earlier, spontaneous chemical reactions are inherently directional, though the reaction may be quite slow. Ordinary experience shows that a mixture of hydrogen and oxygen gases exists indefinitely at room temperature. Yet, if the mixture is exposed to a small amount of powdered platinum metal, or an electric spark, the gases react explosively to produce water. The reverse reaction is not spontaneous; we never observe the spontaneous decomposition of water into gaseous hydrogen and oxygen. Figure 1.2 shows decomposition of water into hydrogen and oxygen gases by electrolysis in an electrochemical cell, where electrical energy is continually provided by the external circuit to drive this nonspontaneous reaction. Another example is shown in the photograph at the beginning of this chapter, where the reaction between sodium metal and chlorine gas occurs explosively after a drop of water is added. We never observe the spontaneous decomposition of sodium chloride into sodium metal and gaseous chlorine. A third example, less dramatic than the previous two, is the spontaneous reaction of copper metal with oxygen at room temperature. This is seen in many older municipal buildings, especially in Europe, where copper metal was used as roofing material. With time, these roofs develop the blue–green patina of copper oxides. We never observe the spontaneous reappearance of shiny metallic copper on these old roofs.

These three examples illustrate that the actual outcome of a spontaneous chemical reaction depends on the reaction rate. The possibility of reaction between hydrogen and oxygen was there all along, but the rate was too slow to be observed until the powdered metal or the electrical spark accelerated the reaction. The possibility of reaction between metallic copper and oxygen was there all along, and the rate was large enough to be observed, if not dramatically fast. Thermodynamics determines whether a reaction is possible, whereas chemical kinetics determines whether it is practical. At the end of this chapter, you will be able to predict whether a chemical reaction is spontaneous, and by the end of the next chapter, you will be able to predict its equilibrium state. But, you must wait until Chapter 18 to see whether a spontaneous reaction can be carried out at a useful rate.

The direction of each of these spontaneous processes is readily apparent by observing the initial and final states, regardless of their paths. This suggests the existence of a new *state function* that indicates the directionality of spontaneous processes. That state function will turn out to be **entropy**, and it will be defined so that the sign of its change indicates the direction in which a proposed process will be spontaneous. Entropy has the interesting property that we cannot predict spontaneity by considering the system alone; we must also consider the entropy changes in the surroundings during the process.

To develop the entropy function, we must first describe spontaneous processes in the language of thermodynamics summarized in Section 12.1. You should revisit each of the examples just discussed to see how it specifically fits this language. Initially, two objects in different thermodynamic states are brought into contact; one will be called “system” and the other “surroundings.” Barriers (constraints) in place between them prevent their interaction. When the constraints are removed, a spontaneous process may occur in which the system and surroundings exchange energy and matter and in which the volume of both system and surroundings may change. Because the two together constitute a *thermodynamic universe*, the total amount of energy, volume, and matter shared between them is fixed. During the process, some or all of these quantities are redistributed between the system and surroundings.

## EXAMPLE 13.1

In the following two spontaneous processes, identify the system, the surroundings, and the constraint(s) removed to enable the processes to occur: (a) a piece of hot metal is cooled by immersion into a barrel of cold water; (b) a teaspoon of table sugar is dissolved in a cup of hot tea.

**Solution**

(a) The hot metal is the system, and the barrel of water is the surroundings. Initially we suppose they are brought into contact with an adiabatic wall between them to prevent heat flow so  $q_{\text{sys}} = -q_{\text{surr}} = 0$ . We initiate the cooling process by removing the adiabatic wall, whereupon thermal energy is transferred from the metal to the water. The thermal energy initially contained just in the system is now dispersed throughout the combined system and surroundings. Together the system and the surroundings are enclosed within adiabatic walls, so there is no interaction with the rest of the physical universe. The spontaneous process involves only energy transfer between system and surroundings.

(b) The sugar is the system, and the hot tea is the surroundings. Initially we imagine that the spoonful of sugar is placed in contact with the hot tea, and is surrounded by an adiabatic wall that prevents heat flow, a rigid wall that defines the volume of the sugar, and an impermeable wall that keeps the sugar separated from the tea. We initiate the dissolution process by removing the adiabatic wall, the rigid wall, and the impermeable wall. After this process the sugar molecules and the thermal energy are dispersed throughout the volume of the combined system and surroundings. The system and surroundings together are enclosed within adiabatic, rigid, and impermeable walls so there is no interaction with the rest of the physical universe. The spontaneous process involves transfer of energy, sugar molecules, and volume between the system and the surroundings.

**Related Problems: 1, 2**

Spontaneous processes are particular examples of irreversible processes defined in Section 12.1. In stark contrast with reversible processes, they do not proceed through a sequence of equilibrium states, and their direction cannot be reversed by an infinitesimal change in the direction of some externally applied force. Spontaneous processes cannot be represented as paths on the equation-of-state surface in Figure 12.2, but their initial and final equilibrium states can be represented as points on that surface.

What determines whether a process under consideration will be spontaneous? Where does a spontaneous process end? How are energy, volume, and matter partitioned between the system and surroundings at equilibrium? What is the nature of the final equilibrium state? These questions cannot be answered by the first law. Their answers require the second law and properties of the entropy, and a few developments are necessary before we can address these questions. We define entropy in terms of molecular motions in Section 13.2 and in terms of macroscopic process variables in Section 13.3. Finally, we present the methods for calculating entropy changes and for predicting spontaneity in Sections 13.4 and 13.5.

## 13.2 Entropy and Spontaneity: A Molecular Statistical Interpretation

What is entropy and why should it be related to the spontaneity of processes in nature? These are deep questions that we can only begin to answer here. To do so, we step outside the confines of classical thermodynamics, which is concerned only with macroscopic properties, and examine the microscopic molecular basis for the second law. Such an approach, called **statistical thermodynamics**, shows that spontaneous change in nature can be understood by using probability theory to predict and explain the behavior of the many atoms and molecules that comprise a macroscopic sample of matter. Statistical thermodynamics also provides theoretical procedures for calculating the entropy of a system from molecular properties.

(a)

(b)

**FIGURE 13.2** The free expansion of a gas into a vacuum. (a) The gas is initially confined to the bulb on the left, with the stopcock (the constraint) closed. (b) Half of the gas is found in each bulb, at equilibrium, after the stopcock is opened.

**FIGURE 13.3** The 16 possible microstates of a system of four molecules that may occupy either side of a container. In only one of these are all four molecules on the left side.

### 13.2.1 Spontaneity and Molecular Motions

Consider a particularly simple spontaneous process: the free *adiabatic* expansion of 1 mol of an ideal gas into a vacuum (Fig. 13.2). The gas is initially held in the left bulb in volume  $V/2$ , whereas the right bulb is evacuated. Before it is opened, the stopcock is a constraint that holds all the molecules in the left bulb. After the stopcock is opened, the gas expands to fill the entire volume,  $V$ .

Now examine the same free expansion from a microscopic point of view. Imagine that the path of one particular tagged molecule can be followed during the expansion and for some period of time after final equilibrium has been established, perhaps through a series of time-lapse snapshots showing the locations of all molecules in the gas. From its starting position on the left side at the beginning of the experiment, the tagged molecule will cross to the right, then back to the left, and so forth. If enough time elapses, the molecule will eventually spend equal amounts of time on the two sides, because there is no physical reason for it to prefer one side to the other. As the adiabatic, free ( $P_{\text{ext}} = 0$ ) process occurs,  $q = 0$  and  $w = 0$ , so  $\Delta U = 0$ . Recall from Section 9.5 that the molecules in an ideal gas have an average internal energy that is proportional to  $T$ , so because  $U$  does not change the temperature does not change. The energy of the molecules remains the same at all locations, and the two sides of the container are identical. No experimental way exists to track the progress of one specific molecule in the gas; therefore, the best we can ask for is the *probability* that the molecule is on the left side at any given instant. (See Appendix C.6 for a review of probability concepts and methods.) The physical reasoning just summarized justifies that the probability that the molecule is on the left side will be  $\frac{1}{2}$ , the same as the probability that it is on the right side. Probability provides the key to understanding the direction of spontaneous change because it enables us to compare the likelihood of finding all the molecules on the left side—after the constraint has been removed—with the likelihood of finding the molecules uniformly distributed over the combined volume of both sides.

Just how unlikely is a spontaneous compression of 1 mol gas from the combined volume back to the left side? The probability that one particular molecule is on the left side at a given time is  $\frac{1}{2}$ . A second specific molecule may be on either the left or the right, so the probability that both are on the left is  $\frac{1}{2} \times \frac{1}{2} = \frac{1}{4}$ . As shown in Figure 13.3, in a gas containing a total of four molecules, all four molecules will be on the left only  $\frac{1}{2} \times \frac{1}{2} \times \frac{1}{2} \times \frac{1}{2} = \frac{1}{16}$  of the time. Continuing this argument for all  $N_A = 6.0 \times 10^{23}$  molecules leads to the probability that all  $N_A$  molecules are on the left:

$$\frac{1}{2} \times \frac{1}{2} \times \cdots \times \frac{1}{2} = \left(\frac{1}{2}\right)^{6.0 \times 10^{23}}$$

To evaluate this number, it is helpful to rewrite it in scientific notation as 1 divided by 10 raised to the power  $a$  (or, equivalently, as  $10^{-a}$ ):

$$\frac{1}{10^a} = \left(\frac{1}{2}\right)^{6.0 \times 10^{23}} = \frac{1}{2^{6.0 \times 10^{23}}}$$

A calculator can handle numbers this large (or this small) only if logarithms are used. Taking the base-10 logarithms of both denominators gives

$$\begin{aligned} a &= \log 2^{(6.0 \times 10^{23})} = 6.0 \times 10^{23} \log 2 \\ &= (6.0 \times 10^{23})(0.30) \\ &= 1.8 \times 10^{23} \end{aligned}$$

The probability that all the molecules will be on the left is 1 in  $10^{1.8 \times 10^{23}}$ .

This is a vanishingly small probability, because  $10^{1.8 \times 10^{23}}$  is an unimaginably large number. It is vastly larger than the number  $1.8 \times 10^{23}$  (which is a large number already). To realize this, consider how such numbers would be written. The number  $1.8 \times 10^{23}$  is fairly straightforward to write out. It contains 22 zeros:

180,000,000,000,000,000,000,000

The number  $10^{1.8 \times 10^{23}}$  is 1 followed by  $1.8 \times 10^{23}$  zeros. Written out, such a number would more than fill all the books in the world. Put in other terms,  $1.8 \times 10^{23}$  corresponds to the number of molecules in about 5 cm<sup>3</sup> water, but  $10^{1.8 \times 10^{23}}$  is far larger than the number of molecules in the entire universe!

The statistical molecular picture explains that the gas expands to fill the whole available volume when the constraint is removed because this more uniform configuration of the molecules is overwhelmingly more probable than the initial configuration with all the molecules on the left side. The same explanation shows that the gas is never observed to compress spontaneously into a smaller volume because this nonuniform configuration of the molecules is overwhelmingly improbable in the absence of the constraint. Nothing in the laws of mechanics prevents a gas from compressing spontaneously. But this event is never seen because it is so improbable.

Thus, spontaneity in nature results from the random, statistical behavior of large numbers of molecules. *The directionality of spontaneous change is a consequence of the large numbers of molecules in the macroscopic systems treated by thermodynamics.* In systems containing fewer molecules, the situation can be quite different because the uniform configuration of molecules, although still the most probable, is no longer so overwhelmingly the most probable configuration. For example, if there were only 6 molecules, instead of  $6 \times 10^{23}$ , it would not be surprising to find them all on the left side at a given time. In fact, the probability that 6 molecules are on the left side is  $(\frac{1}{2})^6 = \frac{1}{64}$ , so there is 1 chance in 64 that this will occur. Such small systems exhibit *statistical fluctuations* of the molecular configuration. Some of the fluctuations correspond to the initial nonuniform configuration maintained by the constraint, despite the absence of the constraint.

### EXAMPLE 13.2

Calculate the probability of a spontaneous compression of 1.00 mol gas by 0.01%—that is, the probability that all the molecules will be found in a volume  $V' = 0.9999V$  at a certain time.

#### Solution

In this case, the probability that a given molecule is in  $V'$  is not  $\frac{1}{2}$  but 0.9999 (the probability that it is in the remainder of  $V$  is 0.0001). The probability that all  $N_A$  molecules are in  $V'$  is

$$\begin{aligned} (0.9999)^{N_A} &= 1/10^a \\ a &= -N_A \log(0.9999) = (6.0 \times 10^{23})(4.3 \times 10^{-5}) \\ &= 2.6 \times 10^{19} \end{aligned}$$

The chance of such a compression occurring spontaneously is 1 in  $10^{2.6 \times 10^{19}}$ , which is still vanishingly small. Thus, a spontaneous compression of even a fraction of a percent will not be seen.

#### Related Problems: 7, 8

## 13.2.2 Entropy and Molecular Motions

We want to define a new function called entropy that will increase when the system undergoes a spontaneous process. How can we relate entropy to the properties of the system and formulate a definition to achieve this goal? Spontaneous

processes occur when constraints are removed from a system; the molecules respond by moving to explore the suddenly increased range of motions now available to them. (Here we are assuming that the gas in the system is isolated from the surroundings; otherwise we must consider the entropy change of both the system and the surroundings to determine what process happens spontaneously.) In the free expansion of a gas, the molecules are initially confined in one part of the container. After the constraint is removed (the stopcock is opened), they are free to stay where they were, but they also are free to move throughout the larger combined volume of the two regions. Qualitatively, the numerical value of the entropy of a macroscopic system held in a particular thermodynamic state should depend on the *range of possible motions* (that is, the range of possible positions and momenta) available to the molecules while the system is held in that particular thermodynamic state. Any change in the macroscopic properties that enables the molecules to move out into larger regions of space or that increases the range of molecular speeds should increase the entropy of the system.

In preparation for defining entropy, we need a precise way to describe the “range of possible motions” of the molecules. This is accomplished by counting the number of microscopic, mechanical states, or **microstates**, available to molecules of the system. This number, denoted by  $\Omega$ , counts all the possible combinations of positions and momenta available to the  $N$  molecules in the system when the system has internal energy  $U$  and volume  $V$ . For the simple model in Figure 13.3,  $\Omega = 16$ . In general,  $\Omega$  is a function of  $U$ ,  $V$ , and  $N$ , denoted as  $\Omega(U, V, N)$ . If the system is a monatomic ideal gas, the atoms do not interact. The position of each atom ranges freely throughout the entire volume,  $V$ . The internal energy consists of the total kinetic energy of the atoms, given as

$$U = \sum_{i=1}^N \varepsilon_i = \sum_{i=1}^N \frac{[p_{xi}^2 + p_{yi}^2 + p_{zi}^2]}{2m}$$

thus, the momenta of the atoms range through all values that satisfy the condition

$$2mU = \sum_{i=1}^N [p_{xi}^2 + p_{yi}^2 + p_{zi}^2]$$

Although we do not provide the details of the calculation, the value of  $\Omega$  for a monatomic ideal gas is given by

$$\Omega(U, V, N) = g V^N U^{(3N/2)}$$

where  $g$  is a collection of constants. Now imagine the walls defining the system are manipulated to change the values of  $U$  and  $V$ . The range of positions and momenta available to the molecules will increase or decrease accordingly. Because  $N$  is a very large number—of order  $10^{23}$ —the value of  $\Omega$  will increase or decrease dramatically when the volume of the system is increased or decreased in an expansion or compression, respectively. It will increase or decrease dramatically when the internal energy of the system is increased or decreased by heating or cooling, respectively.

The equation connecting entropy  $S$  and the number of available microstates  $\Omega$  is

$$S = k_B \ln \Omega \quad [13.1]$$

which was originally discovered by the Austrian physicist Ludwig Boltzmann in the late 19th century (Fig. 13.4). **Boltzmann’s constant**  $k_B$  (see Eq. 9.14) is identified as  $R/N_A$ , the ratio of the universal gas constant  $R$  to Avogadro’s number  $N_A$ . Thus, entropy has the physical dimensions  $\text{J K}^{-1}$ . It is impossible to

**FIGURE 13.4** The fundamental relation between entropy ( $S$ ) and the number of microstates ( $W$ ) was derived by Ludwig Boltzmann in 1868. On his tombstone in Vienna is carved the equation he obtained,  $S = k \log W$ . We would write “ln” instead of “log” for the natural logarithm and  $\Omega$  instead of “ $W$ ” for the number of microstates.

overstate the importance of Boltzmann's relation, because it provides the link between the microscopic world of atoms and molecules and the macroscopic world of bulk matter and thermodynamics. Although this equation holds quite generally, it is difficult to apply because calculating  $\Omega$  is a daunting theoretical task except for the simplest ideal systems. Other equations are used for practical applications in statistical thermodynamics. For our purposes here, the equation provides qualitative insight into the physical meaning of entropy and qualitative interpretation of the magnitude and sign of entropy changes caused by specific thermodynamic processes. The following example illustrates these insights in a simple case in which only the volume of the system changes in the process.

### EXAMPLE 13.3

Consider the free expansion of 1 mol gas from  $V/2$  to  $V$  (see Fig. 13.2). Use Boltzmann's relation to estimate the change in entropy for this process.

#### Solution

Consider the entire apparatus consisting of the filled and the evacuated bulbs to be a thermodynamic universe, so any exchange of thermal energy occurs solely between them; the pair of bulbs is taken to be thermally insulated from their surroundings. Then examine the effects of doubling  $V$  on  $\Omega$ . If the volume is doubled, the number of positions available to a given molecule is doubled also. Therefore, the number of states available to the molecule should be proportional to the volume,  $V$ :

$$\text{number of states available per molecule} = cV$$

where  $c$  is a proportionality constant. The state of a *two*-molecule system is given jointly by the states of the molecules in it, so the number of microscopic states available is just the product of the number of states for each molecule,  $(cV) \times (cV) = (cV)^2$ . For an  $N$ -molecule system,

$$\text{microscopic states available} = \Omega = (cV)^N$$

Inserting this expression into Boltzmann's relation gives the entropy change for the free expansion of 1 mol ( $N_A$  atoms) gas from a volume  $V/2$  to  $V$ :

$$\begin{aligned} \Delta S(\text{microscopic}) &= N_A k_B \ln(cV) - N_A k_B \ln(cV/2) \\ &= N_A k_B \ln\left(\frac{cV}{cV/2}\right) = N_A k_B \ln 2 \end{aligned}$$

Note that the constant  $c$  has dropped out. The calculated change in entropy on expansion of the gas is clearly positive, which is consistent with the increase in the number of available microstates on expansion.

In the next section, the entropy change for this process from the macroscopic view will be calculated to be

$$\Delta S(\text{thermodynamic}) = R \ln 2$$

illustrating explicitly that Boltzmann's microscopic description accurately explains the measured macroscopic results.

**Related Problems: 3, 4, 5, 6, 7, 8, 9, 10**

This example illustrates why Boltzmann's relation must involve the logarithmic function. Because entropy is an extensive variable, its value is proportional to  $N$ . But  $\Omega$  depends on  $N$  through the *power* to which  $cV$  is raised. Therefore, doubling  $N$  doubles  $S$  but leads to  $\Omega$  being squared.

Examples of other processes in which the entropy of the system increases include phase transitions such as the melting of a solid. In a solid, cohesive forces hold the atoms or molecules near their equilibrium positions in the crystal lattice, whereas in the liquid they can move far away from these fixed positions. More microstates are available to the molecules in the liquid, corresponding to a larger value of entropy; for melting of a solid,  $\Delta S_{\text{sys}}$  is positive. In the same way, the entropy increases for evaporation of a liquid because the number of microstates available to the molecules increases enormously. Whereas the molecules in a liquid remain at the bottom of their container, those in a gas move throughout the container, so the number of microstates increases upon vaporization. In some solid-solid phase transformations it is difficult to predict qualitatively which phase has higher entropy. Nonetheless, calculating the relative number of microstates available correctly predicts the sign of the entropy change in a transformation from one such phase to the other.

So far, we have considered microstates that involve only the positions of the molecules in a system. The distribution of energies can also contribute to the

number of microstates. For example, a gas in which all the molecules have the same speed has fewer microstates available to it than does a gas with a distribution of molecular speeds; a spontaneous process is observed experimentally in which a system initially constrained to a single molecular speed moves toward the Maxwell–Boltzmann speed distribution, because this distribution maximizes the number of microstates available for a given total energy. This textbook gives only qualitative microscopic interpretations of these more complex examples. In later courses you will see more thorough interpretations based on the more advanced equations that replace Equation 13.1.

## 13.3 Entropy and Heat: Macroscopic Basis of the Second Law of Thermodynamics

The second law of thermodynamics, which is stated as an abstract generalization of engineering observations on the efficiency of heat engines, has two important consequences for chemistry. It defines the entropy function in terms of measurable macroscopic quantities, providing a means to calculate the changes in entropy caused by specific processes. And, it defines the criterion for predicting whether a particular process will be spontaneous. It is thus useful to re-state the second law in a form directly applicable to chemistry: Part One defines the entropy function, and Part Two shows how to predict spontaneity. We start the discussion with a nonmathematical, qualitative summary of the arguments on efficiency, from which we state the second law in engineering terms and then define the entropy function (Part One of the second law). Section 13.4 applies the definition to calculate entropy changes for a wide variety of processes. Section 13.5 uses these calculations to predict spontaneity of processes (Part Two of the second law).

Section 13.8 presents a mathematical route to the same results developed qualitatively here. Either Section 13.3 or Section 13.8 provides adequate background for the calculations in Sections 13.4 and 13.5, which are essential for chemistry.

### 13.3.1 Background of the Second Law of Thermodynamics

The second law of thermodynamics originated in practical concerns over the efficiency of steam engines at the dawn of the Industrial Age, late in the 18th century, and required about a century for its complete development as an engineering tool. The central issues in that development are summarized as follows. In each stroke of a steam engine, a quantity of hot steam at high pressure is injected into a piston-cylinder assembly, where it immediately expands and pushes the piston outward against an external load, doing useful work by moving the load. The external mechanical structure to which the piston is attached includes a reciprocating mechanism that returns the piston to its original position at the end of the stroke so that a new quantity of steam can be injected to start the next stroke. The engine operates as a cyclic process, returning to the same state at the beginning of each stroke. In each stroke, the expansion process is highly irreversible because the steam is cooled and exhausted from the cylinder at the end of the stroke. In essence, the engine extracts thermal energy from a hot reservoir, uses some of this energy to accomplish useful work, then discards the remainder into a cooler reservoir (the environment). See Figure 13.5 for a schematic representation of a heat engine. The energy lost to the environment cannot be recovered by the engine. The internal combustion engine operates in a similar manner, with injection of hot steam replaced by *in situ* ignition

**FIGURE 13.5** Schematic representation of a heat engine.

**FIGURE 13.6** Operation of a heat engine. In this example the engine withdraws 50 kJ of thermal energy from the hot reservoir, performs 10 kJ of work on its surroundings, and discharges 40 kJ of thermal energy to the lower temperature reservoir.

of combustible fuel that burns in highly exothermic reactions. Its expansion process is similarly irreversible, and some of the energy expended by the hot gases is unrecoverable.

In both engines the efficiency, defined as the ratio of work accomplished by the engine in a cycle ( $-w$  in Figure 13.6) to the heat invested to drive that cycle,  $q_h$  in Figure 13.6, can be improved by reducing the unrecoverable losses to the environment in each cycle. Seeking to maximize efficiency, Sadi Carnot, an officer in Napoleon's French Army Corps of Engineers, modeled operation of the engine with an idealized cyclic process now known as the *Carnot cycle*. He concluded that unrecoverable losses of energy to the environment cannot be completely eliminated, no matter how carefully the engine is designed. Even if the engine is operated as a reversible process (in which case, displacement of the external load is too slow to be of practical interest), its efficiency cannot exceed a fundamental limit known as the *thermodynamic efficiency*. Thus, an engine with 100% efficiency cannot be constructed.

Carnot's conclusion has been restated in more general terms by the English physicist Lord Kelvin in the following form:

*There is no device that can transform heat withdrawn from a reservoir completely into work with no other effect.*

and by the German physicist Rudolf Clausius in the following form:

*There is no device that can transfer heat from a colder to a warmer reservoir without net expenditure of work.*

These statements are consistent with ordinary experience that (1) heat always flows spontaneously from a hotter body to a colder body, and that (2) work is always required to refrigerate a body. With confidence based on experience, Clausius, Kelvin, and later scientists and engineers have assumed these statements to be valid for *all* heat transfer processes and labeled them as equivalent formulations of the second law of thermodynamics.

### 13.3.2 Definition of Entropy

How do we apply these general statements to chemical processes such as the examples described in Section 13.1, which at first glance bear no resemblance to heat engines? Highlights of the argument are summarized here, and a more detailed development is presented in Section 13.8.

Carnot's analysis of efficiency for a heat engine operating *reversibly* showed that in each cycle  $q/T$  at the high temperature reservoir and  $q/T$  at the low temperature environment summed to zero:

$$\frac{q_h}{T_h} + \frac{q_l}{T_l} = 0$$

This result suggests that  $q/T$  is a state function in a reversible process because the sum of its changes in a cyclic process is zero. Clausius extended this result to show that the quantity  $\int (1/T) dq_{\text{rev}}$  is independent of path in *any* reversible process and is, therefore, a state function. Clausius then *defined* the entropy change  $\Delta S = S_f - S_i$  of a system in a process starting in state  $i$  and ending in state  $f$  by the equation

$$\Delta S = S_f - S_i = \int_i^f \frac{dq_{\text{rev}}}{T} \quad [13.2]$$

The definition in Equation 13.2 constitutes Part One of the second law in the form directly related to chemistry. Entropy is therefore a state function and has

physical dimensions  $\text{J K}^{-1}$ . We calculate  $\Delta S = S_f - S_i$  for a specific process by (1) identifying its initial and final equilibrium states  $i$  and  $f$  as points on the equation-of-state surface in Figure 12.2, (2) selecting *any convenient reversible path* between them along which  $dq_{\text{rev}}$  and  $T$  are known, and (3) evaluating this integral along the selected path. It does not matter that the actual process of interest may be irreversible. Because entropy is a state function, its change depends only on the initial and final states, and not at all on the path. *Therefore, we are free to choose any reversible path that connects the initial and final states, purely on grounds of convenience, for calculating  $\Delta S$ .*

This is a beautiful consequence of the fact that  $S$  is a state function. Section 13.4 provides detailed procedures for calculating  $\Delta S$  for numerous types of systems and processes. The calculated values of  $\Delta S$  are then used in Section 13.5 in Part Two of the second law to predict whether a particular contemplated process will be spontaneous.

The preceding discussion emphasizes that the second law, like all other laws of science, is a bold extrapolation of the results of a great deal of direct experimental observation under controlled conditions. Based on his understanding of the Carnot cycle, Clausius assumed, or postulated, that Equation 13.2 is valid for all thermodynamic systems and all processes that begin and end in equilibrium states. For every system there exists a state function called entropy whose changes during a process depend only on the initial and final states, and the magnitude of the changes can be calculated along any convenient reversible path connecting these particular states. In Section 13.5 we see how these calculated entropy changes predict whether a process is spontaneous or not. The second law is not proved to be true by a single definitive experiment, it is not derived as a consequence of some more general theory, and it is not handed down by some higher authority. Rather, it is invoked as one of the “starting points” of thermodynamics, and conclusions drawn from its application to a great variety of processes (not necessarily involving heat engines) are compared with the results obtained in experimental studies. To date, no disagreements have been found between predictions properly made from the second law and the results of properly designed experiments.

## 13.4 Entropy Changes in Reversible Processes

This section outlines procedures for calculating entropy changes that occur in the system and in the surroundings during several types of processes.

### 13.4.1 $\Delta S_{\text{sys}}$ for Isothermal Processes

If the reversible process selected as the pathway connecting the initial and final states is isothermal, the calculation simplifies immediately. Because  $T$  is constant, it comes outside the integral:

$$\Delta S = \int_i^f \frac{dq_{\text{rev}}}{T} = \frac{1}{T} \int_i^f dq_{\text{rev}} = \frac{q_{\text{rev}}}{T} \quad [13.3]$$

Here,  $q_{\text{rev}}$  is the *finite* amount of heat absorbed by the system during the entire reversible isothermal process.

#### Compression/Expansion of an Ideal Gas

Consider an ideal gas enclosed in a piston-cylinder arrangement that is maintained at constant temperature in a heat bath. The gas can be compressed (or

expanded) reversibly by changing the position of the piston to accomplish a specified change in volume. In Section 12.7, the heat transferred between system and bath when the gas is expanded (or compressed) isothermally and reversibly from volume  $V_1$  to  $V_2$  is shown to be

$$q_{\text{rev}} = nRT \ln \left( \frac{V_2}{V_1} \right)$$

The resulting change in entropy, therefore, is

$$\Delta S = nR \ln \left( \frac{V_2}{V_1} \right) \quad (\text{constant } T) \quad [13.4]$$

From Equation 13.4 we see that the entropy of a gas increases during an isothermal expansion ( $V_2 > V_1$ ) and decreases during a compression ( $V_2 < V_1$ ). Boltzmann's relation (see Eq. 13.1) provides the molecular interpretation of these results. The number of microstates available to the system,  $\Omega$ , increases as the volume of the system increases and decreases as volume decreases, and the entropy of the system increases or decreases accordingly.

### Phase Transitions

Another type of constant-temperature process is a phase transition such as the melting of a solid at constant pressure. This occurs reversibly at the fusion temperature,  $T_f$ , because an infinitesimal change in external conditions, such as reducing the temperature, can reverse the melting process. The reversible heat absorbed by the system when 1 mol of substance melts is  $q_{\text{rev}} = \Delta H_{\text{fus}}$ , so

$$\Delta S_{\text{fus}} = \frac{q_{\text{rev}}}{T_f} = \frac{\Delta H_{\text{fus}}}{T_f} \quad [13.5]$$

The entropy increases when a solid melts or a liquid vaporizes, and it decreases when the phase transition occurs in the opposite direction. Again, Boltzmann's relation provides the molecular interpretation. When a solid melts or a liquid vaporizes, the number of accessible microstates  $\Omega$  increases, and thus the entropy increases.

### EXAMPLE 13.4

Calculate the entropy change when 3.00 mol benzene vaporizes reversibly at its normal boiling point of 80.1°C. The molar enthalpy of vaporization of benzene at this temperature is 30.8 kJ mol<sup>-1</sup>. (As the vaporization occurs, the pressure of benzene above the liquid is maintained at 1 atm by increasing the volume available to the gas.)

#### Solution

The entropy change when 1 mol benzene is vaporized at 80.1°C (=353.25 K, 1 atm), is

$$\Delta S_{\text{vap}} = \frac{\Delta H_{\text{vap}}}{T_b} = \frac{30,800 \text{ J mol}^{-1}}{353.25 \text{ K}} = +87.2 \text{ J K}^{-1}$$

When 3.00 mol is vaporized, the entropy change is three times as great:

$$\Delta S = (3.00 \text{ mol})(+87.2 \text{ J K}^{-1} \text{ mol}^{-1}) = +262 \text{ J K}^{-1}$$

**Related Problems: 11, 12**

Remarkably, most liquids have similar values for the molar entropy of vaporization. **Trouton's rule** summarizes this observation:

$$\Delta S_{\text{vap}} = 88 \pm 5 \text{ J K}^{-1} \text{ mol}^{-1} \quad [13.6]$$

Note that the  $\Delta S_{\text{vap}}$  of benzene, calculated in Example 13.4, is within this range. The constancy of  $\Delta S_{\text{vap}}$  means that  $\Delta H_{\text{vap}}$  and  $T_{\text{b}}$ , which vary widely from substance to substance, must do so in the same proportion. Trouton's rule allows enthalpies of vaporization to be estimated from boiling temperatures. However, exceptions exist; the molar entropy of vaporization for water is  $109 \text{ J K}^{-1} \text{ mol}^{-1}$ . The value for water is unusually high because hydrogen bonding in liquid water means that there are many fewer allowed configurations (lower entropy) at a given temperature than in other liquids; thus, water shows a much greater increase in the number of microstates on vaporization.

### 13.4.2 $\Delta S_{\text{sys}}$ for Processes with Changing Temperature

Now consider a reversible process in which the temperature changes. In this case, Equation 13.2 must be used:

$$\Delta S = \int_i^f \frac{1}{T} dq_{\text{rev}}$$

In the integral,  $i$  and  $f$  represent, respectively, the initial and final equilibrium states for the process. The calculation must be conducted along a reversible path connecting  $i$  and  $f$ . For a reversible *adiabatic* process,  $q = 0$  and, therefore,  $\Delta S = 0$ . Such a process is also called an **isentropic process** (that is, the entropy is constant).

In a reversible *isochoric* process, the volume is held constant and the system is heated or cooled by contact with a reservoir whose temperature differs from that of the system by an infinitesimal amount,  $dT$ . As long as there are no phase changes or chemical reactions, the heat transferred in this case is

$$dq_{\text{rev}} = nc_V dT$$

and the entropy change of the system as it is heated from  $T_1$  to  $T_2$  is

$$\Delta S = \int_{T_1}^{T_2} \frac{1}{T} dq_{\text{rev}} = \int_{T_1}^{T_2} \frac{nc_V}{T} dT$$

If  $c_V$  is independent of  $T$  over the temperature range of interest, it can be removed from the integral, giving the result

$$\Delta S = nc_V \int_{T_1}^{T_2} \frac{1}{T} dT = nc_V \ln \left( \frac{T_2}{T_1} \right) \quad (\text{constant } V) \quad [13.7]$$

The analogous result for the entropy change of the system in a reversible *isobaric* process (constant *pressure*) is

$$\Delta S = \int_{T_1}^{T_2} \frac{nc_P}{T} dT = nc_P \ln \left( \frac{T_2}{T_1} \right) \quad (\text{constant } P) \quad [13.8]$$

Entropy always increases with increasing temperature. From the kinetic theory of ideal gases in Chapter 9, it is clear that increasing the temperature of the gas

increases the magnitude of the average kinetic energy per molecule and, therefore, the range of momenta available to molecules. This, in turn, increases  $\Omega$  for the gas and, by Boltzmann's relation, the entropy of the gas.

Now consider an experiment in which identical samples of a gas are taken through identical temperature increases, one sample at constant  $V$  and the other at constant  $P$ . Let's compare the entropy changes in the two processes. From the previous discussion it follows that  $\Delta S_P > \Delta S_V$  because  $c_P > c_V$ . The molecular interpretation is based on the discussion of  $c_P$  and  $c_V$  in Section 12.3. The gas heated at constant  $P$  increases in volume, as well as in temperature; its molecules therefore gain access to a greater range of positions, as well as a greater range of momenta. Consequently, the gas heated at constant  $P$  experiences a *greater* increase in  $\Omega$  than does the gas heated at constant  $V$  and, therefore, a greater increase in  $S$ .

The following example illustrates that the entropy is a state function, for which changes are independent of the path followed.

### EXAMPLE 13.5

- (a) Calculate the entropy change for the process described in Example 12.10: 5.00 mol argon expands reversibly at a constant temperature of 298 K from a pressure of 10.0 to 1.00 atm.
- (b) Calculate the entropy change for the same initial and final states as in part (a) but along a different path. First, the 5.00 mol argon expands reversibly and *adiabatically* between the same two pressures. This is the path followed in Example 12.11; it causes the temperature to decrease to 118.6 K. Then the gas is heated at constant pressure back to 298 K.
- (b) For the adiabatic part of this path, the entropy change is zero. When the gas is then heated reversibly at constant pressure from 118.6 to 298 K, the entropy change is

$$\begin{aligned}\Delta S &= n c_P \ln \left( \frac{T_2}{T_1} \right) \\ &= (5.00 \text{ mol}) \left( \frac{5}{2} \times 8.315 \text{ J K}^{-1} \text{ mol}^{-1} \right) \ln \frac{298 \text{ K}}{118.6 \text{ K}} \\ &= +95.7 \text{ J K}^{-1}\end{aligned}$$

This is the same as the result from part (a), an illustration of the fact that the entropy is a state function. By contrast, the amounts of heat for the two paths are different: 28.5 and 18.6 kJ.

#### Solution

- (a) At constant temperature, the entropy change is

$$\begin{aligned}\Delta S &= nR \ln \left( \frac{V_2}{V_1} \right) = nR \ln \left( \frac{P_1}{P_2} \right) \\ &= (5.00 \text{ mol})(8.315 \text{ J K}^{-1} \text{ mol}^{-1}) \ln 10.0 \\ &= +95.7 \text{ J K}^{-1}\end{aligned}$$

**Related Problems:** 15, 16

### 13.4.3 $\Delta S$ for Surroundings

Usually, the surroundings can be treated as a large *heat bath* that transfers heat to or from the system at the fixed temperature of the bath. In such cases, the heat capacity of the surroundings (heat bath) must be so large that the heat transferred during the process does not change the temperature of the bath. The heat gained by the surroundings during a process is the heat lost from the system. If the process occurs at constant  $P$ , then

$$q_{\text{surr}} = -\Delta H_{\text{sys}}$$

and the entropy change of the surroundings is

$$\Delta S_{\text{surr}} = \frac{-\Delta H_{\text{sys}}}{T_{\text{surr}}} \quad [13.9]$$

Here the surroundings must be large so that the actual heat transferred to it does not bring it out of equilibrium, even though an irreversible process may be happening to the system. If the process occurring in the system is exothermic, the surroundings gain heat and the entropy change of the surroundings is positive. Similarly, an endothermic process in the system is accompanied by a negative entropy change in the surroundings, because the surroundings give up heat during the process to keep the system at the temperature of the heat bath.

If the surroundings lack sufficient heat capacity to maintain constant temperature during the process, then entropy changes for the surroundings must be calculated by the methods demonstrated above for the system, taking explicit account of the temperature change and heat capacity of the surroundings. Examples of both cases are included in the problems at the end of this chapter.

If the process on the system is not at constant  $P$ , you can still use  $q_{\text{surr}} = -q_{\text{sys}}$  (the actual  $q_{\text{sys}}$ , not the  $q_{\text{sys}}$  for the reversible path). Then the entropy change of the surroundings equals  $q_{\text{surr}}/T_{\text{surr}} = -q_{\text{sys}}/T_{\text{surr}}$ .

## 13.5 Entropy Changes and Spontaneity

Part Two of the second law states that a process can occur spontaneously if the total entropy change for the thermodynamic universe of the process is positive:

$$\Delta S_{\text{tot}} = \Delta S_{\text{sys}} + \Delta S_{\text{surr}} > 0$$

We illustrate the calculation first for spontaneous cooling of a hot body and then for irreversible expansion of an ideal gas. Finally we discuss the so-called inequality of Clausius, which provides the basis for Part Two of the second law.

### Spontaneous Cooling of a Hot Body

Consider a spontaneous process in which a sample of hot metal is cooled by sudden immersion in a cold bath. Heat flows from the metal into the bath until they arrive at the same temperature. This spontaneous process is accompanied by an increase in the total entropy for the thermodynamic universe of the process, as illustrated by the following example.

#### EXAMPLE 13.6

A well-insulated ice-water bath at  $0.0^\circ\text{C}$  contains 20 g ice. Throughout this experiment, the bath is maintained at the constant pressure of 1 atm. When a piece of nickel at  $100^\circ\text{C}$  is dropped into the bath, 10.0 g of the ice melts. Calculate the total entropy change for the thermodynamic universe of this process. (Specific heats at constant  $P$ : nickel,  $0.46 \text{ J K}^{-1} \text{ g}^{-1}$ ; water,  $4.18 \text{ J K}^{-1} \text{ g}^{-1}$ ; ice,  $2.09 \text{ J K}^{-1} \text{ g}^{-1}$ . Enthalpy of fusion of ice,  $334 \text{ J g}^{-1}$ .)

#### Solution

Consider the nickel to be the *system* and the ice-water bath to be the *surroundings* in this experiment. Heat flows from the nickel into the bath and melts some of the ice. Consequently, the entropy of the nickel decreases and the entropy of the bath increases. The final equilibrium temperature of both system and bath is  $0.0^\circ\text{C}$ , as indicated by the presence of some ice in the bath at equilibrium.

Before calculating  $\Delta S_{\text{Ni}}$  it is necessary to calculate the mass of the nickel from the calorimetry equation as follows:

$$\begin{aligned} \text{heat lost by Ni} &= \text{heat gained by ice bath} = \text{heat used in melting ice} \\ -m(0.46 \text{ J K}^{-1} \text{ g}^{-1})(273.15 \text{ K} - 373.15 \text{ K}) &= (10.0 \text{ g})(334 \text{ J g}^{-1}) \\ m &= 73 \text{ g} \end{aligned}$$

(Continued)

Because the nickel is cooled at constant  $P$ , the entropy change for the nickel is calculated as

$$\Delta S_{\text{Ni}} = (73 \text{ g})(0.46 \text{ J g}^{-1} \text{ K}^{-1}) \ln (0.73) = -10 \text{ J K}^{-1}$$

Because the ice bath has remained at constant  $T$  throughout the experiment, it can be treated as a “large heat bath,” and its entropy change is calculated as

$$\Delta S_{\text{bath}} = \frac{-\Delta H_{\text{sys}}}{T_{\text{bath}}} = \frac{-(-334 \text{ J g}^{-1})(10.0 \text{ g})}{273.15 \text{ K}} = 12 \text{ J K}^{-1}$$

Now,

$$\Delta S_{\text{tot}} = \Delta S_{\text{Ni}} + \Delta S_{\text{bath}} = -10 + 12 = +2 \text{ J K}^{-1}$$

Thus, the process is spontaneous, driven by the fact that the entropy gain of the melting ice exceeds the entropy loss of the cooling metal.

**Related Problems: 17, 18, 19, 20**

### Irreversible Expansion of an Ideal Gas

Consider a gas confined within a piston-cylinder arrangement and held at constant temperature in a heat bath. Suppose the external pressure is abruptly reduced and held constant at the new lower value. The gas immediately expands against the piston until its internal pressure declines to match the new external pressure. The total entropy of system plus surroundings will increase during this expansion. In preparation for a quantitative example, a general comparison of irreversible and reversible processes connecting the same initial and final states provides insight into why the total entropy increases in a spontaneous process.

The work performed *by* a system ( $-w$ ) as it undergoes an irreversible isothermal expansion is always less than when the expansion is conducted reversibly. To see this, return to the definition of work done *on* a system:

$$w = -\int P_{\text{ext}} dV$$

During an expansion,  $P_{\text{ext}}$  must be less than  $P$ , the pressure of the gas. For a reversible expansion,  $P_{\text{ext}}$  is only infinitesimally smaller (so the system is always close to equilibrium); but for an irreversible expansion,  $P_{\text{ext}}$  is measurably smaller. Therefore, the area under a graph of  $P_{\text{ext}}$  plotted against  $V$  is less than that of a graph of  $P$  against  $V$  (Fig. 13.7), so

$$-w_{\text{irrev}} = \int P_{\text{ext}} dV < \int P dV = -w_{\text{rev}}$$

and the work performed by the system,  $-w_{\text{irrev}}$  is less than  $-w_{\text{rev}}$ . If the system is viewed as an “engine” for performing useful work on the surroundings, a reversible process is always more efficient than an irreversible one.

If the reversible and irreversible processes have the same initial and final states, then  $\Delta U$  is the same for both.

$$\Delta U = w_{\text{irrev}} + q_{\text{irrev}} = w_{\text{rev}} + q_{\text{rev}}$$

But because

$$-w_{\text{irrev}} < -w_{\text{rev}}$$

we must have

$$w_{\text{irrev}} > w_{\text{rev}}$$

and

$$q_{\text{irrev}} < q_{\text{rev}}$$

**FIGURE 13.7** Work done by a system in reversible and irreversible expansions between the same initial and final states. The work performed is greater for the reversible process.

The heat absorbed is a *maximum* when the process is conducted reversibly. The following example illustrates these inequalities.

### EXAMPLE 13.7

Calculate the heat absorbed and the work done on a system of 5.00 mol of an ideal gas as it expands irreversibly at constant temperature  $T = 298\text{ K}$  from a pressure of 10.0 to 1.00 atm. The external pressure is held constant at 1.00 atm.

#### Solution

The initial volume  $V_1$  is

$$V_1 = \frac{nRT}{P_1} = \frac{(5.00\text{ mol})(0.08206\text{ L atm K}^{-1}\text{ mol}^{-1})(298\text{ K})}{10.0\text{ atm}} = 12.2\text{ L}$$

The final volume is 10 times this, or

$$V_2 = 122\text{ L}$$

For a constant external pressure,

$$\begin{aligned} w_{\text{irrev}} &= -P_{\text{ext}}\Delta V \\ &= -(1.00\text{ atm})(122\text{ L} - 12.2\text{ L}) = -110\text{ L atm} \\ &= -11.1\text{ kJ} \end{aligned}$$

At constant  $T$ ,  $\Delta U = 0$ , however, so

$$q_{\text{irrev}} = -w_{\text{irrev}} = 11.1\text{ kJ}$$

In Example 12.10, a reversible expansion between the same two states was carried out, with the result that

$$w_{\text{rev}} = -28.5\text{ kJ}$$

This demonstrates that

$$-w_{\text{irrev}} < -w_{\text{rev}}$$

and

$$q_{\text{irrev}} < q_{\text{rev}}$$

For reversible and irreversible *isothermal* processes connecting the same pair of initial and final states, it is always true that

$$q_{\text{rev}} > q_{\text{irrev}}$$

Dividing this expression by  $T$ , the temperature at which the heat is transferred, gives

$$\frac{q_{\text{rev}}}{T} > \frac{q_{\text{irrev}}}{T}$$

The left side is the entropy change  $\Delta S_{\text{sys}}$ ,

$$\Delta S_{\text{sys}} = \frac{q_{\text{rev}}}{T}$$

so

$$\Delta S_{\text{sys}} > \frac{q_{\text{irrev}}}{T}$$

The last two equations can be combined as

$$\Delta S_{\text{sys}} \geq \frac{q}{T}$$

where the equality applies only to a reversible process. This expression, called the *inequality of Clausius*, states that in any spontaneous process the heat absorbed by the system from surroundings at the same temperature is always less than  $T\Delta S_{\text{sys}}$ . In a reversible process, the heat absorbed is equal to  $T\Delta S_{\text{sys}}$ .

Now let's apply Clausius's inequality to processes occurring within an *isolated* system. In this case, there is no transfer of heat into or out of the system,

and  $q = 0$ . Therefore, for spontaneous processes within an isolated system,  $\Delta S > 0$ .

The thermodynamic universe of a process (that is, a system plus its surroundings) is clearly an isolated system to which Clausius's inequality can be applied. It follows that

1. In a reversible process the total entropy of a system plus its surroundings is unchanged.
2. In an irreversible process the total entropy of a system plus its surroundings must increase.
3. A process for which  $\Delta S_{\text{univ}} < 0$  is not spontaneous.

These statements constitute the heart of the second law, because they justify its predictive power, which we stated as a postulate at the beginning of Section 13.5.

### EXAMPLE 13.8

Calculate  $\Delta S_{\text{tot}} = \Delta S_{\text{sys}} + \Delta S_{\text{surr}}$  for the reversible and irreversible isothermal expansions of Examples 12.10 and 13.7.

#### Solution

For the reversible expansion,

$$q_{\text{rev}} = 28.5 \text{ kJ}$$

$$\Delta S_{\text{sys}} = \frac{q_{\text{rev}}}{T} = \frac{28,500 \text{ J}}{298 \text{ K}} = +95.7 \text{ J K}^{-1}$$

The surroundings give up the same amount of heat at the same temperature. Hence,

$$\Delta S_{\text{surr}} = \frac{-28,500 \text{ J}}{298 \text{ K}} = -95.7 \text{ J K}^{-1}$$

or  $\Delta S_{\text{tot}} = 95.7 - 95.7 = 0$  for the reversible process. For the irreversible expansion, it is still true that

$$\Delta S_{\text{sys}} = +95.7 \text{ J K}^{-1}$$

because  $S$  is a function of state, and the initial and final states are the same as for the reversible expansion. From Example 13.7, only 11.1 kJ of heat is given up by the surroundings in this case.<sup>1</sup> Hence,

$$\Delta S_{\text{surr}} = \frac{-11,100 \text{ J}}{298 \text{ K}} = -37.2 \text{ J K}^{-1}$$

and  $\Delta S_{\text{tot}} = 95.7 - 37.2 = 58.5 \text{ J K}^{-1} > 0$  for the irreversible process.

## 13.6 The Third Law of Thermodynamics

In thermodynamic processes, only *changes* in entropy,  $\Delta S$ , are measured, just as only changes in internal energy,  $\Delta U$ , or enthalpy,  $\Delta H$ , are measured. It is nevertheless useful to define absolute values of entropy relative to some reference state. An important experimental observation that simplifies the choice of reference state is:

*In any thermodynamic process involving only pure phases in their equilibrium states, the entropy change  $\Delta S$  approaches zero as  $T$  approaches 0 K.*

This observation is the **Nernst heat theorem**, named after its discoverer, the German physicist Walther Nernst. It immediately suggests a choice of reference state: The entropy of any pure element in its equilibrium state is defined to approach zero as  $T$  approaches 0 K. From the Nernst theorem, the entropy change for any chemical reaction, including one in which elements react to give

<sup>1</sup>How can the heat from Example 13.7, which is irreversible from the perspective of the system, be reversible from the perspective of the surroundings? This can be accomplished by enclosing the gas in a material (such as a metal) that can efficiently transfer heat to and from the surroundings, and thus remain close to equilibrium, at the same time that the gas itself is far from equilibrium due to the gas currents that occur during the irreversible expansion.

a pure compound, approaches zero at 0 K. The most general form of this statement is the **third law of thermodynamics**:

*The entropy of any pure substance (element or compound) in its equilibrium state approaches zero at the absolute zero of temperature.*

Absolute zero can never actually be reached; therefore, a small extrapolation is needed to make use of this result.

The third law, like the two laws that precede it, is a macroscopic law based on experimental measurements. It is consistent with the microscopic interpretation of the entropy presented in Section 13.2. From quantum mechanics and statistical thermodynamics, we know that the number of microstates available to a substance at equilibrium falls rapidly toward one as the temperature approaches absolute zero. Therefore, the absolute entropy defined as  $k_B \ln \Omega$  should approach zero. The third law states that the entropy of a substance in its equilibrium state approaches zero at 0 K. In practice, equilibrium may be difficult to achieve at low temperatures, because particle motion becomes very slow. In solid CO, molecules remain randomly oriented (CO or OC) as the crystal is cooled, even though in the equilibrium state at low temperatures, each molecule would have a definite orientation. Because a molecule reorients slowly at low temperatures, such a crystal may not reach its equilibrium state in a measurable period. A nonzero entropy measured at low temperatures indicates that the system is not in equilibrium.

### 13.6.1 Standard-State Entropies

Because the entropy of any substance in its equilibrium state is zero at absolute zero, its entropy at any other temperature  $T$  is given by the entropy increase as it is heated from 0 K to  $T$ . If heat is added at constant pressure,

$$\Delta S = n \int_{T_1}^{T_2} \frac{c_p}{T} dT$$

Thus,  $S_T$ , the absolute entropy of 1 mol of substance at temperature  $T$ , is given by

$$S_T = \int_0^T \frac{c_p}{T} dT$$

It is necessary merely to measure  $c_p$  as a function of temperature and determine the area under a plot of  $c_p/T$  versus  $T$  from 0 K to any desired temperature. If a substance melts, boils, or undergoes some other phase change before reaching the temperature  $T$ , the entropy change for that process must be added to  $\int (c_p/T) dT$ .

To calculate entropy changes for chemical reactions, we find it convenient to use the same standard state already selected for enthalpy calculations in Section 12.3. For this purpose, we define the **standard molar entropy** to be the absolute molar entropy  $S^\circ$  at 298.15 K and 1 atm pressure (Fig. 13.8):

$$S^\circ = \int_0^{298.15} \frac{c_p}{T} dT + \Delta S \text{ (phase changes between 0 and 298.15 K)} \quad [13.10]$$

Standard molar entropies  $S^\circ$  are tabulated for a number of elements and compounds in Appendix D. If  $c_p$  is measured in  $\text{J K}^{-1} \text{mol}^{-1}$ , then the entropy  $S^\circ$  will have the same units. For dissolved ions, the arbitrary convention  $S^\circ (\text{H}^+(\text{aq})) = 0$  is applied (just as for the standard enthalpy of formation of  $\text{H}^+$  discussed in Section 12.3). For this reason, some  $S^\circ$  values are negative for aqueous ions—an impossibility for substances.

**FIGURE 13.8** A graph of  $c_p/T$  versus  $T$  for platinum. The black dots represent experimental measurements. The area up to any temperature (here, 298 K) is the molar entropy at that temperature.

Tabulated standard molar entropies are used to calculate entropy changes in chemical reactions at 25°C and 1 atm, just as standard enthalpies of formation are combined to obtain enthalpies of reaction according to Hess's law (see Section 12.5).

### EXAMPLE 13.9

Using the table of standard molar entropies in Appendix D, calculate  $\Delta S^\circ$  for the chemical reaction

with reactants and products at a temperature of 25°C and a pressure of 1 atm.

#### Solution

From the table,

$$S^\circ(\text{N}_2(\text{g})) = 191.50 \text{ J K}^{-1} \text{ mol}^{-1}$$

$$S^\circ(\text{O}_2(\text{g})) = 205.03 \text{ J K}^{-1} \text{ mol}^{-1}$$

$$S^\circ(\text{NO}_2(\text{g})) = 239.95 \text{ J K}^{-1} \text{ mol}^{-1}$$

The entropy change for the reaction is the sum of the entropies of the products, minus the sum of entropies of the reactants, each multiplied by its coefficient in the balanced chemical equation:

$$\begin{aligned} \Delta S^\circ &= 2S^\circ(\text{NO}_2(\text{g})) - S^\circ(\text{N}_2(\text{g})) - 2S^\circ(\text{O}_2(\text{g})) \\ &= (2 \text{ mol})(239.95 \text{ J K}^{-1} \text{ mol}^{-1}) - (1 \text{ mol})(191.50 \text{ J K}^{-1} \text{ mol}^{-1}) - \\ &\quad (2 \text{ mol})(205.03 \text{ J K}^{-1} \text{ mol}^{-1}) \\ &= -121.66 \text{ J K}^{-1} \end{aligned}$$

The factors of 2 multiply  $S^\circ$  for  $\text{NO}_2$  and  $\text{O}_2$  because 2 mol of each appears in the chemical equation. Note that standard molar entropies, unlike standard molar enthalpies of formation  $\Delta H_f^\circ$ , are not zero for elements at 25°C. The negative  $\Delta S^\circ$  results because this is the entropy change of the system only. The surroundings must undergo a positive entropy change in such a way that  $\Delta S_{\text{tot}} \geq 0$ .

**Related Problems:** 21, 22, 23, 24, 25, 26, 27, 28

## 13.7 The Gibbs Free Energy

In Section 13.5, we showed that the change in entropy of a system plus its surroundings (that is, the total change of entropy,  $\Delta S_{\text{tot}}$ ) provides a criterion for deciding whether a process is spontaneous, reversible, or non-spontaneous:

$$\Delta S_{\text{tot}} > 0 \quad \text{spontaneous} \quad [13.11a]$$

$$\Delta S_{\text{tot}} = 0 \quad \text{reversible} \quad [13.11b]$$

$$\Delta S_{\text{tot}} < 0 \quad \text{nonspontaneous} \quad [13.11c]$$

Although the algebraic sign of  $\Delta S_{\text{tot}}$  is a completely general criterion for determining the spontaneity of a process, it requires calculating the entropy change for the surroundings, as well as for the system. It would be much more convenient to have a state function that predicts the feasibility of a process in the system without explicit calculations for the surroundings.

For processes that occur at constant temperature and pressure, which is the most important set of conditions for chemical applications, such a state function exists. It is called the *Gibbs free energy* and is denoted by  $G$ . After a qualitative discussion of spontaneous laboratory processes at fixed  $T$  and  $P$ , we define  $G$  and develop its properties. Finally, we apply  $\Delta G$  to identify conditions for spontaneity in phase transitions and chemical reactions.

### 13.7.1 The Nature of Spontaneous Processes at Fixed $T$ and $P$

Consider a system enclosed in a piston-cylinder assembly, which maintains pressure at the value  $P$ . The assembly is immersed in a heat bath, which maintains temperature at the value  $T$ . Experience shows that spontaneous processes under these conditions consist of spontaneous flow of molecules across a boundary completely internal to the system, separating different regions (called *phases*) of the system (Fig. 13.9).

**FIGURE 13.9** After the constraint between phases A and B is removed, matter can flow spontaneously between phases inside a system held at constant  $T$  (temperature) and  $P$  (pressure) by its surroundings.

Under these conditions, we visualize starting a spontaneous process by bringing phases A and B in Figure 13.9 into contact—both already prepared at  $T$  and  $P$ —but separated by an impermeable membrane (a constraint) that prevents exchange of matter between the phases. Removing the constraint allows spontaneous flow of molecules across the interface between phases. The system does not exchange matter with the surroundings, and the distribution of energy and volume between system and surroundings is not described explicitly. The only function of the surroundings is to maintain  $T$  and  $P$  constant throughout the experiment. Consequently, as we show in the next subsection, spontaneity of the process is determined by the change in Gibbs free energy of the *system only* while  $T$  and  $P$  remain constant.

These processes lead to changes in the structure or composition of the phases. Solutes are redistributed between immiscible solvents. Phase transitions occur between the solid, liquid, and gaseous states. Reactants become products. The system may gain or lose heat from the large heat reservoir while these rearrangements occur in its phases, but  $T$  remains constant. For example, the latent heat of fusion released during freezing of a liquid in the system is absorbed by the bath. Endothermic processes in the system will absorb heat from the bath, and exothermic processes will give heat to the bath.  $P$ - $V$  work may be done on

or by the system at constant  $P$ , depending on whether its density increases or decreases through the rearrangements of its phases.

Whether molecules flow spontaneously from phase A to B, or vice versa, is determined by the associated change in Gibbs free energy, as we show in the following subsection.

### 13.7.2 Gibbs Free Energy and Its Properties

During any process conducted at constant  $T$  and  $P$  as described earlier, the heat gained by the system is  $\Delta H_{\text{sys}} = q_P$  and the heat transferred to the surroundings is  $-q_P = -\Delta H_{\text{sys}}$ . Because the surroundings remain at constant temperature during the process, the transfer of process heat must have the same effect on them as would a reversible transfer of the same amount of heat. Their entropy change is then

$$\Delta S_{\text{surr}} = \frac{-\Delta H_{\text{sys}}}{T_{\text{surr}}}$$

The total entropy change is

$$\begin{aligned}\Delta S_{\text{tot}} &= \Delta S_{\text{sys}} + \Delta S_{\text{surr}} = \Delta S_{\text{sys}} - \frac{\Delta H_{\text{sys}}}{T_{\text{surr}}} \\ &= \frac{-(\Delta H_{\text{sys}} - T_{\text{surr}} \Delta S_{\text{sys}})}{T_{\text{surr}}}\end{aligned}$$

Because the temperature,  $T$ , is the same for both the system and the surroundings, we can rewrite this as

$$\Delta S_{\text{tot}} = \frac{-\Delta(H_{\text{sys}} - TS_{\text{sys}})}{T} \quad [13.12]$$

We define the **Gibbs free energy**  $G$  as

$$G = H - TS \quad [13.13]$$

therefore, Equation 13.12 becomes

$$\Delta S_{\text{tot}} = \frac{-\Delta G_{\text{sys}}}{T} \quad [13.14]$$

Because the absolute temperature  $T$  is always positive,  $\Delta S_{\text{tot}}$  and  $\Delta G_{\text{sys}}$  must have the opposite sign for processes occurring at constant  $T$  and  $P$ . It follows that

$$\Delta G_{\text{sys}} < 0 \quad \text{spontaneous processes} \quad [13.15a]$$

$$\Delta G_{\text{sys}} = 0 \quad \text{reversible processes} \quad [13.15b]$$

$$\Delta G_{\text{sys}} > 0 \quad \text{nonspontaneous processes} \quad [13.15c]$$

for processes conducted at constant temperature and pressure. If  $\Delta G_{\text{sys}} > 0$  for a proposed process, then  $\Delta G_{\text{sys}} < 0$  for the *reverse* of the proposed process, and that reverse process can occur spontaneously. The connection of these relations to experiment is shown in Figure 13.9. Initially we prepare the system at chosen values of  $T$  and  $P$ , then release the appropriate constraint to allow the process to occur. The resulting “flow” of matter between phases A and B goes in the

direction that reduces the value of  $G$  for the system, so that  $\Delta G < 0$  at the selected values of  $T$  and  $P$ .

### 13.7.3 Gibbs Free Energy and Phase Transitions

As a simple application of the Gibbs free energy, consider the freezing of 1 mol liquid water to form ice:

First, let's examine what thermodynamics predicts when this process occurs at the ordinary freezing point of water under atmospheric pressure, 273.15 K. The measured enthalpy change (the heat absorbed at constant pressure) is

$$\Delta H_{273} = q_p = -6007 \text{ J mol}^{-1}$$

At  $T_f = 273.15 \text{ K}$ , water freezes reversibly—the system remains close to equilibrium as it freezes. Therefore, the entropy change is

$$\Delta S_{273} = \frac{q_{\text{rev}}}{T_f} = \frac{-6007 \text{ J mol}^{-1}}{273.15 \text{ K}} = -21.99 \text{ J K}^{-1} \text{ mol}^{-1}$$

The Gibbs free energy change for freezing is  $\Delta G_{\text{freezing}} = G_{\text{ice}} - G_{\text{water}}$  and its value at 273 K is

$$\Delta G_{273} = \Delta H_{273} - T \Delta S_{273} = -6007 \text{ J mol}^{-1} - (273.15 \text{ K})(-21.99 \text{ J K}^{-1} \text{ mol}^{-1}) = 0$$

At the normal freezing point, the Gibbs free energy change is zero because the freezing of water under these conditions is an equilibrium, reversible process.

Now, let's see what thermodynamics predicts as the water is cooled below 273.15 to 263.15 K ( $-10.00^\circ\text{C}$ ). Let's calculate the change in Gibbs free energy as water freezes at this lower temperature.

Assume that  $\Delta H$  and  $\Delta S$  for the freezing process do not depend on temperature. Then we can write

$$\Delta G_{263} = -6007 \text{ J mol}^{-1} - (263.15 \text{ K})(-21.99 \text{ J K}^{-1} \text{ mol}^{-1}) = -220 \text{ J mol}^{-1}$$

An exact calculation takes into account that  $\Delta H$  and  $\Delta S$  *do* depend slightly on temperature, and it leads to

$$\Delta G_{263} = -213 \text{ J mol}^{-1}$$

for the process. Because  $\Delta G < 0$ , thermodynamics predicts the undercooled water will freeze spontaneously at 263.15 K. At a temperature *higher* than  $T_f$ ,  $\Delta G$  is greater than 0, predicting that the liquid would not freeze. This agrees with our experience in nature. Water does not freeze at atmospheric pressure if the temperature is held greater than 273.15 K; instead, the reverse process occurs, and ice melts spontaneously.

Writing the Gibbs free energy change as  $\Delta G = \Delta H - T \Delta S$  shows that a negative value of  $\Delta G$ —and therefore a spontaneous process—is favored by a negative value of  $\Delta H$  and a positive value of  $\Delta S$ . For freezing a liquid,  $\Delta H$  is negative, but  $\Delta S$  for freezing is also negative. Whether a liquid freezes depends on the competition between two factors: an enthalpy change that favors freezing and an entropy change that disfavors freezing (Fig. 13.10). At temperatures less than  $T_f$ , the former dominates and the liquid freezes spontaneously, but at temperatures greater than  $T_f$ , the latter dominates and freezing does not occur. At  $T_f$ , the Gibbs free energies of the two phases are equal ( $\Delta G = 0$ ), and the phases coexist at equilibrium. Similar types of analysis apply to other phase transitions, such as condensing a gas to a liquid.

**FIGURE 13.10** Plots of  $\Delta H$  and  $T\Delta S$  versus temperature for the freezing of water. At 273.15 K, the two curves cross, meaning that at this temperature,  $\Delta G_{\text{freezing}} = 0$  and ice and water coexist. Below this temperature,  $\Delta G_{\text{freezing}} < 0$  and the freezing of water to ice is spontaneous. Above this temperature  $\Delta G_{\text{freezing}} > 0$  and the reverse process, the melting of ice to water, is spontaneous.

**FIGURE 13.11** The dissolution of hydrogen chloride in water,  $\text{HCl}(g) \rightarrow \text{HCl}(aq)$ , is a spontaneous process. In this demonstration, the upper flask is filled with gaseous hydrogen chloride, and a small amount of water is injected into it. As the hydrogen chloride dissolves spontaneously, its pressure declines. The resulting air pressure difference draws water up the tube from the lower flask, allowing more hydrogen chloride to dissolve. The change is so fast that a vigorous fountain of water sprays into the upper flask. The free energy change of the process appears as work, raising the water.

### 13.7.4 Gibbs Free Energy and Chemical Reactions

The change in the Gibbs free energy provides a criterion for the spontaneity of any process occurring at constant temperature and pressure (Fig. 13.11). To predict whether a chemical reaction is spontaneous at given values of  $T$  and  $P$ , it is necessary to determine only the sign of  $\Delta G$  for the reaction at these same conditions. From experience with other state functions, we would expect to calculate  $\Delta G$  for reactions by consulting appropriate tabulations of free energy data. Because we cannot know the absolute value of the Gibbs free energy of a substance (just as we cannot know the absolute value of its internal energy  $U$ ), it is convenient to define a **standard molar Gibbs free energy of formation**,  $\Delta G_f^\circ$ , analogous to the standard molar enthalpy of formation  $\Delta H_f^\circ$  introduced in Section 12.6. From tables of  $\Delta G_f^\circ$  we can calculate  $\Delta G^\circ$  for a wide range of chemical reactions, just as we used Hess's law to calculate  $\Delta H^\circ$  for a reaction from tables of  $\Delta H_f^\circ$  for products and reactants. The next few paragraphs show how tables of  $\Delta G_f^\circ$  are generated and how the data are used to determine spontaneity of reactions.

#### Standard-State Free Energies

The change in the Gibbs free energy for a chemical reaction performed at constant temperature is

$$\Delta G = \Delta H - T \Delta S \quad [13.16]$$

where  $\Delta H$  is the enthalpy change in the reaction (considered in Section 12.6) and  $\Delta S$  is the entropy change in the reaction (see Section 13.4). The standard molar Gibbs free energy of formation  $\Delta G_f^\circ$  of a compound is the change in Gibbs free energy for the reaction in which 1 mol of the compound in its standard state is formed from its elements in their standard states. (You should review the definition of standard states in Section 12.6.) For example,  $\Delta G_f^\circ$  for  $\text{CO}_2(g)$  is given by the Gibbs free energy change for the reaction

in which the partial pressures of all the gases is 1 atm. The value of  $\Delta G_f^\circ$  can be constructed from Equation 13.16 by using  $\Delta H_f^\circ$  and  $\Delta S^\circ$  values for this reaction

and setting  $T = 298.15$  K. For this reaction,  $\Delta H^\circ$  is simply  $\Delta H_f^\circ$  for  $\text{CO}_2(g)$ , because graphite and oxygen are elements in their standard states,

$$\Delta H^\circ = \Delta H_f^\circ(\text{CO}_2) = -393.51 \text{ kJ}$$

The value of  $\Delta S^\circ$  can be obtained from the absolute entropies of the substances involved at  $25^\circ\text{C}$  and 1 atm pressure (both elements and compounds, because the absolute entropy  $S^\circ$  of an element is not zero in its standard state).

$$\begin{aligned}\Delta S^\circ &= S^\circ(\text{CO}_2) - S^\circ(\text{C}) - S^\circ(\text{O}_2) = 213.63 - 5.74 - 205.03 \text{ J K}^{-1} \\ &= +2.86 \text{ J K}^{-1}\end{aligned}$$

The  $\Delta G_f^\circ$  for  $\text{CO}_2$  is then

$$\begin{aligned}\Delta G_f^\circ &= \Delta H_f^\circ - T \Delta S^\circ = -393.51 \text{ kJ} - (298.15 \text{ K})(2.86 \text{ J K}^{-1})(10^{-3} \text{ kJ J}^{-1}) \\ &= -394.36 \text{ kJ}\end{aligned}$$

Appendix D includes a table of  $\Delta G_f^\circ$  values for numerous substances, all obtained by the method just illustrated. Note that our definition makes  $\Delta G_f^\circ = 0$  for an *element* that is already in its standard state.

Because  $G$  is a state function, chemical equations can be added together—with their  $\Delta G_f^\circ$  values combined as in Hess's law for changes in enthalpy—to calculate Gibbs free energy changes for chemical reactions under standard-state conditions.

**FIGURE 13.12** The entropy change of the reaction  $3 \text{NO}(g) \rightarrow \text{N}_2\text{O}(g) + \text{NO}_2(g)$  varies less than 5% between  $0^\circ\text{C}$  and  $300^\circ\text{C}$ ; the enthalpy of reaction is even closer to constancy. The free energy change in the reaction shifts greatly over the temperature range, however, as the magnitude of  $T \Delta S$  increases. Note that the units are very different on the left- (energy) and right-hand vertical axes (entropy).

### EXAMPLE 13.10

Calculate  $\Delta G^\circ$  for the following reaction, using tabulated values for  $\Delta G_f^\circ$  from Appendix D.

#### Solution

$$\begin{aligned}\Delta G^\circ &= \Delta G_f^\circ(\text{N}_2\text{O}) + \Delta G_f^\circ(\text{NO}_2) - 3 \Delta G_f^\circ(\text{NO}) \\ &= (1 \text{ mol})(104.18 \text{ kJ mol}^{-1}) + (1 \text{ mol})(51.29 \text{ kJ mol}^{-1}) - (3 \text{ mol})(86.55 \text{ kJ mol}^{-1}) \\ &= -104.18 \text{ kJ}\end{aligned}$$

### Effects of Temperature on $\Delta G$

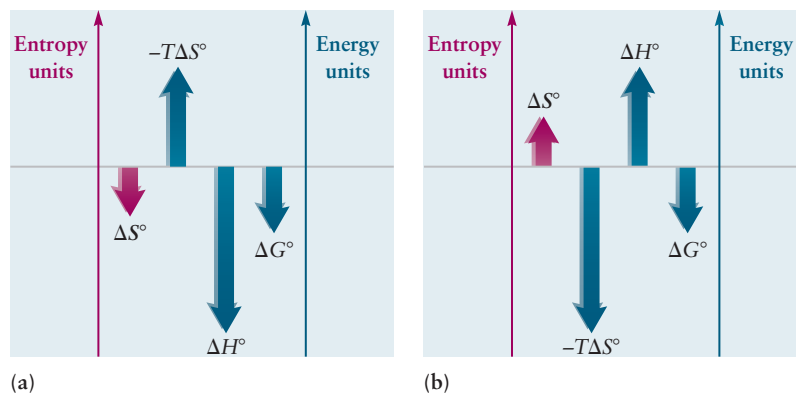

Values of  $\Delta G^\circ$  calculated from the data in Appendix D are accurate only at  $T = 298.15$  K. Values of  $\Delta G^\circ$  can be estimated for reactions at other temperatures and at  $P = 1$  atm using the equation

$$\Delta G^\circ = \Delta H^\circ - T \Delta S^\circ \quad [13.17]$$

and tables of standard entropies and standard enthalpies of formation. The estimates will be close to the true value if  $\Delta H^\circ$  and  $\Delta S^\circ$  are not strongly dependent on  $T$ , which is usually the case (Fig. 13.12).

The value and the sign of  $\Delta G^\circ$  can depend strongly on  $T$ , even when the values of  $\Delta H^\circ$  and  $\Delta S^\circ$  do not, because of the competition between  $\Delta H^\circ$  and  $T \Delta S^\circ$  in Equation 13.17. If  $\Delta H^\circ$  is negative and  $\Delta S^\circ$  is positive, then the reaction is spontaneous at all temperatures when reactants and products are at

**FIGURE 13.13** The competition between  $\Delta H^\circ$  and  $\Delta S^\circ$  determines the temperature range in which a reaction is spontaneous. (a) If both  $\Delta H^\circ$  and  $\Delta S^\circ$  are negative, the reaction is spontaneous at temperatures less than  $T^* = \Delta H^\circ/\Delta S^\circ$ . (b) If both  $\Delta H^\circ$  and  $\Delta S^\circ$  are positive, the reaction is spontaneous at temperatures greater than  $T^* = \Delta H^\circ/\Delta S^\circ$ . Note that the reactants and products must be in their standard states to use  $\Delta G^\circ$  rather than  $\Delta G$  to determine spontaneity.

atmospheric pressure. If  $\Delta H^\circ$  is positive and  $\Delta S^\circ$  is negative, the reaction is never spontaneous. For the other possible combinations, there exists a special temperature  $T^*$ , defined by

$$T^* = \frac{\Delta H^\circ}{\Delta S^\circ} \quad [13.18]$$

at which  $\Delta G^\circ$  equals zero. If both  $\Delta H^\circ$  and  $\Delta S^\circ$  are positive, the reaction will be spontaneous at temperatures greater than  $T^*$ . If both are negative, the reaction will be spontaneous at temperatures less than  $T^*$  (Fig. 13.13). This discussion demonstrates an important result from chemical thermodynamics with practical importance: With knowledge of  $\Delta H^\circ$  and  $\Delta S^\circ$ , we can change the temperature (holding the partial pressures of the gases involved at 1 atm each) to make a reaction spontaneous.

## 13.8 A DEEPER LOOK Carnot Cycles, Efficiency, and Entropy

This section provides a mathematical development of the relation between entropy and heat already presented qualitatively in Section 13.3. No additional results are obtained, but considerably greater insight is provided.

### 13.8.1 The Carnot Cycle

A heat engine and its operation are shown schematically in Section 13.3.1. The engine is a thermodynamic system which interacts with its surroundings in the course of a cyclic process. The engine withdraws (gains) energy in the form of heat from the high-temperature reservoir, and uses part of that energy to perform work on its surroundings. The remainder of the thermal energy is discharged (lost by the engine) to the lower temperature reservoir. In a Carnot cycle (Fig. 13.14), the engine (system) traverses two isothermal and two adiabatic paths to return to its original state. Each path is carried out reversibly (that is, in thermal equilibrium, with internal and external forces nearly balanced at every step). As the system proceeds from state A to C through state B, the system performs work (Fig. 13.14a):

$$w_{ABC} = -\int_{V_A}^{V_C} P dV$$

(Path ABC)

**FIGURE 13.14** Stages of the Carnot cycle. The work done by the system in expansion (a) and on the system by compression (b) is shown by the shaded areas. (c) The net work done per cycle is the area enclosed by the curve ABCDA.

and it is clearly negative for this (expansion) process. If the system then returns from state C to A through state D,

$$w_{CDA} = -\int_{V_C}^{V_A} P dV$$

(Path CDA)

which is now a positive quantity for this (compression) process; work is performed on the system (see Fig. 13.14b). In the course of the cycle, the work performed by the system is the area under curve ABC, whereas that performed on the system is the (smaller) area under curve ADC. The net result of the whole cycle is that work is performed by the system, and the amount of this work is the difference between the two areas, which is the area enclosed by the cycle (see Fig. 13.14c). As in any cyclic process, the overall energy change  $\Delta U$  is zero, thus the net work equals the negative of the total heat added to the system.

We have not yet specified the material contained in the system. Assume initially that it is an ideal gas, for which the results from Section 12.7 apply directly, with  $T_h$  defined to be the higher temperature in the cycle and  $T_l$  the lower temperature.

**Path AB: Isothermal Expansion (temperature  $T_h$ )**

$$w_{AB} = -q_{AB} = -nRT_h \ln\left(\frac{V_B}{V_A}\right)$$

**Path BC: Adiabatic Expansion**

$$q_{BC} = 0$$

$$w_{BC} = nC_V(T_l - T_h) = -nC_V(T_h - T_l)$$

**Path CD: Isothermal Compression (temperature  $T_l$ )**

$$w_{CD} = -q_{CD} = -nRT_l \ln\left(\frac{V_D}{V_C}\right)$$

$$= nRT_l \ln\left(\frac{V_C}{V_D}\right)$$

**Path DA: Adiabatic Compression**

$$q_{DA} = 0$$

$$w_{DA} = nC_V(T_h - T_l)$$

The net work done on the system is

$$\begin{aligned}
 w_{\text{net}} &= w_{\text{AB}} + w_{\text{BC}} + w_{\text{CD}} + w_{\text{DA}} \\
 &= -nRT_{\text{h}} \ln\left(\frac{V_{\text{B}}}{V_{\text{A}}}\right) - nc_{\text{v}}(T_{\text{h}} - T_{\text{l}}) \\
 &\quad + nRT_{\text{l}} \ln\left(\frac{V_{\text{C}}}{V_{\text{D}}}\right) + nc_{\text{v}}(T_{\text{h}} - T_{\text{l}}) \\
 &= -nRT_{\text{h}} \ln\left(\frac{V_{\text{B}}}{V_{\text{A}}}\right) + nRT_{\text{l}} \ln\left(\frac{V_{\text{C}}}{V_{\text{D}}}\right)
 \end{aligned}$$

This can be simplified by noting that  $V_{\text{B}}$  and  $V_{\text{C}}$  lie on one adiabatic path, and  $V_{\text{A}}$  and  $V_{\text{D}}$  lie on another. In Section 12.7, the relation for a reversible adiabatic process was found:

$$\frac{T_2}{T_1} = \left(\frac{V_1}{V_2}\right)^{\gamma-1}$$

Hence,

$$\frac{T_{\text{h}}}{T_{\text{l}}} = \left(\frac{V_{\text{C}}}{V_{\text{B}}}\right)^{\gamma-1} \text{ for path BC}$$

and

$$\frac{T_{\text{h}}}{T_{\text{l}}} = \left(\frac{V_{\text{D}}}{V_{\text{A}}}\right)^{\gamma-1} \text{ for path DA}$$

Equating these expressions gives

$$\left(\frac{V_{\text{C}}}{V_{\text{B}}}\right)^{\gamma-1} = \left(\frac{V_{\text{D}}}{V_{\text{A}}}\right)^{\gamma-1}$$

or

$$\frac{V_{\text{C}}}{V_{\text{B}}} = \frac{V_{\text{D}}}{V_{\text{A}}} \text{ and } \frac{V_{\text{B}}}{V_{\text{A}}} = \frac{V_{\text{C}}}{V_{\text{D}}}$$

Hence, the net work done in one passage around the Carnot cycle is

$$w_{\text{net}} = -nR(T_{\text{h}} - T_{\text{l}}) \ln \frac{V_{\text{B}}}{V_{\text{A}}} \quad [13.19]$$

### 13.8.2 Heat Engines

The Carnot cycle is an idealized model for a heat engine. When a certain amount of heat,  $q_{\text{AB}}$ , is added to the system at the higher temperature,  $T_{\text{h}}$ , a net amount of work,  $-w_{\text{net}}$ , is obtained from the system. In addition, some heat  $q_{\text{CD}}$  is discharged at the lower temperature, but this energy is “degraded” and is no longer available for use in the engine. The **efficiency**,  $\epsilon$ , of such an engine is the ratio of the negative of the net work done on the system,  $-w_{\text{net}}$ , to the heat added along the high-temperature isothermal path:

$$\epsilon = \frac{-w_{\text{net}}}{q_{\text{AB}}}$$

It is the net work that is available for the performance of useful mechanical tasks such as turning electrical generators or dynamos, but it is the heat,  $q_{AB}$ , absorbed at the higher temperature,  $T_h$ , that must be “paid for” in terms of coal or oil consumed to supply it. The efficiency,  $\epsilon$ , must be maximized to get out the most work possible for the lowest cost.

For the ideal gas Carnot cycle, the efficiency is easily calculated:

$$\begin{aligned}\epsilon &= \frac{-w_{\text{net}}}{q_{AB}} = \frac{nR(T_h - T_l) \ln(V_B/V_A)}{nRT_h \ln(V_B/V_A)} \\ \epsilon &= \frac{T_h - T_l}{T_h} = 1 - \frac{T_l}{T_h}\end{aligned}\quad [13.20]$$

This result, called the Carnot efficiency or the **thermodynamic efficiency**, places a fundamental limit on the efficiency with which heat can be converted to mechanical work. Only if the high temperature,  $T_h$ , were infinite or the low temperature,  $T_l$ , were zero would it be possible to have a heat engine operate with 100% efficiency. To maximize efficiency, the greatest possible temperature difference should be used. Although we derived this result specifically for the ideal gas, we will show later in this section that it applies to *any* reversible engine operating between two temperatures. For a *real* engine, which must operate irreversibly, the actual efficiency must be lower than the thermodynamic efficiency.

### EXAMPLE 13.11

Suppose a heat engine absorbs 10.0 kJ of heat from a high-temperature source at  $T_h = 450$  K and discards heat to a low-temperature reservoir at  $T_l = 350$  K. Calculate the thermodynamic efficiency,  $\epsilon$ , of conversion of heat to work; the amount of work performed,  $-w_{\text{net}}$ ; and the amount of heat discharged at  $T_l$ ,  $q_{CD}$ .

#### Solution

$$\epsilon = \frac{T_h - T_l}{T_h} = \frac{450 \text{ K} - 350 \text{ K}}{450 \text{ K}} = 0.222$$

Therefore, the engine can be, at most, 22.2% efficient. Because

$$\epsilon = -w_{\text{net}}/q_{AB},$$

$$w_{\text{net}} = -\epsilon q_{AB} = -(0.222)(10.0 \text{ kJ}) = -2.22 \text{ kJ}$$

Because  $\Delta U$  for the whole cycle is 0,

$$\Delta U = 0 = q_{AB} + q_{CD} + w_{\text{net}}$$

$$q_{CD} = -q_{AB} - w_{\text{net}} = -10.0 + 2.22 = -7.8 \text{ kJ}$$

Therefore, 7.8 kJ is discharged at 350 K. This heat must be removed from the vicinity of the engine by a cooling system; otherwise, it will cause  $T_l$  to increase and reduce the efficiency of the engine.

**Related Problems: 39, 40**

### 13.8.3 Efficiency of General Carnot Engines

This subsection shows that all Carnot engines operating reversibly between two temperatures,  $T_h$  and  $T_l$ , have the same efficiency:

$$\epsilon = \frac{-w_{\text{net}}}{q_h} = \frac{T_h - T_l}{T_h}\quad [13.21]$$

That is, the efficiency calculated for an ideal gas applies equally to any other working fluid. To demonstrate this, we assume the *contrary* true and show that assumption leads to a contradiction with experience. The assumption is, therefore, deemed false.

Assume that there *are* two reversible machines operating between the same two temperatures,  $T_h$  and  $T_l$ , one of which has an efficiency,  $\epsilon_1$ , that is greater than the efficiency,  $\epsilon_2$ , of the other. The two machines are adjusted so that the total work output is the same for both. The more efficient machine is run as a heat engine so that it produces mechanical work  $-w_1$ . This work is used to operate the other machine in the opposite sense (as a heat pump) so that  $w_2 = -w_1$ . The net work input to the *combined* machines is then zero, because the work produced by the first machine is used to run the second.

Now, let's examine what happens to heat in this situation. Because engine 1 is more efficient than engine 2 and because the work is the same for both, engine 1 must withdraw less heat from the hot reservoir at  $T_h$  than is discharged into the same reservoir by engine 2; there is a net transfer of heat *into* the high-temperature reservoir. For the combined engines,  $\Delta U_{\text{tot}} = w_{\text{tot}} = 0$ ; so  $q_{\text{tot}}$  must also be zero, and a net transfer of heat *out of* the low-temperature reservoir must therefore occur. By this reasoning we have devised an apparatus that can transfer heat from a low-temperature to a high-temperature reservoir with no net expenditure of work.

*But that is impossible.* All our experience shows we cannot make a device that transfers heat from a cold body to a hot body without doing work. In fact, exactly the opposite is seen: Heat flows spontaneously from hotter to colder bodies. Our experience is summarized and generalized in the following statement:

*It is impossible to construct a device that will transfer heat from a cold reservoir to a hot reservoir in a continuous cycle with no net expenditure of work.*

This is one form of the second law of thermodynamics, as stated by Rudolf Clausius.

### 13.8.4 Further Discussion of Efficiency

Our assumption led to a conclusion that contradicts experience. Therefore, the original assumption must have been wrong, and there *cannot* be two reversible engines operating between the same two temperatures with different efficiencies. That is, all Carnot engines must have the same efficiency, which is

$$\epsilon = \frac{T_h - T_l}{T_h}$$

for the ideal gas. For any substance, ideal or not, undergoing a Carnot cycle,

$$\epsilon = \frac{-w_{\text{net}}}{q_h} = \frac{q_h + q_l}{q_h} = \frac{T_h - T_l}{T_h}$$

The Carnot cycle forms the basis for a *thermodynamic* scale of temperature. Because  $\epsilon = 1 - (T_l/T_h)$ , the Carnot efficiencies determine temperature ratios and thereby establish a temperature scale. The difficulty of operating real engines close to the reversible limit makes this definition of temperature scale impractical. Instead, real gases at low pressures are used to define and determine temperatures (see Section 9.2).

The last two terms of the preceding equation can be rewritten as

$$1 + \frac{q_l}{q_h} = 1 - \frac{T_l}{T_h}$$

**FIGURE 13.15** A general cyclic process (ABCD) can be approximated to arbitrary accuracy by the sum of a series of Carnot cycles.

and simplified to

$$\frac{q_h}{T_h} + \frac{q_l}{T_l} = 0 \quad [13.22]$$

This simple equation has profound importance because it contains the essence of the second law of thermodynamics, namely, that  $q_{\text{rev}}/T$  is a state function. To see this, consider a *general* reversible cyclic process and draw a series of closely spaced adiabats, as shown in Figure 13.15. (An adiabat is a curve on the  $PV$  diagram showing those thermodynamic states connected by a particular reversible adiabatic process.) Now replace each segment along the given cycle (ABCD) with a series of alternating isothermal and adiabatic segments. Clearly, we can construct a path that is arbitrarily close to the desired curve by taking more and more closely spaced adiabats.

Now follow the evolution of  $\sum_i (q_i/T_i)$  along this curve. The key observation is that the contributions  $q_i/T_i$  appear in pairs: For each  $q_{h,i}/T_{h,i}$  from an isothermal segment along the ABC path, there is a  $q_{l,i}/T_{l,i}$  along the CDA path. Any given pair forms two sides of a Carnot cycle, with the other two sides determined by adiabats; thus,

$$\frac{q_{h,i}}{T_{h,i}} + \frac{q_{l,i}}{T_{l,i}} = 0$$

Summing over  $i$  shows that

$$\sum_i \left( \frac{q_{h,i}}{T_{h,i}} + \frac{q_{l,i}}{T_{l,i}} \right) = 0$$

Because this summation follows the original reversible path to an arbitrary accuracy (if the lengths of the segments are made short enough), it follows that

$$\int \frac{1}{T} dq_{\text{rev}} = 0$$

for *any* closed, reversible path. Although  $q$  is not a state function,  $q_{\text{rev}}/T$  is a state function because, like energy and enthalpy, its total change is zero for any process that begins and ends in the same state. From this result, Clausius *defined* the entropy change  $\Delta S = S_f - S_i$  of a system in a process starting in state  $i$  and ending in state  $f$  by the equation

$$\Delta S = \int_i^f \frac{dq_{\text{rev}}}{T} \quad [13.23]$$

As we have stated, the principles of thermodynamics are based on observations of nature and are not subject to mathematical proof. We have accomplished something quite significant, however. From the assumption—based on physical observation—that heat cannot be transferred from a low-temperature to a high-temperature body without expenditure of work, we have derived the result that  $\int (1/T) dq_{\text{rev}}$  is independent of path and, therefore, is a state function. This result has been subjected to rigorous testing, and no proper test has found it to be invalid. Therefore, we have great confidence in the generality of this result and are entirely comfortable in calling it a scientific law. Some critics might say, “If we have to make some assumption anyway, why don’t we just assume that  $\int (1/T) dq_{\text{rev}}$  is path independent to start with?” This is certainly possible and is practiced in many presentations of thermodynamics. Our approach is different; we prefer to base our assumptions directly on physical observation, not on abstract mathematical axioms.

## CHAPTER SUMMARY

---

This chapter opened with the quest for methods of predicting whether a chemical reaction can occur spontaneously under a given set of conditions. The second law provides the answer: Any process is spontaneous under conditions where the total entropy of the *system and its surroundings* can increase during the process. For the particular case of constant temperature ( $T$ ) and pressure ( $P$ )—the conditions most widely used for chemical reaction—the second law asserts that any process is spontaneous when the Gibbs free energy of the *system alone* can decrease during the process. The temperature dependence of the Gibbs free energy change shows that with knowledge of  $\Delta H^\circ$  and  $\Delta S^\circ$ , we can identify the temperature range in which a given reaction is spontaneous under standard conditions. From the point of view of chemistry, predicting this temperature range is the most important result from the second law. All other material in this chapter can be viewed as preliminary background for arriving at this one crucial result.

The Gibbs free energy is the thermodynamic state function most naturally suited to describing the progress of chemical reactions at constant  $T$  and  $P$ . It provides the basis for predicting the equilibrium composition of the reaction mixture in Chapter 14.

## CONCEPTS AND SKILLS

---

### Section 13.1 – The Nature of Spontaneous Processes

*Identify the system and surroundings involved in a spontaneous process and identify the constraint that was removed to enable the process to occur (Problems 1–2).*

- Initially the system is separated from the surroundings by special walls (constraints) that prevent interaction between them. Adiabatic walls prevent flow

of thermal energy (heat), rigid walls keep their volumes fixed, and impermeable walls prevent flow of matter. Removing one or more of the constraints allows the system and surroundings to exchange energy, matter, volume, or some combination of these. Then, a spontaneous process can occur if that process would increase the total entropy of the combined system and surroundings. Whether a spontaneous process does occur perceptibly depends on its rate. Thermodynamics cannot describe or predict the rates of processes.

### Section 13.2 – Entropy and Spontaneity: A Molecular Statistical Interpretation

*Provide a statistical interpretation of the change in entropy that occurs when a gas undergoes a change in volume (Problems 3–10).*

- Increasing the volume increases the range of possible positions available to the molecules, thereby increasing  $\Omega$ , the number of microstates available to the system. The entropy will increase according to Boltzmann's equation  $S = k_B \ln \Omega$ . Doubling the volume will change the entropy by the amount  $\Delta S = N_A k_B \ln 2$ . Similarly, decreasing the volume will decrease the entropy. Reducing the volume to half of the initial volume will change the entropy by the amount  $\Delta S = N_A k_B \ln(0.5)$ .

### Section 13.3 – Entropy and Heat: Macroscopic Basis of the Second Law of Thermodynamics

*Summarize the justification that entropy is a state function.*

- By analyzing the Carnot cycle description of macroscopic energy transfer processes, Clausius demonstrated that the quantity  $\int (1/T) dq_{\text{rev}}$  is a state function, because its change in value for any reversible process is independent of the path. Based on this result, Clausius defined the procedure for calculating the entropy change  $\Delta S = S_f - S_i$  for a system between any thermodynamic states  $i$  and  $f$   $\Delta S = \int_i^f (1/T) dq_{\text{rev}}$ . The integral can be evaluated along any reversible path between  $i$  and  $f$  so long as  $T$  and  $dq_{\text{rev}}$  are known along the path. Because  $S$  is a state function, this procedure is valid for any process—even an irreversible one—that connects states  $i$  and  $f$ .

### Sections 13.4 and 13.5 – Entropy Changes in Reversible Processes and Entropy Changes and Spontaneity

*Calculate the entropy change for the system and the surroundings for reversible and irreversible processes (Problems 11–20).*

- Because entropy is a state function, changes in entropy are always calculated along a reversible path connecting the specified initial and final states. The details of the calculation depend on the conditions of the reversible path selected (constant  $T$ , constant  $P$ , or constant  $V$ ). Specific cases are summarized as follows and in the list of Key Equations.
  - It is easy to calculate entropy changes for isothermal processes, because  $T$  is constant and comes outside the integral to give  $\Delta S = q_{\text{rev}}/T$ . A specific example is the isothermal compression or expansion of an ideal gas, for which  $\Delta S = nR \ln(V_f/V_i)$ . A second example is any phase transition at constant pressure and temperature where the phases are in equilibrium; for this case  $q_{\text{rev}} = \Delta H_{\text{trans}}$ . The entropy change is then  $\Delta S_{\text{trans}} = \Delta H_{\text{trans}}/T_{\text{trans}}$ .
  - When the temperature changes during a process that does not include a phase transition or a chemical reaction, we account for the variation of  $T$  along the process path by writing  $dq_{\text{rev}} = nc_X dT$ , where  $X$  represents  $V$  or  $P$  for a constant volume or a constant pressure process, respectively. When  $c_X$  is constant, the integral gives  $\Delta S = nc_X \ln(T_f/T_i)$ .

- Usually the surroundings are sufficiently large that they can be considered a constant temperature and constant pressure heat bath during the process. The heat lost by the system during the process is gained by the surroundings, so the entropy change for the surroundings is  $\Delta S_{\text{surr}} = -\Delta H_{\text{sys}}/T_{\text{surr}}$  if the internal pressure of the system was constant. If the surroundings are not large enough to be treated in this way,  $\Delta S_{\text{surr}}$  is calculated by the same procedures as  $\Delta S_{\text{sys}}$ .
- To determine whether a process is spontaneous, we must calculate the total entropy change,  $\Delta S_{\text{tot}} = \Delta S_{\text{sys}} + \Delta S_{\text{surr}}$ . If  $\Delta S_{\text{tot}} > 0$ , the process is spontaneous. If  $\Delta S_{\text{tot}} < 0$ , the process cannot occur spontaneously. If  $\Delta S_{\text{tot}} = 0$ , the system is at equilibrium, and no process will occur.

### Section 13.6 – The Third Law of Thermodynamics

*Describe the measurements of absolute entropy, and calculate standard-state entropy changes for chemical reactions (Problems 21–28).*

- The third law of thermodynamics states that the entropy of any pure substance in equilibrium approaches 0 as the temperature approaches absolute zero. Therefore the absolute entropy at any value of  $T$  can be obtained by measuring  $c_p$  and integrating the ratio  $c_p/T$  over this temperature range. The entropy changes for any phase transitions that occur in the temperature range must be included. Standard state values at  $T = 298.15$  K are tabulated from results based on the equation

$$S^\circ = \int_0^{298.15} (c_p/T) dT + \Delta S \quad \begin{array}{l} \text{(for all phase changes} \\ \text{between 0 and 298.15 K)} \end{array} \quad [13.10]$$

- The standard state entropy change for a chemical reaction is calculated by summing the standard state entropy values for the products (multiplied by stoichiometric coefficients from the balanced equation for the reaction) and subtracting the standard state entropy values for the reactants (multiplied by stoichiometric coefficients).

### Section 13.7 – The Gibbs Free Energy

*Define the Gibbs free energy function and state the criterion it provides for the spontaneity of a process.*

- When processes are conducted at fixed temperature and pressure, spontaneity is determined by changes in the Gibbs free energy,  $G = H - TS$ , for the system with no consideration of changes in the surroundings. If  $\Delta G < 0$ , the process is spontaneous. If  $\Delta G > 0$ , the process cannot occur spontaneously. If  $\Delta G = 0$ , the system is at equilibrium, and no process will occur.

*Calculate the change in Gibbs free energy for reversible and spontaneous phase transition (Problems 29–32).*

- This change is calculated using  $\Delta G = \Delta H - T_{tr}\Delta S$  at the temperature  $T_{tr}$  of the transition.  $\Delta H_{tr}$  is the measured enthalpy change of the transition occurring at constant pressure. The entropy change is calculated as  $\Delta S_{tr} = \Delta H_{tr}/T_{tr}$  only if the temperature and pressure are such that the two phases are at equilibrium with each other. If they are not, then you must calculate  $\Delta S$  from the sum of a few steps (since entropy is a state function). These terms are summed to obtain  $\Delta G_{tr}$  for the transition.

*Calculate the change in Gibbs free energy for chemical reactions and identify temperature ranges in which a particular reaction is spontaneous (Problems 33–38).*

- Tabulations of the standard Gibbs free energy of formation for each substance in its standard state have been prepared by combining absolute entropy values with standard enthalpy of formation values. We can determine

whether any chemical reaction is spontaneous by calculating its value of  $\Delta G$  from the tabulated standard Gibbs free energy for its reactants and products. The algebraic sign of  $\Delta G$  tells us whether the reaction is spontaneous. When the reactants and products are in their standard state partial pressures or concentrations, whether a reaction is spontaneous depends on the relation between  $\Delta H^\circ$  and  $\Delta S^\circ$  at the temperature of the reaction. If  $\Delta H^\circ < 0$  and  $\Delta S^\circ > 0$ , the reaction is spontaneous at all temperatures. If  $\Delta H^\circ > 0$  and  $\Delta S^\circ < 0$ , the reaction is never spontaneous. For other combinations, there is a special temperature  $T^* = \Delta H^\circ/\Delta S^\circ$  at which  $\Delta G^\circ = 0$ . If both  $\Delta H^\circ$  and  $\Delta S^\circ$  are positive, the reaction is spontaneous for temperatures greater than  $T^*$ . If both  $\Delta H^\circ$  and  $\Delta S^\circ$  are negative, the reaction is spontaneous for temperatures less than  $T^*$ .

## KEY EQUATIONS

Sections 13.4 and 13.5—Entropy Changes in Reversible Processes. Entropy Changes and Spontaneity.

$$\Delta S = \int_i^f \frac{dq_{\text{rev}}}{T} \quad (\text{for all processes})$$

$$\Delta S = \int_i^f \frac{dq_{\text{rev}}}{T} = \frac{1}{T} \int_i^f dq_{\text{rev}} = \frac{q_{\text{rev}}}{T} \quad (\text{constant } T)$$

$$\Delta S_{\text{trans}} = \frac{q_{\text{rev}}}{T_{\text{trans}}} = \frac{\Delta H_{\text{trans}}}{T_{\text{trans}}} \quad (\text{reversible phase transitions at constant } T \text{ and } P)$$

$$\Delta S = nR \ln \left( \frac{V_2}{V_1} \right) \quad (\text{ideal gas, change of } V \text{ at constant } T)$$

$$\Delta S = \int_{T_1}^{T_2} \frac{nc_V}{T} dT = nc_V \ln \left( \frac{T_2}{T_1} \right) \quad (\text{constant } V \text{ and constant } c_V) \\ \text{with no phase changes or chemical reactions}$$

$$\Delta S = \int_{T_1}^{T_2} \frac{nc_P}{T} dT = nc_P \ln \left( \frac{T_2}{T_1} \right) \quad (\text{constant } P \text{ and constant } c_P) \\ \text{with no phase changes or chemical reactions}$$

$$\Delta S_{\text{surr}} = \frac{-\Delta H_{\text{sys}}}{T_{\text{surr}}} \quad (\text{surroundings are a large "heat bath" and pressure of the system is constant})$$

$$\Delta S_{\text{tot}} = \Delta S_{\text{sys}} + \Delta S_{\text{surr}} > 0 \quad (\text{spontaneous process})$$

## CUMULATIVE EXERCISE

### Purifying Nickel from Its Ores

Impure nickel, obtained from the smelting of its sulfide ores in a blast furnace, can be converted to metal of 99.90% to 99.99% purity by the Mond process, which relies on the equilibrium

The standard enthalpy of formation of nickel tetracarbonyl,  $\text{Ni}(\text{CO})_4(g)$ , is  $-602.9 \text{ kJ mol}^{-1}$ , and its absolute entropy  $S^\circ$  is  $410.6 \text{ J K}^{-1} \text{ mol}^{-1}$ .

- (a) Predict (without referring to a table) whether the entropy change of the system (the reacting atoms and molecules) is positive or negative in this process.

- (b) At a temperature where this reaction is spontaneous, predict whether the entropy change of the surroundings is positive or negative.
- (c) Use the data in Appendix D to calculate  $\Delta H^\circ$  and  $\Delta S^\circ$  for this reaction.
- (d) At what temperature is  $\Delta G^\circ = 0$  for this reaction?
- (e) The first step in the Mond process is the equilibration of impure nickel with CO and  $\text{Ni}(\text{CO})_4$  at about  $50^\circ\text{C}$ . In this step, the goal is to draw as much nickel as possible into the vapor-phase complex. Calculate  $\Delta G^\circ$  for the preceding reaction at  $50^\circ\text{C}$ .
- (f) In the second step of the Mond process, the gases are removed from the reaction chamber and heated to about  $230^\circ\text{C}$ . At high enough temperatures, the sign of  $\Delta G^\circ$  is reversed and the reaction occurs in the opposite direction, depositing pure nickel. In this step, the goal is to deposit as much nickel as possible from the vapor-phase complex. Calculate  $\Delta G^\circ$  for the preceding reaction at  $230^\circ\text{C}$ .
- (g) The Mond process relies on the volatility of  $\text{Ni}(\text{CO})_4$  for its success. Under room conditions, this compound is a liquid, but it boils at  $42.2^\circ\text{C}$  with an enthalpy of vaporization of  $29.0 \text{ kJ mol}^{-1}$ . Calculate the entropy of vaporization of  $\text{Ni}(\text{CO})_4$ , and compare it with that predicted by Trouton's rule.
- (h) A recently developed variation of the Mond process carries out the first step at higher pressures and at a temperature of  $150^\circ\text{C}$ . Estimate the maximum pressure of  $\text{Ni}(\text{CO})_4(g)$  that can be attained before the gas will liquefy at this temperature (that is, calculate the vapor pressure of  $\text{Ni}(\text{CO})_4(\ell)$  at  $150^\circ\text{C}$ ).

### Answers

- (a) Negative
- (b) Positive
- (c)  $\Delta H^\circ = -160.8 \text{ kJ}$ ;  $\Delta S^\circ = -409.5 \text{ J K}^{-1}$
- (d)  $392.7 \text{ K} = 119.5^\circ\text{C}$
- (e)  $\Delta G^\circ = -28.4 \text{ kJ}$
- (f)  $\Delta G^\circ = +46.0 \text{ kJ}$
- (g)  $92.0 \text{ J K}^{-1} \text{ mol}^{-1}$ , close to the Trouton's rule value of  $88 \text{ J K}^{-1} \text{ mol}^{-1}$
- (h)  $16.7 \text{ atm}$

## PROBLEMS

Answers to problems whose numbers are red appear in Appendix G. Problems that are more challenging are indicated with asterisks.

### 13.1 The Nature of Spontaneous Processes

- For each of the following processes, identify the system and the surroundings. Identify those processes that are spontaneous. For each spontaneous process, identify the constraint that has been removed to enable the process to occur:
  - Ammonium nitrate dissolves in water.
  - Hydrogen and oxygen explode in a closed bomb.
  - A rubber band is rapidly extended by a hanging weight.
  - The gas in a chamber is slowly compressed by a weighted piston.
  - A glass shatters on the floor.
- For each of the following processes, identify the system and the surroundings. Identify those processes that are spontaneous. For each spontaneous process, identify the constraint that has been removed to enable the process to occur:
  - A solution of hydrochloric acid is titrated with a solution of sodium hydroxide.
  - Zinc pellets dissolve in aqueous hydrochloric acid.
  - A rubber band is slowly extended by a hanging weight.
  - The gas in a chamber is rapidly compressed by a weighted piston.
  - A tray of water freezes in the freezing compartment of an electric refrigerator.

### 13.2 Entropy and Spontaneity: A Molecular Statistical Interpretation

3. (a) How many “microstates” are there for the numbers that come up on a pair of dice?  
(b) What is the probability that a roll of a pair of dice will show two sixes?
4. (a) Suppose a volume is divided into three equal parts. How many microstates can be written for all possible ways of distributing four molecules among the three parts?  
(b) What is the probability that all four molecules are in the leftmost third of the volume at the same time?
5. When  $\text{H}_2\text{O}(\ell)$  and  $\text{D}_2\text{O}(\ell)$  are mixed, the following reaction occurs spontaneously:

There is little difference between the enthalpy of an O—H bond and that of an O—D bond. What is the main driving force for this reaction?

6. The two gases  $\text{BF}_3(\text{g})$  and  $\text{BCl}_3(\text{g})$  are mixed in equal molar amounts. All B—F bonds have about the same bond enthalpy, as do all B—Cl bonds. Explain why the mixture tends to react to form  $\text{BF}_2\text{Cl}(\text{g})$  and  $\text{BCl}_2\text{F}(\text{g})$ .
7. Two large glass bulbs of identical volume are connected by means of a stopcock. One bulb initially contains 1.00 mol  $\text{H}_2$ ; the other contains 1.00 mol helium (He). The stopcock is opened and the gases are allowed to mix and reach equilibrium. What is the probability that all the  $\text{H}_2$  in the first bulb will diffuse into the second bulb and all the He gas in the second bulb will diffuse into the first bulb?
8. A mixture of 2.00 mol nitrogen and 1.00 mol oxygen is in thermal equilibrium in a 100-L container at  $25^\circ\text{C}$ . Calculate the probability that at a given time all the nitrogen will be found in the left half of the container and all the oxygen in the right half.
9. Predict the sign of the system’s entropy change in each of the following processes.
  - (a) Sodium chloride melts.
  - (b) A building is demolished.
  - (c) A volume of air is divided into three separate volumes of nitrogen, oxygen, and argon, each at the same pressure and temperature as the original air.
10. Predict the sign of the system’s entropy change in each of the following processes.
  - (a) A computer is constructed from iron, copper, carbon, silicon, gallium, and arsenic.
  - (b) A container holding a compressed gas develops a leak and the gas enters the atmosphere.
  - (c) Solid carbon dioxide (dry ice) sublimates to gaseous carbon dioxide.
12. Tetraphenylgermane,  $(\text{C}_6\text{H}_5)_4\text{Ge}$ , has a melting point of  $232.5^\circ\text{C}$ , and its enthalpy increases by  $106.7 \text{ J g}^{-1}$  during fusion. Calculate the molar enthalpy of fusion and molar entropy of fusion of tetraphenylgermane.
13. The normal boiling point of acetone is  $56.2^\circ\text{C}$ . Use Trouton’s rule to estimate its molar enthalpy of vaporization.
14. The molar enthalpy of vaporization of liquid hydrogen chloride is  $16.15 \text{ kJ mol}^{-1}$ . Use Trouton’s rule to estimate its normal boiling point.
15. If 4.00 mol hydrogen ( $c_p = 28.8 \text{ J K}^{-1} \text{ mol}^{-1}$ ) is expanded reversibly and isothermally at 400 K from an initial volume of 12.0 L to a final volume of 30.0 L, calculate  $\Delta U$ ,  $q$ ,  $w$ ,  $\Delta H$ , and  $\Delta S$  for the gas.
16. Suppose 60.0 g hydrogen bromide,  $\text{HBr}(\text{g})$ , is heated reversibly from 300 to 500 K at a constant volume of 50.0 L, and then allowed to expand isothermally and reversibly until the original pressure is reached. Using  $c_p(\text{HBr}(\text{g})) = 29.1 \text{ J K}^{-1} \text{ mol}^{-1}$ , calculate  $\Delta U$ ,  $q$ ,  $w$ ,  $\Delta H$ , and  $\Delta S$  for this process. Assume that HBr is an ideal gas under these conditions.

### 13.5 Entropy Changes and Spontaneity

17. Exactly 1 mol ice is heated reversibly at atmospheric pressure from  $-20^\circ\text{C}$  to  $0^\circ\text{C}$ , melted reversibly at  $0^\circ\text{C}$ , and then heated reversibly at atmospheric pressure to  $20^\circ\text{C}$ .  $\Delta H_{\text{fus}} = 6007 \text{ J mol}^{-1}$ ;  $c_p(\text{ice}) = 38 \text{ J K}^{-1} \text{ mol}^{-1}$ ; and  $c_p(\text{water}) = 75 \text{ J K}^{-1} \text{ mol}^{-1}$ . Calculate  $\Delta S$  for the system, the surroundings, and the thermodynamic universe for this process.
18. Suppose 1.00 mol water at  $25^\circ\text{C}$  is flash-evaporated by allowing it to fall into an iron crucible maintained at  $150^\circ\text{C}$ . Calculate  $\Delta S$  for the water,  $\Delta S$  for the iron crucible, and  $\Delta S_{\text{tot}}$  if  $c_p(\text{H}_2\text{O}(\ell)) = 75.4 \text{ J K}^{-1} \text{ mol}^{-1}$  and  $c_p(\text{H}_2\text{O}(\text{g})) = 36.0 \text{ J K}^{-1} \text{ mol}^{-1}$ . Take  $\Delta H_{\text{vap}} = 40.68 \text{ kJ mol}^{-1}$  for water at its boiling point of  $100^\circ\text{C}$ .
19. In Example 12.3, a process was considered in which 72.4 g iron initially at  $100.0^\circ\text{C}$  was added to 100.0 g water initially at  $10.0^\circ\text{C}$ , and an equilibrium temperature of  $16.5^\circ\text{C}$  was reached. Take  $c_p(\text{Fe})$  to be  $25.1 \text{ J K}^{-1} \text{ mol}^{-1}$  and  $c_p(\text{H}_2\text{O})$  to be  $75.3 \text{ J K}^{-1} \text{ mol}^{-1}$ , independent of temperature. Calculate  $\Delta S$  for the iron,  $\Delta S$  for the water, and  $\Delta S_{\text{tot}}$  in this process.
20. Iron has a heat capacity of  $25.1 \text{ J K}^{-1} \text{ mol}^{-1}$ , approximately independent of temperature between  $0^\circ\text{C}$  and  $100^\circ\text{C}$ .
  - (a) Calculate the enthalpy and entropy change of 1.00 mol iron as it is cooled at atmospheric pressure from  $100^\circ\text{C}$  to  $0^\circ\text{C}$ .
  - (b) A piece of iron weighing 55.85 g and at  $100^\circ\text{C}$  is placed in a large reservoir of water held at  $0^\circ\text{C}$ . It cools irreversibly until its temperature equals that of the water. Assuming the water reservoir is large enough that its temperature remains close to  $0^\circ\text{C}$ , calculate the entropy changes for the iron and the water and the total entropy change in this process.
11. Tungsten melts at  $3410^\circ\text{C}$  and has an enthalpy change of fusion of  $35.4 \text{ kJ mol}^{-1}$ . Calculate the entropy of fusion of tungsten.

### 13.4 Entropy Changes in Reversible Processes

11. Tungsten melts at  $3410^\circ\text{C}$  and has an enthalpy change of fusion of  $35.4 \text{ kJ mol}^{-1}$ . Calculate the entropy of fusion of tungsten.

## 13.6 The Third Law of Thermodynamics

21. (a) Use data from Appendix D to calculate the standard entropy change at 25°C for the reaction

- (b) Suppose the hydrazine ( $\text{N}_2\text{H}_4$ ) is in the gaseous, rather than liquid, state. Will the entropy change for its reaction with oxygen be higher or lower than that calculated in part (a)? (*Hint:* Entropies of reaction can be added when chemical equations are added, in the same way that Hess's law allows enthalpies to be added.)
22. (a) Use data from Appendix D to calculate the standard entropy change at 25°C for the reaction

- (b) Suppose that 1.00 mol each of solid acetamide,  $\text{CH}_3\text{CONH}_2(\text{s})$ , and water,  $\text{H}_2\text{O}(\ell)$ , react to give the same products. Will the standard entropy change be larger or smaller than that calculated for the reaction in part (a)?
23. The alkali metals react with chlorine to give salts:

Using the data in Appendix D, compute  $\Delta S^\circ$  of each reaction and identify a periodic trend, if any.

24. All of the halogens react directly with  $\text{H}_2(\text{g})$  to give binary compounds. The reactions are

Using the data in Appendix D, compute  $\Delta S^\circ$  of each reaction and identify a periodic trend, if any.

25. The dissolution of calcium chloride in water

is a spontaneous process at 25°C, even though the standard entropy change of the preceding reaction is negative ( $\Delta S^\circ = -44.7 \text{ J K}^{-1}$ ). What conclusion can you draw about the change in entropy of the surroundings in this process?

26. Quartz,  $\text{SiO}_2(\text{s})$ , does not spontaneously decompose to silicon and oxygen at 25°C, 1.0 atm in the reaction

even though the standard entropy change of the reaction is large and positive ( $\Delta S^\circ = +182.02 \text{ J K}^{-1}$ ). Explain.

27. Use the microscopic interpretation of entropy from Section 13.2 to explain why the entropy change of the system in Problem 26 is positive.

28. (a) Why is the entropy change of the system negative for the reaction in Problem 25, when the ions become dispersed through a large volume of solution? (*Hint:* Think about the role of the solvent, water.)  
(b) Use Appendix D to calculate  $\Delta S^\circ$  for the corresponding dissolution of  $\text{CaF}_2(\text{s})$ . Explain why this value is even more negative than that given in Problem 25.

## 13.7 The Gibbs Free Energy

29. The molar enthalpy of fusion of solid ammonia is  $5.65 \text{ kJ mol}^{-1}$ , and the molar entropy of fusion is  $28.9 \text{ J K}^{-1} \text{ mol}^{-1}$ .

- (a) Calculate the Gibbs free energy change for the melting of 1.00 mol ammonia at 170 K.  
(b) Calculate the Gibbs free energy change for the conversion of 3.60 mol solid ammonia to liquid ammonia at 170 K.  
(c) Will ammonia melt spontaneously at 170 K?  
(d) At what temperature are solid and liquid ammonia in equilibrium at a pressure of 1 atm?

30. Solid tin exists in two forms: white and gray. For the transformation

the enthalpy change is  $-2.1 \text{ kJ}$  and the entropy change is  $-7.4 \text{ J K}^{-1}$ .

- (a) Calculate the Gibbs free energy change for the conversion of 1.00 mol white tin to gray tin at  $-30^\circ\text{C}$ .  
(b) Calculate the Gibbs free energy change for the conversion of 2.50 mol white tin to gray tin at  $-30^\circ\text{C}$ .  
(c) Will white tin convert spontaneously to gray tin at  $-30^\circ\text{C}$ ?  
(d) At what temperature are white and gray tin in equilibrium at a pressure of 1 atm?

31. Ethanol's enthalpy of vaporization is  $38.7 \text{ kJ mol}^{-1}$  at its normal boiling point,  $78^\circ\text{C}$ . Calculate  $q$ ,  $w$ ,  $\Delta U$ ,  $\Delta S_{\text{sys}}$ , and  $\Delta G$  when 1.00 mol ethanol is vaporized reversibly at  $78^\circ\text{C}$  and 1 atm. Assume that the vapor is an ideal gas and neglect the volume of liquid ethanol relative to that of its vapor.

32. Suppose 1.00 mol superheated ice melts to liquid water at 25°C. Assume the specific heats of ice and liquid water have the same value and are independent of temperature. The enthalpy change for the melting of ice at  $0^\circ\text{C}$  is  $6007 \text{ J mol}^{-1}$ . Calculate  $\Delta H$ ,  $\Delta S_{\text{sys}}$ , and  $\Delta G$  for this process.

33. At  $1200^\circ\text{C}$ , the reduction of iron oxide to elemental iron and oxygen is not spontaneous:

Show how this process can be made to proceed if all the oxygen generated reacts with carbon:

This observation is the basis for the smelting of iron ore with coke to extract metallic iron.

34. The primary medium for free energy storage in living cells is adenosine triphosphate (ATP). Its formation from adenosine diphosphate (ADP) is not spontaneous:

Cells couple ATP production with the metabolism of glucose (a sugar):

The reaction of 1 molecule of glucose leads to the formation of 38 molecules of ATP from ADP. Show how the coupling makes this reaction spontaneous. What fraction of the free energy released in the oxidation of glucose is stored in the ATP?

35. A process at constant  $T$  and  $P$  can be described as spontaneous if  $\Delta G < 0$  and nonspontaneous if  $\Delta G > 0$ . Over what range of temperatures is each of the following processes spontaneous? Assume that all gases are at a pressure of 1 atm. (*Hint:* Use Appendix D to calculate  $\Delta H$  and  $\Delta S$  [assumed independent of temperature and equal to  $\Delta H^\circ$  and  $\Delta S^\circ$ , respectively], and then use the definition of  $\Delta G$ .)
- (a) The rusting of iron, a complex reaction that can be approximated as

- (b) The preparation of  $\text{SO}_3(\text{g})$  from  $\text{SO}_2(\text{g})$ , a step in the manufacture of sulfuric acid:

- (c) The production of the anesthetic dinitrogen oxide through the decomposition of ammonium nitrate:

36. Follow the same procedure used in Problem 35 to determine the range of temperatures over which each of the following processes is spontaneous.

- (a) The preparation of the poisonous gas phosgene:

- (b) The laboratory-scale production of oxygen from the decomposition of potassium chlorate:

- (c) The reduction of iron(II) oxide (wüstite) by coke (carbon), a step in the production of iron in a blast furnace:

37. Explain how it is possible to reduce tungsten(VI) oxide ( $\text{WO}_3$ ) to metal with hydrogen at an elevated temperature. Over what temperature range is this reaction spontaneous? Use the data of Appendix D.

38. Tungsten(VI) oxide can also be reduced to tungsten by heating it with carbon in an electric furnace:

- (a) Calculate the standard free energy change ( $\Delta G^\circ$ ) for this reaction, and comment on the feasibility of the process at room conditions.
- (b) What must be done to make the process thermodynamically feasible, assuming  $\Delta H$  and  $\Delta S$  are nearly independent of temperature?

### 13.8 A Deeper Look . . . Carnot Cycles, Efficiency, and Entropy

39. A thermodynamic engine operates cyclically and reversibly between two temperature reservoirs, absorbing heat from the high-temperature bath at 450 K and discharging heat to the low-temperature bath at 300 K.

- (a) What is the thermodynamic efficiency of the engine?
- (b) How much heat is discarded to the low-temperature bath if 1500 J of heat is absorbed from the high-temperature bath during each cycle?
- (c) How much work does the engine perform in one cycle of operation?

40. In each cycle of its operation, a thermal engine absorbs 1000 J of heat from a large heat reservoir at 400 K and discharges heat to another large heat sink at 300 K. Calculate:

- (a) The thermodynamic efficiency of the heat engine, operated reversibly
- (b) The quantity of heat discharged to the low-temperature sink each cycle
- (c) The maximum amount of work the engine can perform each cycle

## ADDITIONAL PROBLEMS

41. Ethanol ( $\text{CH}_3\text{CH}_2\text{OH}$ ) has a normal boiling point of  $78.4^\circ\text{C}$  and a molar enthalpy of vaporization of  $38.74 \text{ kJ mol}^{-1}$ . Calculate the molar entropy of vaporization of ethanol and compare it with the prediction of Trouton's rule.

42. A quantity of ice is mixed with a quantity of hot water in a sealed, rigid, insulated container. The insulation prevents heat exchange between the ice–water mixture and the surroundings. The contents of the container soon reach equilibrium. State whether the total *internal energy* of the

contents decreases, remains the same, or increases in this process. Make a similar statement about the total *entropy* of the contents. Explain your answers.

43. (a) If 2.60 mol  $O_2(g)$  ( $c_p = 29.4 \text{ J K}^{-1} \text{ mol}^{-1}$ ) is compressed reversibly and adiabatically from an initial pressure of 1.00 atm and 300 K to a final pressure of 8.00 atm, calculate  $\Delta S$  for the gas.  
 (b) Suppose a different path from that in part (a) is used. The gas is first heated at constant pressure to the same final temperature, and then compressed reversibly and isothermally to the same final pressure. Calculate  $\Delta S$  for this path and show that it is equal to that found in part (a).
44. One mole of a monatomic ideal gas begins in a state with  $P = 1.00 \text{ atm}$  and  $T = 300 \text{ K}$ . It is expanded reversibly and adiabatically until the volume has doubled; then it is expanded irreversibly and isothermally into a vacuum until the volume has doubled again; and then it is heated reversibly at constant volume to 400 K. Finally, it is compressed reversibly and isothermally until a final state with  $P = 1.00 \text{ atm}$  and  $T = 400 \text{ K}$  is reached. Calculate  $\Delta S_{\text{sys}}$  for this process. (*Hint*: There are two ways to solve this problem—an easy way and a hard way.)
- \*45. The motion of air masses through the atmosphere can be approximated as adiabatic (because air is a poor conductor of heat) and reversible (because pressure differences in the atmosphere are small). To a good approximation, air can be treated as an ideal gas with average molar mass  $29 \text{ g mol}^{-1}$  and average heat capacity  $29 \text{ J K}^{-1} \text{ mol}^{-1}$ .  
 (a) Show that the displacement of the air masses occurs at constant entropy ( $\Delta S = 0$ ).  
 (b) Suppose the average atmospheric pressure near the earth's surface is  $P_0$  and the temperature is  $T_0$ . The air is displaced upward until its temperature is  $T$  and its pressure is  $P$ . Determine the relation between  $P$  and  $T$ . (*Hint*: Consider the process as occurring in two steps: first a cooling from  $T_0$  to  $T$  at constant pressure, and then an expansion from  $P_0$  to  $P$  at constant temperature. Equate the sum of the two entropy changes to  $\Delta S_{\text{tot}} = 0$ .)  
 (c) In the lower atmosphere, the dependence of pressure on height,  $h$ , above the earth's surface can be approximated as

$$\ln(P/P_0) = -Mgh/RT$$

where  $M$  is the molar mass ( $\text{kg mol}^{-1}$ ),  $g$  the acceleration due to gravity ( $9.8 \text{ m s}^{-2}$ ), and  $R$  the gas constant. If the air temperature at sea level near the equator is  $38^\circ\text{C}$  ( $\sim 100^\circ\text{F}$ ), calculate the air temperature at the summit of Mount Kilimanjaro, 5.9 km above sea level. (For further discussion of this problem, see L. K. Nash, *J. Chem. Educ.* 61:23, 1984.)

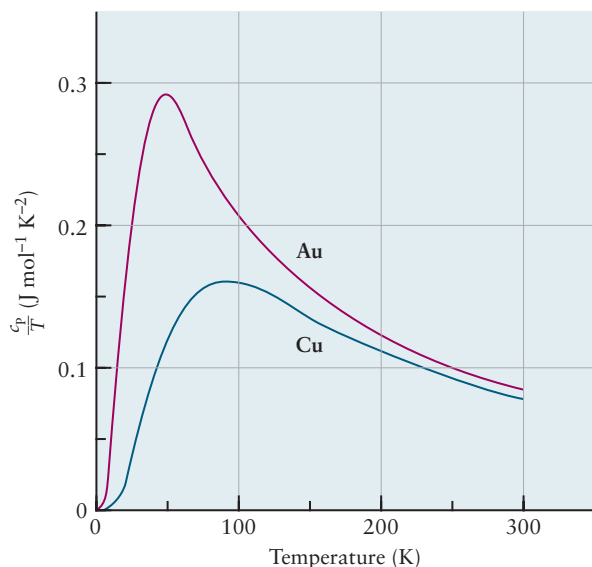

46. Calculate the entropy change that results from mixing 54.0 g water at 273 K with 27.0 g water at 373 K in a vessel whose walls are perfectly insulated from the surroundings. Consider the specific heat of water to be constant over the temperature range from 273 to 373 K and to have the value  $4.18 \text{ J K}^{-1} \text{ g}^{-1}$ .
47. Problem 20 asked for the entropy change when a piece of iron is cooled by immersion in a reservoir of water at  $0^\circ\text{C}$ .  
 (a) Repeat Problem 20(b), supposing that the iron is cooled to  $50^\circ\text{C}$  in a large water reservoir held at that temperature before being placed in the  $0^\circ\text{C}$  reservoir.  
 (b) Repeat the calculation supposing that four water reservoirs at  $75^\circ\text{C}$ ,  $50^\circ\text{C}$ ,  $25^\circ\text{C}$ , and  $0^\circ\text{C}$  are used.  
 (c) As more reservoirs are used, what happens to  $\Delta S$  for the iron, for the water, and for the universe? How would you attempt to conduct a reversible cooling of the iron?
48. Problem 42 in Chapter 9 described an optical atomic trap. In one experiment, a gas of 500 sodium atoms is confined in a volume of  $1000 \mu\text{m}^3$ . The temperature of the system is  $0.00024 \text{ K}$ . Compute the probability that, by chance, these 500 slowly moving sodium atoms will all congregate in the left half of the available volume. Express your answer in scientific notation.
- \*49. Suppose we have several different ideal gases,  $i = 1, 2, 3, \dots, N$ , each occupying its own volume  $V_i$ , all at the same pressure and temperature. The boundaries between the volumes are removed so that the gases mix at constant temperature in the total volume  $V = \sum_i V_i$ .  
 (a) Using the microscopic interpretation of entropy, show that

$$\Delta S = -nR \sum_i X_i \ln X_i$$

for this process, where  $n$  is the total number of moles of gas and  $X_i$  is the mole fraction of gas  $i$ .

- (b) Calculate the entropy change when 50 g each of  $O_2(g)$ ,  $N_2(g)$ , and  $Ar(g)$  are mixed at 1 atm and  $0^\circ\text{C}$ .  
 (c) Using Table 9.1, calculate the entropy change when 100 L of air (assumed to be a mixture of ideal gases) at 1 atm and  $25^\circ\text{C}$  is separated into its component gases at the same pressure and temperature.
- \*50. The  $N_2O$  molecule has the structure N—N—O. In an ordered crystal of  $N_2O$ , the molecules are lined up in a regular fashion, with the orientation of each determined by its position in the crystal. In a random crystal (formed on rapid freezing), each molecule has two equally likely orientations.  
 (a) Calculate the number of microstates available to a random crystal of  $N_A$  (Avogadro's number) of molecules.  
 (b) Calculate the entropy change when 1.00 mol of a random crystal is converted to an ordered crystal.

51. By examining the following graphs, predict which element—copper or gold—has the higher absolute entropy at a temperature of 200 K.

- \*52. Consider the process described in Problem 19 in Chapter 12. Use the results from that problem to do the following.

- (a) Calculate  $\Delta S$  for the system, the surroundings, and the universe.  
 (b) If the absolute entropy per mole of the gas *before* the expansion is  $158.2 \text{ J K}^{-1} \text{ mol}^{-1}$ , calculate  $\Delta G_{\text{sys}}$  for the process.

53. Two different crystalline forms of sulfur are the rhombic form and the monoclinic form. At atmospheric pressure, rhombic sulfur undergoes a transition to monoclinic when it is heated above 368.5 K:

- (a) What is the sign of the entropy change ( $\Delta S$ ) for this transition?  
 (b)  $|\Delta H|$  for this transition is  $400 \text{ J mol}^{-1}$ . Calculate  $\Delta S$  for the transition.

- \*54. Use data from Appendix D to estimate the temperature at which  $\text{I}_2(g)$  and  $\text{I}_2(s)$  are in equilibrium at a pressure of 1 atm. Can this equilibrium actually be achieved? Refer to Appendix F for data on iodine.

55. The molar enthalpy of fusion of ice at  $0^\circ\text{C}$  is  $6.02 \text{ kJ mol}^{-1}$ ; the molar heat capacity of undercooled water is  $75.3 \text{ J mol}^{-1} \text{ K}^{-1}$ . (a) One mole of undercooled water at  $-10^\circ\text{C}$  is induced to crystallize in a heat-insulated vessel. The result is a mixture of ice and water at  $0^\circ\text{C}$ . What fraction of this mixture is ice? (b) Calculate  $\Delta S$  for the system.

56. A certain substance consists of two modifications A and B;  $\Delta G^\circ$  for the transition from A to B is positive. The two modifications produce the same vapor. Which has the higher vapor pressure? Which is the more soluble in a solvent common to both?

57. From the values in Appendix D, calculate the values of  $\Delta G^\circ$  and  $\Delta H^\circ$  for the reaction.

at  $25^\circ\text{C}$ . Which of the two oxides is more stable at  $25^\circ\text{C}$  and  $P_{\text{O}_2} = 1 \text{ atm}$ ?

58. The strongest known chemical bond is that in carbon monoxide, CO, with bond enthalpy of  $1.05 \times 10^3 \text{ kJ mol}^{-1}$ . Furthermore, the entropy increase in a gaseous dissociation of the kind  $\text{AB} \rightleftharpoons \text{A} + \text{B}$  is about  $110 \text{ J mol}^{-1} \text{ K}^{-1}$ . These factors establish a temperature above which there is essentially no chemistry of molecules. Show why this is so, and find the temperature.

59. The  $\Delta G_f^\circ$  of  $\text{Si}_3\text{N}_4(s)$  is  $-642.6 \text{ kJ mol}^{-1}$ . Use this fact and the data in Appendix D to compute  $\Delta G^\circ$  of the reaction.

60. The compound  $\text{Pt}(\text{NH}_3)_2\text{I}_2$  comes in two forms, the cis and the trans, which differ in their molecular structure. The following data are available:

	$\Delta H_f^\circ$ (kJ mol <sup>-1</sup> )	$\Delta G_f^\circ$ (kJ mol <sup>-1</sup> )
cis	-286.56	-130.25
trans	-316.94	-161.50

Combine these data with data from Appendix D to compute the standard entropies ( $S^\circ$ ) of both of these compounds at  $25^\circ\text{C}$ .

61. (a) Use data from Appendix D to calculate  $\Delta H^\circ$  and  $\Delta S^\circ$  at  $25^\circ\text{C}$  for the reaction

- (b) Calculate  $\Delta G^\circ$  at 590 K, assuming  $\Delta H^\circ$  and  $\Delta S^\circ$  are independent of temperature.

- (c) Careful high-temperature measurements show that when this reaction is performed at 590 K,  $\Delta H_{590}^\circ$  is  $158.36 \text{ kJ}$  and  $\Delta S_{590}^\circ$  is  $177.74 \text{ J K}^{-1}$ . Use these facts to compute an improved value of  $\Delta G_{590}^\circ$  for this reaction. Determine the percentage error in  $\Delta G_{590}^\circ$  that comes from using the 298-K values in place of 590-K values in this case.

62. (a) The normal boiling point of carbon tetrachloride ( $\text{CCl}_4$ ) is  $76.5^\circ\text{C}$ . A student looks up the standard enthalpies of formation of  $\text{CCl}_4(\ell)$  and of  $\text{CCl}_4(g)$  in Appendix D. They are listed as  $-135.44$  and  $-102.9 \text{ kJ mol}^{-1}$ , respectively. By subtracting the first from the second, she computes  $\Delta H^\circ$  for the vaporization of  $\text{CCl}_4$  to be  $32.5 \text{ kJ mol}^{-1}$ . But Table 12.2 states that the  $\Delta H_{\text{vap}}$  of  $\text{CCl}_4$  is  $30.0 \text{ kJ mol}^{-1}$ . Explain the discrepancy.

- (b) Calculate the molar entropy change of vaporization ( $\Delta S_{\text{vap}}$ ) of  $\text{CCl}_4$  at  $76.5^\circ\text{C}$ .

63. The typical potassium ion concentration in the fluid outside a cell is 0.0050 M, whereas that inside a muscle cell is 0.15 M.
- (a) What is the spontaneous direction of motion of ions through the cell wall?
- (b) In *active transport*, cells use free energy stored in ATP (see Problem 34) to move ions in the direction opposite their spontaneous direction of flow. Calculate the cost in free energy to move 1.00 mol  $K^+$  through the cell wall by active transport. Assume no change in  $K^+$  concentrations during this process.

## CUMULATIVE PROBLEMS

64. When a gas undergoes a reversible adiabatic expansion, its entropy remains constant even though the volume increases. Explain how this can be consistent with the microscopic interpretation of entropy developed in Section 13.2. (*Hint*: Consider what happens to the distribution of velocities in the gas.)
65. The normal boiling point of liquid ammonia is 240 K; the enthalpy of vaporization at that temperature is 23.4 kJ mol<sup>-1</sup>. The heat capacity of gaseous ammonia at constant pressure is 38 J mol<sup>-1</sup> K<sup>-1</sup>.
- (a) Calculate  $q$ ,  $w$ ,  $\Delta H$ , and  $\Delta U$  for the following change in state:
- $$2.00 \text{ mol NH}_3(\ell, 1 \text{ atm}, 240 \text{ K}) \longrightarrow 2.00 \text{ mol NH}_3(g, 1 \text{ atm}, 298 \text{ K})$$
- Assume that the gas behaves ideally and that the volume occupied by the liquid is negligible.
- (b) Calculate the entropy of vaporization of  $NH_3$  at 240 K.
66. (a) Using the standard molar entropies for gaseous and liquid ethanol in Appendix D, calculate  $\Delta H$  and  $\Delta S$  for the reaction
- $$C_2H_5OH(g, 1 \text{ atm}, 25^\circ C) \longrightarrow C_2H_5OH(\ell, 1 \text{ atm}, @ 25^\circ C)$$
- Then, treating the gas as ideal, consider whether the reaction
- $$C_2H_5OH(g, 0.05 \text{ atm}, 25^\circ C) \longrightarrow C_2H_5OH(\ell, 0.05 \text{ atm}, 25^\circ C)$$
- has the same  $\Delta H$  and  $\Delta S$ . To do this, you might wish to make an alternate three-step process between the initial and final states to calculate the change in state functions at 0.05 atm. (Try a path where you first change the pressure of the gas reversibly from 0.05 atm to 1 atm, and then undergo the phase transition at 1 atm, followed by decreasing the pressure of the liquid from 1 atm back to 0.05 atm.)
- (b) The equilibrium vapor pressure of ethanol at 298.15 K is 0.078 atm. Will ethanol gas at 0.05 atm and 298.15 K spontaneously condense to liquid ethanol? First answer this by thinking about it qualitatively. Then support it with a calculation. Use the change in entropy of the system you calculated above, and calculate the change in entropy of the surroundings, and the change in entropy of the universe for the condensation of one mole of ethanol gas at 0.05 atm and 298.15 K to the liquid at 0.05 atm and 298.15 K. Give all three numerical answers and state whether the second law of thermodynamics predicts that the gas will condense spontaneously. Assume that for the liquid, but not the gas, that neither  $S$  nor  $H$  change appreciably as you change the pressure of the liquid (within this pressure range) while holding the temperature constant.

Gaseous ammonia,  $\text{NH}_3$ , and gaseous hydrogen chloride,  $\text{HCl}$ , react to form solid  $\text{NH}_4\text{Cl}$ , the white “smoke.” In the reverse reaction, solid  $\text{NH}_4\text{Cl}$  decomposes when heated to form gaseous  $\text{NH}_3$  and  $\text{HCl}$ .

Every time we carry out a chemical reaction—from fundamental research studies to practical industrial applications—the *yield* of the reaction is extremely important. Did we obtain all the product we could expect? Chapter 2 shows how to calculate the amount of product expected when we start a reaction with particular amounts of the reactants. This calculation assumes that the reaction goes to completion—that is, all of the limiting reagent is consumed. The resulting number, called the theoretical yield, represents the maximum amount of product that could be obtained from that reaction.

In practice, many reactions do not go to completion but rather approach a state or position of **equilibrium**. This equilibrium position, at which the reaction apparently comes to an end, is a mixture of products and unconsumed reactants present in fixed relative amounts. Once equilibrium has been achieved, there is

no further net conversion of reactants to products unless the experimental conditions of the reaction (temperature and pressure) are changed. The equilibrium state is characterized by the **equilibrium constant**, which has a unique value for each reaction. Knowing the equilibrium constant and the initial amounts of reactants and products, we can calculate the composition of the equilibrium reaction mixture. Knowing the equilibrium constant and its dependence on experimental conditions, we can manipulate conditions to maximize the practical yield of that reaction. Calculating the equilibrium composition for a particular reaction and its dependence on experimental conditions is therefore a practical skill of enormous importance in chemistry.

In this chapter we define the equilibrium constant, its dependence on conditions, and its role in manipulating the yield of reactions. We illustrate these general principles with applications to reactions in the gas phase and to heterogeneous reactions. Detailed applications to reactions in aqueous solutions and electrochemical reactions are presented in the three following chapters.

The fact that reactions go to the equilibrium position was discovered empirically, and the equilibrium constant was first defined empirically. All the aforementioned applications can be accomplished with empirically determined equilibrium constants. Nonetheless, the empirical approach leaves unanswered several important fundamental questions: Why should the equilibrium state exist? Why does the equilibrium constant take its particular mathematical form? These and related questions are answered by recognizing that the chemical equilibrium position is the *thermodynamic equilibrium state* of the reaction mixture. Once we have made that connection, thermodynamics explains the existence and the mathematical form of the equilibrium constant. Thermodynamics also gives procedures for calculating the value of the equilibrium constant from the thermochemical properties of the pure reactants and products, as well as procedures for predicting its dependence on experimental conditions.

Some instructors prefer to introduce equilibrium from the empirical viewpoint and later use thermodynamics to explain the empirical developments. Others prefer to develop the background of thermodynamics first and then apply it to chemical equilibrium. We have organized this chapter to allow either approach. After an introductory section on the general nature of chemical equilibrium, we define the equilibrium constant empirically in Section 14.2, and then give a thermodynamic description in Section 14.3. Similarly, we discuss the direction of change in chemical reactions empirically in Section 14.6 and give a thermodynamic treatment in Section 14.7. Readers who have studied thermodynamics before starting this chapter should read the sections in the order presented. Readers who have not yet studied thermodynamics should skip over Sections 14.3 and 14.7 and return to them after studying Chapters 12 and 13 on thermodynamics. We provide signposts for both sets of readers at the end of each section.

## 14.1 The Nature of Chemical Equilibrium

### 14.1.1 Approach to Equilibrium

Most chemical reactions are carried out by mixing the selected reactants in a vessel and adjusting  $T$  and  $P$  until the desired products appear. Once reaction conditions have been identified, the greatest concern is to maximize the yield of the reaction.

Let's start by observing a particular reaction that illustrates all the aspects of equilibrium we need to understand. We have selected the reactions of cobalt(II) ions in aqueous solutions in which chloride ion is also present because the progress and outcome of the reactions are directly visible. The cobalt(II) ions can form

**FIGURE 14.1** Chemical equilibrium in the cobalt chloride–HCl system. (a) The pink color is due to the hexaaqua complex ion  $[\text{Co}(\text{H}_2\text{O})_6]^{2+}$ . (b) The blue color is due to the tetrachloro complex ion  $[\text{CoCl}_4]^{2-}$ . (c) Adding HCl to the pink solution in (a) converts some of the Co(II) to the tetrachloro complex. The lavender color of a sample of the resulting solution shown in (c) is produced by the combination of pink hexaaqua species and blue tetrachloro species. (d) Adding water to the blue solution in (b) converts some of the Co(II) to the hexaaqua species. The combination of the two gives the lavender color. The same equilibrium state is reached by running the reaction from the left (c) and from the right (d).

various different complex ions, depending on the amount of chloride present. For example, if  $\text{CoCl}_2 \cdot 6\text{H}_2\text{O}$  is dissolved in pure water to the concentration 0.08 M, the resulting solution is pale pink in color due to the hexaaquacobalt(II) complex ion  $[\text{Co}(\text{H}_2\text{O})_6]^{2+}$  (Fig. 14.1a). If  $\text{CoCl}_2 \cdot 6\text{H}_2\text{O}$  is dissolved in 10 M HCl to the concentration 0.08 M, the solution is deep blue due to the tetrachlorocobalt(II) complex ion  $[\text{CoCl}_4]^{2-}$  (see Fig. 14.1b). Solutions containing a mixture of both Co(II) species are lavender, as shown in Figure 14.1c, d.

The hexaaqua complex can be converted into the tetrachloro complex by reaction with chloride ion:

If we add concentrated HCl (reactant B, on the left side of the equation) to the pink solution in Figure 14.1a until the Co(II) concentration is 0.044 M and the HCl concentration is 5.5 M, the result is a lavender-colored solution, *a sample of which* is shown in Figure 14.1c. Optical absorption spectroscopy measurements to be described in Chapter 20 confirm the presence of both Co(II) species in the solution in Figure 14.1c. Ninety-eight percent of the Co is found in the pink hexaaqua complex, and the remaining two percent is in the blue

**FIGURE 14.2** Sketch of the change with time of the concentrations of products and reactants in the spontaneous reactions illustrated in Figure 14.1. For ease of display, concentrations are expressed as percent of the total Co(II) present in each species. (a) Partial conversion of pink hexaaqua complex A into blue tetrachloro complex C. (b) Partial conversion of blue tetrachloro complex C into pink hexaaqua complex A. After changes in the slope of each species, concentrations become imperceptibly small, and we say the reaction has arrived at chemical equilibrium.

tetrachloro complex.<sup>1</sup> If the lavender solution is allowed to stand at constant temperature for several hours and the measurements repeated, the results are the same.

The reaction can also be carried out from “right to left” as written. If we add pure water (product D, on the right side of the equation) to the blue solution in Figure 14.1b until the cobalt concentration is 0.044 M and the HCl concentration is 5.5 M, the result is a lavender-colored solution, *a sample of which* is shown in Figure 14.1d. Just as we saw after running the reaction “left to right,” optical absorption spectroscopy confirms that 98% of the Co(II) is present in the pink hexaaqua complex and 2% is present in the blue tetrachloro complex. Again, we find no further change in composition of the mixture, even after a long wait.

These data show that the reaction has not gone to completion but has apparently halted at an intermediate state containing products as well as unconsumed reactants. Moreover, the same final state can be achieved from either direction. This result is typical of most chemical reactions, even though it is not generally as visually apparent as here.

The questions raised in the first paragraph require quantitative investigations of the reaction mixture, which we carry out as follows. In the first experiment, we start the reaction by mixing initial concentrations of A and B, denoted as  $[A]_0$  and  $[B]_0$ . As the reaction proceeds, we periodically sample the reaction mixture. For each sample, we measure the concentration of A, B, and C and plot concentration of each species versus time. The results of the first experiment are represented schematically in Figure 14.2a, which shows the consumption of A and the production of C. Similarly, we start the second experiment with the initial concentration  $[C]_0$ , and add water. The results are represented schematically in Figure 14.2b, which shows the consumption of C and the production of A.

As the reaction proceeds, we see that the concentration of each species changes progressively more slowly. This fact is indicated by the decreasing

<sup>1</sup>It may appear surprising to find such imbalance in the concentration of the Co(II) species when the color intensities of the pink and lavender solutions in Figure 14.1a and Figure 14.1c appear quite similar. This difference is explained by the fact that the blue tetrachloro complex absorbs light much more efficiently than the pink hexaaqua complex.

absolute values (decreasing in magnitude) of the slope [ $m = \Delta(\text{conc.})/\Delta t$ ] sketched on the concentration curves during progressively later time intervals. Eventually, the slopes become close enough to zero to show that the concentration of each species has become constant in time. When this condition has been achieved, we say the reaction is at *chemical equilibrium*, and the reaction mixture is at the *equilibrium composition*.<sup>2</sup> At later times, there is no further change in composition of the reaction mixture; the concentration of each of the species  $X = A, B, C$  remains at its equilibrium value denoted by  $[X]_{\text{eq}}$ .

### 14.1.2 Characteristics of the Equilibrium State

We can gain insight into the equilibrium state by comparing chemical reactions to the familiar phase equilibrium between liquid water and water vapor (see Section 10.4 and Fig. 10.17). Let's represent the transfer of water molecules in this phase equilibrium as a chemical equation:

The double arrows ( $\rightleftharpoons$ ) emphasize the dynamic nature of phase equilibrium: Liquid water evaporates to form water vapor, and at the same time vapor condenses to give liquid. An analogous dynamic description applies to a chemical equilibrium, in which bonds are broken or formed as atoms move back and forth between reactant and product molecules. When the initial concentrations of the reactants are high, collisions between their molecules cause product molecules to form. Once the concentrations of the products have increased sufficiently, the reverse reaction (forming "reactants" from "products") begins to occur. As the equilibrium state is approached, the forward and backward rates of reaction become equal and there is no further net change in reactant or product concentrations. Just as the equilibrium between liquid water and water vapor is a dynamic process on the molecular scale, with evaporation and condensation taking place simultaneously, the chemical equilibrium between reactants and products also occurs through the continuous formation of molecules of product from reactant molecules and their reaction back into reactant molecules with equal rates. Chemical equilibrium is not a static condition, although macroscopic properties such as concentrations do stop changing when equilibrium is attained. *Chemical equilibrium is the consequence of a dynamic balance between forward and backward reactions.*

The experimental results shown in Figures 14.1 and 14.2 demonstrate that the same equilibrium state is reached whether one starts with the reactants or with the products. This fact can be used to test whether a system is truly in equilibrium or whether the reaction is just so slow that changes in concentration are unmeasurably small, even though the system is far from equilibrium. If the same state is reached starting from either reactants or products, that state is a true equilibrium state.

Equilibrium states have four fundamental characteristics:

1. They display no macroscopic evidence of change.
2. They are reached through spontaneous (in the sense of Chapter 13) processes.
3. They show a dynamic balance of forward and reverse processes.
4. They are the same regardless of direction of approach.

We frequently also encounter so-called *steady states* in which the macroscopic concentrations of species are not changing with time, even though the

<sup>2</sup>You must exercise judgment in deciding when the slope is "sufficiently close to zero" and the concentrations are "effectively constant." There is no one instant at which equilibrium is achieved.

system is not at equilibrium. Steady states are maintained not by a dynamic balance between forward and reverse processes, but rather by the competition between a process that supplies the species to the system and a process that removes the species from the system. Many chemical reactions occur in living systems in steady states and do not represent an equilibrium between reactants and products. You must be certain that a reaction is at equilibrium and not in steady state before applying the methods of this chapter to explain the relative concentrations of reactants and products.

## 14.2 The Empirical Law of Mass Action

Extensive studies of the type summarized in Figure 14.2 for broad classes of reactions represented generally as

have demonstrated a most remarkable result. No matter what initial concentrations of reactants are selected at the beginning of the experiment, the value of the ratio

$$\frac{[C]_{\text{eq}}^c [D]_{\text{eq}}^d}{[A]_{\text{eq}}^a [B]_{\text{eq}}^b}$$

measured *at equilibrium* is always the same. Even if the experiment is started with an arbitrary initial mixture of reactants and products, the reaction will consume some species and produce others until it achieves this same value of this ratio at equilibrium. This ratio is called the **empirical equilibrium constant** for the reaction and denoted as  $K_C$ . The results of these studies are summarized in the following equation called the **law of mass action**, first stated in approximate form in 1864 by two Norwegians, C. M. Guldberg (a mathematician) and his brother-in-law P. Waage (a chemist):

$$\frac{[C]_{\text{eq}}^c [D]_{\text{eq}}^d}{[A]_{\text{eq}}^a [B]_{\text{eq}}^b} = K_C \quad [14.1a]$$

The subscript C denotes that the reaction is carried out in solution and that the empirical equilibrium constant  $K_C$  is evaluated by directly measuring the concentration of each species in the equilibrium state of the reaction. In general,  $K_C$  has dimensions (concentration) <sup>$c+d-a-b$</sup> ; it will be dimensionless only for those reactions for which  $a + b = c + d$ .

Similar results have been obtained for reactions carried out in the gas phase, where the amount of each reactant and product in the reaction mixture is measured by its partial pressure  $P_X$ . For gas-phase reactions, the empirical law of mass action takes the form

$$\frac{(P_C)_{\text{eq}}^c (P_D)_{\text{eq}}^d}{(P_A)_{\text{eq}}^a (P_B)_{\text{eq}}^b} = K_P \quad [14.1b]$$

In general,  $K_P$  has dimensions (pressure) <sup>$c+d-a-b$</sup> ; it will be dimensionless only for those reactions for which  $a + b = c + d$ .

The significance of the empirical law of mass action is twofold. First, the numerical value of  $K_C$  or  $K_P$  is an inherent property of the chemical reaction itself and does not depend on the specific initial concentrations of reactants and products selected. Second, the magnitude of  $K_P$  or  $K_C$  gives direct information about the nature of the equilibrium state or position of the reaction. If the

equilibrium constant is very large, then at equilibrium the concentration or partial pressures of products are large compared with those of the reactants. In this case, stoichiometry can be used to estimate the number of moles or the masses of product formed because the reaction is near completion. If the equilibrium constant is very small, the concentration or partial pressures of reactants are large compared with those for products, and the extent of reaction is very limited. If the equilibrium constant has a value close to 1, both reactants and products are present in significant proportions at equilibrium.

The law of mass action is the basis for equilibrium calculations, which pervade the science of chemistry. All follow the same general pattern: Suppose we know the numerical value of  $K_C$  or  $K_P$  for a reaction of interest, and suppose we run an experiment by mixing selected initial concentrations of reactants. We can then use Equation 14.1 to calculate the concentration of the products and reactants at equilibrium, without doing the laborious measurements described in Figure 14.2. In this and succeeding chapters in Unit 4, we demonstrate these calculations for reactions in the gas phase, for acid–base reactions involving ionic species in aqueous solutions, and for heterogeneous reactions occurring at the interface between different states of matter. In preparation for these calculations, we now show how to write the empirical law of mass action for these classes of reactions.

### 14.2.1 Law of Mass Action for Gas-Phase Reactions

Many reactions are conveniently carried out entirely in the gas phase. Molecules in the gas phase are highly mobile, and the collisions necessary for chemical reactions occur frequently. Two examples are the key steps in the production of hydrogen from the methane in natural gas. The first is the **reforming reaction**:

The second step is called the **water gas shift reaction**:

This process is currently the main industrial method for the preparation of hydrogen. Its success relies critically on application of the equilibrium principles developed in this chapter.

To write the mass action law, a first glance at Equation 14.1b suggests we need only examine the balanced equation for the reaction and insert the equilibrium partial pressure of each reactant and product into Equation 14.1b and raise it to a power equivalent to its stoichiometric coefficient in the balanced equation. A deeper study of equilibrium shows that instead of inserting just the partial pressure for each reactant or product, we must insert the value of the partial pressure *relative to* a specified reference pressure  $P_{\text{ref}}$ . The result is the following expression, denoted by  $K$  with no subscript:

$$\left[ \frac{(P_C/P_{\text{ref}})^c (P_D/P_{\text{ref}})^d}{(P_A/P_{\text{ref}})^a (P_B/P_{\text{ref}})^b} \right]_{\text{eq}} = K$$

Note that  $K$  is dimensionless. Collecting the terms involving  $P_{\text{ref}}$  on the right side of the equation gives

$$\left[ \frac{P_C^c P_D^d}{P_A^a P_B^b} \right]_{\text{eq}} = K (P_{\text{ref}})^{(c+d-a-b)}$$

which must be equal to  $K_P$ . It is customary to choose  $P_{\text{ref}}$  as atmospheric pressure, which can be expressed as  $P_{\text{ref}} = 1 \text{ atm}$ ,  $P_{\text{ref}} = 760 \text{ torr}$ , or  $P_{\text{ref}} = 101,325 \text{ Pa}$ . If all pressures are expressed in atmospheres, then  $P_{\text{ref}} = 1 \text{ atm}$ , and the right side

shows that  $K_p$  has the same *numerical value* as the dimensionless quantity  $K$ , with  $P_{\text{ref}}$  factors serving only to make the equation dimensionally correct. If some other unit is chosen for pressures, the  $P_{\text{ref}}$  factors no longer have a numerical value of unity and must be inserted explicitly into the equilibrium expression.

The dimensionless quantity  $K$  is the *thermodynamic equilibrium constant*, which can be calculated from tabulated data on the products and reactants, even if the empirical equilibrium constant defined in Equation 14.1b is not known (see Section 14.3). Therefore,  $K$  is the preferred tool for analyzing reaction equilibria in general. The informal procedure by which we replaced  $K_p$  with  $K$  is made rigorous by the thermodynamic treatment of equilibrium in Section 14.3. Meantime, we can freely use the result in advance of formal justification.

The convention we follow in this book is always to describe chemical equilibrium in terms of the thermodynamic equilibrium constant  $K$ , even when analyzing reactions empirically. We express all partial pressures in units of atmospheres, and choose  $P_{\text{ref}} = 1 \text{ atm}$  for gas phase reactions. This choice allows us to use the dimensionless thermodynamic equilibrium constant because  $P_{\text{ref}}$  raised to any power equals one. The  $P_{\text{ref}}$  factors will not be explicitly included because their value is unity with these choices of pressure unit and reference pressure. Thus, we write the mass action law for a general reaction involving ideal gases as

$$\frac{(P_C)_{\text{eq}}^c (P_D)_{\text{eq}}^d}{(P_A)_{\text{eq}}^a (P_B)_{\text{eq}}^b} = K \quad [14.2a]$$

with  $K$  dimensionless. The following example illustrates these practices.

### EXAMPLE 14.1

Write equilibrium expressions for the following gas-phase chemical equilibria.

#### Solution

(a) 
$$\frac{(P_{\text{NO}})_{\text{eq}}^2 (P_{\text{Cl}_2})_{\text{eq}}}{(P_{\text{NOCl}})_{\text{eq}}^2} = K$$

The powers of 2 come from the factors of 2 in the balanced equation.

(b) 
$$\frac{(P_{\text{CO}_2})_{\text{eq}}}{(P_{\text{CO}})_{\text{eq}} (P_{\text{O}_2})_{\text{eq}}^{1/2}} = K$$

Fractional powers appear in the equilibrium expression whenever they are present in the balanced equation.

**Related Problems: 1, 2, 3, 4**

## 14.2.2 Law of Mass Action for Reactions in Solution

A great many reactions are carried out in a convenient solvent for reactants and products. Dissolved reactants can be rapidly mixed, and the reaction process is easily handled. Water is a specially favored solvent because its polar structure allows a broad range of polar and ionic species to be dissolved. Water itself is partially ionized in solution, liberating  $\text{H}^+$  and  $\text{OH}^-$  ions that can participate in reactions with the dissolved species. This leads to the important subject of acid–base equilibria in aqueous solutions (see Chapter 15), which is based on the equilibrium principles developed in this chapter. We limit the discussion in this subsection to cases in which the solvent does not participate in the reaction.

The procedure for reactions in solution is the same as that for gas-phase reactions. A deeper study of equilibrium shows that we must insert the value of

each concentration at equilibrium *relative to* a specified reference concentration  $c_{\text{ref}}$  in Equation 14.1a. The result is the following expression, denoted by  $K$  with no subscript:

$$\left[ \frac{([\text{C}]/c_{\text{ref}})^c ([\text{D}]/c_{\text{ref}})^d}{([\text{A}]/c_{\text{ref}})^a ([\text{B}]/c_{\text{ref}})^b} \right]_{\text{eq}} = K$$

The square bracket  $[X]$  represents the concentration of species  $X$  in units of  $\text{mol L}^{-1}$ . If all factors containing  $c_{\text{ref}}$  are collected on the right side and the reference state for each reactant and product is defined to be an ideal solution with a concentration  $c_{\text{ref}} = 1 \text{ M}$ , the dimensionless thermodynamic equilibrium constant  $K$  is numerically equal to  $K_{\text{C}}$ .

Just as with gaseous reactions, the convention we follow in this book is to describe solution equilibria in terms of the thermodynamic equilibrium constant  $K$ . Thus, we express solution concentrations in units of  $\text{mol L}^{-1}$  with the reference state as  $c_{\text{ref}} = 1 \text{ M}$ , and we state values of  $K$  without dimensions. Thus, the mass action law for solution reactions becomes

$$\frac{[\text{C}]_{\text{eq}}^c [\text{D}]_{\text{eq}}^d}{[\text{A}]_{\text{eq}}^a [\text{B}]_{\text{eq}}^b} = K \quad [14.2b]$$

The following example illustrates these practices.

### EXAMPLE 14.2

Household laundry bleach is a solution of sodium hypochlorite ( $\text{NaOCl}$ ) prepared by adding gaseous  $\text{Cl}_2$  to a solution of sodium hydroxide:

The active bleaching agent is the hypochlorite ion, which can decompose to chloride and chlorate ions in a side reaction that competes with bleaching:

Write the equilibrium expression for the decomposition reaction.

#### Solution

$$\frac{[\text{Cl}^-]_{\text{eq}}^2 [\text{ClO}_3^-]_{\text{eq}}}{[\text{ClO}^-]_{\text{eq}}^3} = K$$

The exponents come from the coefficients in the balanced chemical equation.

#### Related Problems: 7, 8

### 14.2.3 Law of Mass Action for Reactions Involving Pure Substances and Multiple Phases

A variety of equilibria occur in heterogeneous systems that involve pure solids and liquids as well as gases and dissolved species. Molecular species cross the interfaces between phases in order to participate in reactions. A whole class of examples (Chapter 16) is based on the dissolution of slightly soluble salts, where the dissolved ions are in equilibrium with the pure solid. Another class includes the reaction of pure metals with acids to produce hydrogen gas:

Yet another example shows how iron sulfide residues from mining operations introduce iron and sulfur as pollutants in water streams:

Reactions in aqueous solution sometimes involve water as a direct participant. In addition to familiar aqueous acid–base chemistry, many organic reactions fall into this class. One example is the hydrolysis of ethyl acetate to produce acetic acid and ethanol:

Several examples illustrate the procedures for writing the mass action law for heterogeneous reactions and for reactions involving pure solids or liquids.

1. Recall the phase equilibrium between liquid water and water vapor from Section 10.4:

Experiments show that as long as *some* liquid water is in the container, the pressure of water vapor at 25°C is 0.03126 atm. The position of this equilibrium is not affected by the amount of liquid water present, and therefore liquid water should not appear in the mass action law. Recall that for a gas or solute, a ratio of pressures or concentrations appears in the law of mass action. This ratio is equal to 1 when the gas or solute is in its reference state (1 atm or 1 M). For a pure liquid appearing in an equilibrium chemical equation, the convention is to take that pure liquid as the reference state, so the liquid water contributes only a factor of 1 to the equilibrium expression and can thus be omitted. We postpone justification of this rule to Section 14.3.

2. An analogous situation occurs in the equilibrium between solid iodine and iodine dissolved in aqueous solution:

Experiment shows that the position of the equilibrium (given by the concentration of  $\text{I}_2$  dissolved at a given temperature) is independent of the amount of solid present, as long as there is some. The pure solid iodine does not appear in the mass action law.

3. Another example involves the decomposition of calcium carbonate:

If calcium carbonate is heated, it decomposes into calcium oxide (lime) and carbon dioxide; the reverse reaction is favored at sufficiently high pressures of carbon dioxide. The equilibrium can be studied experimentally, and it is found that at any given temperature the equilibrium pressure of  $\text{CO}_2(g)$  is constant, independent of the amounts of  $\text{CaCO}_3(s)$  and  $\text{CaO}(s)$ , as long as some of each is present (Fig. 14.3). The two pure solids do not appear in the mass action law, which reduces to the partial pressure of  $\text{CO}_2$ .

**FIGURE 14.3** As long as both  $\text{CaO}(s)$  and  $\text{CaCO}_3(s)$  are present at equilibrium in a closed container, the partial pressure of  $\text{CO}_2(g)$  at a fixed temperature does not depend on the amounts of the two solids present.

The general procedure for writing the mass action law for these more complex reactions is:

1. Gases enter the equilibrium expression as partial pressures, measured in atmospheres.
2. Dissolved species enter as concentrations, in moles per liter.
3. Pure solids and pure liquids do not appear in equilibrium expressions; neither does a solvent that participates in a chemical reaction, provided the solution is dilute.
4. Partial pressures and concentrations of products appear in the numerator, and those of reactants in the denominator; each is raised to a power equal to its coefficient in the balanced chemical equation for the reaction.

This procedure gives the dimensionless thermodynamic equilibrium constant  $K$  and the resulting expressions will be justified by the thermodynamic treatment of equilibrium in Section 14.3.

The following example illustrates these practices.

### EXAMPLE 14.3

Hypochlorous acid (HOCl) is produced by bubbling chlorine through an agitated suspension of mercury(II) oxide in water. The chemical equation for this process is

Write the equilibrium expression for this reaction.

#### Solution

$$\frac{[\text{HOCl}]_{\text{eq}}^2}{(P_{\text{Cl}_2})_{\text{eq}}} = K$$

The HgO and HgO·HgCl<sub>2</sub> do not appear because they are solids, and water does not appear because it is a pure liquid. Chlorine, as a gas, enters as its equilibrium partial pressure in atmospheres. The HOCl appears as its equilibrium concentration, in moles per liter. Both the concentration of HOCl and the partial pressure of Cl<sub>2</sub> are raised to the second power because their coefficients in the balanced chemical equation are 2.

**Related Problems: 9, 10, 11, 12**

The preceding discussion has specified the procedures for setting up the mass action law for broad classes of chemical reactions and are ready to be used in equilibrium calculations.

The empirical procedures leave unanswered numerous fundamental questions about chemical equilibrium. Why should the law of mass action exist in the first place, and why should it take the particular mathematical form shown here? Why should the equilibrium constant take a unique value for each individual chemical reaction? What factors determine that value? Why does the value of the equilibrium constant change slightly when studied over broad ranges of concentration? Why should the equilibrium constant depend on temperature? Is there a quantitative explanation for the temperature dependence?

All these questions are answered by the thermodynamic description of the equilibrium constant, provided in the next section. Readers who have already studied thermodynamics should continue to Section 14.3.

Readers who have not yet studied thermodynamics should go to Sections 14.4 and 14.5, which give detailed applications of equilibrium calculations based on the mass action law procedures just described. Sections 14.4 and 14.5 do not require background in thermodynamics.

## 14.3 Thermodynamic Description of the Equilibrium State

Thermodynamics views a chemical reaction as a process in which atoms “flow” from reactants to products. If the reaction is spontaneous and is carried out at constant  $T$  and  $P$ , thermodynamics requires that  $\Delta G < 0$  for the process (see Section 13.7). Consequently,  $G$  always *decreases* during a spontaneous chemical reaction. When a chemical reaction has reached equilibrium,  $\Delta G = 0$ ; that is, there is no further tendency for the reaction to occur in either the forward or the reverse direction. We will use the condition  $\Delta G = 0$  in the following three subsections to develop the mass action law and the thermodynamic equilibrium constant for gaseous, solution, and heterogeneous reactions.

### 14.3.1 Reactions among Ideal Gases

As background, it is necessary to know how the Gibbs free energy changes with pressure at constant temperature, because in chemical equilibria, the partial pressures of gases can differ from 1 atm.

#### Dependence of Gibbs Free Energy of an Ideal Gas on Pressure

If the pressure of an ideal gas is changed from  $P_1$  to  $P_2$  with the temperature held constant, the free energy change is

$$\Delta G = \Delta(H - TS) = \Delta H - T\Delta S = -T\Delta S$$

The last equality is true because  $\Delta H = 0$  when the pressure of an ideal gas is changed at constant temperature. The entropy change for an ideal gas in an isothermal process was calculated in Section 13.5:

$$\Delta S = nR \ln \left( \frac{V_2}{V_1} \right) = nR \ln \left( \frac{P_1}{P_2} \right) = -nR \ln \left( \frac{P_2}{P_1} \right)$$

so

$$\Delta G = nRT \ln \left( \frac{P_2}{P_1} \right) \quad [14.3a]$$

Let us choose the value of  $P_1$  to be 1 atm, which has already been defined as the standard state of gaseous substances for measurements both of enthalpy of formation (see Section 12.6) and Gibbs free energy of formation (see Section 13.7). Then, Equation 14.3a relates the Gibbs free energy of the gas at any pressure  $P_2$  to its value at 1 atm. If we call 1 atm the *reference state* for the gas, then the change in Gibbs free energy in taking the gas isothermally from the reference state to any pressure  $P$  is given by

$$\Delta G = nRT \ln \left( \frac{P}{P_{\text{ref}}} \right) = nRT \ln P \quad [14.3b]$$

Equation 14.3b is a shorthand version that can be used only when the pressure  $P$  is expressed in atm. The presence of  $P_{\text{ref}}$  in the denominator makes the argument of the natural logarithm function dimensionless. Choosing  $P_{\text{ref}} = 1$  atm gives  $P_{\text{ref}}$  the numerical value 1, which for convenience we do not write explicitly. Nonetheless, you should always remember this (invisible)  $P_{\text{ref}}$  is required to make the equation dimensionally correct when the general pressure  $P$  in the equation is expressed in atm. If some unit of pressure other than atm is selected,  $P_{\text{ref}}$  no longer has value 1 and the  $P_{\text{ref}}$  selected must be carried explicitly in the equations.

### The Equilibrium Expression for Reactions in the Gas Phase

Consider now a mixture of gases that react chemically, such as the NO, N<sub>2</sub>O, and NO<sub>2</sub> given in Example 13.10:

If all of the partial pressures are 1 atm, then  $\Delta G$  for this reaction is just  $\Delta G^\circ$  at 25°C. If the pressures differ from 1 atm,  $\Delta G$  must be calculated from a three-step process (Fig. 14.4). In step 1 the partial pressure of the reactant (in this case, 3 mol of NO) is changed from its initial value,  $P_{\text{NO}}$ , to the reference pressure  $P_{\text{ref}} = 1$  atm:

$$\Delta G_1 = 3RT \ln \left( \frac{P_{\text{ref}}}{P_{\text{NO}}} \right) = RT \ln \left( \frac{P_{\text{ref}}}{P_{\text{NO}}} \right)^3$$

In step 2 the reaction is carried out with all reactants and products at partial pressures of  $P_{\text{ref}} = 1$  atm:

$$\Delta G_2 = \Delta G^\circ$$

In step 3 the partial pressures of the products (in this case, 1 mol of N<sub>2</sub>O and 1 mol of NO<sub>2</sub>) are changed from  $P_{\text{ref}} = 1$  atm to  $P_{\text{N}_2\text{O}}$  and  $P_{\text{NO}_2}$ :

$$\Delta G_3 = RT \ln \left( \frac{P_{\text{N}_2\text{O}}}{P_{\text{ref}}} \right) + RT \ln \left( \frac{P_{\text{NO}_2}}{P_{\text{ref}}} \right) = RT \ln \left[ \left( \frac{P_{\text{N}_2\text{O}}}{P_{\text{ref}}} \right) \left( \frac{P_{\text{NO}_2}}{P_{\text{ref}}} \right) \right]$$

The overall Gibbs free energy change  $\Delta G$  for the reaction is the sum of the free energy changes for the three steps in the path:

$$\begin{aligned} \Delta G &= \Delta G_1 + \Delta G_2 + \Delta G_3 \\ &= \Delta G^\circ + RT \ln \left[ \frac{(P_{\text{N}_2\text{O}}/P_{\text{ref}})(P_{\text{NO}_2}/P_{\text{ref}})}{(P_{\text{NO}}/P_{\text{ref}})^3} \right] \end{aligned}$$

The ratio of partial pressures in square brackets above is called the reaction quotient  $Q$ ; in it are the instantaneous partial pressures of the species involved

**FIGURE 14.4** A three-step process (tan arrows) to calculate  $\Delta G$  of a reaction (gray arrow) for which reactants and products are not in their standard states of 1 atm. This figure suggests that the reaction is run at pressure higher than 1 atm, which is true for most industrial processes. But, the procedure is valid at any pressure.

as the reaction runs spontaneously in the forward or the reverse direction. Thus, you can re-write the equation above as  $\Delta G = \Delta G^\circ + RT \ln Q$ .

When a chemical reaction has reached equilibrium,  $\Delta G = 0$  and  $Q$  is now equal to  $K$ . Under these conditions setting  $\Delta G = 0$  and subtracting  $\Delta G^\circ$  from both sides of the preceding equation (where the subscript eq reminds you that the actual partial pressures have now reached equilibrium) gives

$$-\Delta G^\circ = RT \ln \left[ \frac{(P_{\text{N}_2\text{O}}/P_{\text{ref}})_{\text{eq}} (P_{\text{NO}_2}/P_{\text{ref}})_{\text{eq}}}{(P_{\text{NO}}/P_{\text{ref}})_{\text{eq}}^3} \right]$$

Because  $\Delta G^\circ$  depends only on temperature, the quantity  $\Delta G^\circ/RT$  must be a constant at each value of  $T$ . Therefore, in the last equation, the ratio of partial pressures inside the natural logarithm function must also be constant *at equilibrium* at each value of  $T$ . Consequently, this ratio of partial pressures is denoted by  $K(T)$  and is called the *thermodynamic equilibrium constant* for the reaction. Finally, we have

$$-\Delta G^\circ = RT \ln K(T) \quad [14.4]$$

For the general reaction

the result, obtained in the same way, is

$$-\Delta G^\circ = RT \ln \left[ \frac{(P_C/P_{\text{ref}})_{\text{eq}}^c (P_D/P_{\text{ref}})_{\text{eq}}^d}{(P_A/P_{\text{ref}})_{\text{eq}}^a (P_B/P_{\text{ref}})_{\text{eq}}^b} \right] = RT \ln K(T) \quad (\text{at equilibrium})$$

The thermodynamic equilibrium constant for reactions involving ideal gases,

$$\left[ \frac{(P_C/P_{\text{ref}})_{\text{eq}}^c (P_D/P_{\text{ref}})_{\text{eq}}^d}{(P_A/P_{\text{ref}})_{\text{eq}}^a (P_B/P_{\text{ref}})_{\text{eq}}^b} \right] = K$$

has the same form as the empirical law of mass action with  $K_p$  for gaseous reactions introduced in Section 14.2. It is common to omit the subscript eq in this expression since the context indicates whether the ratio is  $K$  or, if not at equilibrium,  $Q$ . The thermodynamic expression provides deeper understanding of that empirical result in three important ways. First, the law of mass action is seen to be a consequence of the reaction system being in thermodynamic equilibrium. Second, the thermodynamic equilibrium constant can be calculated from  $\Delta G^\circ$  (that is, from  $\Delta H^\circ$  and  $\Delta S^\circ$ ), so the *extent* of any equilibrium chemical reaction can be deduced from calorimetric data alone. Third, unlike  $K_p$ , the thermodynamic equilibrium constant  $K$  is always a dimensionless quantity because the pressure of a reactant or product always appears as a ratio to the reference pressure  $P_{\text{ref}}$ . The algebraic rearrangements leading to Equation 14.2a have already shown that  $K$  is numerically equal to  $K_p$  if we express all partial pressures in units of atm and select the reference state to be  $P_{\text{ref}} = 1$  atm. Other choices of pressure units or reference states require the  $P_{\text{ref}}$  factors to be carried explicitly.

The convention we follow in this book, already stated in Section 14.2, is to describe chemical equilibrium in terms of the thermodynamic equilibrium constant  $K$ . The mass action law for a general reaction involving ideal gases is written as

$$\frac{(P_C)_{\text{eq}}^c (P_D)_{\text{eq}}^d}{(P_A)_{\text{eq}}^a (P_B)_{\text{eq}}^b} = K$$

with  $K$  dimensionless. The value of  $K$  can be calculated from Equation 14.4 using tables of data in Appendix D. The following example illustrates these practices.

**EXAMPLE 14.4**

The  $\Delta G^\circ$  of the chemical reaction

was calculated in Example 13.10. Now calculate the equilibrium constant of this reaction at 25°C.

**Solution**

The standard free energy change for the conversion of 3 mol of NO to 1 mol of  $\text{N}_2\text{O}$  and 1 mol of  $\text{NO}_2$  was found to be  $-104.18$  kJ. To keep the units of the calculation correct, the  $\Delta G^\circ$  is rewritten as  $-104.18$  kJ mol $^{-1}$ , where “per mole” signifies “per mole of the reaction as it is written,” that is, per

3 mol of NO, 1 mol of  $\text{N}_2\text{O}$ , and 1 mol of  $\text{NO}_2$ , the number of moles in the balanced equation. Substitution gives

$$\begin{aligned} \ln K &= \frac{-\Delta G^\circ}{RT} \\ &= \frac{-(-104,180 \text{ J mol}^{-1})}{(8.315 \text{ J K}^{-1}\text{mol}^{-1})(298.15 \text{ K})} = 42.03 \\ K &= e^{42.03} = 1.8 \times 10^{18} \end{aligned}$$

**Related Problems: 13, 14**

The conversion of  $\text{NO}(g)$  to  $\text{N}_2\text{O}(g)$  plus  $\text{NO}_2(g)$  is spontaneous under standard conditions. The forward reaction under these conditions is scarcely observed because its rate is so slow. Nonetheless, its equilibrium constant can be calculated! Such calculations often have enormous impact in evaluating proposed solutions to practical problems. For example, the calculation shows that this reaction could be used to reduce the amount of NO in cooled exhaust gases from automobiles. The fundamental reaction tendency is there, but successful application requires finding a route to increasing the reaction rate at standard conditions. Had the equilibrium constant calculated from thermodynamics been small, this proposed application would be doomed at the outset and investment in it would not be justified.

### 14.3.2 Reactions in Ideal Solutions

The thermodynamic description of reactions in solution parallels that for ideal gas reactions. Although the result is not derived here, the Gibbs free energy change for  $n$  mol of a solute, as an ideal (dilute) solution changes in concentration from  $c_1$  to  $c_2$  mol L $^{-1}$ , is

$$\Delta G = nRT \ln \left( \frac{c_2}{c_1} \right) \quad [14.5a]$$

If the reference state for the solute is defined to be an ideal solution with a concentration  $c_{\text{ref}} = 1$  M, the change in Gibbs free energy for taking the solution from the reference state to the concentration  $c$  is given by

$$\Delta G = nRT \ln \left( \frac{c}{c_{\text{ref}}} \right) = nRT \ln c \quad [14.5b]$$

The overall change in Gibbs free energy for a reaction in solution is

$$\Delta G = \Delta G^\circ + RT \ln \left[ \frac{([\text{C}]/c_{\text{ref}})^c ([\text{D}]/c_{\text{ref}})^d}{([\text{A}]/c_{\text{ref}})^a ([\text{B}]/c_{\text{ref}})^b} \right]$$

where the square bracket [X] represents the concentration of species X in units of mol L $^{-1}$ . Again you can re-write the equation above as  $\Delta G = \Delta G^\circ + RT \ln Q$ , where  $Q$  is the ratio of the actual instantaneous concentrations of the species involved as the reaction runs spontaneously in the forward or the reverse direction. When the reaction arrives at equilibrium,  $\Delta G = 0$ , and  $Q$  is now equal to  $K$ .

Setting  $\Delta G = 0$  and subtracting  $\Delta G^\circ$  from both sides gives an expression relating the equilibrium constant  $K$  to  $\Delta G^\circ$ :

$$-\Delta G^\circ = RT \ln K \quad [14.6]$$

for reactions involving dissolved species.

In this book we describe solution equilibria in terms of the thermodynamic equilibrium constant  $K$  rather than the empirical  $K_C$  introduced in Section 14.2. Thus, we give solution concentrations in units of  $\text{mol L}^{-1}$  with the reference state as  $c_{\text{ref}} = 1 \text{ M}$ , and state values of  $K$  as dimensionless quantities. The mass action law for solution reactions becomes

$$\left[ \frac{[\text{C}]^c [\text{D}]^d}{[\text{A}]^a [\text{B}]^b} \right]_{\text{eq}} = K$$

and is numerically equivalent to  $K_C$ . (As we are now in equilibrium, each concentration is understood to be an equilibrium concentration, even though we will often omit the subscript eq in later Chapters.) When working with this expression, you must keep in mind the role of the (invisible)  $c_{\text{ref}}$  factors in making the equation dimensionally correct. This expression is the foundation for the discussions of acid–base equilibria in aqueous solutions in the next chapter.

Solution-phase equilibrium constants can be calculated from tables of standard free energies for solutes in aqueous solution at  $25^\circ\text{C}$  (see Appendix D). The procedure is demonstrated by the following example.

#### EXAMPLE 14.5

Calculate  $\Delta G^\circ$  and the equilibrium constant at  $25^\circ\text{C}$  for the chemical reaction

whose equilibrium expression we developed in Example 14.2.

#### Solution

We calculate the change in standard Gibbs free energy using the  $\Delta G_f^\circ$  values for these aqueous ions in their standard states tabulated in Appendix D:

$$\begin{aligned} \Delta G^\circ &= 2 \Delta G_f^\circ(\text{Cl}^-(aq)) + \Delta G_f^\circ(\text{ClO}_3^-(aq)) - 3 \Delta G_f^\circ(\text{ClO}^-(aq)) \\ &= (2 \text{ mol})(-131.23 \text{ kJ mol}^{-1}) + (1 \text{ mol})(-7.95 \text{ kJ mol}^{-1}) - \\ &\quad (3 \text{ mol})(-36.8 \text{ kJ mol}^{-1}) \\ &= -160.01 \text{ kJ} \end{aligned}$$

As in Example 14.4, we calculate  $K$  by inserting the value for  $\Delta G^\circ$  into the equation

$$\begin{aligned} \ln K &= \frac{-\Delta G^\circ}{RT} = \frac{-(-160,010 \text{ J mol}^{-1})}{(8.315 \text{ J K}^{-1} \text{ mol}^{-1})(298.15 \text{ K})} = 64.54 \\ K &= e^{64.54} = 1.1 \times 10^{28} \end{aligned}$$

The decomposition of hypochlorite ion in bleach is thus a spontaneous process at even very small concentrations of reactants and large concentrations of products, with a very large equilibrium constant at  $25^\circ\text{C}$ . But, this reaction is very slow at room temperature, so the laundry bleach solution remains stable. If the temperature is raised to about  $75^\circ\text{C}$ , the reaction occurs rapidly and the bleach solution decomposes.

### 14.3.3 Reactions Involving Pure Solids and Liquids and Multiple Phases: The Concept of Activity

The mass action law for homogeneous reactions in ideal gases and ideal solutions is written in Section 14.2 by straightforward inspection of the balanced equation for the reaction under study. If one or more of the reactants or products is a solid or liquid in its pure state, the procedure is less obvious, because “concentration” has no meaning for a pure species. This apparent difficulty is resolved by the concept of **activity**, which is a convenient means for comparing the properties of a substance in a general thermodynamic state with its properties in a specially selected reference state. A full treatment of equilibrium in terms of activity requires thermodynamic results beyond the scope of this book. Here we sketch the essential ideas leading to the more general form of the mass action law and merely state the range of validity of the idealized expressions presented.

The activity concept arises from the dependence of the Gibbs free energy on the pressure of a pure substance or on the composition of a solution, regardless of the phase of the system. The discussion just before Equation 14.3 shows that the change in Gibbs free energy when an ideal gas is taken from a reference state  $P_{\text{ref}}$  to any pressure  $P$  is given by

$$\Delta G = nRT \ln \left( \frac{P}{P_{\text{ref}}} \right) = nRT \ln P$$

The last form is used only when pressure  $P$  is expressed in atmospheres and  $P_{\text{ref}} = 1 \text{ atm}$ . A similar equation can be developed for more complex systems—and keep the same simple mathematical form—if we *define* the activity  $a$  by the equation

$$\Delta G = nRT \ln a \quad [14.7]$$

Of course if a system is already in its reference state, then  $\Delta G = 0$  and the activity in this state is 1. The change in Gibbs free energy in taking a system from the reference state to any general thermodynamic state determines the activity  $a$  in the general state.

The activity is connected to pressure or to concentration by the **activity coefficient**. The *activity coefficient*  $\gamma_i$  of a nonideal gaseous species at pressure  $P_i$  is defined by the equation

$$a_i = \frac{\gamma_i P_i}{P_{\text{ref}}} \quad [14.8a]$$

The reference state is chosen to be an ideal gas at one atmosphere. Comparing Equations 14.7 and 14.8a with Equation 14.3 shows that  $\gamma_i$  takes the value 1 for ideal gases. The activity of an ideal gas is the ratio of its pressure to the selected reference pressure. If pressures are given in units of atmospheres, then the activity of an ideal gas is numerically equal to its pressure. Similarly, the activity coefficient  $\gamma_i$  for solute  $i$  in a solution at concentration  $c_i$  is defined by the equation

$$a_i = \frac{\gamma_i c_i}{c_{\text{ref}}} \quad [14.8b]$$

The activity coefficient  $\gamma_i$  equals 1 in the reference state, selected as an ideal solution with convenient concentration. For solute species in the dilute solutions considered in this book, concentration is most conveniently expressed in

molarity, and the reference state is selected to be an ideal solution at concentration  $c_{\text{ref}} = 1 \text{ M}$ .

The reference states for pure solids and liquids are chosen to be those forms stable at 1 atm, just as in the definition of standard states for enthalpy of formation (see Chapter 12) and Gibbs free energy of formation (see Chapter 13). Pure substances in their reference states are assigned activity of value 1.

Once reference states have been defined, the activity coefficients  $\gamma_i$  can be determined from experimental  $P$ - $V$ - $T$  and calorimetric data by procedures that are not described in this book. Then, Equation 14.7 can be written explicitly in terms of pressure, temperature, and concentrations when needed for specific calculations. In its present version, Equation 14.7 is especially well suited for general discussions, because it summarizes much complicated information about nonideal systems in a simple and compact form.

Starting from Equation 14.7, arguments similar to those preceding Equation 14.4 lead to the thermodynamic equilibrium constant  $K$  regardless of the phase of each product or reactant:

$$\left[ \frac{a_{\text{C}}^c \cdot a_{\text{D}}^d}{a_{\text{A}}^a \cdot a_{\text{B}}^b} \right]_{\text{eq}} = K \quad [14.9]$$

Substituting the appropriate ideal expression for the activity of gaseous or dissolved species from Equation 14.8a or 14.8b leads to the forms of the mass action law and the equilibrium constant  $K$  already derived earlier in Section 14.3 for reactions in ideal gases or in ideal solutions. We write the mass action law for reactions involving pure solids and liquids and multiple phases by substituting unity for the activity of pure liquids or solids and the appropriate ideal expression for the activity of each gaseous or dissolved species into Equation 14.9. Once a proper reference state and concentration units have been identified for *each* reactant and product, we use tabulated free energies based on these reference states to calculate the equilibrium constant.

The following example illustrates the method.

### EXAMPLE 14.6

The compound urea, important in biochemistry, can be prepared in aqueous solution by the following reaction:

- (a) Write the mass action law for this reaction. (b) Calculate  $\Delta G^\circ$  for this reaction at 25°C. (c) Calculate  $K$  for this reaction at 25°C.

#### Solution

- (a) In terms of activities for each species, the equilibrium expression is

$$\left[ \frac{a_{\text{urea}} \cdot a_{\text{H}_2\text{O}}}{a_{\text{CO}_2} \cdot a_{\text{NH}_3}^2} \right]_{\text{eq}} = K$$

Choose the reference state for the gases to be  $P_{\text{ref}} = 1 \text{ atm}$ , for the urea to be  $c_{\text{ref}} = 1 \text{ M}$ , and for water to be the pure

liquid with unit activity. Then at low pressures and concentrations, the limiting idealized mass action law is

$$\left[ \frac{[\text{urea}]}{P_{\text{CO}_2} \cdot P_{\text{NH}_3}^2} \right]_{\text{eq}} = K$$

with [urea] in units of  $\text{mol L}^{-1}$  and the partial pressures in atm. The (invisible)  $P_{\text{ref}}$  and  $c_{\text{ref}}$  factors must always be kept in mind, because they make  $K$  dimensionless in this expression. This expression can be extended to higher pressures and concentrations, where nonideality becomes important, by inserting the appropriate activity coefficients.

- (b) The procedure is the same as in Examples 14.4 and 14.5. The  $\Delta G_f^\circ$  values for gaseous  $\text{CO}_2$  and  $\text{NH}_3$  and liquid  $\text{H}_2\text{O}$  with the reference states just specified are obtained directly

(Continued)

from Appendix D. Because the data for urea in Appendix D are based on a *solid* reference state, we consult an alternate source<sup>3</sup> to obtain  $\Delta G_f^\circ(\text{urea}(aq)) = -203.84 \text{ kJ mol}^{-1}$  with the reference state an ideal solution with  $c = 1 \text{ M}$ . From these data we obtain

$$\begin{aligned}\Delta G^\circ &= -203.84 - 237.18 + 394.36 + 2(16.48) \\ &= -13.70 \text{ kJ mol}^{-1}\end{aligned}$$

(c) Following the procedure in Example 14.5 we find  $K = 251.1$ .

This example illustrates a very important point: Before using  $\Delta G_f^\circ$  values to estimate equilibrium constants, *be certain* you know the reference state for the tabulated values.

**Related Problems: 15, 16**

Equilibrium expressions written in this way are accurate to about 5% when the pressures of gases do not exceed several atmospheres and the concentrations of solutes do not exceed 0.1 M. These cases cover all the applications discussed in this book, so we do not need correction factors. For concentrated ionic solutions, the corrections can become very large. In accurate studies of solution equilibria, especially in biochemical applications, activities must be used in place of partial pressures or concentrations. You should consult more advanced books when you need these techniques.

## 14.4 The Law of Mass Action for Related and Simultaneous Equilibria

Each time we write the mass action law, it is based on a specific balanced chemical equation in which the reaction is carried out as written “left to right.” Chemical reactions can be carried out in various alternative ways, including “in reverse” and in concert with other reactions. These variations lead to relationships among equilibrium expressions, which are best illustrated in a series of examples.

### 14.4.1 Relationships among Equilibrium Expressions

(1) Suppose a reaction is written in two opposing directions:

In the first reaction, hydrogen and oxygen combine to form water vapor, whereas in the second, water vapor dissociates into hydrogen and oxygen. The equilibrium constants  $K_1$  and  $K_2$  are clearly the inverse of each other, so their product  $K_1 K_2 = 1$ . This is true quite generally: The equilibrium constant for a reverse reaction is the reciprocal of the equilibrium constant for the corresponding forward reaction.

(2) What happens if a balanced chemical equation is multiplied by a constant? In the preceding example, multiplying the first equation by  $\frac{1}{2}$  gives

<sup>3</sup>Thermodynamic data for many biological molecules in solution are given in F. H. Carpenter, *J. Am. Chem. Soc.*, 82, 1120 (1960).

This is a perfectly satisfactory way to write the equation for the chemical reaction; it says that 1 mol of hydrogen reacts with  $\frac{1}{2}$  mol of oxygen to yield 1 mol of water vapor. The corresponding equilibrium expression is

$$\left[ \frac{P_{\text{H}_2\text{O}}}{P_{\text{H}_2} P_{\text{O}_2}^{1/2}} \right]_{\text{eq}} = K_3$$

Comparison with the expression for  $K_1$  shows that

$$K_3 = K_1^{1/2}$$

When a balanced chemical equation is multiplied by a constant factor, the corresponding equilibrium constant is raised to a power equal to that factor.

- (3) A further variation is to add two equations to give a third. In this case the equilibrium constant for the third equation is the product of the equilibrium constants for the first two. For example, at 25°C,

Adding the two chemical equations gives

Removing  $\text{Br}_2(g)$  from both sides leaves

and, by inspection,  $K_3 = K_1 K_2 = (0.45)(0.051) = 0.023$ .

- (4) If a second equation is *subtracted* from the first, the resulting equilibrium constant is that of the first *divided* by that of the second (subtracting a reaction is the same as adding the reverse reaction). The operations of addition and subtraction applied to chemical equations transform into multiplication and division of the equilibrium expressions and equilibrium constants.

### EXAMPLE 14.7

The concentrations of the oxides of nitrogen are monitored in air-pollution reports. At 25°C, the equilibrium constant for the reaction

is

$$\left[ \frac{P_{\text{NO}_2}}{P_{\text{NO}} P_{\text{O}_2}^{1/2}} \right]_{\text{eq}} = K_1 = 1.3 \times 10^6$$

and that for

is

$$\left[ \frac{P_{\text{NO}}}{P_{\text{N}_2}^{1/2} P_{\text{O}_2}^{1/2}} \right]_{\text{eq}} = K_2 = 6.5 \times 10^{-16}$$

Find the equilibrium constant  $K_3$  for the reaction

#### Solution

Adding the chemical equations for the first two reactions gives

The equilibrium constant for this reaction,  $K'_3$ , is just the product of  $K_1$  and  $K_2$ , or  $K_1 K_2$ . The constant sought,  $K_3$ , is defined by a chemical equation that is twice this, so  $K'_3$  must be raised to the power 2 (that is, squared) to give  $K_3$ :

$$K_3 = (K'_3)^2 = (K_1 K_2)^2 = 7.1 \times 10^{-19}$$

**Related Problems:** 17, 18, 19, 20

### 14.4.2 Consecutive Equilibria

Many real-world applications of chemistry and biochemistry involve fairly complex sets of reactions occurring in sequence and/or in parallel. Each of these individual reactions is governed by its own equilibrium constant. To describe the overall progress of the entire coupled set of reactions we write all the involved equilibrium expressions and treat them as a set of *simultaneous algebraic equations*, because the concentrations of various chemical species appear in several expressions in the set. Examination of relative values of equilibrium constants shows that some reactions dominate the overall coupled set of reactions, and this chemical insight enables mathematical simplifications in the simultaneous equations. We study coupled equilibria in considerable detail in Chapter 15 on acid–base equilibrium. In Section 14.6 we provide a brief introduction to this topic in the context of an important biological process.

## 14.5 Equilibrium Calculations for Gas-Phase and Heterogeneous Reactions

Equilibrium calculations, used throughout the science of chemistry in both basic and applied work, involve specific procedures. The present section presents these problem-solving techniques in the context of gas-phase and heterogeneous reactions, but they are applicable in *all* equilibrium calculations. The strategy comprises three basic steps:

1. Always start by writing the balanced equation for the reaction being studied.
2. Visualize the reaction as proceeding through three steps:
  - a. the reactants are brought together at their *initial partial pressures*, but not yet allowed to react;
  - b. the reaction is initiated and causes *changes in partial pressures* of all products and reactants;
  - c. the reaction reaches equilibrium, and all products and reactants are present at their *equilibrium partial pressures*. (Note the similarity to the procedures described in Chapter 13 for initiating spontaneous processes by manipulating thermodynamic constraints.)
3. Develop approximation schemes when possible by neglecting a very small quantity when it is added to or subtracted from a much larger quantity.

We illustrate these calculation methods with several examples that fall into two broad classes: evaluating the equilibrium constant from reaction data, and calculating the amounts of products and reactants present at equilibrium when the equilibrium constant is known.

### 14.5.1 Evaluating Equilibrium Constants from Reaction Data

In Section 14.3 we showed how to evaluate  $K$  from calorimetric data on the pure reactants and products. Occasionally, these thermodynamic data may not be available for a specific reaction, or a quick estimate of the value of  $K$  may suffice. In these cases we can evaluate the equilibrium constant from measurements made directly on the reaction mixture. If we can measure the equilibrium partial pressures of all the reactants and products, we can evaluate the equilibrium constant by substituting these measured values (in units of atmospheres) into the equilibrium expression. In many cases it is not practical to measure directly the equilibrium partial pressure of each separate reactant and

product. Nonetheless, the equilibrium constant can usually be derived from other available data, although the determination is less direct. We illustrate the method in the following two examples.

**FIGURE 14.5** Phosgene,  $\text{COCl}_2$ , is a chemical intermediate used in making polyurethanes for foams and surface coatings.

### EXAMPLE 14.8

Phosgene,  $\text{COCl}_2$  (Fig. 14.5), forms from  $\text{CO}$  and  $\text{Cl}_2$  according to the equilibrium

At  $600^\circ\text{C}$ , a gas mixture of  $\text{CO}$  and  $\text{Cl}_2$  is prepared that has initial partial pressures (before reaction) of  $0.60\text{ atm}$  for  $\text{CO}$  and  $1.10\text{ atm}$  for  $\text{Cl}_2$ . After the reaction mixture has reached equilibrium, the partial pressure of  $\text{COCl}_2(g)$  at this temperature is measured to be  $0.10\text{ atm}$ . Calculate the equilibrium constant for this reaction. The reaction is carried out in a vessel of fixed volume.

#### Solution

Only the equilibrium partial pressure of  $\text{COCl}_2(g)$  and the *initial* partial pressures of the other two gases are given. To find the equilibrium constant, it is necessary to determine the equilibrium partial pressures of  $\text{CO}$  and  $\text{Cl}_2$ . To do this, we set up a simple table:

	$\text{CO}(g)$	+	$\text{Cl}_2(g)$	$\rightleftharpoons$	$\text{COCl}_2(g)$
Initial partial pressure (atm)	0.60		1.10		0
Change in partial pressure (atm)	?		?		+0.10
Equilibrium partial pressure (atm)	?		?		0.10

Note that the first two lines must add to give the third. We use the relationships built into the balanced chemical equation to fill in the blanks in the table. Because this is the only reaction taking place, every mole of  $\text{COCl}_2$  produced consumes exactly 1 mol of  $\text{CO}$  and exactly 1 mol of  $\text{Cl}_2$ . According to the ideal gas equation, the partial pressures of gases are proportional to the number of moles of each gas present as long as the volume and temperature are held fixed. Therefore, the change in partial pressure of each gas must be proportional to the change in its number of moles as the mixture goes toward equilibrium. If the partial pressure of  $\text{COCl}_2$  *increases* by  $0.10\text{ atm}$  through reaction, the partial pressures of  $\text{CO}$  and  $\text{Cl}_2$  must each *decrease* by  $0.10\text{ atm}$ . Inserting these values into the table gives

	$\text{CO}(g)$	+	$\text{Cl}_2(g)$	$\rightleftharpoons$	$\text{COCl}_2(g)$
Initial partial pressure (atm)	0.60		1.10		0
Change in partial pressure (atm)	-0.10		-0.10		+0.10
Equilibrium partial pressure (atm)	0.50		1.00		0.10

where the last line was obtained by adding the first two.

We now insert the equilibrium partial pressures into the equilibrium expression to calculate the equilibrium constant:

$$K = \left[ \frac{P_{\text{COCl}_2}}{(P_{\text{CO}})(P_{\text{Cl}_2})} \right]_{\text{eq}} = \frac{(0.10)}{(0.50)(1.00)} = 0.20$$

**Related Problems:** 21, 22, 23, 24

For a reaction in which some of the coefficients in the balanced equation are not equal to 1, deriving expressions for the changes in the partial pressures of the products and reactants requires care. Consider the combustion of ethane at constant volume:

If the initial partial pressures are all 1.00 atm and there is a net reaction from left to right in this equation, the table is

	$2 \text{ C}_2\text{H}_6(\text{g})$	+ $7 \text{ O}_2(\text{g})$	$\rightleftharpoons$	$4 \text{ CO}_2(\text{g})$	+ $6 \text{ H}_2\text{O}(\text{g})$
Initial partial pressure	1.00			1.00	1.00
Change in partial pressure	$-2y$			$+4y$	$+6y$
Equilibrium partial pressure	$1.00 - 2y$			$1.00 + 4y$	$1.00 + 6y$

If the  $\text{C}_2\text{H}_6$  partial pressure decreases by  $2y$  atm, that of  $\text{O}_2$  must decrease by  $7y$ , because the coefficients in the balanced equation are 2 and 7. The changes in partial pressures of products will have the opposite sign (positive instead of negative), because as reactants disappear, products appear. Their magnitudes are determined according to the coefficients in the balanced equation.

### EXAMPLE 14.9

Graphite (a form of solid carbon) is added to a vessel that contains  $\text{CO}_2(\text{g})$  at a pressure of 0.824 atm at a certain high temperature. The pressure rises due to a reaction that produces  $\text{CO}(\text{g})$ . The total pressure reaches an equilibrium value of 1.366 atm. (a) Write a balanced equation for the process. (b) Calculate the equilibrium constant.

#### Solution

(a) The reaction can only be the oxidation of C by  $\text{CO}_2$  during which the  $\text{CO}_2$  is itself reduced to CO. The reaction and its equilibrium expression are written as

(b) To determine the equilibrium constant, we set up the standard table to describe reaction progress:

	$\text{C}(\text{s})$	+	$\text{CO}_2(\text{g})$	$\rightleftharpoons$	$2 \text{ CO}(\text{g})$
Initial partial pressure (atm)			0.824		0
Change in partial pressure (atm)			$-x$		$+2x$
Equilibrium partial pressure (atm)			$0.824 - x$		$2x$

The total pressure at equilibrium is

$$P_{\text{tot}} = 0.824 \text{ atm} - x + 2x = 0.824 + x = 1.366 \text{ atm}$$

Solving for  $x$  gives

$$x = 1.366 - 0.824 = 0.542 \text{ atm}$$

The equilibrium partial pressures of the two gases are

$$P_{\text{CO}} = 2x = 1.084 \text{ atm}$$

$$P_{\text{CO}_2} = 0.824 - 0.542 = 0.282 \text{ atm}$$

The equilibrium constant for the reaction is therefore

$$K = \frac{(1.084)^2}{0.282} = 4.17$$

**Related Problems: 25, 26**

## 14.5.2 Calculating Equilibrium Compositions When $K$ Is Known

The law of mass action relates the equilibrium composition to the equilibrium constant. We can use these expressions to predict the outcomes of chemical reactions. How to approach the problem depends on the type of experimental data available.

Suppose you are asked to determine the partial pressures of reactants and products at equilibrium, given initial partial pressures of the reactants. This is illustrated by the following example.

### EXAMPLE 14.10

Suppose  $\text{H}_2(\text{g})$  and  $\text{I}_2(\text{g})$  are sealed in a flask at  $T = 400 \text{ K}$  with partial pressures  $P_{\text{H}_2} = 1.320 \text{ atm}$  and  $P_{\text{I}_2} = 1.140 \text{ atm}$ . At this temperature  $\text{H}_2$  and  $\text{I}_2$  do not react rapidly to form  $\text{HI}(\text{g})$ , although after a long enough time they would produce  $\text{HI}(\text{g})$  at its equilibrium partial pressure. Suppose, instead, that the gases are heated in the sealed flask to  $600 \text{ K}$ , a temperature at which they quickly reach equilibrium:

The equilibrium constant for the reaction is 92.6 at  $600 \text{ K}$ :

$$\left[ \frac{P_{\text{HI}}^2}{P_{\text{H}_2} P_{\text{I}_2}} \right]_{\text{eq}} = 92.6$$

- (a) What are the equilibrium values of  $P_{\text{H}_2}$ ,  $P_{\text{I}_2}$ , and  $P_{\text{HI}}$  at  $600 \text{ K}$ ?  
 (b) What percentage of the  $\text{I}_2$  originally present has reacted when equilibrium is reached?

#### Solution

- (a) Suppose  $\text{H}_2$  and  $\text{I}_2$  did *not* react at  $600 \text{ K}$ . From the ideal gas law at constant volume, their partial pressures would be

$$P_{\text{H}_2}^\circ = 1.320 \text{ atm} \times \left( \frac{600 \text{ K}}{400 \text{ K}} \right) = 1.980 \text{ atm}$$

$$P_{\text{I}_2}^\circ = 1.140 \text{ atm} \times \left( \frac{600 \text{ K}}{400 \text{ K}} \right) = 1.710 \text{ atm}$$

Of course, these gases *do* react, and the extent of the reaction can be calculated. To do this, set up a table as in Example 14.8:

	$\text{H}_2(\text{g})$	+	$\text{I}_2(\text{g})$	$\rightleftharpoons$	$2 \text{HI}(\text{g})$
Initial partial pressure (atm)	1.980		1.710		0
Change in partial pressure (atm)	$-x$		$-x$		$+2x$
Equilibrium partial pressure (atm)	$1.980 - x$		$1.710 - x$		$2x$

If the partial pressure of  $\text{H}_2$  decreases by  $x \text{ atm}$  as the reaction proceeds, then the partial pressure of  $\text{I}_2$  must also decrease by  $x \text{ atm}$  because each mole of  $\text{H}_2$  reacts with 1 mol of  $\text{I}_2$ . By similar reasoning, the partial pressure of  $\text{HI}$  increases by  $2x \text{ atm}$ : 2 mol of  $\text{HI}$  forms from each mole of  $\text{H}_2$ . Inserting the equilibrium partial pressures into the equilibrium expression results in the equation

$$\frac{(2x)^2}{(1.980 - x)(1.710 - x)} = 92.6$$

(Continued)

Multiplying and collecting terms gives

$$88.6x^2 - 341.694x + 313.525 = 0$$

Solving for  $x$  using the quadratic formula (see Appendix C) gives

$$x = \frac{-(-341.694) \pm \sqrt{(341.694)^2 - 4(88.6)(313.525)}}{2(88.6)}$$

$$= 1.5044 \text{ atm or } 2.3522 \text{ atm}$$

The second root is physically impossible because it leads to negative answers for the equilibrium partial pressures of the  $\text{H}_2(\text{g})$  and  $\text{I}_2(\text{g})$ . Discarding it leaves

$$P_{\text{HI}} = 2 \times 1.5044 \text{ atm} = 3.0088 \text{ atm}$$

$$P_{\text{H}_2} = 1.980 \text{ atm} - 1.5044 \text{ atm} = 0.4756 \text{ atm}$$

$$P_{\text{I}_2} = 1.710 \text{ atm} - 1.5044 \text{ atm} = 0.2056 \text{ atm}$$

It is a good idea to check such results by inserting the calculated equilibrium partial pressures back into the equilibrium expression to make sure that the known value of  $K$  comes out.

$$\text{Check: } \frac{(3.0088)^2}{(0.4756)(0.2056)} = 92.6$$

As the final step, round off each answer to the correct number of significant digits:  $P_{\text{HI}} = 3.01 \text{ atm}$ ,  $P_{\text{H}_2} = 0.48 \text{ atm}$ ,  $P_{\text{I}_2} = 0.21 \text{ atm}$ . Rounding off sooner makes the  $K$  calculated in the check differ somewhat from 92.6.

- (b) The fraction of  $\text{I}_2$  that has *not* reacted is the ratio of the number of moles of  $\text{I}_2$  present at the end to that present at the beginning. Because neither volume nor temperature changes during the reaction, this equals the ratio of the final partial pressure of  $\text{I}_2$  (0.2056 atm) to its initial partial pressure (1.710 atm):

$$\text{percentage unreacted} = \frac{0.2056 \text{ atm}}{1.710 \text{ atm}} \times 100\% = 12\%$$

The percentage that *has* reacted is then 88%.

**Related Problems:** 27, 28, 29, 30, 31, 32

The concentrations of any products initially present must also be included in equilibrium calculations, as illustrated by the following example.

### EXAMPLE 14.11

Hydrogen is made from natural gas (methane) for immediate consumption in industrial processes, such as ammonia production. The first step is called the “steam reforming of methane”:

The equilibrium constant for this reaction is  $1.8 \times 10^{-7}$  at 600 K. Gaseous  $\text{CH}_4$ ,  $\text{H}_2\text{O}$ , and  $\text{CO}$  are introduced into an evacuated container at 600 K, and their initial partial pressures (before reaction) are 1.40 atm, 2.30 atm, and 1.60 atm, respectively. Determine the partial pressure of  $\text{H}_2(\text{g})$  that will result at equilibrium.

(Continued)

**Solution**

The equilibrium expression is

$$\left[ \frac{(P_{\text{CO}})(P_{\text{H}_2})^3}{(P_{\text{CH}_4})(P_{\text{H}_2\text{O}})} \right]_{\text{eq}} = K$$

Set up the table of partial pressures:

	$\text{CH}_4(\text{g})$	+	$\text{H}_2\text{O}(\text{g})$	$\rightleftharpoons$	$\text{CO}(\text{g})$	+	$3 \text{H}_2(\text{g})$
Initial partial pressure	1.40		2.30		1.60		0
Change in partial pressure	$-y$		$-y$		$+y$		$+3y$
Equilibrium partial pressure	$1.40 - y$		$2.30 - y$		$1.60 + y$		$3y$

Insert the equilibrium partial pressures into the equilibrium expression:

$$\frac{(1.60 + y)(3y)^3}{(1.40 - y)(2.30 - y)} = 1.8 \times 10^{-7}$$

If we expand this equation by multiplying through by the denominator, a polynomial equation of fourth order in  $y$  would result, for which the quadratic formula from the preceding problem would be useless. How can we solve the equation?

The equilibrium constant in this case is quite small, so the extent of reaction will also be small. This suggests that  $y$  will be a small number relative to the partial pressures of the gases present initially. Let's try the approximation that  $y$  can be ignored where it is added to a number that is close to one; that is, let's replace  $1.60 + y$  with  $1.60$  in the preceding equation, and make the same approximation for the two terms in the denominator. When  $y$  *multiplies* something, as in the  $(3y)^3$  term, of course we cannot set it equal to zero. The result of these steps is the approximate equation

$$\frac{(1.60)(3y)^3}{(1.40)(2.30)} = 1.8 \times 10^{-7}$$

$$y^3 = 1.34 \times 10^{-8}$$

The cube roots of both sides give

$$y = 2.38 \times 10^{-3}$$

This value is indeed small compared with 1.60, 1.40, and 2.30, so our approximation of neglecting  $y$  relative to these numbers is justified. Finally, at equilibrium we have

$$P_{\text{H}_2} = 3y = 7.1 \times 10^{-3} \text{ atm}$$

**Related Problems: 33, 34, 35, 36**

Suppose the data for a gas-phase equilibrium are given in terms of concentrations rather than partial pressures. In such cases we convert all concentrations to partial pressures before starting the calculations. Or, we can rewrite the equilibrium expression in terms of concentration variables. The concentration  $[A]$  of an ideal gas is related to its partial pressure  $P_A$  through

$$[A] = \frac{n_A}{V} = \frac{P_A}{RT}$$

which can be written

$$P_A = RT[A]$$

We can substitute such a relation for each species appearing in the equilibrium expression. It is best to put the factors of  $P_{\text{ref}} = 1 \text{ atm}$  back into the equilibrium

expression to examine the units of the resulting equations. For the general gas-phase reaction

the equilibrium expression is

$$\left[ \frac{(RT[C]/P_{\text{ref}})^c (RT[D]/P_{\text{ref}})^d}{(RT[A]/P_{\text{ref}})^a (RT[B]/P_{\text{ref}})^b} \right]_{\text{eq}} = K$$

Rearranging gives

$$\left[ \frac{[C]^c [D]^d}{[A]^a [B]^b} \right]_{\text{eq}} = K(RT/P_{\text{ref}})^{+a+b-c-d}$$

This expression relates concentrations of gas-phase species at equilibrium. If  $a + b - c - d = 0$  (that is, if there is no change in the total number of moles of gases in the reaction mixture), the right side of the equilibrium expression reduces to  $K$ .

### EXAMPLE 14.12

At elevated temperatures,  $\text{PCl}_5$  dissociates extensively according to

At  $300^\circ\text{C}$ , the equilibrium constant for this reaction is  $K = 11.5$ . The concentrations of  $\text{PCl}_3$  and  $\text{Cl}_2$  at equilibrium in a container at  $300^\circ\text{C}$  are both  $0.0100 \text{ mol L}^{-1}$ . Calculate  $[\text{PCl}_5]$ .

#### Solution

Two moles of gases are produced for each mole of gas consumed, so  $RT/P_{\text{ref}}$  must be raised to the power  $1 - 2 = -1$ . Hence,

$$\begin{aligned} \left[ \frac{[\text{PCl}_3][\text{Cl}_2]}{[\text{PCl}_5]} \right]_{\text{eq}} &= K \left( \frac{RT}{P_{\text{ref}}} \right)^{-1} = K \left( \frac{P_{\text{ref}}}{RT} \right) \\ &= 11.5 \times \frac{1 \text{ atm}}{(0.08206 \text{ L atm mol}^{-1} \text{ K}^{-1})(573 \text{ K})} = 0.245 \frac{\text{mol}}{\text{L}} \end{aligned}$$

Solving this equation for  $[\text{PCl}_5]$  gives

$$\begin{aligned} [\text{PCl}_5] &= \frac{[\text{PCl}_3][\text{Cl}_2]}{0.245 \text{ mol L}^{-1}} = \frac{(0.0100 \text{ mol L}^{-1})(0.0100 \text{ mol L}^{-1})}{0.245 \text{ mol L}^{-1}} \\ &= 4.08 \times 10^{-4} \text{ mol L}^{-1} \end{aligned}$$

**Related Problems:** 31, 32

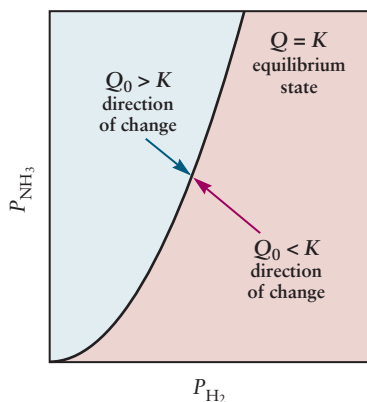

## 14.6 The Direction of Change in Chemical Reactions: Empirical Description

The specific examples in Section 14.5 illustrate how the law of mass action gives information about the nature of the equilibrium state. The law of mass action also explains and predicts the direction in which a reaction will proceed spontaneously when reactants and products are initially mixed together with arbitrary partial pressures or compositions. This requires a new concept, the

(a)

(b)

**FIGURE 14.6** If nitrogen and hydrogen are mixed in 1:3 proportions together with some ammonia, they react according to the chemical equation

(a) If the initial reaction quotient  $Q_0$  is less than  $K$ , it increases with time; if it is greater than  $K$ , it decreases.  
 (b) With three moles of  $\text{H}_2$  available for each mole of  $\text{N}_2$ , a parabolic curve represents the partial pressures of ammonia and of hydrogen that coexist at equilibrium. From initial nonequilibrium conditions on either side, the partial pressures approach equilibrium along lines with slope  $-2/3$ , because three moles of  $\text{H}_2$  are consumed to produce two moles of  $\text{NH}_3$ .

reaction quotient  $Q$ , which is related to the equilibrium constant. Through the *principle of Le Châtelier* (described below), the mass action law also explains how a reaction in equilibrium responds to an external perturbation.

### 14.6.1 The Reaction Quotient

The **reaction quotient**  $Q$  for a general gas-phase reaction is defined as

$$Q = \frac{(P_C)^c (P_D)^d}{(P_A)^a (P_B)^b}$$

where the partial pressures are the actual values measured at any point during the reaction, not just at equilibrium. The distinction between  $Q$  and  $K$  is crucial. The equilibrium constant  $K$  is determined by the partial pressures of reactants and products at equilibrium, and it is a constant, dependent only on the temperature. The reaction quotient  $Q$  depends on the actual instantaneous partial pressures, whatever they may be; thus,  $Q$  changes with time. As the reaction approaches equilibrium,  $Q$  approaches  $K$ . The initial partial pressures  $P_A^\circ$ ,  $P_B^\circ$ ,  $P_C^\circ$ , and  $P_D^\circ$  give an initial reaction quotient  $Q_0$ , whose magnitude relative to  $K$  determines the direction in which the reaction will proceed spontaneously toward equilibrium. If  $Q_0$  is *less* than  $K$ , then  $Q$  must *increase* as time goes on. To increase  $Q$  the reaction must proceed spontaneously in the forward direction. To see that it will, in Section 14.7 we simply rewrite  $\Delta G = \Delta G^\circ + RT \ln Q$  using equation 14.6. This gives  $\Delta G = -RT \ln K + RT \ln Q = RT \ln (Q/K)$ . Thus,  $\Delta G$  will be negative if  $Q < K$  and the reaction will proceed spontaneously in the forward direction, increasing  $Q$ . There is an increase in the product partial pressures and a decrease in reactant partial pressures as the reaction proceeds from left to right. If  $Q_0$  is *greater* than  $K$ , similar reasoning shows that the reaction will proceed from right to left, with  $Q$  *decreasing* with time until it becomes equal to  $K$  (Fig. 14.6).

#### EXAMPLE 14.13

The reaction between nitrogen and hydrogen to produce ammonia

is essential in making nitrogen-containing fertilizers. This reaction has an equilibrium constant equal to  $1.9 \times 10^{-4}$  at  $400^\circ\text{C}$ . Suppose that 0.10 mol of  $\text{N}_2$ , 0.040 mol of  $\text{H}_2$ , and 0.020 mol of  $\text{NH}_3$  are sealed in a 1.00-L vessel at  $400^\circ\text{C}$ . In which direction will the reaction proceed?

#### Solution

The initial pressures  $P_i = n_i RT/V$  are readily calculated to be

$$P_{\text{N}_2} = 5.5 \text{ atm} \quad P_{\text{H}_2} = 2.2 \text{ atm} \quad P_{\text{NH}_3} = 1.1 \text{ atm}$$

The initial numerical value of  $Q$  is therefore

$$Q_0 = \frac{(P_{\text{NH}_3}^\circ)^2}{P_{\text{N}_2}^\circ (P_{\text{H}_2}^\circ)^3} = \frac{(1.1)^2}{(5.5)(2.2)^3} = 2.1 \times 10^{-2}$$

Because  $Q_0 > K$ , the reaction will proceed from right to left and ammonia will dissociate until equilibrium is reached.

**Related Problems:** 45, 46, 47, 48

## CONNECTION TO BIOLOGY

## Hemoglobin and Oxygen Transport

Humans and animals require oxygen for the aerobic metabolic processes that provide the energy necessary to sustain life. Food (a fuel) is oxidized in a series of enzyme-mediated reactions to produce energy; the products of the reactions being  $\text{CO}_2$  and  $\text{H}_2\text{O}$ . Oxygen is carried from the lungs to tissues bound to the protein molecule hemoglobin (Hb), and it is stored in muscle by a related protein called myoglobin (Mb). Hemoglobin and myoglobin are both oxygen transport proteins in which  $\text{O}_2$  is covalently bound to iron in an octahedral coordination complex built around the porphyrin molecule heme (see Section 8.3). Iron is coordinated to four nitrogen atoms in the planar porphyrin structure, leaving a fifth site available that binds the heme to the protein via the amino acid histidine, and a sixth site available to reversibly bind oxygen. The solubility of oxygen in whole blood can be as high as  $10^{-2} \text{ mol L}^{-1}$  only because it is chemically bound to hemoglobin. The solubility of  $\text{O}_2$  in blood plasma, which contains no hemoglobin, is only about  $10^{-4} \text{ mol L}^{-1}$ , a value that is very close to its solubility in pure water (as determined by its Henry's Law constant, see Section 11.6). The partial pressure of  $\text{O}_2$  in the lungs is about 100 torr, which is sufficiently high to saturate all of the available oxygen binding sites in hemoglobin. Highly oxygenated blood from the lungs is delivered throughout the body via the circulatory system, eventually reaching the capillaries, where the  $\text{O}_2$  partial pressure is only about 40 torr. Hemoglobin releases a significant fraction of the bound oxygen under these low-pressure conditions; it can either be taken up and stored by myoglobin in muscle or transported directly to cells for their use in metabolism.

**FIGURE C14.1** Myoglobin (Mb) (Adapted from Reginald H. Garrett and Charles M. Grisham, fig. 15.21 (top), p. 468, *Biochemistry*. Boston: Brooks/Cole, Cengage Learning, 2010; Cengage Learning)

Why is oxygen bound so strongly by hemoglobin in the lungs and then released so readily to myoglobin through capillaries? The answer requires an understanding of the differences between the simple heterogeneous equilibrium established between oxygen and myoglobin and the more complicated set of simultaneous equilibria established between oxygen and hemoglobin. The differences arise as a consequence of

the very different molecular structures of the two proteins. Myoglobin is a monomeric globular protein that contains 154 amino acids in a helical configuration (represented by the green ribbon structure) and a single heme group shown in red (Fig. C14.1).

Hemoglobin, on the other hand, is a tetramer with two identical  $\alpha$  subunits that each contains 141 amino acids and a single heme group, and two identical  $\beta$  subunits that each contains 146 amino acids and a single heme group. Each member of an identical pair of monomers is labeled by a number, and all four monomers are colored differently, for clarity (Fig. C14.2).

The uptake of oxygen by myoglobin follows the hyperbolic Michaelis–Menten equation (see Section 18.8) as shown by the blue line in Fig. C14.3, which is a plot of the **fractional saturation** versus the oxygen partial pressure. This behavior is characteristic of a simple enzyme/substrate equilibrium as represented by the following equation and equilibrium constant.

$$K = \frac{[\text{Mb}(\text{O}_2)]}{[\text{Mb}]\text{P}_{\text{O}_2}} = 271$$

The graph shows that binding saturates at very low oxygen partial pressures; half of the available sites are filled at  $\text{P}_{\text{O}_2} = 1$  torr.

The experimental binding curve for hemoglobin is quite different, however. The S-shaped red curve shows that relatively few oxygen molecules are bound at low partial pressures but that the fractional saturation increases rapidly with increasing  $\text{P}_{\text{O}_2}$ ; half saturation

**FIGURE C14.2** Hemoglobin (Hb) (Adapted from Reginald H. Garrett and Charles M. Grisham, fig. 15.21 (bottom), p. 468, *Biochemistry*. Boston: Brooks/Cole, Cengage Learning, 2010; © Cengage Learning)

occurs at about 30 torr, a much higher pressure than for myoglobin. Curves of this type are characteristic of cooperative behavior. Binding the first  $O_2$  molecule to one heme group in hemoglobin causes a conformational change that makes it easier to bind the second  $O_2$  molecule to a different heme group and so forth until all four sites are occupied. Evidence for this conclusion is provided by comparing the values of the consecutive equilibrium constants, as shown below.

$$K_1 = \left[ \frac{[\text{Hb}(\text{O}_2)]}{[\text{Hb}]P_{\text{O}_2}} \right]_{\text{eq}} = 4.88$$

$$K_2 = \left[ \frac{[\text{Hb}(\text{O}_2)_2]}{[\text{Hb}(\text{O}_2)]P_{\text{O}_2}} \right]_{\text{eq}} = 15.4$$

$$K_3 = \left[ \frac{[\text{Hb}(\text{O}_2)_3]}{[\text{Hb}(\text{O}_2)_2]P_{\text{O}_2}} \right]_{\text{eq}} = 6.49$$

$$K_4 = \left[ \frac{[\text{Hb}(\text{O}_2)_4]}{[\text{Hb}(\text{O}_2)_3]P_{\text{O}_2}} \right]_{\text{eq}} = 1750$$

The four equilibrium constants are not equal to each other, and  $K_4$  is much larger than the other three. Reducing  $P_{\text{O}_2}$  clearly reduces the fraction of bound oxygen

(Le Châtelier's principle) for both proteins but the two molecules respond quite differently to decreasing oxygen partial pressures. Hemoglobin and myoglobin are both nearly saturated at partial pressures of 100 torr (in the lungs), but the fraction of oxygen bound to hemoglobin has dropped to 55% at 30 torr (in capillaries) while the fraction bound to myoglobin in muscle remains high at 90%. These different responses to changes in the oxygen partial pressure are responsible for transfer of  $O_2$  from hemoglobin (in blood) to myoglobin (in muscle). See chart below.

Archibald Hill derived a simple model to account for the S-shaped curve observed that provides some physical insight into the nature of the cooperativity involved. Suppose, for example, that binding was an all or nothing event. The overall reaction and resulting equilibrium constant expression would be

from which we express the fractional saturation as follows,

$$X = \frac{[\text{Hb}(\text{O}_2)_4]}{[\text{Hb}(\text{O}_2)_4] + [\text{Hb}]} \quad X = \frac{(P_{\text{O}_2})^4}{(P_{\text{O}_2})^4 + K}$$

which is plotted in black. The most general form proposed by Hill replaces the exponent 4 with a number  $n$  that is chosen to fit particular situations.  $n = 1$  corresponds to the myoglobin case with no cooperativity, and a fit to the hemoglobin curve produces  $n = 2.8$ , which demonstrates a high degree of, but not perfect, cooperativity.

**FIGURE C14.3** A plot of the fraction of the binding sites of hemoglobin (red) and myoglobin (blue) that are occupied at equilibrium as a function of the partial pressure of  $O_2$ . (Adapted from Reginald H. Garrett and Charles M. Grisham, *Biochemistry*. Boston: Brooks/Cole, Cengage Learning, 2010; © Cengage Learning)

**EXAMPLE 14.14**

Solid ammonium chloride is in equilibrium with ammonia and hydrogen chloride gases:

The equilibrium constant at 275°C is  $1.04 \times 10^{-2}$ .

We place 0.980 g of solid  $\text{NH}_4\text{Cl}$  into a closed vessel with volume 1.000 L and heat to 275°C. (a) In what direction does the reaction proceed? (b) What is the partial pressure of each gas at equilibrium? (c) What is the mass of solid  $\text{NH}_4\text{Cl}$  at equilibrium?

**Solution**

(a) We evaluate the reaction quotient

$$Q = P_{\text{NH}_3}P_{\text{HCl}}$$

Initially,  $Q_0 = 0$  because neither gas is present. By comparison,  $K = 1.04 \times 10^{-2}$ . Because  $Q < K$ , the reaction will proceed spontaneously from left to right. Some of the solid  $\text{NH}_4\text{Cl}$  will decompose, and some gaseous  $\text{NH}_3$  and  $\text{HCl}$  will appear in the vessel.

(b) We set up the standard table for the equilibrium calculation:

	$\text{NH}_4\text{Cl}(s)$	$\rightleftharpoons$	$\text{NH}_3(g)$	+	$\text{HCl}(g)$
Initial partial pressure (atm)			0		0
Change in partial pressure (atm)			+x		+x
Equilibrium partial pressure (atm)			+x		+x

Because  $\text{NH}_3$  and  $\text{HCl}$  are formed in equimolar amounts, they will have the same partial pressure at equilibrium. The equilibrium expression is

$$(P_{\text{NH}_3}P_{\text{HCl}})_{\text{eq}} = K = 1.04 \times 10^{-2}$$

$$x^2 = 1.04 \times 10^{-2}$$

$$x = 0.102$$

At equilibrium, the partial pressures are

$$P_{\text{NH}_3} = P_{\text{HCl}} = 0.102 \text{ atm}$$

(c) The number of moles of  $\text{NH}_4\text{Cl}$  that decomposed is equal to the number of moles of each gas produced. We calculate this number, treating the gases as ideal

$$n_{\text{NH}_3} = n_{\text{HCl}} = \frac{(1.02 \times 10^{-1} \text{ atm})(1.000 \text{ L})}{(0.08206 \text{ L atm mol}^{-1} \text{ K}^{-1})(548.2 \text{ K})} = 2.268 \times 10^{-3} \text{ mol}$$

The mass of  $\text{NH}_4\text{Cl}$  consumed is  $(2.268 \times 10^{-3} \text{ mol})(53.49 \text{ g mol}^{-1}) = 0.121 \text{ g}$ . The remaining mass is 0.859 g. The percentage decomposition of the original sample is 12.4%.

**Related Problems: 49, 50**

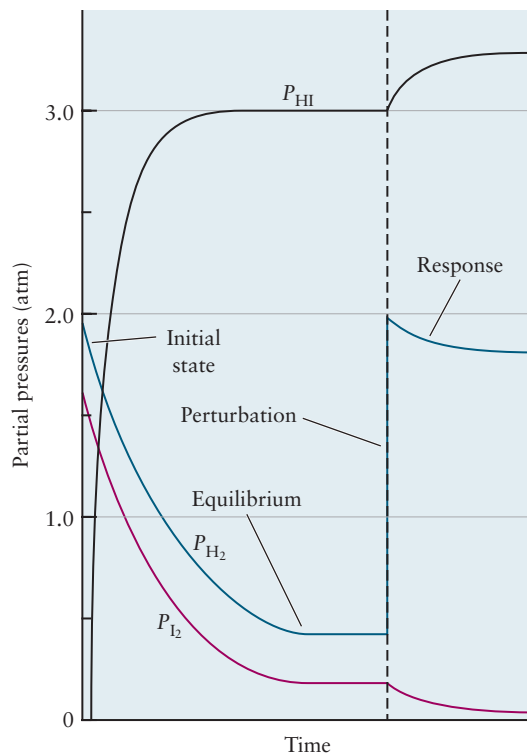

**14.6.2 External Effects on K: Principle of Le Châtelier**

Suppose a system at equilibrium is perturbed by some external stress such as a change in volume or temperature or a change in the partial pressure or concentration of one of the reactants or products. How will the system respond? The qualitative answer is embodied in a principle stated by Henri Le Châtelier in 1884:

*A system in equilibrium that is subjected to a stress will react in a way that tends to counteract the stress.*

**FIGURE 14.7** Partial pressures versus time for the equilibrium

The part of the graph to the left of the dashed vertical line shows the approach to equilibrium starting from the initial conditions specified in Example 14.10. Then the equilibrium state is abruptly perturbed by an increase in the partial pressure of  $\text{H}_2$  to 2.000 atm. In accordance with Le Châtelier's principle, the system responds (Example 14.15) in such a way as to decrease the partial pressure of  $\text{H}_2$ —that is, to counteract the perturbation that moved it away from equilibrium in the first place.

**Le Châtelier's principle** provides a way to predict qualitatively the direction of change of a system under an external perturbation. It relies heavily on  $Q$  as a predictive tool.

### Effects of Changing the Concentration of a Reactant or Product

As a simple example, consider what happens when a small quantity of a reactant is added to an equilibrium mixture. The addition of reactant lowers the reaction quotient  $Q$  below  $K$  and a net reaction takes place in the forward direction, partially converting reactants to products, until  $Q$  again equals  $K$ . The system partially counteracts the stress (the increase in the quantity of one of the reactants) and attains a new equilibrium state. If one of the *products* is added to an equilibrium mixture,  $Q$  temporarily becomes *greater* than  $K$  and a net *back* reaction occurs, partially counteracting the imposed stress by reducing the concentration of products (Fig. 14.7).

#### EXAMPLE 14.15

An equilibrium gas mixture of  $\text{H}_2(\text{g})$ ,  $\text{I}_2(\text{g})$ , and  $\text{HI}(\text{g})$  at 600 K has

$$P_{\text{H}_2} = 0.4756 \text{ atm} \quad P_{\text{I}_2} = 0.2056 \text{ atm} \quad P_{\text{HI}} = 3.009 \text{ atm}$$

This is essentially the final equilibrium state of Example 14.10. Enough  $\text{H}_2$  is added to increase its partial pressure to 2.000 atm at 600 K before any reaction takes place. The mixture then once again reaches equilibrium at 600 K. What are the final partial pressures of the three gases?

(Continued)

**Solution**

Set up the usual table, in which “initial” now means the moment after the addition of the new  $\text{H}_2$  but before it reacts further.

	$\text{H}_2(\text{g})$	+	$\text{I}_2(\text{g})$	$\rightleftharpoons$	$2 \text{HI}(\text{g})$
Initial partial pressure (atm)	2.000		0.2056		3.009
Change in partial pressure (atm)	$-x$		$-x$		$+2x$
Equilibrium partial pressure (atm)	$2.000 - x$		$0.2056 - x$		$3.009 + 2x$

From Le Châtelier’s principle it follows that net reaction to consume  $\text{H}_2$  will occur after addition of  $\text{H}_2$ , and this fact has been used in assigning a negative sign to the change in the partial pressure of  $\text{H}_2$  in the table.

Substitution of the equilibrium partial pressures into the equilibrium law gives

$$\frac{(3.009 + 2x)^2}{(2.000 - x)(0.2056 - x)} = 92.6$$

Expansion of this expression results in the quadratic equation

$$88.60x^2 - 216.275x + 29.023 = 0$$

which can be solved to give

$$x = 0.1425 \text{ or } 2.299$$

The second root would lead to negative partial pressures of  $\text{H}_2$  and  $\text{I}_2$  and is therefore physically impossible. Substitution of the first root into the expressions from the table gives

$$P_{\text{H}_2} = 2.000 - 0.1425 = 1.86 \text{ atm}$$

$$P_{\text{I}_2} = 0.2056 - 0.1425 = 0.063 \text{ atm}$$

$$P_{\text{HI}} = 3.009 + 2(0.1425) = 3.29 \text{ atm}$$

$$\text{Check: } \frac{(3.29)^2}{(1.86)(0.063)} = 92.4$$

HI is synthesized industrially by reacting elemental iodine with  $\text{H}_2$ . Because iodine is so much more expensive than hydrogen, the reaction conditions are chosen to maximize the conversion of iodine to product. This objective is accomplished by keeping hydrogen greatly in excess to drive the equilibrium to the right. The product is removed continuously to provide an additional thermodynamic driving force for conversion to product. Most industrial operations are designed in such a way that products can be removed continuously to achieve high overall yields, even for reactions with small equilibrium constants.

**Effects of Changing the Volume**

Le Châtelier’s principle also predicts the effect of a change in volume on gas-phase equilibrium. We find it easier to think about changes in volume in terms of the changes in pressure they would produce and to see how the system can respond to these changes in pressure. Decreasing the volume of a gaseous system increases its total pressure, and the system responds, if possible, to reduce the total pressure. For example, in the equilibrium

**FIGURE 14.8** An equilibrium mixture of  $P_2$  and  $P_4$  (center) is compressed (left). Some  $P_2$  molecules combine to give  $P_4$  molecules, to reduce the total number of molecules and thus the total pressure. If the volume is increased (right), some  $P_4$  molecules dissociate to pairs of  $P_2$  molecules to increase the total number of molecules and the pressure exerted by those molecules.

the reaction shifts in the forward direction when the volume is decreased. This occurs because every two molecules of  $P_2$  consumed produce only one molecule of  $P_4$ , thus reducing the total pressure and partially compensating for the external stress caused by the change in volume. In contrast, an *increase* in volume favors reactants over products in this system, and some  $P_4$  dissociates to form  $P_2$  (Fig. 14.8). If there is no difference in the total numbers of gas-phase molecules on the two sides of the equation, then a change in volume has no effect on the equilibrium.

This effect of changing the volume of an equilibrium reacting mixture can also be understood by using the reaction quotient. For the phosphorus equilibrium just described, the reaction quotient is

$$Q = \frac{P_{P_4}}{(P_{P_2})^2}$$

Initially,  $Q_0$  equals  $K$ . Suppose the volume is then decreased by a factor of 2; because the temperature is unchanged, this initially increases each partial pressure by a factor of 2. Because there are two powers of the pressure in the denominator and only one in the numerator, this decreases  $Q$  by a factor of 2, making it lower than  $K$ . Reaction must then occur in the forward direction until  $Q$  again equals  $K$ .

When the volume of a system is decreased, its total pressure increases. Another way to increase the total pressure is to add an inert gas such as argon to the reaction mixture without changing the total volume. In this case the effect on the equilibrium is entirely different. Because the partial pressures of the reactant and product gases are unchanged by an inert gas, adding argon at constant volume has no effect on the position of the equilibrium.

### Effects of Changing the Temperature

Chemical reactions can be classified as either an **endothermic reaction** (taking up heat from the surroundings) or an **exothermic reaction** (giving off heat) (see Section 12.6). Raising the temperature of an equilibrium mixture by adding heat causes reactions to occur in such a way as to absorb some of the added heat. The equilibrium in an endothermic reaction shifts from left to right, while that in an exothermic reaction shifts from right to left, with “products” reacting to give “reactants.” Equivalently, we can describe the shifts in terms of the effect of temperature on equilibrium constants. The equilibrium constant for an endothermic reaction increases with increasing temperature, while that for an exothermic reaction decreases with increasing temperature.

**FIGURE 14.9** The equilibrium between  $\text{N}_2\text{O}_4$  and  $\text{NO}_2$  depends on temperature. The tube on the right, held in an ice bath at  $0^\circ\text{C}$ , contains mostly  $\text{N}_2\text{O}_4$ . Its color is pale because only  $\text{NO}_2$  is colored. The deeper color in the tube on the left, which is held at  $50^\circ\text{C}$ , reflects the increased  $\text{NO}_2$  present in equilibrium at the higher temperature. The tubes contain the same masses of substance, distributed in different ways between  $\text{NO}_2$  and  $\text{N}_2\text{O}_4$ .

© Cengage Learning/Charles D. Winters

This effect is illustrated by the equilibrium between nitrogen dioxide ( $\text{NO}_2$ ) and its dimer, dinitrogen tetroxide ( $\text{N}_2\text{O}_4$ ), briefly considered in Example 9.6, expressed by the chemical equation

Because  $\text{NO}_2$  is a brown gas but  $\text{N}_2\text{O}_4$  is colorless, the equilibrium between them can be studied by observing the color of a tube containing the two gases. At high temperatures,  $\text{NO}_2$  predominates and a brown color results; as the temperature is lowered, the partial pressure of  $\text{N}_2\text{O}_4$  increases and the color fades (Fig. 14.9).

The equilibrium expression for the  $\text{N}_2\text{O}_4$ – $\text{NO}_2$  equilibrium is

$$\left[ \frac{P_{\text{N}_2\text{O}_4}}{(P_{\text{NO}_2})^2} \right]_{\text{eq}} = K$$

$K$  has the numerical value 8.8 at  $T = 25^\circ\text{C}$ , provided the partial pressures of  $\text{N}_2\text{O}_4$  and  $\text{NO}_2$  are expressed in atmospheres. This reaction is exothermic ( $\Delta H = -58.02 \text{ kJ mol}^{-1}$  at 298 K) because energy must be liberated when dimers are formed. Consequently,  $K$  decreases as the temperature  $T$  increases, so the amount of  $\text{N}_2\text{O}_4$  present for a given partial pressure of  $\text{NO}_2$  falls with increasing temperature as the dimer dissociates at elevated temperatures.

### Maximizing the Yield of a Reaction

As an application of Le Châtelier's principle, consider the reaction

which is the basis of the industrial synthesis of ammonia. Because this reaction is exothermic, the yield of ammonia is increased by working at as low a temperature as possible (Fig. 14.10a). At too low a temperature, the reaction is very slow, so a compromise temperature near  $500^\circ\text{C}$  is typically used. Because the number of moles of gas decreases as the reaction occurs, the yield of product is enhanced by decreasing the volume of the reaction vessel. Typically, total pressures of 150 to 300 atm are used (see Fig. 14.10b), although some plants work at up to 900 atm of pressure. Even at high pressures, the yield of ammonia is usually only 15% to

**FIGURE 14.10** (a) The equilibrium mole percentage of ammonia in a 1:3 mixture of  $\text{N}_2$  and  $\text{H}_2$  varies with temperature; low temperatures favor high yields of  $\text{NH}_3$ . The data shown correspond to a fixed total pressure of 300 atm. (b) At a fixed temperature (here,  $500^\circ\text{C}$ ), the yield of  $\text{NH}_3$  increases with increasing total pressure.

20% because the equilibrium constant is so small. To overcome this, ammonia plants operate in a cyclic process in which the gas mixture is cooled after ammonia is produced so that the ammonia liquefies (its boiling point is much higher than those of nitrogen and hydrogen) and is removed from the reaction vessel. Continuous removal of products helps drive the reaction to completion.

## 14.7 The Direction of Change in Chemical Reactions: Thermodynamic Explanation

The specific examples in Section 14.5 demonstrate that when  $K \gg 1$  the reaction has progressed far toward products, and when  $K \ll 1$  the reaction has remained near reactants. The empirical discussion in Section 14.6 shows how the reaction quotient  $Q$  and Le Châtelier's principle can predict the direction of spontaneous reaction and the response of an equilibrium state to an external perturbation. Here, we use the thermodynamic description of  $K$  from Section 14.3 to provide the thermodynamic basis for these results obtained empirically in Sections 14.5 and 14.6. We identify those thermodynamic factors that determine the magnitude of  $K$ . We also provide a thermodynamic criterion for predicting the direction in which a reaction proceeds from a given initial condition.

### 14.7.1 The Magnitude of the Equilibrium Constant

The expression connecting the standard Gibbs free energy change and the equilibrium constant can be rewritten as

$$\ln K = \frac{-\Delta G^\circ}{RT} = \frac{\Delta S^\circ}{R} - \frac{\Delta H^\circ}{RT}$$

so that

$$K = \exp\left[\frac{-\Delta G^\circ}{RT}\right] = \exp\left[\frac{\Delta S^\circ}{R}\right] \exp\left[\frac{-\Delta H^\circ}{RT}\right]$$

Here  $K$  is large (favoring the products) if  $\Delta S^\circ$  is positive and large and  $\Delta H^\circ$  is negative and large. In other words, an increase in the number of microstates ( $\Delta S^\circ > 0$ ) and a decrease in enthalpy ( $\Delta H^\circ < 0$ ) both favor a large  $K$ . Thus, the same factors that favor reaction spontaneity by making  $\Delta G^\circ$  negative also favor a large  $K$  if they can make  $\Delta G^\circ$  large in magnitude as well as negative in sign. If  $\Delta H^\circ$  and  $\Delta S^\circ$  have the *same* sign, the value of  $K$  will be a compromise between one effect that raises  $K$  and another that lowers it.

### 14.7.2 Free Energy Changes and the Reaction Quotient

The direction in which a spontaneous chemical reaction proceeds after it is initiated with a given initial concentration of products and reactants is the direction in which  $\Delta G < 0$ . If the initial condition is “to the left” of the equilibrium state, products will be formed at the expense of reactants; if the initial condition is “to the right” of the equilibrium state, products will be converted back to reactants. This criterion can be made quantitative and expressed in terms of the initial concentrations as follows.

Proceeding as in Section 14.3, we find  $\Delta G$  for the general gas-phase reaction

**FIGURE 14.11** The free energy of a reaction system is plotted against its progress from pure reactants (left) to pure products (right). Equilibrium comes at the minimum of the curve. To the reactant side of equilibrium,  $\Delta G < 0$  and  $Q < K$ . A reaction mixture with initial condition in this range will spontaneously move toward equilibrium by converting more reactants into products. To the product side of equilibrium,  $\Delta G > 0$  and  $Q > K$ . A reaction mixture prepared in this range will spontaneously move toward equilibrium by converting products back into reactants.

**FIGURE 14.12** The temperature dependence of the equilibrium constant for the reaction

Experimental data are shown by points.

to be

$$\Delta G = \Delta G^\circ + RT \ln \left[ \frac{(P_C/P_{\text{ref}})^c (P_D/P_{\text{ref}})^d}{(P_A/P_{\text{ref}})^a (P_B/P_{\text{ref}})^b} \right]$$

At equilibrium, where  $\Delta G = 0$ , the combination of partial pressures appearing inside the brackets becomes the equilibrium constant,  $K$ . Away from equilibrium, this combination of partial pressures is the reaction quotient  $Q$ , introduced in Section 14.6:

$$\Delta G = \Delta G^\circ + RT \ln Q$$

The equilibrium constant can be substituted for  $\Delta G^\circ$  in this equation to obtain a very useful relation between  $\Delta G$ ,  $K$ , and  $Q$  as follows:

$$\begin{aligned} \Delta G &= \Delta G^\circ + RT \ln Q = -RT \ln K + RT \ln Q \\ &= RT \ln (Q/K) \end{aligned} \quad [14.10]$$

If the reaction quotient  $Q$  is less than  $K$ ,  $\Delta G < 0$  and the reaction will proceed spontaneously as written, from left to right. If  $Q > K$ , then  $\Delta G > 0$  and the reverse reaction (right to left) will occur spontaneously until equilibrium is reached. These conditions are represented schematically in Figure 14.11. The second law of thermodynamics thus provides a very useful criterion for the direction of reaction in terms of the initial value of the reaction quotient.

There exists a deep relationship between Figure 14.6, which represents actual events occurring in the laboratory, and Figure 14.11, which represents the thermodynamic driving force (that is, the Gibbs free energy) governing these events. The function shown in Figure 14.11 is a thermodynamic potential function analogous to the mechanical potential functions we introduced in Chapter 3. The slope of this function at every point on the curve is the thermodynamic driving force for the direction the reaction will take when the system has the composition described by that point.

### 14.7.3 Temperature Dependence of Equilibrium Constants

Le Châtelier's principle is a qualitative way of describing the *stability* of equilibrium states against sudden perturbations in concentration, pressure, and temperature. The responses of the system to all three effects can be described quantitatively by thermodynamics. Here we describe the effect of temperature, which is the most useful of these quantitative descriptions.

The temperature dependence of the equilibrium constant is determined by the equation

$$-RT \ln K = \Delta G^\circ = \Delta H^\circ - T\Delta S^\circ$$

If  $\Delta H^\circ$  and  $\Delta S^\circ$  are independent of temperature, then all the temperature dependence of  $K$  lies in the factor of  $T$  and the equation can be used to relate the values of  $K$  at two different temperatures, as follows. At least over a limited temperature range,  $\Delta H^\circ$  and  $\Delta S^\circ$  do not vary much with temperature. To the extent that their temperature dependence may be neglected, it is evident that  $\ln K$  is a linear function of  $1/T$  as shown in Figure 14.12.

$$\ln K = -\frac{\Delta G^\circ}{RT} = -\frac{\Delta H^\circ}{RT} + \frac{\Delta S^\circ}{R} \quad [14.11]$$

**FIGURE 14.13** Sketch of  $\ln K$  against  $1/T$  for an exothermic reaction and for an endothermic reaction, as predicted by thermodynamics. Temperature increases to the left on this diagram. As  $T$  increases,  $K$  for the endothermic reaction increases and  $K$  for the exothermic reaction decreases in accordance with the principle of Le Châtelier.

A graph of  $\ln K$  against  $1/T$  is approximately a straight line with slope  $-\Delta H^\circ/R$  and intercept  $\Delta S^\circ/R$  (see Fig. 14.12). If the value of  $K$  is known for one temperature and  $\Delta H^\circ$  is also known,  $K$  can be calculated for other temperatures.

In addition to the graphical method, an equation can be obtained to connect the values of  $K$  at two different temperatures. Let  $K_1$  and  $K_2$  be the equilibrium constants for a reaction at temperatures  $T_1$  and  $T_2$ , respectively. Then

$$\ln K_2 = -\frac{\Delta H^\circ}{RT_2} + \frac{\Delta S^\circ}{R}$$

$$\ln K_1 = -\frac{\Delta H^\circ}{RT_1} + \frac{\Delta S^\circ}{R}$$

Subtracting the second equation from the first gives

$$\ln\left(\frac{K_2}{K_1}\right) = -\frac{\Delta H^\circ}{R}\left[\frac{1}{T_2} - \frac{1}{T_1}\right] \quad [14.12]$$

This is known as the **van't Hoff equation** after the Dutch chemist Jacobus van't Hoff. Given  $\Delta H^\circ$  and  $K$  at one temperature, we can use the equation to calculate  $K$  at another temperature, within the approximation that  $\Delta H^\circ$  and  $\Delta S^\circ$  are independent of temperature. Alternatively, we can use the van't Hoff equation to determine  $\Delta H^\circ$  for reactions for which  $K$  is known at two or more temperatures. This approach is useful for finding enthalpy changes for reactions that might be difficult or inconvenient to measure directly by calorimetric methods.

The effect of a temperature change on the equilibrium constant depends on the sign of  $\Delta H^\circ$ . If  $\Delta H^\circ$  is negative (the reaction is exothermic, giving off energy as heat), then increasing the temperature *reduces*  $K$ . If  $\Delta H^\circ$  is positive (the reaction is endothermic, taking up energy as heat), then increasing the temperature *increases*  $K$ . These observations obtained from thermodynamics provide the quantitative basis for Le Châtelier's principle (Fig. 14.13).

### EXAMPLE 14.16

Calculate  $K$  for the equilibrium of Example 14.4 at  $T = 400$  K, assuming  $\Delta H^\circ$  to be approximately independent of temperature over the range from 298 to 400 K.

#### Solution

The first step is to calculate  $\Delta H^\circ$  for the reaction. Appendix D provides data to calculate

$$\Delta H^\circ = -155.52 \text{ kJ}$$

(Continued)

From the van't Hoff equation,

$$\begin{aligned}\ln\left(\frac{K_{400}}{K_{298}}\right) &= -\frac{\Delta H^\circ}{R}\left[\frac{1}{400\text{ K}} - \frac{1}{298\text{ K}}\right] \\ &= \frac{155,520\text{ J mol}^{-1}}{8.315\text{ J K}^{-1}\text{ mol}^{-1}}\left[\frac{1}{400\text{ K}} - \frac{1}{298\text{ K}}\right] = -16.01 \\ \frac{K_{400}}{K_{298}} &= e^{-16.01} = 1.1 \times 10^{-7}\end{aligned}$$

Taking  $K_{298}$  to be  $1.8 \times 10^{18}$  (from Example 14.4) gives

$$K_{400} = (1.8 \times 10^{18})(1.1 \times 10^{-7}) = 2.0 \times 10^{11}$$

Because the reaction is exothermic, an increase in temperature reduces the equilibrium constant.

An alternative way to do this calculation would be to determine both  $\Delta H^\circ$  and  $\Delta S^\circ$  and from them to calculate  $\Delta G$  at 400 K.

**Related Problems: 61, 62, 63, 64, 65, 66**

### 14.7.4 Temperature Dependence of Vapor Pressure

Suppose pure liquid water is in equilibrium with its vapor at temperature  $T$ :

The temperature dependence of  $K$  (and therefore of the vapor pressure  $P_{\text{H}_2\text{O}(\text{g})}$ ) can be described by the van't Hoff equation in the same way as chemical reactions. If  $\Delta H_{\text{vap}}$  and  $\Delta S_{\text{vap}}$  are approximately independent of temperature, then from the van't Hoff equation,

$$\ln\left(\frac{K_2}{K_1}\right) = \ln\left(\frac{P_2}{P_1}\right) = -\frac{\Delta H_{\text{vap}}}{R}\left[\frac{1}{T_2} - \frac{1}{T_1}\right]$$

where  $P_2$  and  $P_1$  are the vapor pressures at temperatures  $T_2$  and  $T_1$ . From this equation, the vapor pressure at any given temperature can be estimated if its value at some other temperature is known and if the enthalpy of vaporization is also known.

At the normal boiling point of a substance,  $T_b$ , the equilibrium vapor pressure is 1 atm. If  $T_1$  is taken to correspond to  $T_b$  and  $T_2$  to some other temperature  $T$ , the van't Hoff equation is

$$\ln P = -\frac{\Delta H_{\text{vap}}}{R}\left[\frac{1}{T} - \frac{1}{T_b}\right] \quad [14.13]$$

where  $P$  is the equilibrium vapor pressure at temperature  $T$ , expressed in atmospheres.

#### EXAMPLE 14.17

The  $\Delta H_{\text{vap}}$  for water is  $40.66\text{ kJ mol}^{-1}$  at the normal boiling point,  $T_b = 373\text{ K}$ . Assuming  $\Delta H_{\text{vap}}$  and  $\Delta S_{\text{vap}}$  are approximately independent of temperature from  $50^\circ\text{C}$  to  $100^\circ\text{C}$ , estimate the vapor pressure of water at  $50^\circ\text{C}$  ( $323\text{ K}$ ).

#### Solution

$$\begin{aligned}\ln P_{323} &= \frac{-40660\text{ J mol}^{-1}}{8.315\text{ J K}^{-1}\text{ mol}^{-1}}\left[\frac{1}{323\text{ K}} - \frac{1}{373\text{ K}}\right] = -2.03 \\ P_{323} &= 0.13\text{ atm}\end{aligned}$$

This differs slightly from the experimental value, 0.1217 atm, because  $\Delta H_{\text{vap}}$  *does* change with temperature, an effect that was neglected in the approximate calculation.

**Related Problems: 67, 68**

## 14.8 Distribution of a Single Species between Immiscible Phases: Extraction and Separation Processes

© Cengage Learning/Leon Levandowski

**FIGURE 14.14** Iodine is dissolved in water and poured on top of carbon tetrachloride in a separatory funnel (left). After the funnel is shaken (right), the iodine reaches a partition equilibrium between the upper (aqueous) phase and the lower ( $\text{CCl}_4$ ) phase. The deeper color in the lower phase indicates that iodine dissolves preferentially in the denser  $\text{CCl}_4$  phase.

An important type of heterogeneous equilibrium involves partitioning a solute species between two immiscible solvent phases. Such equilibria are used in many separation processes in chemical research and in industry.

Suppose two immiscible liquids, such as water and carbon tetrachloride, are put in a container. “Immiscible” means mutually insoluble; these liquids separate into two phases with the less dense liquid, in this case water, lying on top of the other liquid. A visible boundary, the meniscus, separates the two phases. If a solute such as iodine is added to the mixture and the vessel is shaken to distribute the iodine through the container (Fig. 14.14), the iodine is partitioned between the two phases at equilibrium with a characteristic concentration ratio, the **partition coefficient**  $K$ . This is the equilibrium constant for the process

and can be written as

$$\left[ \frac{[\text{I}_2]_{\text{CCl}_4}}{[\text{I}_2]_{aq}} \right]_{\text{eq}} = K$$

in which  $[\text{I}_2]_{\text{CCl}_4}$  and  $[\text{I}_2]_{aq}$  are the concentrations (in moles per liter) of  $\text{I}_2$  in the  $\text{CCl}_4$  and aqueous phases, respectively. At  $25^\circ\text{C}$ ,  $K$  has the value 85 for this equilibrium. The fact that  $K$  is greater than 1 shows that iodine is more soluble in  $\text{CCl}_4$  than in water. If iodide ion ( $\text{I}^-$ ) is dissolved in the water, then it can react with iodine to form the triiodide ion  $\text{I}_3^-$ :

This consumes  $\text{I}_2(aq)$  and, by Le Châtelier’s principle, causes more  $\text{I}_2$  in the first equilibrium to move from the  $\text{CCl}_4$  phase to the aqueous phase.

### 14.8.1 Extraction Processes

**Extraction** takes advantage of the partitioning of a solute between two immiscible solvents to remove that solute from one solvent into another. Suppose iodine is present as a contaminant in water that also contains other solutes that are insoluble in carbon tetrachloride. In such a case, most of the iodine could be removed by shaking the aqueous solution with  $\text{CCl}_4$ , allowing the two phases to separate, and then pouring off the water layer from the heavier layer of carbon tetrachloride. The greater the equilibrium constant for the partition of a solute from the original solvent into the extracting solvent, the more complete such a separation will be.

#### EXAMPLE 14.18

An aqueous solution has an iodine concentration of  $2.00 \times 10^{-3} \text{ M}$ . Calculate the percentage of iodine remaining in the aqueous phase after extraction of 0.100 L of this aqueous solution with 0.050 L of  $\text{CCl}_4$  at  $25^\circ\text{C}$ .

#### Solution

The number of moles of  $\text{I}_2$  present is

$$(2.00 \times 10^{-3} \text{ mol L}^{-1})(0.100 \text{ L}) = 2.00 \times 10^{-4} \text{ mol}$$

(Continued)

Suppose that  $y$  mol remains in the aqueous phase and  $(2.00 \times 10^{-4} - y)$  mol passes into the  $\text{CCl}_4$  phase. Then

$$\begin{aligned} \left[ \frac{[\text{I}_2]_{\text{CCl}_4}}{[\text{I}_2]_{\text{aq}}} \right]_{\text{eq}} &= K = 85 \\ &= \frac{(2.00 \times 10^{-4} - y)/0.050}{y/0.100} \\ &= \frac{2(2.00 \times 10^{-4} - y)}{y} \end{aligned}$$

Note that the volumes of the two solvents used are unchanged because they are immiscible. Solving for  $y$  gives

$$y = 4.6 \times 10^{-6} \text{ mol}$$

The fraction remaining in the aqueous phase is  $(4.6 \times 10^{-6}) / (2.0 \times 10^{-4}) = 0.023$ , or 2.3%. Additional extractions could be carried out to remove more of the  $\text{I}_2$  from the aqueous phase.

**Related Problems: 71, 72, 73, 74**

**FIGURE 14.15** Paper chromatography separates a line of ink, drawn across the bottom of the paper, into its component colors. As the water rises through the paper, the different components of the ink are attracted differently to the water and the paper and are separated.

One extraction process used industrially on a large scale is the purification of sodium hydroxide for use in the manufacture of rayon. The sodium hydroxide produced by electrolysis typically contains 1% sodium chloride and 0.1% sodium chlorate as impurities. If a concentrated aqueous solution of sodium hydroxide is extracted with liquid ammonia, the  $\text{NaCl}$  and  $\text{NaClO}_3$  are partitioned into the ammonia phase in preference over the aqueous phase. The heavier aqueous phase is added to the top of an extraction vessel filled with ammonia, and equilibrium is reached as droplets of it settle through the ammonia phase to the bottom. This procedure reduces impurity concentrations in the sodium hydroxide solution to about 0.08%  $\text{NaCl}$  and 0.0002%  $\text{NaClO}_3$ .

## 14.8.2 Chromatographic Separations

Partition equilibria are the basis of an important class of separation techniques called **chromatography**. This word comes from the Greek root *chroma*, meaning “color,” and was chosen because the original chromatographic separations involved colored substances. The technique can be applied to a variety of mixtures of substances (Fig. 14.15).

Chromatography is a continuous extraction process in which solute species are exchanged between two phases. One, the mobile phase, moves with respect to the other, stationary phase. The partition ratio  $K$  of a solute  $A$  between the stationary and mobile phases is

$$\left[ \frac{[A]_{\text{stationary}}}{[A]_{\text{mobile}}} \right]_{\text{eq}} = K$$

As the mobile phase containing solute passes over the stationary phase, the solute molecules move between the two phases. True equilibrium is never fully established because the motion of the fluid phase continually brings fresh solvent into contact with the stationary phase. Nevertheless, the partition coefficient  $K$  provides a guide to the behavior of a particular solute. The greater  $K$  is, the more time the solute spends in the stationary phase and therefore the slower its progress through the separation system. Solutes with different values of  $K$  are separated by their different rates of travel.

Different types of chromatography use different mobile and stationary phases; Table 14.1 lists some of the most important. *Column chromatography* (Fig. 14.16) uses a tube packed with a porous material, often a silica gel on which water has been adsorbed. Water is therefore the stationary liquid phase in this case. Other solvents such as pyridine or benzene are used in the mobile phase; in some cases it is most efficient to use different solvents in succession to separate the components of a solute mixture. As the solute fractions reach the bottom of the column, they are separated for analysis or use. Column chromatography is

TABLE 14.1

Chromatographic Separation Techniques<sup>†</sup>

Name	Mobile Phase	Stationary Phase
Gas-liquid	Gas	Liquid adsorbed on a porous solid in a tube
Gas-solid	Gas	Porous solid in a tube
Column	Liquid	Liquid adsorbed on a porous solid in a tubular column
Paper	Liquid	Liquid held in the pores of a thick paper
Thin layer	Liquid	Liquid or solid; solid is held on glass plate and liquid may be adsorbed on it
Ion exchange	Liquid	Solid (finely divided ion-exchange resin) in a tubular column

<sup>†</sup>Adapted from D. A. Skoog and D. M. West, *Analytical Chemistry* (Saunders College Publishing, Philadelphia, 1980), table 18-1.

**FIGURE 14.16** (a) In a column chromatograph, the top of the column is loaded with a mixture of solutes to be separated (green). (b) Upon addition of solvent, the different solutes travel at different rates, giving rise to bands. The separate fractions can be collected in different flasks for use or analysis.

**FIGURE 14.17** In a gas–liquid chromatograph, the sample is vaporized and passes through a column, carried in a stream of an inert gas such as helium or nitrogen. The residence time of any substance on the column depends on its partition coefficient from the vapor to the liquid in the column. A species leaving the column at a given time can be detected by a variety of techniques. The result is a gas chromatogram, with a peak corresponding to each substance in the mixture.

important in industry because it is easily increased from laboratory to production scale.

*Gas–liquid chromatography* (Fig. 14.17) is one of the most important separation techniques for modern chemical research. The stationary phase is again a liquid adsorbed on a porous solid, but the mobile phase is now gaseous. The sample is vaporized and passes through the column, carried in a stream of an inert gas such as helium or nitrogen. The residence time in the column depends on the partition coefficient of the solute species, allowing an efficient separation of mixtures. The solute leaving the column at a given time can be detected by a variety of techniques that produce a *gas chromatogram* with a peak corresponding to each solute species in the mixture. Gas–liquid chromatography is widely used for separating the products of organic reactions. It can also be used to determine the purity of substances, because even very small amounts of impurities appear clearly as separate peaks in the chromatogram. The technique is important in the separation and identification of trace amounts of possibly toxic substances in environmental and biological samples. Amounts on the order of parts per trillion ( $10^{-12}$  g in a 1-g sample) can be detected and identified.

## CHAPTER SUMMARY

Most chemical reactions do not go to completion. They arrive at the equilibrium state, after which there is no further net change in the amount of products or reactants. At the microscopic level, the reaction continues in both forward and reverse directions, at equal rates in these opposing directions. So, chemical equilibrium—which we measure at the macroscopic level—is characterized by a dynamical balance of events on the microscopic level. At the equilibrium state, concentrations of products and reactants always satisfy the mass action law, and so are related by the equilibrium constant. The equilibrium constant is a unique property of each chemical reaction. Knowledge of the equilibrium constant enables us to calculate the equilibrium concentrations of products and reactants that result from any set of initial concentrations for that reaction. Equilibrium calculations have enormous predictive power for interpreting and optimizing the outcome of chemical reactions. Thermodynamics explains all the empirical observations of chemical equilibrium and provides means for quantitative

predictions. Thermodynamics explains the form of the mass action law, shows how to calculate the equilibrium constant from tabulations of Gibbs free energy for products and reactants, explains the temperature dependence of the equilibrium constant, and predicts the direction of change in response to any disturbance of the equilibrium state.

## CONCEPTS AND SKILLS

### Section 14.1 – The Nature of Chemical Equilibrium

*Describe the nature of the equilibrium state in chemical reactions.*

- The equilibrium state shows no macroscopic evidence of change. On the microscopic level it is a dynamic balance between forward and reverse processes. The equilibrium state is reached through a spontaneous process. It is the same regardless of whether it is approached from the reactant side of the chemical equation or from the product side.

### Section 14.2 – The Empirical Law of Mass Action

*Set up the equilibrium expression for homogeneous reactions in the gas phase (Problems 1–6).*

- Starting from the balanced equation for the reaction, place the partial pressure of each product in the numerator of the equilibrium expression and the partial pressure of each reactant in the denominator. Raise each of these to a power equal to its stoichiometric coefficient in the balanced reaction equation. The result is

$$\left[ \frac{P_C^c P_D^d}{P_A^a P_B^b} \right]_{\text{eq}} = K$$

- Each partial pressure is expressed in units of atm, and is understood to be relative to a reference state with  $P_{\text{ref}} = 1_{\text{atm}}$ . Thus  $K$  is a dimensionless quantity.

*Set up the equilibrium expression for homogeneous reactions in solution (Problems 7–8).*

- Proceed as for the gas phase example. The result is

$$\left[ \frac{[C]^c [D]^d}{[A]^a [B]^b} \right]_{\text{eq}} = K$$

- Each concentration is expressed in units of moles per liter, and is understood to be relative to a reference state with  $c_{\text{ref}} = 1 \text{ mol L}^{-1}$ . Thus  $K$  is a dimensionless quantity.

*Set up the equilibrium expression for heterogeneous reactions (Problems 9–12).*

- Proceed as in the previous cases, but representing the concentration of each product or reactant as its activity. The result is

$$\left[ \frac{a_C^c a_D^d}{a_A^a a_B^b} \right]_{\text{eq}} = K$$

- Each activity is expressed relative to the proper standard state ( $a = 1$ ) for that species, so  $K$  is a dimensionless quantity. For practical calculations involving dilute solutions and gases at low pressure, replace  $a$  for a gas with

its limiting form of partial pressure in atm,  $a$  for a solute with its concentration in moles per liter, and  $a$  for a pure solid or liquid with its reference state value  $a = 1$ .

### Section 14.3 – Thermodynamic Description of the Equilibrium State

Relate the equilibrium constant of a reaction to its change in standard Gibbs free energy (Problems 13–16).

- Calculate  $\Delta G$  the change in Gibbs free energy for the reaction by a three-step process:  $\Delta G_1$  is the change for taking reactants from their initial conditions to standard state conditions.  $\Delta G_2$  is the change for converting reactants to products at standard state conditions.  $\Delta G_3$  is the change for taking products from standard state conditions to their final conditions. The equilibrium condition  $\Delta G = 0$  leads to the relation  $-\Delta G^\circ = RT \ln K(T)$  from which we calculate  $K(T)$  by first calculating the change in standard Gibbs free energy. Pay careful attention to the reference state for each standard free energy value you use in these calculations and note that all of these steps must be at the same temperature.

### Section 14.4 – The Law of Mass Action for Related and Simultaneous Equilibria

Combine the equilibrium constants for individual reactions to obtain net equilibrium constants for combined reactions (Problems 17–20).

- $K_{\text{reverse}} = 1/K_{\text{forward}}$
- $K$  (equation multiplied by  $n$ ) =  $K^n$
- $K_3 = K_1K_2 \dots$  when a series of reactions is added to give an overall reaction.

### Section 14.5 – Equilibrium Calculations for Gas-Phase and Heterogeneous Reactions

Calculate equilibrium constants from experimental measurements of partial and total pressures (Problems 21–26).

- Substitute experimental results measured at equilibrium into the equilibrium expression and evaluate  $K$ . If the equilibrium partial pressures are not known directly, they can be calculated from other experimental data and then substituted into the equilibrium expression to determine  $K$ . The procedures are illustrated in Examples 14.9 and 14.10.

Calculate the equilibrium partial pressures of all species involved in a gas-phase or gas-solid reaction from the initial pressure(s) of the reactants (Problems 27–36).

- Assume that partial pressure of one of the species decreases by  $y$  atm while reaching the equilibrium state. Use the coefficients in the balanced reaction to write an equation for the partial pressure of each species at equilibrium in terms of  $y$ . Substitute these equilibrium partial pressures into the equilibrium relation, solve for  $y$ , and evaluate the partial pressure of each species at equilibrium.

Relate concentrations to partial pressures in equilibrium calculations (Problems 37–38).

- Define the concentration for each species A as the number of moles of A per unit volume,  $[A] = n_A/V$ , and relate this to the partial pressure of A through the ideal gas law  $P_A = RT[A]$ . Substitute the partial pressure for each species, divided by  $P_{\text{ref}}$ , into the equilibrium expression, insert the value of  $K$ , and solve to obtain the equilibrium concentration of each species.

### Section 14.6 – The Direction of Change in Chemical Reactions: Empirical Description

Determine the direction in which a chemical reaction will proceed spontaneously by calculating its reaction quotient (Problems 45–46).

- Calculate the reaction quotient from the experimental data at a particular experimental condition. Compare the magnitude of  $Q$  at that condition to  $K$  and predict the direction of the reaction from the following guidelines:

- $Q = \frac{P_C^c P_D^d}{P_A^a P_B^b}$
- $Q < K \Rightarrow$  reaction moves to the right.
- $Q = K \Rightarrow$  system at equilibrium, no reaction.
- $Q > K \Rightarrow$  reaction moves to the left.

State Le Châtelier's principle and give several applications (Problems 47–58).

- Le Châtelier's Principle—A system in equilibrium that is subjected to a stress will react in a way to partially counteract the stress. Several specific cases are:
  - Stress 1: Increase concentration or pressure of species A.
  - Response 1: Reaction will move in appropriate direction to decrease A.
  - Stress 2: Increase pressure.
  - Response 2: Reaction will move in the direction that produces fewer gaseous molecules in order to decrease the pressure.
  - Stress 3: Decrease volume (same as increase pressure).
  - Response 3: Reaction moves in the direction that produces fewer gaseous molecules in order to decrease the pressure.
  - Stress 4: Increase temperature.
  - Response 4: Reaction moves in appropriate direction to absorb heat and decrease the temperature.

### Section 14.7 – The Direction of Change in Chemical Reactions: Thermodynamics Explanation

Relate the temperature dependence of the equilibrium constant for a reaction to the standard enthalpy change for the reaction (Problems 59–70).

- Over temperature ranges where the standard enthalpy change of the reaction and the standard entropy change do not depend on temperature, the values of  $K$  at two different temperatures are related by the van't Hoff equation:

$$\ln\left(\frac{K_2}{K_1}\right) = -\frac{\Delta H^\circ}{R} \left[\frac{1}{T_2} - \frac{1}{T_1}\right]$$

- This equation shows that  $K$  increases with temperature for endothermic reactions and decreases with  $T$  for exothermic reactions, as predicted by the principle of Le Châtelier.

### Section 14.8 – Distribution of a Single Species between Immiscible Phases: Extraction and Separation Processes

Use the law of mass action to explain the distribution of a solute between two immiscible solvents (Problems 71–74).

- Distribution of a solute between immiscible phases is a concrete illustration of the spontaneous transfer of molecules across a boundary internal to the system, at fixed  $T$  and  $P$ , as described in Figure 13.9. The law of mass action characterizes the equilibrium state after such processes, giving the relative amounts of

solute in the two phases. The partition coefficient, analogous to the chemical equilibrium constant, determines the distribution between phases.

*Outline the basis for separation of compounds by partition chromatography.*

- Partition chromatography relies on a mobile phase containing the solute flowing past a fresh solvent into which the solute is extracted. The effectiveness of the fresh solvent in extracting the solute is determined by the partition coefficient for the solute between the two immiscible solvents chosen for the process.

## CUMULATIVE EXERCISE

Gunter Marx Photography/CORBIS

**FIGURE 14.18** A stockpile of sulfur near chemical plants in Los Angeles.

This cumulative exercise is divided into two parts. Readers who have not yet studied thermodynamics should stop after Part 1; those who have studied thermodynamics should continue with Part 2.

### Production of Sulfuric Acid—Part 1

Sulfuric acid is produced in larger volume than any other chemical and has a tremendous number of applications, ranging from fertilizer manufacture to metal treatment and chemical synthesis. Sulfur in its pure form is shown in Figure 14.18.

The modern industrial production of sulfuric acid involves three steps, for which the balanced chemical equations are:

1.  $\text{S}(s) + \text{O}_2(g) \rightleftharpoons \text{SO}_2(g)$
2.  $\text{SO}_2(g) + \frac{1}{2}\text{O}_2(g) \rightleftharpoons \text{SO}_3(g)$
3.  $\text{SO}_3(g) + \text{H}_2\text{O}(\ell) \rightleftharpoons \text{H}_2\text{SO}_4(\ell)$

- (a) Write an equilibrium expression for each of these steps, with equilibrium constants  $K_1$ ,  $K_2$ , and  $K_3$ .
- (b) If these reactions could be carried out at 25°C, the equilibrium constants would be  $3.9 \times 10^{52}$ ,  $2.6 \times 10^{12}$ , and  $2.6 \times 10^{14}$ . Write a balanced equation for the overall reaction and calculate its equilibrium constant at 25°C.
- (c) Although the products of all three equilibria are strongly favored at 25°C [See the data given in part (b)], reactions 1 and 2 occur too slowly to be practical; they must be carried out at elevated temperatures. At 700°C, the partial pressures of  $\text{SO}_2$ ,  $\text{O}_2$ , and  $\text{SO}_3$  in an equilibrium mixture are measured to be 2.23 atm, 1.14 atm, and 6.26 atm, respectively. Calculate  $K_2$  at 700°C.
- (d) At 300°C,  $K_2$  has the value  $1.3 \times 10^4$ . Suppose some  $\text{SO}_3$  is introduced into an evacuated vessel at an initial partial pressure of 0.89 atm. Calculate the partial pressure of  $\text{SO}_2$  that will be reached at equilibrium, assuming that only reaction 2 takes place under these conditions. (*Hint:*  $K_2$  is large enough that you can assume the fraction of  $\text{SO}_3$  dissociated is very small.)
- (e) Some  $\text{SO}_2$  is placed in a flask and heated with oxygen to 600°C, at which point  $K_2 = 9.5$ . At equilibrium, 62% of it has reacted to give  $\text{SO}_3$ . Calculate the partial pressure of oxygen at equilibrium in this reaction mixture.
- (f) Equal numbers of moles of  $\text{SO}_2$ ,  $\text{O}_2$ , and  $\text{SO}_3$  are mixed and heated to 600°C, where their total pressure before reaction is 0.090 atm. Will reaction 2 occur from right to left or from left to right? Will the total pressure increase or decrease during the course of the reaction?
- (g) Reactions 1 and 3 are both exothermic. State the effects on equilibria 1 and 3 of increasing the temperature and of decreasing the volume. (*Note:* A change in volume has little effect on liquids and solids taking part in a reaction.)

**Answers—Part 1**

- (a)  $\left[ \frac{P_{\text{SO}_2}}{P_{\text{O}_2}} \right]_{\text{eq}} = K_1$        $\left[ \frac{P_{\text{SO}_3}}{P_{\text{SO}_2} P_{\text{O}_2}^{1/2}} \right]_{\text{eq}} = K_2$        $\left[ \frac{1}{P_{\text{SO}_3}} \right]_{\text{eq}} = K_3$
- (b)  $\text{S}(s) + \frac{3}{2} \text{O}_2(g) + \text{H}_2\text{O}(\ell) \rightleftharpoons \text{H}_2\text{SO}_4(\ell)$ ;  $K = K_1 K_2 K_3 = 2.2 \times 10^{79}$
- (c)  $K_2$  is 2.63.
- (d) The  $\text{SO}_2$  partial pressure is  $2.1 \times 10^{-3}$  atm.
- (e) The  $\text{O}_2$  partial pressure is 0.029 atm.
- (f) Left to right; pressure will decrease.
- (g) Increasing the temperature will shift both equilibria to the left. Decreasing the volume will not affect equilibrium 1 and will shift equilibrium 3 to the right.

**Production of Sulfuric Acid—Part 2**

We continue with examination of reactions 1, 2, and 3 in the production of sulfuric acid.

- (h) Calculate  $\Delta G^\circ$  for each reaction at  $25^\circ\text{C}$ . (Standard state of sulfur is rhombic.)
- (i) Write a balanced equation for the overall reaction, and calculate its value of  $\Delta G^\circ$  at  $25^\circ\text{C}$ .
- (j) Part (h) shows all three reactions are spontaneous at  $25^\circ\text{C}$  if the partial pressures of each species involved is 1 atm. Nonetheless, reactions 1 and 2 occur too slowly at  $25^\circ\text{C}$  to be practical; they must be carried out at higher temperatures. Calculate  $\Delta G^\circ$  for 1, 2, and 3 at  $700^\circ\text{C}$ .
- (k) Determine the highest temperature at which all three reactions are spontaneous.

**Answers—Part 2**

- (h) At  $25^\circ\text{C}$ :  $\Delta G_1^\circ = -300.19 \text{ kJ mol}^{-1}$ ;  $\Delta G_2^\circ = -70.86 \text{ kJ mol}^{-1}$ ;  $\Delta G_3^\circ = -81.64 \text{ kJ mol}^{-1}$
- (i)  $\text{S}(s) + \frac{3}{2} \text{O}_2(g) + \text{H}_2\text{O}(\ell) \rightleftharpoons \text{H}_2\text{SO}_4(\ell)$ ;  $\Delta G_{\text{net}}^\circ = -452.89 \text{ kJ mol}^{-1}$
- (j) At  $700^\circ\text{C}$ :  $\Delta G_1^\circ = -307.81 \text{ kJ mol}^{-1}$ ;  $\Delta G_2^\circ = -7.47 \text{ kJ mol}^{-1}$ ;  $\Delta G_3^\circ = +32.64 \text{ kJ mol}^{-1}$
- (k) Because reaction 1 has  $\Delta H^\circ < 0$  and  $\Delta S^\circ > 0$ , it is spontaneous at all temperatures if the partial pressures of each species is 1 atm. (If the gaseous species are not each at 1 atm, the  $RT \ln Q$  term can change the sign of  $\Delta G$  to be different than  $\Delta G^\circ$ , so be careful not to make conclusions about spontaneity from  $\Delta G^\circ$  alone.) Because both reaction 2 and reaction 3 have  $\Delta H^\circ < 0$  and  $\Delta S^\circ < 0$ , each is spontaneous at temperatures below the temperature  $T^*$  at which  $\Delta G = 0$ . With the higher ratio of  $\Delta S^\circ$  to  $\Delta H^\circ$ , reaction 3 is the first to become nonspontaneous, at  $T^* = 508^\circ\text{C}$  (under conditions where every partial pressure is 1 atm).

## PROBLEMS

Answers to problems whose numbers are red appear in Appendix G. Problems that are more challenging are indicated with asterisks.

### 14.2 The Empirical Law of Mass Action

1. Write equilibrium expressions for the following gas-phase reactions.

2. Write equilibrium expressions for the following gas-phase reactions.

3. At a moderately elevated temperature, phosphoryl chloride ( $\text{POCl}_3$ ) can be produced in the vapor phase from the gaseous elements. Write a balanced chemical equation and an equilibrium expression for this system. Note that gaseous phosphorus consists of  $\text{P}_4$  molecules at moderate temperatures.

4. If confined at high temperature, ammonia and oxygen quickly react and come to equilibrium with their products, water vapor and nitrogen oxide. Write a balanced chemical equation and an equilibrium expression for this system.

5. An important step in the industrial production of hydrogen is the reaction of carbon monoxide with water:

- (a) Use the law of mass action to write the equilibrium expression for this reaction.

- (b) At  $500^\circ\text{C}$ , the equilibrium constant for this reaction is 3.9. Suppose that the equilibrium partial pressures of CO and  $\text{H}_2\text{O}$  are both 0.10 atm and that of  $\text{CO}_2$  is 0.70 atm. Calculate the equilibrium partial pressure of  $\text{H}_2(\text{g})$ .

6. Phosgene ( $\text{COCl}_2$ ) is an important intermediate in the manufacture of certain plastics. It is produced by the reaction

- (a) Use the law of mass action to write the equilibrium expression for this reaction.

- (b) At  $600^\circ\text{C}$ , the equilibrium constant for this reaction is 0.20. Calculate the partial pressure of phosgene in equilibrium with a mixture of CO (at 0.0020 atm) and  $\text{Cl}_2$  (at 0.00030 atm).

7.  $\text{N}_2\text{O}_4$  is soluble in the solvent cyclohexane; however, dissolution does not prevent  $\text{N}_2\text{O}_4$  from breaking down to give  $\text{NO}_2$  according to the equation

An effort to compare this solution equilibrium with the similar equilibrium in the gas gave the following actual experimental data at  $20^\circ\text{C}$ :

$[\text{N}_2\text{O}_4]$ (mol L <sup>-1</sup> )	$[\text{NO}_2]$ (mol L <sup>-1</sup> )
$0.190 \times 10^{-3}$	$2.80 \times 10^{-3}$
$0.686 \times 10^{-3}$	$5.20 \times 10^{-3}$
$1.54 \times 10^{-3}$	$7.26 \times 10^{-3}$
$2.55 \times 10^{-3}$	$10.4 \times 10^{-3}$
$3.75 \times 10^{-3}$	$11.7 \times 10^{-3}$
$7.86 \times 10^{-3}$	$17.3 \times 10^{-3}$
$11.9 \times 10^{-3}$	$21.0 \times 10^{-3}$

- (a) Graph the *square* of the concentration of  $\text{NO}_2$  versus the concentration of  $\text{N}_2\text{O}_4$ .

- (b) Compute the average equilibrium constant of this reaction.

8.  $\text{NO}_2$  is soluble in carbon tetrachloride ( $\text{CCl}_4$ ). As it dissolves, it dimerizes to give  $\text{N}_2\text{O}_4$  according to the equation

A study of this equilibrium gave the following experimental data at  $20^\circ\text{C}$ :

$[\text{N}_2\text{O}_4]$ (mol L <sup>-1</sup> )	$[\text{NO}_2]$ (mol L <sup>-1</sup> )
$0.192 \times 10^{-3}$	$2.68 \times 10^{-3}$
$0.721 \times 10^{-3}$	$4.96 \times 10^{-3}$
$1.61 \times 10^{-3}$	$7.39 \times 10^{-3}$
$2.67 \times 10^{-3}$	$10.2 \times 10^{-3}$
$3.95 \times 10^{-3}$	$11.0 \times 10^{-3}$
$7.90 \times 10^{-3}$	$16.6 \times 10^{-3}$
$11.9 \times 10^{-3}$	$21.4 \times 10^{-3}$

- (a) Graph the concentration of  $\text{N}_2\text{O}_4$  versus the *square* of the concentration of  $\text{NO}_2$ .

- (b) Compute the average equilibrium constant of this reaction.

9. Using the law of mass action, write the equilibrium expression for each of the following reactions.

10. Using the law of mass action, write the equilibrium expression for each of the following reactions.

11. Using the law of mass action, write the equilibrium expression for each of the following reactions.

12. Using the law of mass action, write the equilibrium expression for each of the following reactions.

### 14.3 Thermodynamic Description of the Equilibrium State

13. Calculate  $\Delta G^\circ$  and the equilibrium constant  $K$  at  $25^\circ\text{C}$  for the reaction

using data in Appendix D.

14. Write a reaction for the dehydrogenation of gaseous ethane ( $\text{C}_2\text{H}_6$ ) to acetylene ( $\text{C}_2\text{H}_2$ ). Calculate  $\Delta G^\circ$  and the equilibrium constant for this reaction at  $25^\circ\text{C}$ , using data from Appendix D.

15. Use the thermodynamic data from Appendix D to calculate the equilibrium constant at  $25^\circ\text{C}$  for the following reactions:

Write the equilibrium expression for each reaction.

16. Use the thermodynamic data from Appendix D to calculate equilibrium constants at  $25^\circ\text{C}$  for the following reactions.

Write the equilibrium expression for each reaction.

### 14.4 The Law of Mass Action for Related and Simultaneous Equilibria

17. At a certain temperature, the value of the equilibrium constant for the reaction

is  $K_1$ . How is  $K_1$  related to the equilibrium constant  $K_2$  for the related equilibrium

at the same temperature?

18. At  $25^\circ\text{C}$ , the equilibrium constant for the reaction

is 32.6. Calculate the equilibrium constant at  $25^\circ\text{C}$  for the reaction

19. Suppose that  $K_1$  and  $K_2$  are the respective equilibrium constants for the two reactions

Give the equilibrium constant for the reaction

in terms of  $K_1$  and  $K_2$ .

20. At 1330 K, germanium(II) oxide ( $\text{GeO}$ ) and tungsten(VI) oxide ( $\text{W}_2\text{O}_6$ ) are both gases. The following two equilibria are established simultaneously:

The equilibrium constants for the two are respectively  $7.0 \times 10^3$  and  $38 \times 10^3$ . Compute  $K$  for the reaction

### 14.5 Equilibrium Calculations for Gas-Phase and Heterogeneous Reactions

21. At 454 K,  $\text{Al}_2\text{Cl}_6(g)$  reacts to form  $\text{Al}_3\text{Cl}_9(g)$  according to the equation

In an experiment at this temperature, the equilibrium partial pressure of  $\text{Al}_2\text{Cl}_6(g)$  is 1.00 atm and the equilibrium partial pressure of  $\text{Al}_3\text{Cl}_9(g)$  is  $1.02 \times 10^{-2}$  atm. Compute the equilibrium constant of the preceding reaction at 454 K.

22. At 298 K,  $\text{F}_3\text{SSF}(g)$  decomposes partially to  $\text{SF}_2(g)$ . At equilibrium, the partial pressure of  $\text{SF}_2(g)$  is  $1.1 \times 10^{-4}$  atm and the partial pressure of  $\text{F}_3\text{SSF}$  is 0.0484 atm.

- (a) Write a balanced equilibrium equation to represent this reaction.  
 (b) Compute the equilibrium constant corresponding to the equation you wrote.

23. The compound 1,3-di-*t*-butylcyclohexane exists in two forms that are known as the chair and boat conformations because their molecular structures resemble those objects. Equilibrium exists between the two forms, represented by the equation

At 580 K, 6.42% of the molecules are in the chair form. Calculate the equilibrium constant for the preceding reaction as written.

24. At  $248^\circ\text{C}$  and a total pressure of 1.000 atm, the fractional dissociation of  $\text{SbCl}_5$  is 0.718 for the reaction

This means that 718 of every 1000 molecules of  $\text{SbCl}_5$  originally present have dissociated. Calculate the equilibrium constant.

25. Sulfuryl chloride ( $\text{SO}_2\text{Cl}_2$ ) is a colorless liquid that boils at  $69^\circ\text{C}$ . Above this temperature, the vapors dissociate into sulfur dioxide and chlorine:

This reaction is slow at  $100^\circ\text{C}$ , but it is accelerated by the presence of some  $\text{FeCl}_3$  (which does not affect the final position of the equilibrium). In an experiment, 3.174 g of  $\text{SO}_2\text{Cl}_2(\ell)$  and a small amount of solid  $\text{FeCl}_3$  are put into an evacuated 1.000-L flask, which is then sealed and heated to  $100^\circ\text{C}$ . The total pressure in the flask at that temperature is found to be 1.30 atm.

- (a) Calculate the partial pressure of each of the three gases present.  
 (b) Calculate the equilibrium constant at this temperature.
26. A certain amount of  $\text{NOBr}(\text{g})$  is sealed in a flask, and the temperature is raised to 350 K. The following equilibrium is established:

The total pressure in the flask when equilibrium is reached at this temperature is 0.675 atm, and the vapor density is  $2.219 \text{ g L}^{-1}$ .

- (a) Calculate the partial pressure of each species.  
 (b) Calculate the equilibrium constant at this temperature.
27. The dehydrogenation of benzyl alcohol to make the flavoring agent benzaldehyde is an equilibrium process described by the equation

At 523 K, the value of its equilibrium constant is  $K = 0.558$ .

- (a) Suppose 1.20 g of benzyl alcohol is placed in a 2.00-L vessel and heated to 523 K. What is the partial pressure of benzaldehyde when equilibrium is attained?  
 (b) What fraction of benzyl alcohol is dissociated into products at equilibrium?
28. Isopropyl alcohol can dissociate into acetone and hydrogen:

At  $179^\circ\text{C}$ , the equilibrium constant for this dehydrogenation reaction is 0.444.

- (a) If 10.00 g of isopropyl alcohol is placed in a 10.00-L vessel and heated to  $179^\circ\text{C}$ , what is the partial pressure of acetone when equilibrium is attained?  
 (b) What fraction of isopropyl alcohol is dissociated at equilibrium?
29. A weighed quantity of  $\text{PCl}_5(\text{s})$  is sealed in a 100.0-cm<sup>3</sup> glass bulb to which a pressure gauge is attached. The bulb is heated to  $250^\circ\text{C}$ , and the gauge shows that the pressure in the bulb rises to 0.895 atm. At this temperature, the solid  $\text{PCl}_5$  is all vaporized and also partially dissociated into  $\text{Cl}_2(\text{g})$  and  $\text{PCl}_3(\text{g})$  according to the equation

At  $250^\circ\text{C}$ ,  $K = 2.15$  for this reaction. Assume that the contents of the bulb are at equilibrium and calculate the partial pressure of the three different chemical species in the vessel.

30. Suppose 93.0 g of  $\text{HI}(\text{g})$  is placed in a glass vessel and heated to 1107 K. At this temperature, equilibrium is quickly established between  $\text{HI}(\text{g})$  and its decomposition products,  $\text{H}_2(\text{g})$  and  $\text{I}_2(\text{g})$ :

The equilibrium constant at 1107 K is 0.0259, and the total pressure at equilibrium is observed to equal 6.45 atm. Calculate the equilibrium partial pressures of  $\text{HI}(\text{g})$ ,  $\text{H}_2(\text{g})$ , and  $\text{I}_2(\text{g})$ .

31. The equilibrium constant at 350 K for the reaction

has a value of 322. Bromine at an initial partial pressure of 0.0500 atm is mixed with iodine at an initial partial pressure of 0.0400 atm and held at 350 K until equilibrium is reached. Calculate the equilibrium partial pressure of each of the gases.

32. The equilibrium constant for the reaction of fluorine and oxygen to form oxygen difluoride ( $\text{OF}_2$ ) is 40.1 at 298 K:

Suppose some  $\text{OF}_2$  is introduced into an evacuated container at 298 K and allowed to dissociate until its partial pressure reaches an equilibrium value of 1.00 atm. Calculate the equilibrium partial pressures of  $\text{F}_2$  and  $\text{O}_2$  in the container.

33. At  $25^\circ\text{C}$ , the equilibrium constant for the reaction

is  $4.2 \times 10^{-31}$ . Suppose a container is filled with nitrogen (at an initial partial pressure of 0.41 atm), oxygen (at an initial partial pressure of 0.59 atm), and nitrogen oxide (at an initial partial pressure of 0.22 atm). Calculate the partial pressures of all three gases after equilibrium is reached at this temperature.

34. At  $25^\circ\text{C}$ , the equilibrium constant for the reaction

is  $5.9 \times 10^{-13}$ . Suppose a container is filled with nitrogen dioxide at an initial partial pressure of 0.89 atm. Calculate the partial pressures of all three gases after equilibrium is reached at this temperature.

- \*35. The equilibrium constant for the synthesis of ammonia

has the value  $K = 6.78 \times 10^5$  at  $25^\circ\text{C}$ . Calculate the equilibrium partial pressures of  $\text{N}_2(\text{g})$ ,  $\text{H}_2(\text{g})$ , and  $\text{NH}_3(\text{g})$  at  $25^\circ\text{C}$  if the total pressure is 1.00 atm and the H:N atom ratio in the system is 3:1. (*Hint:* Try the approximation that  $P_{\text{N}_2}$  and  $P_{\text{H}_2} \ll P_{\text{NH}_3}$ , and see if the resulting equations are simplified.)

- \*36. At  $400^\circ\text{C}$ ,  $K = 3.19 \times 10^{-4}$  for the reaction in problem 35. Repeat the calculation for  $P_{\text{N}_2}$ ,  $P_{\text{H}_2}$ , and  $P_{\text{NH}_3}$  assuming the same total pressure and composition. (*Hint:* Try the approximation that  $P_{\text{NH}_3} \ll P_{\text{N}_2}$  and  $P_{\text{H}_2}$  and see if the resulting equations are simplified.)

37. Calculate the concentration of phosgene ( $\text{COCl}_2$ ) that will be present at  $600^\circ\text{C}$  in equilibrium with carbon monoxide (at a concentration of  $2.3 \times 10^{-4} \text{ mol L}^{-1}$ ) and chlorine (at a concentration of  $1.7 \times 10^{-2} \text{ mol L}^{-1}$ ). (Use the data of problem 6.)

38. The reaction

has an equilibrium constant at  $100^\circ\text{C}$  of 2.40. Calculate the concentration of  $\text{SO}_2$  that will be present at  $100^\circ\text{C}$  in equilibrium with  $\text{SO}_2\text{Cl}_2$  (at a concentration of  $3.6 \times 10^{-4} \text{ mol L}^{-1}$ ) and chlorine (at a concentration of  $6.9 \times 10^{-3} \text{ mol L}^{-1}$ ).

39. At 298 K, the equilibrium constant for the reaction

is  $4.0 \times 10^{-6}$ , and that for

is  $3.2 \times 10^{-4}$ . Suppose some solid  $\text{Fe}_2\text{O}_3$ , solid Fe, and liquid  $\text{H}_2\text{O}$  are brought into equilibrium with  $\text{CO}(\text{g})$  and  $\text{CO}_2(\text{g})$  in a closed container at 298 K. Calculate the ratio of the partial pressure of  $\text{CO}(\text{g})$  to that of  $\text{CO}_2(\text{g})$  at equilibrium.

40. A sample of ammonium carbamate placed in a glass vessel at  $25^\circ\text{C}$  undergoes the reaction

The total pressure of gases in equilibrium with the solid is found to be 0.115 atm.

- (a) Calculate the partial pressures of  $\text{NH}_3$  and  $\text{CO}_2$ .  
(b) Calculate the equilibrium constant at  $25^\circ\text{C}$ .

41. The equilibrium constant for the reaction

at  $340^\circ\text{C}$  is  $K = 4.0$ .

- (a) If the partial pressure of ammonia is  $P_{\text{NH}_3} = 0.80 \text{ atm}$  and solid ammonium chloride is present, what is the equilibrium partial pressure of hydrogen chloride at  $340^\circ\text{C}$ ?  
(b) An excess of solid  $\text{NH}_4\text{Cl}$  is added to a container filled with ammonia at  $340^\circ\text{C}$  and a pressure of 1.50 atm. Calculate the pressures of  $\text{NH}_3(\text{g})$  and  $\text{HCl}(\text{g})$  reached at equilibrium.

42. The equilibrium constant for the reaction

at  $25^\circ\text{C}$  is  $K = 0.345$ .

- (a) If the partial pressure of hydrogen is  $P_{\text{H}_2} = 1.00 \text{ atm}$  and solid iodine is present, what is the equilibrium partial pressure of hydrogen iodide,  $P_{\text{HI}}$ , at  $25^\circ\text{C}$ ?  
(b) An excess of solid  $\text{I}_2$  is added to a container filled with hydrogen at  $25^\circ\text{C}$  and a pressure of 4.00 atm. Calculate the pressures of  $\text{H}_2(\text{g})$  and  $\text{HI}(\text{g})$  reached at equilibrium.

43. Pure solid  $\text{NH}_4\text{HSe}$  is placed in an evacuated container at  $24.8^\circ\text{C}$ . Eventually, the pressure above the solid reaches the equilibrium pressure 0.0184 atm due to the reaction

- (a) Calculate the equilibrium constant of this reaction at  $24.8^\circ\text{C}$ .  
(b) In a different container, the partial pressure of  $\text{NH}_3(\text{g})$  in equilibrium with  $\text{NH}_4\text{HSe}(\text{s})$  at  $24.8^\circ\text{C}$  is 0.0252 atm. What is the partial pressure of  $\text{H}_2\text{Se}(\text{g})$ ?  
44. The total pressure of the gases in equilibrium with solid sodium hydrogen carbonate at  $110^\circ\text{C}$  is 1.648 atm, corresponding to the reaction

( $\text{NaHCO}_3$  is used in dry chemical fire extinguishers because the products of this decomposition reaction smother the fire.)

- (a) Calculate the equilibrium constant at  $110^\circ\text{C}$ .  
(b) What is the partial pressure of water vapor in equilibrium with  $\text{NaHCO}_3(\text{s})$  at  $110^\circ\text{C}$  if the partial pressure of  $\text{CO}_2(\text{g})$  is 0.800 atm?

#### 14.6 The Direction of Change in Chemical Reactions: Empirical Description

45. Some  $\text{Al}_2\text{Cl}_6$  (at a partial pressure of 0.473 atm) is placed in a closed container at 454 K with some  $\text{Al}_3\text{Cl}_9$  (at a partial pressure of  $1.02 \times 10^{-2} \text{ atm}$ ). Enough argon is added to raise the total pressure to 1.00 atm.

- (a) Calculate the initial reaction quotient for the reaction

- (b) As the gas mixture reaches equilibrium, will there be net production or consumption of  $\text{Al}_3\text{Cl}_9$ ? (Use the data given in problem 21.)

46. Some  $\text{SF}_2$  (at a partial pressure of  $2.3 \times 10^{-4} \text{ atm}$ ) is placed in a closed container at 298 K with some  $\text{F}_3\text{SSF}$  (at a partial pressure of 0.0484 atm). Enough argon is added to raise the total pressure to 1.000 atm.

- (a) Calculate the initial reaction quotient for the decomposition of  $\text{F}_3\text{SSF}$  to  $\text{SF}_2$ .

- (b) As the gas mixture reaches equilibrium, will there be net formation or dissociation of  $\text{F}_3\text{SSF}$ ? (Use the data given in problem 22.)

47. The progress of the reaction

can be monitored visually by following changes in the color of the reaction mixture ( $\text{Br}_2$  is reddish brown, and  $\text{H}_2$  and  $\text{HBr}$  are colorless). A gas mixture is prepared at 700 K, in which 0.40 atm is the initial partial pressure of both  $\text{H}_2$  and  $\text{Br}_2$  and 0.90 atm is the initial partial pressure of  $\text{HBr}$ . The color of this mixture then fades as the reaction progresses toward equilibrium. Give a condition that must be satisfied by the equilibrium constant  $K$  (for example, it must be greater than or smaller than a given number).

48. Recall from our discussion of the  $\text{NO}_2\text{-N}_2\text{O}_4$  equilibrium that  $\text{NO}_2$  has a brownish color. At elevated temperatures,  $\text{NO}_2$  reacts with  $\text{CO}$  according to

The other three gases taking part in this reaction are colorless. When a gas mixture is prepared at 500 K, in which 3.4 atm is the initial partial pressure of both  $\text{NO}_2$  and  $\text{CO}$ , and 1.4 atm is the partial pressure of both  $\text{NO}$  and  $\text{CO}_2$ , the brown color of the mixture is observed to fade as the reaction progresses toward equilibrium. Give a condition that must be satisfied by the equilibrium constant  $K$  (for example, it must be greater than or smaller than a given number).

49. The equilibrium constant for the “water gas” reaction

is  $K = 2.6$  at a temperature of 1000 K. Calculate the reaction quotient  $Q$  for each of the following conditions, and state which direction the reaction shifts in coming to equilibrium.

- (a)  $P_{\text{H}_2\text{O}} = 0.600$  atm;  $P_{\text{CO}} = 1.525$  atm;  $P_{\text{H}_2} = 0.805$  atm  
 (b)  $P_{\text{H}_2\text{O}} = 0.724$  atm;  $P_{\text{CO}} = 1.714$  atm;  $P_{\text{H}_2} = 1.383$  atm
50. The equilibrium constant for the reaction

at  $110^\circ\text{C}$  is equal to 0.0023. Calculate the reaction quotient  $Q$  for each of the following conditions and determine whether solid sulfur is consumed or produced as the reaction comes to equilibrium.

- (a)  $P_{\text{I}_2} = 0.461$  atm;  $P_{\text{H}_2\text{S}} = 0.050$  atm;  $P_{\text{HI}} = 0.0$  atm  
 (b)  $P_{\text{I}_2} = 0.461$  atm;  $P_{\text{H}_2\text{S}} = 0.050$  atm;  $P_{\text{HI}} = 9.0$  atm
51. At  $T = 1200^\circ\text{C}$  the reaction

has an equilibrium constant  $K = 0.612$ .

- (a) Suppose the initial partial pressure of  $\text{P}_4$  is 5.00 atm and that of  $\text{P}_2$  is 2.00 atm. Calculate the reaction quotient  $Q$  and state whether the reaction proceeds to the right or to the left as equilibrium is approached.  
 (b) Calculate the partial pressures at equilibrium.  
 (c) If the volume of the system is then increased, will there be net formation or net dissociation of  $\text{P}_4$ ?
52. At  $T = 100^\circ\text{C}$  the reaction

has an equilibrium constant  $K = 2.4$ .

- (a) Suppose the initial partial pressure of  $\text{SO}_2\text{Cl}_2$  is 1.20 atm, and  $P_{\text{SO}_2} = P_{\text{Cl}_2} = 0$ . Calculate the reaction quotient  $Q$  and state whether the reaction proceeds to the right or to the left as equilibrium is approached.  
 (b) Calculate the partial pressures at equilibrium.  
 (c) If the volume of the system is then decreased, will there be net formation or net dissociation of  $\text{SO}_2\text{Cl}_2$ ?

53. Explain the effect of each of the following stresses on the position of the following equilibrium:

The reaction as written is exothermic.

- (a)  $\text{N}_2\text{O}(\text{g})$  is added to the equilibrium mixture without change of volume or temperature.  
 (b) The volume of the equilibrium mixture is reduced at constant temperature.  
 (c) The equilibrium mixture is cooled.  
 (d) Gaseous argon (which does not react) is added to the equilibrium mixture while both the total gas pressure and the temperature are kept constant.  
 (e) Gaseous argon is added to the equilibrium mixture without changing the volume.
54. Explain the effect of each of the following stresses on the position of the equilibrium

The reaction as written is endothermic.

- (a)  $\text{O}_2(\text{g})$  is added to the equilibrium mixture without changing volume or temperature.  
 (b) The mixture is compressed at constant temperature.  
 (c) The equilibrium mixture is cooled.  
 (d) An inert gas is pumped into the equilibrium mixture while the total gas pressure and the temperature are kept constant.  
 (e) An inert gas is added to the equilibrium mixture without changing the volume.
55. In a gas-phase reaction, it is observed that the equilibrium yield of products is increased by lowering the temperature and by reducing the volume.
- (a) Is the reaction exothermic or endothermic?  
 (b) Is there a net increase or a net decrease in the number of gas molecules in the reaction?

56. The equilibrium constant of a gas-phase reaction increases as temperature is increased. When the nonreacting gas neon is admitted to a mixture of reacting gases (holding the temperature and the total pressure fixed and increasing the volume of the reaction vessel), the product yield is observed to decrease.

- (a) Is the reaction exothermic or endothermic?  
 (b) Is there a net increase or a net decrease in the number of gas molecules in the reaction?
57. The most extensively used organic compound in the chemical industry is ethene ( $\text{C}_2\text{H}_4$ ). The two equations

represent the way in which vinyl chloride ( $\text{C}_2\text{H}_3\text{Cl}$ ) is synthesized for eventual use in polymeric plastics (polyvinyl chloride, PVC). The byproduct of the reaction,  $\text{HCl}$ , is now most cheaply made by this and similar reactions, rather than by direct combination of  $\text{H}_2$  and  $\text{Cl}_2$ . Heat is given off in the first reaction and taken up in the second. Describe how you would design an industrial process to maximize the yield of vinyl chloride.

58. Methanol is made via the exothermic reaction

Describe how you would control the temperature and pressure to maximize the yield of methanol.

### 14.7 The Direction of Change in Chemical Reactions: Thermodynamic Explanation

59. One way to manufacture ethanol is by the reaction

The  $\Delta H_f^\circ$  of  $\text{C}_2\text{H}_4(g)$  is  $52.3 \text{ kJ mol}^{-1}$ ; of  $\text{H}_2\text{O}(g)$ ,  $-241.8 \text{ kJ mol}^{-1}$ ; and of  $\text{C}_2\text{H}_5\text{OH}(g)$ ,  $-235.3 \text{ kJ mol}^{-1}$ . Without doing detailed calculations, suggest the conditions of pressure and temperature that will maximize the yield of ethanol at equilibrium.

60. Dimethyl ether (
- $\text{CH}_3\text{OCH}_3$
- ) is a good substitute for environmentally harmful propellants in aerosol spray cans. It is produced by the dehydration of methanol:

Describe reaction conditions that favor the equilibrium production of this valuable chemical. As a basis for your answer, compute  $\Delta H^\circ$  and  $\Delta S^\circ$  of the reaction from the data in Appendix D.

61. The equilibrium constant at
- $25^\circ\text{C}$
- for the reaction

is 6.8. At  $200^\circ\text{C}$  the equilibrium constant is  $1.21 \times 10^{-3}$ . Calculate the enthalpy change ( $\Delta H$ ) for this reaction, assuming that  $\Delta H^\circ$  and  $\Delta S^\circ$  of the reaction are constant over the temperature range from  $25^\circ\text{C}$  to  $200^\circ\text{C}$ .

62. Stearic acid dimerizes when dissolved in hexane:

The equilibrium constant for this reaction is 2900 at  $28^\circ\text{C}$ , but it drops to 40 at  $48^\circ\text{C}$ . Estimate  $\Delta H^\circ$  and  $\Delta S^\circ$  for the reaction.

63. The equilibrium constant for the reaction

is measured to be  $9.3 \times 10^9$  at 298 K and  $3.3 \times 10^7$  at 398 K.

- (a) Calculate  $\Delta G^\circ$  at 298 K for the reaction.  
 (b) Calculate  $\Delta H^\circ$  and  $\Delta S^\circ$ , assuming the enthalpy and entropy changes to be independent of temperature between 298 and 398 K.

64. Stearic acid also dimerizes when dissolved in carbon tetrachloride:

The equilibrium constant for this reaction is 2780 at  $22^\circ\text{C}$ , but it drops to 93.1 at  $42^\circ\text{C}$ . Estimate  $\Delta H^\circ$  and  $\Delta S^\circ$  for the reaction.

65. For the synthesis of ammonia from its elements,

the equilibrium constant  $K = 5.9 \times 10^5$  at 298 K, and  $\Delta H^\circ = -92.2 \text{ kJ mol}^{-1}$ . Calculate the equilibrium constant for the reaction at 600 K, assuming no change in  $\Delta H^\circ$  and  $\Delta S^\circ$  between 298 K and 600 K.

66. The cumulative exercise at the end of Chapter 14 explored reaction steps in the manufacture of sulfuric acid, including the oxidation of sulfur dioxide to sulfur trioxide:

At  $25^\circ\text{C}$  the equilibrium constant for this reaction is  $2.6 \times 10^{12}$ , but the reaction occurs very slowly. Calculate  $K$  for this reaction at  $550^\circ\text{C}$ , assuming  $\Delta H^\circ$  and  $\Delta S^\circ$  are independent of temperature in the range from  $25^\circ\text{C}$  to  $550^\circ\text{C}$ .

67. The vapor pressure of ammonia at
- $-50^\circ\text{C}$
- is 0.4034 atm; at
- $0^\circ\text{C}$
- , it is 4.2380 atm.

- (a) Calculate the molar enthalpy of vaporization ( $\Delta H_{\text{vap}}$ ) of ammonia.  
 (b) Calculate the normal boiling temperature of  $\text{NH}_3(\ell)$ .

68. The vapor pressure of butyl alcohol (
- $\text{C}_4\text{H}_9\text{OH}$
- ) at
- $70.1^\circ\text{C}$
- is 0.1316 atm; at
- $100.8^\circ\text{C}$
- , it is 0.5263 atm.

- (a) Calculate the molar enthalpy of vaporization ( $\Delta H_{\text{vap}}$ ) of butyl alcohol.  
 (b) Calculate the normal boiling point of butyl alcohol.

69. Although iodine is not very soluble in pure water, it dissolves readily in water that contains
- $\text{I}^-(aq)$
- ion, thanks to the reaction

The equilibrium constant of this reaction was measured as a function of temperature with these results:

$T$ :	$3.8^\circ\text{C}$	$15.3^\circ\text{C}$	$25.0^\circ\text{C}$	$35.0^\circ\text{C}$	$50.2^\circ\text{C}$
$K$ :	1160	841	689	533	409

- (a) Plot  $\ln K$  on the  $y$  axis as a function of  $1/T$ , the reciprocal of the absolute temperature.  
 (b) Estimate the  $\Delta H^\circ$  of this reaction.

70. Barium nitride vaporizes slightly at high temperature as it undergoes the dissociation

At 1000 K the equilibrium constant is  $4.5 \times 10^{-19}$ . At 1200 K the equilibrium constant is  $6.2 \times 10^{-12}$ .

- (a) Estimate  $\Delta H^\circ$  for this reaction.  
 (b) The equation is rewritten as

Now the equilibrium constant is  $2.0 \times 10^{-37}$  at 1000 K and  $3.8 \times 10^{-23}$  at 1200 K. Estimate  $\Delta H^\circ$  of *this* reaction.

### 14.8 Distribution of a Single Species between Immiscible Phases: Extraction and Separation Processes

71. An aqueous solution, initially
- $1.00 \times 10^{-2} \text{ M}$
- in iodine (
- $\text{I}_2$
- ), is shaken with an equal volume of an immiscible organic solvent,
- $\text{CCl}_4$
- . The iodine distributes itself between the aqueous and
- $\text{CCl}_4$
- layers, and when equilibrium is reached

at 27°C, the concentration of  $I_2$  in the aqueous layer is  $1.30 \times 10^{-4}$  M. Calculate the partition coefficient  $K$  at 27°C for the reaction

72. An aqueous solution, initially  $2.50 \times 10^{-2}$  M in iodine ( $I_2$ ), is shaken with an equal volume of an immiscible organic solvent,  $CS_2$ . The iodine distributes itself between the aqueous and  $CS_2$  layers, and when equilibrium is reached at 25°C, the concentration of  $I_2$  in the aqueous layer is  $4.16 \times 10^{-5}$  M. Calculate the partition coefficient  $K$  at 25°C for the reaction

73. Benzoic acid ( $C_6H_5COOH$ ) dissolves in water to the extent of  $2.00 \text{ g L}^{-1}$  at 15°C and in diethyl ether to the extent of  $6.6 \times 10^2 \text{ g L}^{-1}$  at the same temperature.  
(a) Calculate the equilibrium constants at 15°C for the two reactions

and

- (b) From your answers to part (a), calculate the partition coefficient  $K$  for the reaction

74. Citric acid ( $C_6H_8O_7$ ) dissolves in water to the extent of  $1300 \text{ g L}^{-1}$  at 15°C and in diethyl ether to the extent of  $22 \text{ g L}^{-1}$  at the same temperature.

- (a) Calculate the equilibrium constants at 15°C for the two reactions

and

- (b) From your answers to part (a), calculate the partition coefficient  $K$  for the reaction

## ADDITIONAL PROBLEMS

75. At 298 K, unequal amounts of  $BCl_3(g)$  and  $BF_3(g)$  were mixed in a container. The gases reacted to form  $BFCl_2(g)$  and  $BClF_2(g)$ . When equilibrium was finally reached, the four gases were present in these relative chemical amounts:  $BCl_3(90)$ ,  $BF_3(470)$ ,  $BClF_2(200)$ ,  $BFCl_2(45)$ .

- (a) Determine the equilibrium constants at 298 K of the two reactions

- (b) Determine the equilibrium constant of the reaction

and explain why knowing this equilibrium constant really adds nothing to what you knew in part (a).

76. Methanol can be synthesized by means of the equilibrium reaction

for which the equilibrium constant at 225°C is  $6.08 \times 10^{-3}$ . Assume that the ratio of the pressures of  $CO(g)$  and  $H_2(g)$  is 1:2. What values should they have if the partial pressure of methanol is to be 0.500 atm?

77. At equilibrium at 425.6°C, a sample of *cis*-1-methyl-2-ethylcyclopropane is 73.6% converted into the *trans* form:

- (a) Compute the equilibrium constant  $K$  for this reaction.  
(b) Suppose that 0.525 mol of the *cis* compound is placed in a 15.00-L vessel and heated to 425.6°C. Compute the equilibrium partial pressure of the *trans* compound.

78. The equilibrium constant for the reaction

is 2.42 at 450 K.

- (a) A pure sample of the reactant, which is named “*t*-butanol,” is confined in a container of fixed volume at a temperature of 450 K and at an original pressure of 0.100 atm. Calculate the fraction of this starting material that is converted to products at equilibrium.

- (b) A second sample of the reactant is confined, this time at an original pressure of 5.00 atm. Again, calculate the fraction of the starting material that is converted to products at equilibrium.

79. At 627°C and 1 atm,  $SO_3$  is partly dissociated into  $SO_2$  and  $O_2$ :

The density of the equilibrium mixture is  $0.925 \text{ g L}^{-1}$ . What is the degree of dissociation of  $SO_3$  under these circumstances?

80. Acetic acid in the vapor phase consists of both monomeric and dimeric forms in equilibrium:

At 110°C the equilibrium constant for this reaction is 3.72.

- (a) Calculate the partial pressure of the dimer when the total pressure is 0.725 atm at equilibrium.

- (b) What percentage of the acetic acid is dimerized under these conditions?

- \*81. Repeat the calculation of problem 36 with a total pressure of 100 atm. (*Note:* Here it is necessary to solve the equation by successive approximations. See Appendix C.)

82. At 900 K the equilibrium constant for the reaction

has the value  $K = 0.587$ . What will be the equilibrium partial pressure of  $\text{O}_2(\text{g})$  if a sample of  $\text{SO}_3$  weighing 0.800 g is heated to 900 K in a quartz-glass vessel whose volume is 100.0  $\text{cm}^3$ ? (Note: Here it is necessary to solve the equation by successive approximations. See Appendix C.)

- \*83. At 298 K chlorine is only slightly soluble in water. Thus, under a pressure of 1.00 atm of  $\text{Cl}_2(\text{g})$ , 1.00 L of water at equilibrium dissolves just 0.091 mol of  $\text{Cl}_2$ .

In such solutions the  $\text{Cl}_2(\text{aq})$  concentration is 0.061 M and the concentrations of  $\text{Cl}^-(\text{aq})$  and  $\text{HOCl}(\text{aq})$  are both 0.030 M. These two additional species are formed by the equilibrium

There are no other Cl-containing species. Compute the equilibrium constants  $K_1$  and  $K_2$  for the two reactions.

84. At 400°C the reaction

has an equilibrium constant equal to  $K_1$ . How is  $K_1$  related to the equilibrium constant  $K_2$  of the reaction

at 400°C?

85. Ammonium hydrogen sulfide, a solid, decomposes to give  $\text{NH}_3(\text{g})$  and  $\text{H}_2\text{S}(\text{g})$ . At 25°C, some  $\text{NH}_4\text{HS}(\text{s})$  is placed in an evacuated container. A portion of it decomposes, and the total pressure at equilibrium is 0.659 atm. Extra  $\text{NH}_3(\text{g})$  is then injected into the container, and when equilibrium is reestablished, the partial pressure of  $\text{NH}_3(\text{g})$  is 0.750 atm.

- (a) Compute the equilibrium constant for the decomposition of ammonium hydrogen sulfide.  
(b) Determine the final partial pressure of  $\text{H}_2\text{S}(\text{g})$  in the container.

86. The equilibrium constant for the reaction

is  $6 \times 10^{15}$  at 25°C. Suppose 7.32 g of KOH and 9.41 g of  $\text{KHCO}_3$  are placed in a closed evacuated container and allowed to reach equilibrium. Calculate the pressure of  $\text{CO}_2(\text{g})$  at equilibrium.

87. The equilibrium constant for the reduction of nickel(II) oxide to nickel at 754°C is 255.4, corresponding to the reaction

If the total pressure of the system at 754°C is 2.50 atm, calculate the partial pressures of  $\text{CO}(\text{g})$  and  $\text{CO}_2(\text{g})$ .

88. Both glucose (corn sugar) and fructose (fruit sugar) taste sweet, but fructose tastes sweeter. Each year in the United States, tons of corn syrup destined to sweeten food are treated to convert glucose as fully as possible to the sweeter fructose. The reaction is an equilibrium:

- (a) A 0.2564 M solution of pure glucose is treated at 25°C with an enzyme (catalyst) that causes the preceding equilibrium to be reached quickly. The final concentration of fructose is 0.1175 M. In another experiment at the same temperature, a 0.2666 M solution of pure fructose is treated with the same enzyme and the final concentration of glucose is 0.1415 M. Compute an average equilibrium constant for the preceding reaction.  
(b) At equilibrium under these conditions, what percentage of glucose is converted to fructose?
89. At 300°C the equilibrium constant for the reaction

is  $K = 11.5$ .

- (a) Calculate the reaction quotient  $Q$  if initially  $P_{\text{PCl}_3} = 2.0$  atm,  $P_{\text{Cl}_2} = 6.0$  atm, and  $P_{\text{PCl}_5} = 0.10$  atm. State whether the reaction proceeds to the right or to the left as equilibrium is approached.  
(b) Calculate  $P_{\text{PCl}_3}$ ,  $P_{\text{Cl}_2}$ , and  $P_{\text{PCl}_5}$  at equilibrium.  
(c) If the volume of the system is then increased, will the amount of  $\text{PCl}_5$  present increase or decrease?
90. Although the process of dissolution of helium gas in water is favored in terms of energy, helium is only very slightly soluble in water. What keeps this gas from dissolving in great quantities in water?

91. The hydrogenation of pyridine to piperidine

is an equilibrium process whose equilibrium constant is given by the equation

$$\log_{10} K = -20.281 + \frac{10.560 \text{ K}}{T}$$

- (a) Calculate the value of  $K$  at  $T = 500$  K.  
(b) If the partial pressure of hydrogen is 1.00 atm, what fraction of the nitrogen is in the form of pyridine molecules at  $T = 500$  K?
92. The breaking of the O—O bond in peroxydisulfuryl difluoride ( $\text{FO}_2\text{SOOSO}_2\text{F}$ ) gives  $\text{FO}_2\text{SO}$ :

The compound on the left of this equation is a colorless liquid that boils at 67.1°C. Its vapor, when heated to about 100°C, turns brown as the product of the reaction forms. Suppose that, in a sample of the vapor, the intensity of the brown color doubles between 100°C and 110°C and that the total pressure increases only by the 2.7% predicted for an ideal gas. Estimate  $\Delta H^\circ$  for the preceding reaction.

93. Polychlorinated biphenyls (PCBs) are a major environmental problem. These oily substances have many uses, but they resist breakdown by bacterial action when spilled in the environment and, being fat-soluble, can accumulate to dangerous concentrations in the fatty tissues of fish and animals. One little-appreciated complication in controlling the problem is that there are 209 different PCBs, all now in the environment. They are generally similar, but their solubilities in fats differ considerably. The best measure of this is  $K_{ow}$ , the equilibrium constant for the partition of a PCB between the fat-like solvent octanol and water.

An equimolar mixture of PCB-2 and PCB-11 in water is treated with an equal volume of octanol. Determine the ratio between the amounts of PCB-2 and PCB-11 in the water at equilibrium. At room temperature,  $K_{ow}$  is  $3.98 \times 10^4$  for PCB-2 and  $1.26 \times 10^5$  for PCB-11.

94. Refer to the data in problems 73 and 74. Suppose 2.00 g of a solid consisting of 50.0% benzoic acid and 50.0% citric acid by mass is added to 100.0 mL of water and 100.0 mL of diethyl ether and the whole assemblage is shaken. When the immiscible layers are separated and the solvents are removed by evaporation, two solids result. Calculate the percentage (by mass) of the major component in each solid.
95. At 25°C the partition coefficient for the equilibrium
- $$\text{I}_2(aq) \rightleftharpoons \text{I}_2(\text{CCl}_4)$$
- has the value  $K = 85$ . To 0.100 L of an aqueous solution, which is initially  $2 \times 10^{-3}$  M in  $\text{I}_2$ , we add 0.025 L of  $\text{CCl}_4$ . The mixture is shaken in a separatory funnel and allowed to separate into two phases, and the  $\text{CCl}_4$  phase is withdrawn.
- Calculate the fraction of the  $\text{I}_2$  remaining in the aqueous phase.
  - Suppose the remaining aqueous phase is shaken with another 0.025 L of  $\text{CCl}_4$  and again separated. What fraction of the  $\text{I}_2$  from the original aqueous solution is *now* in the aqueous phase?
  - Compare your answer with that of Example 14.18, in which the same total amount of  $\text{CCl}_4$  (0.050 L) was used in a *single* extraction. For a given total amount of extracting solvent, which is the more efficient way to remove iodine from water?
96. From the data in Appendix D calculate  $\Delta H^\circ$ ,  $\Delta G^\circ$ , and  $K$ , for the following reaction at 298 K:

## CUMULATIVE PROBLEMS

97. The reaction

is endothermic and begins to occur at moderate temperatures.

- In which direction do you expect deviations to occur from Boyle's law,  $P \propto 1/V$  (constant  $T$ ), for gaseous  $\text{P}_4$ ?
  - In which direction do you expect deviations to occur from Charles's law,  $V \propto T$  (constant  $P$ ), for gaseous  $\text{P}_4$ ?
98. A 4.72-g mass of methanol,  $\text{CH}_3\text{OH}$ , is placed in an evacuated 1.00-L flask and heated to 250°C. It vaporizes and then reaches the following equilibrium:

A tiny hole forms in the side of the container, allowing a small amount of gas to effuse out. Analysis of the escaping gases shows that the rate of escape of the hydrogen is 33 times the rate of escape of the methanol. Calculate the equilibrium constant for the preceding reaction at 250°C.

99. The triple bond in the  $\text{N}_2$  molecule is very strong, but at high enough temperatures even it breaks down. At 5000 K, when the total pressure exerted by a sample of nitrogen is 1.00 atm,  $\text{N}_2(g)$  is 0.65% dissociated at equilibrium:

At 6000 K with the same total pressure, the proportion of  $\text{N}_2(g)$  dissociated at equilibrium rises to 11.6%. Use the van't Hoff equation to estimate the  $\Delta H$  of this reaction.

100. At 25°C the equilibrium constant for the reaction

is  $1.6 \times 10^3$ . Over what range of relative humidities do you expect  $\text{CaSO}_4(s)$  to be converted to  $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ ? (Note: The relative humidity is the partial pressure of water vapor divided by its equilibrium vapor pressure and multiplied by 100%. Use Table 10.3.)

101. Calculate the equilibrium pressure (in atmospheres) of  $\text{O}_2(g)$  over a sample of pure  $\text{NiO}(s)$  in contact with pure  $\text{Ni}(s)$  at 25°C. The  $\text{NiO}(s)$  decomposes according to the equation

Use data from Appendix D.

102. (a) From the values in Appendix D, find the enthalpy change and the Gibbs free energy change when one mole of benzene  $\text{C}_6\text{H}_6$  is vaporized at 25°C.
- (b) Calculate the vapor pressure of benzene at 25°C.
- (c) Assuming that the enthalpy and entropy of vaporization are constant, estimate the normal boiling point of benzene.

103. Snow and ice sublime spontaneously when the partial pressure of water vapor is below the equilibrium vapor pressure of ice. At 0°C the vapor pressure of ice is 0.0060 atm (the triple-point pressure of water). Taking the enthalpy of sublimation of ice to be 50.0 kJ mol<sup>-1</sup>, calculate the partial pressure of water vapor below which ice will sublime spontaneously at -15°C.
104. The sublimation pressure of solid NbI<sub>5</sub> is the pressure of gaseous NbI<sub>5</sub> present in equilibrium with the solid. It is given by the empirical equation

$$\log P = -6762/T + 8.566$$

The vapor pressure of liquid NbI<sub>5</sub>, on the other hand, is given by

$$\log P = -4653/T + 5.43$$

In these two equations,  $T$  is the absolute temperature in kelvins and  $P$  is the pressure in atmospheres.

- (a) Determine the enthalpy and entropy of sublimation of NbI<sub>5</sub>(s).
- (b) Determine the enthalpy and entropy of vaporization of NbI<sub>5</sub>(l).
- (c) Calculate the normal boiling point of NbI<sub>5</sub>(l).
- (d) Calculate the triple-point temperature and pressure of NbI<sub>5</sub>. (*Hint*: At the triple point of a substance, the liquid and solid are in equilibrium and must have the same vapor pressure. If they did not, vapor would continually escape from the phase with the higher vapor pressure and collect in the phase with the lower vapor pressure.)
105. In an extraction process, a solute species is partitioned between two immiscible solvents. Suppose the two solvents are water and carbon tetrachloride. State which phase will have the higher concentration of each of the following solutes: (a) CH<sub>3</sub>OH, (b) C<sub>2</sub>Cl<sub>6</sub>, (c) Br<sub>2</sub>, (d) NaCl. Explain your reasoning.
106. The gaseous compounds allene and propyne are isomers with formula C<sub>3</sub>H<sub>4</sub>. Calculate the equilibrium constant and the standard enthalpy change at 25°C for the isomerization reaction

from the following data, all of which apply to 298 K:

	$\Delta H_f^\circ$ (kJ mol <sup>-1</sup> )	$\Delta G_f^\circ$ (kJ mol <sup>-1</sup> )
Allene	192	202
Propyne	185	194

107. (a) Calculate the standard free-energy change and the equilibrium constant for the dimerization of NO<sub>2</sub> to N<sub>2</sub>O<sub>4</sub> at 25°C (see Appendix D).
- (b) Calculate  $\Delta G$  for this reaction at 25°C when the pressures of NO<sub>2</sub> and N<sub>2</sub>O<sub>4</sub> are each held at 0.010 atm. Which way will the reaction tend to proceed?

108. There are two isomeric hydrocarbons with formula C<sub>4</sub>H<sub>10</sub>, butane and isobutane, which we denote here B and I. The standard enthalpies of formation for the gaseous species are -124.7 kJ mol<sup>-1</sup> for B, -131.3 kJ mol<sup>-1</sup> for I; the standard free energies of formation are -15.9 kJ mol<sup>-1</sup> for B, -18.0 kJ mol<sup>-1</sup> for I.
- (a) Which is the more stable under standard conditions, and which has the higher entropy?
- (b) The reaction B  $\rightleftharpoons$  I can occur in the presence of a catalyst. Calculate the equilibrium constant at 298 K for the conversion of B to I, and calculate the percentage of B in the equilibrium mixture.
109. At 3500 K the equilibrium constant for the reaction CO<sub>2</sub>(g) + H<sub>2</sub>(g)  $\rightleftharpoons$  CO(g) + H<sub>2</sub>O(g) is 8.28.
- (a) What is  $\Delta G^\circ(3500)$  for this reaction?
- (b) What is  $\Delta G$  at 3500 K for transforming 1 mol CO<sub>2</sub> and 1 mol H<sub>2</sub>, both held at 0.1 atm, to 1 mol CO and 1 mol H<sub>2</sub>O, both held at 2 atm?
- (c) In which direction would this last reaction run spontaneously?
110. At 1200 K in the presence of solid carbon, an equilibrium mixture of CO and CO<sub>2</sub> (called “producer gas”) contains 98.3 mol percent CO and 1.69 mol percent of CO<sub>2</sub> when the total pressure is 1 atm. The reaction is

- (a) Calculate  $P_{\text{CO}}$  and  $P_{\text{CO}_2}$ .
- (b) Calculate the equilibrium constant.
- (c) Calculate  $\Delta G^\circ$  for this reaction.
111. (a) Formulate the equilibrium expression for the endothermic reaction
- $$\text{AgCl} \cdot \text{NH}_3(s) \rightleftharpoons \text{AgCl}(s) + \text{NH}_3(g)$$
- (b) What is the effect on  $P_{\text{NH}_3}$  at equilibrium if additional AgCl(s) is added?
- (c) What is the effect on  $P_{\text{NH}_3}$  at equilibrium if additional NH<sub>3</sub>(g) is pumped into or out of the system, provided that neither of the two solid phases shown in the chemical equation is completely used up?
- (d) What is the effect on  $P_{\text{NH}_3}$  of lowering the temperature?
112. Solid ammonium carbonate decomposes according to the equation

At a certain elevated temperature the total pressure of the gases NH<sub>3</sub>, CO<sub>2</sub>, and H<sub>2</sub>O generated by the decomposition of, and at equilibrium with, pure solid ammonium carbonate is 0.400 atm. Calculate the equilibrium constant for the reaction considered. What would happen to  $P_{\text{NH}_3}$  and  $P_{\text{CO}_2}$  if  $P_{\text{H}_2\text{O}}$  were adjusted by external means to be 0.200 atm without changing the relative amounts of NH<sub>3</sub>(g) and CO<sub>2</sub>(g) and with (NH<sub>4</sub>)<sub>2</sub>CO<sub>3</sub>(s) still being present?

Many naturally occurring dyes change color as the acidity of their surroundings changes. The compound cyanidin is blue in the basic sap of the cornflower and red in the acidic sap of the poppy. Such dyes can be used as indicators of the degree of acidity in a medium.

According to Section 11.3, an acid is a substance that upon dissolving in water increases the concentration of hydronium ( $\text{H}_3\text{O}^+$ ) ions above the value found in pure water, and a base is a substance that increases the concentration of hydroxide ( $\text{OH}^-$ ) ions above its value in pure water. Despite this carefully phrased definition, it is commonplace to describe acids as substances that dissociate to give protons (which upon hydration become hydronium ions) and bases as substances that dissociate to give hydroxide ions. If the dissociation is complete, we can easily calculate the concentration of hydronium and hydroxide ions in the solution and then calculate the yield of acid–base neutralization reactions, and acid–base titrations, by the methods of stoichiometry in solution. But experience shows that many acid–base reactions do not go to completion. So, to predict the amount (or concentration) of their products, we have to use the ideas and methods of chemical equilibrium developed in Chapter 14. The present chapter deals

with this fundamental aspect of acid–base chemistry which is key to its applications in the physical and biological sciences, in engineering, and in medicine: How far do acid–base reactions proceed before reaching equilibrium?

The reactions of acids and bases lie at the heart of nearly all branches of chemistry. Many acid–base reactions occur in the gaseous and solid states and in nonaqueous solutions. This chapter focuses on acid–base reactions in aqueous solutions, which play important roles in everyday life. Vinegar, orange juice, and battery fluid are familiar acidic aqueous solutions. Basic solutions are produced when such common products as borax, baking soda, and antacids are dissolved in water. Acid–base chemistry will appear many times throughout the rest of this book. We consider the effects of acidity on the dissolution of solids in Chapter 16, on redox reactions in electrochemical cells in Chapter 17, and on the rates of reaction in Chapter 18. At the end of this chapter we relate acid strength to molecular structure in organic acids, and in Chapter 23 we point out the central roles of amino acids and nucleic acids in biochemistry.

## 15.1 Classifications of Acids and Bases

### 15.1.1 Arrhenius Acids and Bases

**FIGURE 15.1** The structure of the hydronium ion ( $\text{H}_3\text{O}^+$ ) in the gas phase.

In Section 11.3 we described the Arrhenius definition of acids and bases. An **acid** is a substance that when dissolved in water increases the concentration of hydronium ion ( $\text{H}_3\text{O}^+$ ) above the value it takes in pure water. A **base** increases the concentration of hydroxide ion ( $\text{OH}^-$ ). Arrhenius acids and bases typically release ions into the solution. Throughout this chapter, we will use the hydronium ion (Fig. 15.1) to better represent the true nature of hydrogen ions in water. The hydronium ion may have as many as four molecules of water attached to it by hydrogen bonding. (See Section 10.3.) Depending upon the specific context we refer to this species as the hydrogen ion, the proton, or the hydronium ion in this chapter.

The Arrhenius model views acid–base neutralization as an exchange reaction in which the  $\text{H}^+$  from the acid and the  $\text{OH}^-$  from the base separate from their original bonding partners and combine to form the neutral water molecule, and the original bonding partners combine to form a salt. (See Section 11.3.)

The Arrhenius model also describes other familiar reactions of the acids. Three broad types summarize the results of a very large number of reactions:

1. Acids react with carbonates and hydrogen carbonates such as  $\text{Na}_2\text{CO}_3$  or  $\text{NaHCO}_3$  to liberate gaseous  $\text{CO}_2$  and produce a salt and water. An example reaction is

Notice that in the *net ionic* version of the reaction above, it is recognized that because  $\text{HCl}$  is a strong acid,  $\text{HCl}(aq)$  is really  $\text{H}_3\text{O}^+(aq) + \text{Cl}^-(aq)$ , and the  $\text{Cl}^-$  is canceled from both sides to write the net ionic reaction of sodium carbonate with hydrochloric acid.

2. Acids react with oxides of metals to form salts and water. An example reaction is

**FIGURE 15.2** As zinc dissolves in dilute hydrochloric acid, bubbles of hydrogen appear, and zinc chloride forms in solution.

© Cengage Learning/Leon Levandowski

3. Acids react with zinc, iron, and many metal elements to generate gaseous  $\text{H}_2$  and form salts (Fig. 15.2). An example reaction is

In the first example, hydrogen ions in the solution react with the carbonate or the hydrogen carbonate ions to form carbonic acid ( $\text{H}_2\text{CO}_3$ ), which decomposes to produce water and carbon dioxide. The  $\text{CO}_2$  has very limited solubility in water and escapes as gas bubbles.

In the second example, hydrogen ions in the solution are attracted to the negative charge on the oxide ions at the surface of the solid, and react with these ions to produce molecules of  $\text{H}_2\text{O}$ . The metal ions are freed from the solid into the solution.

In the third example, hydrogen ions are displaced from the solution by so-called “active metals.” This reaction will be discussed in detail in Chapter 17.

The first example illustrates a key aspect of acid–base reactions: A proton is transferred from a molecule defined to be the acid,  $\text{H}_3\text{O}^+$ , to an acceptor molecule  $\text{HCO}_3^-$ . Proton transfer reactions in which the acceptor is some species other than  $\text{OH}^-$  are common throughout organic chemistry, inorganic chemistry, and biochemistry. Proton transfer reactions may occur in solvents other than water, and even in the gaseous and solid states. All these diverse reactions can be organized and discussed systematically by using generalized definitions of acids and bases, which include the Arrhenius definition as a limiting case. We describe these more general definitions as background for discussing acid–base equilibria for very broad classes of compounds. The first of these models was proposed independently by Johannes Brønsted and Thomas Lowry in 1923, and the second was introduced by G. N. Lewis in the same year.

### 15.1.2 Brønsted–Lowry Acids and Bases

A **Brønsted–Lowry acid** is defined as a substance that can *donate* a proton, and a **Brønsted–Lowry base** is a substance that can *accept* a proton. In a Brønsted–Lowry acid–base reaction, a proton is transferred from the acid to the base. For example, when acetic acid is dissolved in water, an acid–base reaction occurs in which protons are transferred from acetic acid molecules to water molecules:

The net result is the transfer of a proton from acetic acid to water to form the hydronium ion  $\text{H}_3\text{O}^+(aq)$  (Fig. 15.1).

Examination of ball-and-stick models and Lewis electron diagrams for the molecules gives some sense of how this reaction occurs. Acetic acid molecules and water molecules experience numerous collisions while diffusing through solution. In some fraction of these collisions the molecules happen to be positioned so the  $\text{O}-\text{H}$  bond on the acetic acid and the  $\text{O}$  atom on the water molecule are nearly in a straight line. Some fraction of these specially aligned collisions occur with sufficient kinetic energy to push these three atoms and all their electrons quite close together, distort the structure of the molecules, and

increase their potential energy. This highly energetic configuration of the two molecules can relax by rearranging the electron density around the nuclei to form a new stable state with lower potential energy, in which the bonds in the molecules have been rearranged. It appears that a proton ( $\text{H}^+$ ) is released from the hydroxyl group ( $\text{O}-\text{H}$ ) of acetic acid and attaches itself to a lone pair on the water molecule, forming the new covalent bond in the product hydronium ion and freeing the bonding pair in the hydroxyl group to form the acetate ion. The net result of these proton transfer reactions is the conversion of a bonding electron pair in acetic acid to a nonbonding pair in the acetate ion and a conversion of one of the nonbonding pairs of electrons in the reactant water molecule to a covalently shared pair in the new  $\text{O}-\text{H}$  bond in the hydronium ion ( $\text{H}_3\text{O}^+$ )(aq). In fact we cannot claim to track the motions of any specific electron pairs during this reaction; we know from Chapters 4 through 6 that quantum mechanics does not allow us to know that level of detail. Nonetheless, the description of this reaction as the result of the redistribution of two electron pairs that breaks the  $\text{O}-\text{H}$  bond in acetic acid and forms a new  $\text{O}-\text{H}$  bond in the hydronium ion is a convenient, visual summary of the events that occur in the reaction.

Acids and bases occur as **conjugate acid–base pairs**, which are related by transfer of a proton. In an acid–base reaction, the acid donates a proton to the base and in the process is converted to its conjugate base. The base accepts the proton and is converted to its conjugate acid. In the preceding example, acetic acid  $\text{CH}_3\text{COOH}$  and the acetate anion  $\text{CH}_3\text{COO}^-$  form such a pair, in which  $\text{CH}_3\text{COO}^-$  is the conjugate base of  $\text{CH}_3\text{COOH}$  (equivalently,  $\text{CH}_3\text{COOH}$  is the conjugate acid of  $\text{CH}_3\text{COO}^-$ ). In the same reaction,  $\text{H}_3\text{O}^+$  and  $\text{H}_2\text{O}$  form a conjugate acid–base pair, where  $\text{H}_2\text{O}$  is the base and  $\text{H}_3\text{O}^+$  is its conjugate acid. The equilibrium state of an acid–base reaction will include the acid and its conjugate base, as well as the base and its conjugate acid. It is useful to picture this equilibrium as the competition between two bases for hydrogen ions. For example, when ammonia is dissolved in water,

the two bases  $\text{NH}_3$  and  $\text{OH}^-$  compete for hydrogen ions to determine the equilibrium position of the reaction.

Unlike the Arrhenius definition, the Brønsted–Lowry definition has the advantage of not being limited to aqueous solutions, and is used to describe proton transfer reactions in nonaqueous solvents. An example with liquid ammonia as the solvent is

The  $\text{NH}_3$  acts as both base and solvent, just as  $\text{H}_2\text{O}$  acts as both base and solvent in the proton transfer reaction with acetic acid discussed above.

Some molecules and ions function either as acids or bases depending on reaction conditions and are called **amphoteric**. The most common example is water itself. Water acts as an acid when donating a proton to  $\text{NH}_3$  (the conjugate base of water being  $\text{OH}^-$ ) and as a base in accepting a hydrogen ion from  $\text{CH}_3\text{COOH}$  (the conjugate acid of water being  $\text{H}_3\text{O}^+$ ). In the same way, the hydrogen carbonate ion can act as an acid

or as a base:

Many examples of proton transfer reactions found in organic chemistry and biochemistry are described by the Brønsted–Lowry model. The various organic functional groups defined in Chapter 7 can participate in these reactions. Ethane ( $\text{CH}_3\text{CH}_3$ ) is an extremely weak acid (see later) that can donate a proton to form its conjugate base  $\text{CH}_3\text{CH}_2^-$ , an example of a carbanion, a species that plays an important role in organic reaction mechanisms. Ethanol ( $\text{CH}_3\text{CH}_2\text{OH}$ ) can donate a proton to form its conjugate base  $\text{CH}_3\text{CH}_2\text{O}^-$ , but in this anion the extra electron is localized primarily on the O atom, not a C atom. The carboxylic acids, of which acetic acid is an example, can give up the proton that is bonded to O (the so-called acidic proton) to form their anionic conjugated bases. Methylamine ( $\text{CH}_3\text{NH}_2$ ) can accept a proton to form its conjugate acid the methylammonium ion ( $\text{CH}_3\text{NH}_3^+$ ). The acid–base behavior of organic molecules is discussed in some detail in Section 15.8.

### EXAMPLE 15.1

The following two reactions involve proton transfer. In each reaction, identify the acid and the base. Identify the conjugate base of the acid, and the conjugate acid of the base. Draw Lewis electron dot diagrams for each molecule, and describe the rearrangement of bonding in the reaction as nonbonding electron pairs become covalently shared pairs and vice versa.

#### Solution

- (a) The ammonium ion is the acid, and water is the base. A proton ( $\text{H}^+$ ) is released from the ammonium ion and attaches itself to a lone pair on the water molecule to form the new covalent bond in the species  $\text{H}_3\text{O}^+$ , the conjugate acid of water (the base). The reaction converts one of the original N–H bonding pairs into a lone (nonbonding) pair forming  $\text{NH}_3$ , the conjugate base of  $\text{NH}_4^+$  (the acid).

- (b) Ethanol is the acid and amide ion is the base. A proton ( $\text{H}^+$ ) is released from ethanol and attaches itself to a lone pair on the amide ion, producing ammonia (the conjugate acid of the amide ion) and the ethoxide ion (the conjugate base of ethanol). An electron pair that was originally a covalently shared pair in ethanol becomes a nonbonding electron pair in the conjugate base of ethanol as the  $\text{H}^+$  moves over to accept (bond to) the nonbonding electron pair in  $\text{NH}_2^-$ . We use this language of *accepting an electron pair* for the  $\text{H}^+$  to motivate the Lewis definition of acids and bases in the next section.

**Related Problems: 1, 2, 3, 4**

## 15.1.3 Lewis Acids and Bases

The Lewis model (Chapter 3), which focuses on the electron pair bond, provides a more general definition of acid–base behavior, of which the Arrhenius and Brønsted–Lowry definitions are special cases. Examination of the Lewis electron dot diagrams for molecules in a typical Brønsted–Lowry acid–base reaction shows that two bases compete for a proton by offering electron pairs that can be accepted by the proton to form new bonds.

A **Lewis base** is any species that donates lone-pair electrons, and a **Lewis acid** is any species that accepts such electron pairs. The Brønsted–Lowry acids and bases considered so far fit this description (with the Lewis acid,  $\text{H}^+$ , acting as an acceptor toward various Lewis bases such as  $\text{NH}_3$  and  $\text{OH}^-$ , the electron pair donors). The Lewis acid–base model is much more general than the Brønsted–Lowry model because it applies to other reactions that do *not* involve hydrogen ion transfers. An example is the reaction between electron-deficient  $\text{BF}_3$  and electron-rich  $\text{NH}_3$ .

Here ammonia, the Lewis base, donates lone-pair electrons to  $\text{BF}_3$ , the Lewis acid or electron acceptor. The pair of electrons donated by the Lewis base is not removed from its valence shell but instead is shared with the Lewis acid to form a new covalent bond. The bond that forms is called a **coordinate covalent bond** (or a **dative bond**, see Section 8.2) in which both electrons are provided by a lone pair on the Lewis base.

Octet-deficient compounds involving elements of Group III, such as boron and aluminum, are often strong Lewis acids because Group III atoms (electron pair acceptors) can achieve octet configurations by forming coordinate covalent bonds with electron pair donors such as atoms and ions from Groups V through VII. Compounds of main-group elements from the later periods can also act as Lewis acids because they can accept (or share) additional electrons through valence shell expansion (see Section 3.9). In such reactions the central atom accepts a share in additional lone pairs beyond the eight electrons needed to satisfy the octet rule. For example,  $\text{SnCl}_4$  is a Lewis acid that accepts electron pairs from two chloride ions to form  $\text{SnCl}_6^{2-}$  as follows:

After the reaction, each tin atom is surrounded by 12 rather than 8 valence electrons.

**EXAMPLE 15.2**

In the following reactions, identify the Lewis acid and the Lewis base.

**Solution**

(a) In  $\text{AlCl}_3$  the Al atom has only six valence electrons. Thus  $\text{AlCl}_3$  acts as a Lewis acid to accept electrons from the lone pairs on the Lewis base  $\text{Cl}^-$ .

(b) The Lewis base  $\text{NH}_3$  donates a lone pair of electrons to form a coordinate covalent bond with the proton from acetic acid. The proton is the Lewis acid, not the acetic acid.

(c) The transition metal ion  $\text{Co}^{3+}$  is the Lewis acid, accepting electron pairs from the Lewis bases, the  $\text{F}^-$  ions, to form coordinate covalent bonds.

**Related Problems: 5, 6, 7, 8**

The Lewis definition systematizes the chemistry of a great many binary oxides, which can be considered to be anhydrides of acids or bases. An **acid anhydride** is obtained by removing water from an oxoacid (see Section 11.3) until only the oxide remains; thus,  $\text{CO}_2$  is the anhydride of carbonic acid ( $\text{H}_2\text{CO}_3$ ).

**EXAMPLE 15.3**

What is the acid anhydride of phosphoric acid ( $\text{H}_3\text{PO}_4$ )?

**Solution**

If the formula unit  $\text{H}_3\text{PO}_4$  (which contains an odd number of hydrogen atoms) is doubled,  $\text{H}_6\text{P}_2\text{O}_8$  is obtained. Subtraction

of 3  $\text{H}_2\text{O}$  from this gives  $\text{P}_2\text{O}_5$ , which is the empirical formula of tetraphosphorus decaoxide ( $\text{P}_4\text{O}_{10}$ ). This compound is the acid anhydride of phosphoric acid.

**Related Problems: 9, 10**

The oxides of most of the nonmetals are acid anhydrides, which react with an excess of water to form acidic solutions. Examples include

Silica ( $\text{SiO}_2$ ) is the acid anhydride of the very weak silicic acid  $\text{H}_2\text{SiO}_3$ , a gelatinous material that is insoluble in water but readily dissolves in strongly basic aqueous solutions according to

An oxide of Group I and II metals is a **base anhydride**, obtained by removing water from the corresponding hydroxides. Calcium oxide,  $\text{CaO}$ , is the base anhydride of calcium hydroxide,  $\text{Ca}(\text{OH})_2$ . The removal of water from  $\text{Ca}(\text{OH})_2$  is the reverse of the addition of water to the oxide:

The base anhydride of  $\text{NaOH}$  is  $\text{Na}_2\text{O}$ . Oxides of metals in the middle groups of the periodic table (III through V) lie on the border between ionic and covalent compounds and are frequently amphoteric. An example is aluminum

**FIGURE 15.3** Among the oxides of the main-group elements, acidity tends to increase from left to right and from bottom to top in the periodic table. Oxygen difluoride is only weakly acidic, however. Oxides shown in light blue are derived from metals, those in dark blue from metalloids, and those in dark red from nonmetals.

oxide (Al<sub>2</sub>O<sub>3</sub>), which dissolves to only a limited extent in water but much more readily in either acids or bases:

Figure 15.3 summarizes the acid–base character of the main-group oxides in the first periods.

Although oxoacids and hydroxides are Arrhenius acids and bases (they release H<sub>3</sub>O<sup>+</sup>(aq) or OH<sup>−</sup>(aq) into aqueous solution), acid and base anhydrides do not fall into this classification because they contain neither H<sup>+</sup> nor OH<sup>−</sup> ions. Acid anhydrides are acids in the Lewis sense, (they accept electron pairs), and base anhydrides are bases in the Lewis sense, (their O<sup>2−</sup> ions donate electron pairs). The reaction between an acid anhydride and a base anhydride is then a Lewis acid–base reaction. An example of such a reaction is

Here, the Lewis base CaO donates an electron pair (one of the lone pairs of the oxygen atom) to the Lewis acid (CO<sub>2</sub>) to form a coordinate covalent bond in the resulting ion. Similar Lewis acid–base reactions can be written for other acid–base anhydride pairs. Sulfur trioxide, for example, reacts with metal oxides to form sulfates:

Note that these reactions are not redox reactions (oxidation numbers do not change), nor are they acid–base reactions in the Arrhenius or Brønsted–Lowry sense. But they are usefully classified as acid–base reactions in the Lewis sense.

### 15.1.4 Comparison of Arrhenius, Brønsted–Lowry, and Lewis Definitions

The neutralization reaction between HCl and NaOH,

introduced in Section 11.3 shows the progressive generality in these definitions. By the Arrhenius definition, HCl is the acid and NaOH is the base. By the Brønsted–Lowry definition, H<sub>3</sub>O<sup>+</sup> is the acid and OH<sup>−</sup> is the base. According to the Lewis model, H<sup>+</sup> is the acid and OH<sup>−</sup> is the base, because the proton accepts the lone pair donated by hydroxide ion in the reaction

## 15.2 Properties of Acids and Bases in Aqueous Solutions: The Brønsted–Lowry Scheme

Chapters 10 and 11 describe the special properties of liquid water. Because of its substantial dipole moment, water is especially effective as a solvent, stabilizing both polar and ionic solutes. In acid–base reactions water is not only the solvent, but also participates as a reactant. Water plays an integral role in virtually all biochemical reactions essential to the survival of living organisms; these reactions involve acids, bases, and ionic species. In view of the wide-ranging importance of these reactions, we devote the remainder of this chapter to acid–base behavior and related ionic reactions in aqueous solution. The Brønsted–Lowry definition of acids and bases is especially well suited to describe these reactions.

### 15.2.1 Autoionization of Water

Water can act as both acid and base in the same reaction. The resulting equilibrium is

or

This reaction is called the **autoionization of water**, which leads to small but measurable concentrations of hydronium and hydroxide ions at equilibrium. The equilibrium expression for this reaction is

$$[\text{H}_3\text{O}^+][\text{OH}^-] = K_w \quad [15.1]$$

Note that we have omitted the subscript eq for simplicity; the concentrations in this and all equilibrium constant expressions are equilibrium ones. The equilibrium constant for this particular reaction has a special symbol:  $K_w$ , and a special name, the **ion product constant for water**; its value is  $1.0 \times 10^{-14}$  at 25°C. Because the liquid water appears in this equilibrium reaction equation as a pure substance, it is considered already to be in its reference state, and therefore contributes only the factor 1 to the mass action law equilibrium expression. The reasons for this are discussed more fully in Sections 14.2 and 14.3. The temperature dependence of  $K_w$  is given in Table 15.1; all problems in this chapter are assumed to refer to 25°C unless otherwise stated.

Pure water contains no ions other than  $\text{H}_3\text{O}^+$  and  $\text{OH}^-$ , and to maintain overall electrical neutrality, an equal number of ions of each type must be present. Putting these facts into the equilibrium expression Equation 15.1 gives

$$\begin{aligned} [\text{H}_3\text{O}^+] &= [\text{OH}^-] = y \\ y^2 &= 1.0 \times 10^{-14} \\ y &= 1.0 \times 10^{-7} \end{aligned}$$

so that in pure water at 25°C the concentrations of both  $\text{H}_3\text{O}^+$  and  $\text{OH}^-$  are  $1.0 \times 10^{-7}$  M.

TABLE 15.1

Temperature Dependence of  $K_w$

$T(^{\circ}\text{C})$	$K_w$	pH of Water
0	$0.114 \times 10^{-14}$	7.47
10	$0.292 \times 10^{-14}$	7.27
20	$0.681 \times 10^{-14}$	7.08
25	$1.01 \times 10^{-14}$	7.00
30	$1.47 \times 10^{-14}$	6.92
40	$2.92 \times 10^{-14}$	6.77
50	$5.47 \times 10^{-14}$	6.63
60	$9.61 \times 10^{-14}$	6.51

## 15.2.2 Strong Acids and Bases

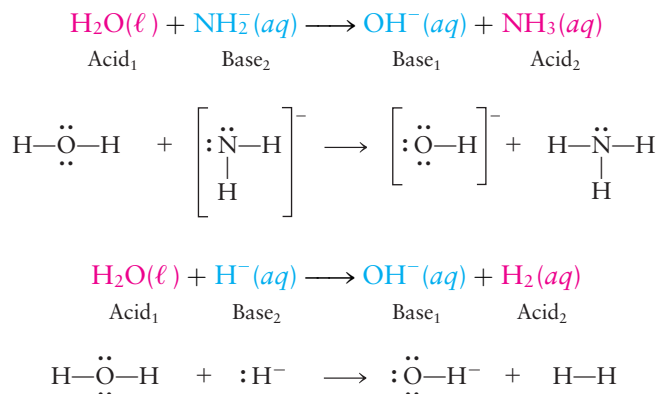

An aqueous acidic solution contains an excess of  $\text{H}_3\text{O}^+$  over  $\text{OH}^-$  ions. A **strong acid** is one that ionizes almost completely in aqueous solution. When the strong acid HCl (hydrochloric acid) is put in water, the reaction

occurs. A single rather than a double arrow indicates that the reaction is essentially complete. (*Note:* Although we use this convention in Sections 15.2, 15.3, and 15.4, we often simply use single arrows in the rest of this chapter and subsequent chapters even when the equilibrium constant favors reactants.) Another strong acid is perchloric acid ( $\text{HClO}_4$ ). (See Table 11.1.) If 0.10 mol of either of these acids is dissolved in enough water to make 1.0 L of solution, 0.10 M concentration of  $\text{H}_3\text{O}^+(\text{aq})$  results. Because the acid–base properties of solutions are determined by their concentrations of  $\text{H}_3\text{O}^+(\text{aq})$ , these two strong acids have the same effect in water despite differences we shall see shortly in their intrinsic abilities to donate hydrogen ions. Water is said to have a **leveling effect** on a certain group of acids ( $\text{HCl}$ ,  $\text{HBr}$ ,  $\text{HI}$ ,  $\text{H}_2\text{SO}_4$ ,  $\text{HNO}_3$ , and  $\text{HClO}_4$ ) because they all behave as strong acids when water is the solvent. The reactions of these acids with water all lie so far to the right at equilibrium that the differences between the acids are negligible. The concentration of  $\text{H}_3\text{O}^+$  in a 0.10 M solution of *any* strong acid that donates one hydrogen ion per molecule is simply 0.10 M. We use this result in Equation 15.1 to obtain the  $\text{OH}^-$  concentration

$$[\text{OH}^-] = \frac{K_w}{[\text{H}_3\text{O}^+]} = \frac{1.0 \times 10^{-14}}{0.10} = 1.0 \times 10^{-13} \text{ M}$$

In the same fashion, we define a **strong base** as one that reacts essentially completely to give  $\text{OH}^-(\text{aq})$  ion when put in water. The amide ion ( $\text{NH}_2^-$ ) and the hydride ion ( $\text{H}^-$ ) are both strong bases. For every mole per liter of either of these ions that is added to water, one mole per liter of  $\text{OH}^-(\text{aq})$  forms. Note that the other products in these reactions are aqueous  $\text{NH}_3$  and  $\text{H}_2$ , respectively:

The important base sodium hydroxide, an ionic solid, increases the  $\text{OH}^-$  concentration in water when it dissolves:

For every mole of NaOH that dissolves in water, one mole of  $\text{OH}^-(aq)$  forms, so NaOH is a strong base. Strong bases are leveled in aqueous solution in the same way that strong acids are leveled. If 0.10 mol of NaOH or  $\text{NH}_2^-$  or  $\text{H}^-$  is put into enough water to make 1.0 L of solution, then in every case

$$[\text{OH}^-] = 0.10 \text{ M}$$

$$[\text{H}_3\text{O}^+] = \frac{1.0 \times 10^{-14}}{0.10} = 1.0 \times 10^{-13} \text{ M}$$

**FIGURE 15.4** A simple pH meter with a digital readout. Most soft drinks are quite acidic due to the reaction of dissolved  $\text{CO}_2$  with water to make carbonic acid ( $\text{H}_2\text{CO}_3$ ).

The  $\text{OH}^-$  contribution from the autoionization of water is negligible here, as was the contribution of  $\text{H}_3\text{O}^+$  from autoionization in the 0.10 M HCl and  $\text{HClO}_4$  solutions. When only a very small amount of strong acid or base is added to pure water (for example,  $10^{-7} \text{ mol L}^{-1}$ ), we have to include the autoionization of water to describe the concentration of hydronium and hydroxide ions accurately.

### 15.2.3 The pH Function

In aqueous solution the concentration of hydronium ion can range from 10 M to  $10^{-15} \text{ M}$ . It is convenient to compress this enormous range by introducing a logarithmic acidity scale, called **pH** and defined by

$$\text{pH} = -\log_{10} [\text{H}_3\text{O}^+] \quad [15.2]$$

Pure water at 25°C has  $[\text{H}_3\text{O}^+] = 1.0 \times 10^{-7} \text{ M}$ , so

$$\text{pH} = -\log_{10} (1.0 \times 10^{-7}) = -(-7.00) = 7.00$$

A 0.10 M solution of HCl has  $[\text{H}_3\text{O}^+] = 0.10 \text{ M}$ , so

$$\text{pH} = -\log_{10} (0.10) = -\log_{10} (1.0 \times 10^{-1}) = -(-1.00) = 1.00$$

and at 25°C a 0.10 M solution of NaOH has

$$\text{pH} = -\log_{10} \left( \frac{1.0 \times 10^{-14}}{0.10} \right) = -\log_{10} (1.0 \times 10^{-13}) = -(-13.00) = 13.00$$

As these examples show, calculating the pH is especially easy when the concentration of  $\text{H}_3\text{O}^+$  is exactly a power of 10, because the logarithm is then just the power to which 10 is raised. In other cases we need a calculator. When we know the pH, we calculate the concentration of  $\text{H}_3\text{O}^+$  by raising 10 to the power ( $-\text{pH}$ ).

Because the most commonly encountered  $\text{H}_3\text{O}^+$  concentrations are less than 1 M, the negative sign is put in the definition of the pH function to give a positive value in most cases. A *high* pH means a *low* concentration of  $\text{H}_3\text{O}^+$  and vice versa. At 25°C,

$$\text{pH} < 7 \quad \text{Acidic solution} \quad [15.3a]$$

$$\text{pH} = 7 \quad \text{Neutral solution} \quad [15.3b]$$

$$\text{pH} > 7 \quad \text{Basic solution} \quad [15.3c]$$

**FIGURE 15.5** Many everyday materials are acidic or basic aqueous solutions with a wide range of pH values.

At other temperatures the pH of water differs from 7.00 (see Table 15.1). A change of one pH unit implies that the concentrations of  $\text{H}_3\text{O}^+$  and  $\text{OH}^-$  change by a factor of 10 (that is, one order of magnitude). The pH is most directly measured with a **pH meter** (Fig. 15.4). The mechanism by which pH meters operate is described in Chapter 17. Figure 15.5 shows the pH values for several common fluids.

## EXAMPLE 15.4

- (a) A solution is prepared by dissolving 0.23 mol of NaH(s) in enough water to form 2.8 L of solution. Calculate its pH.
- (b) The pH of some orange juice at 25°C is 2.85. Calculate  $[\text{H}_3\text{O}^+]$  and  $[\text{OH}^-]$ .

## Solution

- (a) Because  $\text{H}^-$  is a strong base, it reacts to give 0.23 mol of  $\text{OH}^-$ :

The concentration is

$$[\text{OH}^-] = \frac{0.23 \text{ mol}}{2.8 \text{ L}} = 8.2 \times 10^{-2} \text{ M}$$

$$[\text{H}_3\text{O}^+] = \frac{1.0 \times 10^{-14}}{8.2 \times 10^{-2}} = 1.22 \times 10^{-13} \text{ M}$$

The pH is then

$$\text{pH} = -\log_{10} (1.22 \times 10^{-13}) = 12.91$$

(b) 
$$\text{pH} = 2.85 = -\log_{10} [\text{H}_3\text{O}^+]$$

$$[\text{H}_3\text{O}^+] = 10^{-2.85}$$

This can be evaluated by using a calculator to give

$$[\text{H}_3\text{O}^+] = 1.4 \times 10^{-3} \text{ M}$$

$$[\text{OH}^-] = \frac{1.0 \times 10^{-14}}{1.4 \times 10^{-3}} = 7.1 \times 10^{-12}$$

Related Problems: 13, 14, 15, 16

## 15.3 Acid and Base Strength

Acids are classified as strong or weak, depending on the extent to which they are ionized in solution. In a **weak acid** the transfer of hydrogen ions to water does not proceed to completion. A weak acid such as acetic acid is thus also a **weak electrolyte**; its aqueous solutions do not conduct electricity as well as a strong acid of the same concentration because fewer ions are present. A weak acid shows smaller values for colligative properties than a strong acid (recall the effect of dissolved acetic acid on the freezing point of water in Fig. 11.20).

The Brønsted–Lowry theory helps to establish a quantitative scale for acid strength. The ionization of an acid (symbolized by “HA”) in aqueous solution can be written as

where  $\text{A}^-$  is the conjugate base of HA. The equilibrium expression for this chemical reaction (see Section 14.2) is

$$\frac{[\text{H}_3\text{O}^+][\text{A}^-]}{[\text{HA}]} = K_a \quad [15.4]$$

where the subscript “a” stands for “acid.”<sup>1</sup> For example, if the symbol  $\text{A}^-$  refers to the cyanide ion ( $\text{CN}^-$ ), we write

$$\frac{[\text{H}_3\text{O}^+][\text{CN}^-]}{[\text{HCN}]} = K_a$$

where  $K_a$  is the **acid ionization constant** for hydrogen cyanide (Fig. 15.6) in water and has a numerical value of  $6.17 \times 10^{-10}$  at 25°C. Table 15.2 gives values of  $K_a$ , and the useful quantity  $\text{p}K_a = -\log_{10} K_a$ , for a number of important acids. The acid ionization constant is a quantitative measure of the strength of the acid in a particular solvent (in the present case, water). Because a weak acid does not

**FIGURE 15.6** Hydrogen cyanide, HCN, is a highly toxic gas that dissolves in water to form equally toxic solutions of hydrocyanic acid.

<sup>1</sup> $\text{H}_2\text{O}(\ell)$  is in its reference state, so it contributes the factor 1 (see Sections 14.2 and 14.3).

(1), (2), and (3) indicate the first, second, and third ionization constants, respectively.

react completely with the solvent, the concentrations of the products are low at equilibrium, and K<sub>a</sub> is small. A strong acid reacts nearly completely so the concentration of HA in the denominator is nearly 0, and K<sub>a</sub> is large. Determining the value of K<sub>a</sub> for strong acids is difficult because the concentration of HA is too small to be measured accurately. Relative acid strengths for such strong acids are estimated by using a solvent that is a weaker base than water. If the solvent is a sufficiently weak base (i.e., has significantly less tendency to accept H<sup>+</sup> than does H<sub>2</sub>O), a relatively strong acid may not dissociate completely. For example, in the solvent diethyl ether (C<sub>2</sub>H<sub>5</sub>OC<sub>2</sub>H<sub>5</sub>), HCl is a weaker proton donor than HClO<sub>4</sub>. Therefore HCl is a weaker acid than HClO<sub>4</sub>.

**FIGURE 15.7** The relative strengths of some acids and their conjugate bases.

The strength of a base is inversely related to the strength of its conjugate acid; the weaker the acid, the stronger its conjugate base, and vice versa. This fact is demonstrated by the values in Figure 15.7. We can see the origin of this fact by writing the equation for the ionization of a base such as ammonia in water in the form

which gives an equilibrium expression of the form

$$\frac{[\text{NH}_4^+][\text{OH}^-]}{[\text{NH}_3]} = K_b$$

where the subscript “b” on  $K_b$  stands for “base.” Because  $[\text{OH}^-]$  and  $[\text{H}_3\text{O}^+]$  are related through the water autoionization equilibrium expression

$$[\text{OH}^-][\text{H}_3\text{O}^+] = K_w$$

the  $K_b$  expression can be written as

$$K_b = \frac{[\text{NH}_4^+]K_w}{[\text{NH}_3][\text{H}_3\text{O}^+]} = \frac{K_w}{K_a}$$

where  $K_a$  is the acid ionization constant for  $\text{NH}_4^+$ , the conjugate acid of the base  $\text{NH}_3$ . This general relationship between the  $K_b$  of a base and the  $K_a$  of its conjugate acid shows that  $K_b$  need not be tabulated separately from  $K_a$ , because the two are related through

$$K_w = K_a K_b \quad [15.5]$$

Equation 15.5 is the basis of the inverse relationship between the strength of a base and its conjugate acid illustrated in Figure 15.7. Taking the logarithm of both sides of the equation and multiplying through by  $-1$  shows that

$$\text{p}K_a + \text{p}K_b = \text{p}K_w$$

for a conjugate acid–base pair. This equation shows the inverse relationship in terms of  $\text{p}K$  values: the weaker the acid ( $\text{p}K_a$  large,  $K_a$  small), the stronger the conjugate base ( $\text{p}K_b$  small,  $K_b$  large). When values are needed for  $K_b$  or  $\text{p}K_b$ , they can be easily calculated from the tabulated values for  $K_a$  and  $\text{p}K_a$ . For example, we obtain the value of  $K_b$  for ammonia ( $\text{NH}_3$ ) from the  $K_a$  value for the ammonium ion ( $\text{NH}_4^+$ ) in Table 15.2:

$$K_{b,\text{NH}_3} = \frac{K_w}{K_{a,\text{NH}_4^+}} = \frac{1.0 \times 10^{-14}}{5.6 \times 10^{-10}} = 1.8 \times 10^{-5}$$

The ammonium ion is a very weak acid. Its conjugate base ammonia is a moderately weak base.

When two bases compete for protons, the stronger base dominates the equilibrium state in the sense that it holds the larger fraction of protons and is therefore present in a lesser amount in its basic form at equilibrium. The stronger acid donates hydrogen ions to the stronger base, producing a weaker acid and a weaker base at equilibrium. To see this consider the equilibrium

with equilibrium constant

$$\frac{[\text{HCN}][\text{F}^-]}{[\text{HF}][\text{CN}^-]} = K$$

The two bases  $\text{F}^-$  and  $\text{CN}^-$  compete for hydrogen ions. We can construct this net reaction by starting with one acid ionization reaction,

$$\frac{[\text{H}_3\text{O}^+][\text{F}^-]}{[\text{HF}]} = K_a = 6.6 \times 10^{-4}$$

and *subtracting* from it a second acid ionization reaction:

$$\frac{[\text{H}_3\text{O}^+][\text{CN}^-]}{[\text{HCN}]} = K'_a = 6.17 \times 10^{-10}$$

When the net reaction is the difference of two reactions, the equilibrium constant for the net reaction is the ratio of those for the separate reactions. (Section 14.4) The numerical value of  $K$  is

$$K = \frac{K_a}{K'_a} = \frac{6.6 \times 10^{-4}}{6.17 \times 10^{-10}} = 1.1 \times 10^6$$

**FIGURE 15.8** Hydrogen fluoride, HF, is a colorless liquid that boils at 19.5°C. It dissolves in water to give solutions of hydrofluoric acid, a weak acid.

Because HCN is a weaker acid than HF (Fig. 15.8),  $K'_a$  is smaller than  $K_a$ , and  $K$  is larger than 1. The equilibrium described by  $K$  lies strongly to the right. Most of the hydrogen ions end up associated with  $\text{CN}^-(aq)$ , the stronger base, rather than with  $\text{F}^-(aq)$ , the weaker base. The dissolved species present in greatest amount at equilibrium are  $\text{HCN}(aq)$ , which is a weaker acid than  $\text{HF}(aq)$ , and  $\text{F}^-(aq)$  which is a weaker base than  $\text{CN}^-(aq)$ .

Similar manipulations of chemical reaction equations and their associated equilibrium expressions predict the direction and extent of proton transfer in all Brønsted–Lowry acid–base reactions.

### EXAMPLE 15.5

Predict the direction of proton transfer in the reaction of acetic acid and ammonia in aqueous solution. Describe qualitatively the extent of reaction and the composition of the equilibrium state.

#### Solution

The equilibrium expression for this reaction is

$$\frac{[\text{CH}_3\text{COO}^-][\text{NH}_4^+]}{[\text{CH}_3\text{COOH}][\text{NH}_3]} = K$$

This reaction can be constructed by subtracting the second acid ionization from the first acid ionization below:

$$\frac{[\text{H}_3\text{O}^+][\text{CH}_3\text{COO}^-]}{[\text{CH}_3\text{COOH}]} = K_{a1}$$

$$\frac{[\text{H}_3\text{O}^+][\text{NH}_3]}{[\text{NH}_4^+]} = K_{a2}$$

The equilibrium constant for the net reaction is the ratio of the equilibrium constants for the separate reactions. Inserting values from Table 15.2 gives the result

$$K = \frac{K_{a1}}{K_{a2}} = \frac{1.76 \times 10^{-5}}{5.6 \times 10^{-10}} = 3.1 \times 10^4$$

The equilibrium described by  $K$  lies strongly to the right. The net result is donation of  $\text{H}^+$  by the stronger acid  $\text{CH}_3\text{COOH}(aq)$  to the stronger base  $\text{NH}_3(aq)$  to produce the weaker acid  $\text{NH}_4^+(aq)$  and the weaker base  $\text{CH}_3\text{COO}^-(aq)$ . Most of the  $\text{H}^+$  ends up associated with the  $\text{NH}_3(aq)$  rather than the  $\text{CH}_3\text{COO}^-(aq)$ . If the reaction begins with the same amounts of acetic acid and ammonia, the ratio of products to reactants in the equilibrium state is 30,000:1.

**Related Problems:** 23, 24

## 15.3.1 Molecular Structure and Acid Strength

The strength of an acid is determined by its tendency to lose a proton, converting it to its conjugate base, which is an anion. The more stable the anion, the further the reaction can proceed from left to right. Acid strength, therefore, depends on the ability of the anion to accommodate its negative charge, which increases with the electronegativity of the central atom in the anion.

**FIGURE 15.9** In part (a) the atom X is electropositive, so extra electron density (blue areas) accumulates on the OH group. The X—O bond then breaks easily, making the compound a base. In part (b) X is electronegative, so electron density is drawn from the H atom to the X—O bond. Now it is the O—H bond that breaks easily, and the compound is an acid.

Trends in the relative strength of oxoacids are explained by the influence of electronegativity and bond polarity on the ease of donating a proton. The proton donated by an **oxoacid** in aqueous solution was previously bonded to an oxygen atom in the acid molecule. Examples include sulfuric acid ( $H_2SO_4$ ), nitric acid ( $HNO_3$ ), and phosphoric acid ( $H_3PO_4$ ). If the central atom is designated X, then oxoacids have the structure

where X can be bonded to additional —OH groups, to oxygen atoms, or to hydrogen atoms. How does the strength of the oxoacid change as the electronegativity of X changes? Consider first the extreme case in which X is a highly electropositive element, such as an alkali metal. Of course, NaOH is not an acid at all, but a base. The sodium atom in Na—O—H gives up a full electron to make  $Na^+$  and  $OH^-$  ions. Because the X—O bond here is almost completely ionic, the  $OH^-$  group has a net negative charge that holds the  $H^+$  tightly to the oxygen and prevents formation of  $H^+$  ions. The less electropositive alkaline-earth elements behave similarly. They form hydroxides, such as  $Mg(OH)_2$ , that are somewhat weaker bases than NaOH but in no way act as acids.

Now suppose the central atom X becomes more electronegative, reaching values between 2 and 3, as in the oxoacids of the elements B, C, P, As, S, Se, Br, and I. As X becomes more effective at withdrawing electron density from the oxygen atom, the X—O bond becomes more covalent. This leaves less negative charge on the oxygen atom, and consequently the oxoacid releases  $H^+$  more readily (Fig. 15.9). Other things being equal, acid strength should increase with increasing electronegativity of the central atom. This trend is observed among the oxoacids listed in Table 15.2.

The strength of oxoacids with a given central element X increases with the number of lone oxygen atoms attached to the central atom. If the formula of these acids is written as  $XO_n(OH)_m$ , the corresponding acid strengths fall into distinct classes according to the value of  $n$ , the number of lone oxygen atoms (see Table 15.3). Each increase of 1 in  $n$  increases the acid ionization constant  $K_a$  by a factor of about  $10^5$ . Another way to describe this effect is to focus on the stability of the conjugate base,  $XO_{n+1}(OH)_{m-1}^-$ , of the oxoacid. The greater the number of lone oxygen atoms attached to the central atom, the more easily the net negative charge can be spread out over the ion, and therefore the more stable the base. This leads to a larger  $K_a$ .

An unusual and interesting structural result can be obtained from Table 15.3. Figure 15.10a shows the simplest Lewis diagram for phosphorous acid ( $H_3PO_3$ ) in which each atom achieves an octet configuration. Such a diagram could also be written  $P(OH)_3$  and would be analogous to  $As(OH)_3$ , which has no lone oxygen atoms bonded to the central atom ( $n = 0$ ). On the basis of this analogy, we would expect the value of  $K_a$  for  $P(OH)_3$  to be on the order of  $10^{-9}$  (a very weak acid). But in fact,  $H_3PO_3$  is only a moderately weak acid ( $K_a = 1 \times 10^{-2}$ ) and fits better into the class of acids with one lone oxygen atom bonded to the central atom. X-ray diffraction measurements support this structural conclusion inferred from

**FIGURE 15.10** (a) The simplest Lewis diagram that can be drawn for  $H_3PO_3$  gives an incorrect structure. This acid would be triprotic, like  $H_3PO_4$ . (b) The observed structure of  $H_3PO_3$  requires assigning formal charge to the P atom and the lone O atom. The hydrogen atom attached to the P is not released into acid solution, so the acid is diprotic.

TABLE 15.3

Acid Ionization Constants for Oxoacids of the Nonmetals

$X(OH)_m$ Very Weak	$K_a$	$XO(OH)_m$ Weak	$K_a$	$XO_2(OH)_m$ Strong	$K_a$	$XO_3(OH)_m$ Very Strong	$K_a$
Cl(OH)	$3 \times 10^{-8}$	$H_2PO(OH)$	$8 \times 10^{-2}$	$SeO_2(OH)_2$	$10^3$	$ClO_3(OH)$	$2 \times 10^7$
Te(OH) <sub>6</sub>	$2 \times 10^{-8}$	$IO(OH)_5$	$2 \times 10^{-2}$	$ClO_2(OH)$	$5 \times 10^2$		
Br(OH)	$2 \times 10^{-9}$	$SO(OH)_2$	$2 \times 10^{-2}$	$SO_2(OH)_2$	$1 \times 10^2$		
As(OH) <sub>3</sub>	$6 \times 10^{-10}$	$ClO(OH)$	$1 \times 10^{-2}$	$NO_2(OH)$	$2 \times 10^1$		
B(OH) <sub>3</sub>	$6 \times 10^{-10}$	$HPO(OH)_2$	$1 \times 10^{-2}$	$IO_2(OH)$	$1.6 \times 10^1$		
Ge(OH) <sub>4</sub>	$4 \times 10^{-10}$	$PO(OH)_3$	$8 \times 10^{-3}$				
Si(OH) <sub>4</sub>	$2 \times 10^{-10}$	$AsO(OH)_3$	$5 \times 10^{-3}$				
I(OH)	$4 \times 10^{-11}$	$SeO(OH)_2$	$3 \times 10^{-3}$				
		$TeO(OH)_2$	$3 \times 10^{-3}$				
		$NO(OH)$	$5 \times 10^{-4}$				

chemical behavior. So, the structure of  $H_3PO_3$  is best represented by Figure 15.10b and corresponds either to a Lewis diagram with more than eight electrons around the central phosphorus atom or to one with formal charges on the central phosphorus and lone oxygen atoms. The formula of this acid is written as  $HPO(OH)_2$  in Table 15.3. Unlike phosphoric acid ( $H_3PO_4$ ), which is a triprotic acid,  $H_3PO_3$  is a diprotic acid. The third hydrogen atom, the one directly bonded to the phosphorus atom, does not ionize even in strongly basic aqueous solution.

### 15.3.2 Indicators

An **acid–base indicator** is a soluble dye that changes color noticeably over a fairly narrow range of pH. The typical indicator is a weak organic acid that has a different color from its conjugate base (Fig. 15.11). Litmus changes from red to blue as its acid form is converted to base. Good indicators have such intense colors that only a few drops of a dilute indicator solution must be added to the solution being studied. The very low concentration of indicator molecules has almost no effect on the pH of solution. The color changes of the indicator reflect the effects of the *other* acids and bases present in the solution.

If the acid form of a given indicator is represented as  $HIn$  and the conjugate base form as  $In^-$ , their acid–base equilibrium is

$$\frac{[H_3O^+][In^-]}{[HIn]} = K_a$$

where  $K_a$  is the acid ionization constant for the indicator. This expression can be rearranged to give

$$\frac{[H_3O^+]}{K_a} = \frac{[HIn]}{[In^-]} \quad [15.6]$$

**FIGURE 15.11** Color differences in four indicators: bromophenol red, thymolphthalein, phenolphthalein, and bromocresol green. In each case the acidic form is on the left and the basic form is on the right.

© Cengage Learning/Leon Lewandowski

If the concentration of hydronium ion  $[\text{H}_3\text{O}^+]$  is large relative to  $K_a$ , this ratio is large, and  $[\text{HIn}]$  is large compared with  $[\text{In}^-]$ . The solution has the color of the acid form of the indicator because most of the indicator molecules are in the acid form. Litmus, for example, has a  $K_a$  near  $10^{-7}$ . If the pH is 5, then

$$\frac{[\text{H}_3\text{O}^+]}{K_a} = \frac{10^{-5}}{10^{-7}} = 100$$

Thus, approximately 100 times as many indicator molecules are in the acid form as in the base form, and the solution is red.

As the concentration of hydronium ion is reduced, more molecules of acid indicator ionize to give the base form. When  $[\text{H}_3\text{O}^+]$  is near  $K_a$ , almost equal amounts of the two forms are present, and the color is a mixture of the colors of the two indicator states (violet for litmus). A further decrease in  $[\text{H}_3\text{O}^+]$  to a value much smaller than  $K_a$  then leads to a predominance of the base form, with the corresponding color being observed.

Different indicators have different values for  $K_a$  and thus show color changes at different pH values (Fig. 15.12). The weaker an indicator is as an acid, the higher the pH at which the color change takes place. Such color changes occur over a range of 1 to 2 pH units. Methyl red, for example, is red when the pH is below 4.8 and yellow above 6.0; shades of orange are seen at intermediate pH values. This limits the accuracy to which the pH can be

**FIGURE 15.12** Indicators change their colors at very different pH values, so the best choice of indicator depends on the particular experimental conditions.

**FIGURE 15.13** Red cabbage extract is a natural pH indicator. When the solution is highly acidic, the extract gives the solution a red color. As the solution becomes less and less acidic (more basic), the color changes from red to violet to yellow.

© Cengage Learning/Charles D. Winters

determined through the use of indicators. Section 15.6 shows that this fact does not affect the analytical determination of acid or base concentrations through titration, provided that an appropriate indicator is used.

Many natural dyes found in fruits, vegetables, and flowers act as pH indicators by changing color with changes in acidity (Fig. 15.13). A particularly striking example is cyanidin, which is responsible both for the red color of poppies and the blue color of cornflowers. The sap of the poppy is sufficiently acidic to turn cyanidin red, but the sap of the cornflower is basic and makes the dye blue. (See the image that appears at the start of this chapter.) Related natural dyes called anthocyanins contribute to the colors of raspberries, strawberries, and blackberries.

## 15.4 Equilibria Involving Weak Acids and Bases

The reactions of weak acids and bases with water do not go to completion. So, to calculate the pH of their solutions, we use  $K_a$  or  $K_b$  and the laws of chemical equilibrium. The calculations follow the pattern of Example 14.10 for gas equilibria. In that case the initial gas-phase pressures  $P^\circ$  are known, and we calculate the pressures of products resulting from the incomplete reaction. Here we know the initial concentration of acid or base, and calculate the concentrations of products resulting from its partial reaction with water.

### 15.4.1 Weak Acids

A weak acid has a  $K_a$  smaller than 1. Values of the  $pK_a$  start at zero for the strongest weak acid and range upward for progressively weaker acids. (If the  $pK_a$  is greater than 14, the compound is ineffective as an acid in aqueous solution.) When a weak acid is dissolved in water, the original concentration of HA is almost always known, but partial reaction with water consumes some HA and generates  $A^-$  and  $H_3O^+$ :

To calculate the amounts of  $\text{H}_3\text{O}^+$ ,  $\text{A}^-$ , and  $\text{HA}$  at equilibrium, we use the methods of Chapter 14, with partial pressures replaced by concentrations. A new feature here is that one of the products ( $\text{H}_3\text{O}^+$ ) can also come from a second source, the autoionization of the solvent, water. In most of the applications we study, this second effect is small and can be neglected in the equations. Even so, it is a good idea to verify at the end of each calculation that the  $[\text{H}_3\text{O}^+]$  from the acid ionization alone exceeds  $10^{-7}$  M by at least one order of magnitude. Otherwise, we have to use the more complete method of analysis given in Section 15.9.

### EXAMPLE 15.6

Acetic acid ( $\text{CH}_3\text{COOH}$ ) has a  $K_a$  of  $1.76 \times 10^{-5}$  at  $25^\circ\text{C}$ . Suppose 1.000 mol is dissolved in enough water to give 1.000 L of solution. Calculate the pH and the fraction of acetic acid ionized at equilibrium.

#### Solution

The initial concentration of acetic acid is 1.000 M. If  $y$  mol  $\text{L}^{-1}$  ionizes, then

	$\text{CH}_3\text{COOH}(\text{aq}) + \text{H}_2\text{O}(\ell) \rightleftharpoons \text{H}_3\text{O}^+(\text{aq}) + \text{CH}_3\text{COO}^-(\text{aq})$		
Initial concentration (M)	1.000	$\approx 0$	0
Change in concentration (M)	$-y$	$+y$	$+y$
Equilibrium concentration (M)	$1.000 - y$	$y$	$y$

Note that we ignored the  $\text{H}_3\text{O}^+$  initially present from the ionization of water because we expect it to be smaller than  $y$  for all but the weakest acids or the most dilute solutions. Then, the equilibrium expression states that

$$\frac{[\text{H}_3\text{O}^+][\text{CH}_3\text{COO}^-]}{[\text{CH}_3\text{COOH}]} = \frac{y^2}{1.000 - y} = K_a = 1.76 \times 10^{-5}$$

This equation could be solved using the quadratic formula, as we did in Chapter 14, or by using a programmable calculator. But it is important to develop approximation methods that enable quick solutions and also develop chemical insight and intuition into the equilibrium process. These approximations are based on the fact that acetic acid is a weak acid, and therefore only a small fraction is ionized at equilibrium. Therefore it is reasonable to assume that  $y$  is small relative to 1.000 (that is, the final equilibrium concentration of  $\text{CH}_3\text{COOH}$  is close to its initial concentration). This gives

$$\frac{y^2}{1.000 - y} \approx \frac{y^2}{1.000} = 1.76 \times 10^{-5}$$

$$y = 4.20 \times 10^{-3}$$

so

$$[\text{H}_3\text{O}^+] = y = 4.20 \times 10^{-3} \text{ M}$$

Now we have to check whether the approximations are indeed valid. First,  $y$  is indeed much smaller than the original concentration of 1.000 M (by a factor of 200), so neglecting it in the denominator is justified. Second, the concentration of  $\text{H}_3\text{O}^+$  from acetic acid ( $4.2 \times 10^{-3}$  M) is large compared with  $10^{-7}$  M, so neglecting the water ionization is also justified. Therefore,

$$\text{pH} = -\log_{10}(4.2 \times 10^{-3}) = 2.38$$

(Continued)

The fraction ionized is the ratio of the concentration of  $\text{CH}_3\text{COO}^-$  present at equilibrium to the concentration of  $\text{CH}_3\text{COOH}$  present in the first place:

$$\frac{y}{1.000} = y = 4.2 \times 10^{-3}$$

The percentage of the acetic acid that is ionized is 0.42%. Fewer than one in a hundred of the molecules of this typical weak acid dissociate in this solution.

**Related Problems: 27, 28, 29, 30**

Approximation methods of the type used in this example are also used in Example 14.10 and are discussed more extensively in Appendix C. As the solution of a weak acid becomes more dilute, a greater fraction of it ionizes, as shown by the following example.

### EXAMPLE 15.7

Suppose that 0.00100 mol of acetic acid is used instead of the 1.000 mol in the preceding example. Calculate the pH and the percentage of acetic acid ionized.

#### Solution

Once again we assume that the contribution of the ionization of water to  $[\text{H}_3\text{O}^+]$  is negligible, and check the validity of the assumption at the end of the calculation. Hence,

$$[\text{CH}_3\text{COOH}] = 0.00100 - y$$

$$[\text{CH}_3\text{COO}^-] = [\text{H}_3\text{O}^+] = y$$

$$\frac{y^2}{0.00100 - y} = 1.76 \times 10^{-5}$$

In this case,  $y$  is *not* small relative to 0.00100 because a substantial fraction of the acetic acid molecules ionizes, so  $y$  cannot be neglected in the denominator. There are two alternatives for solving the problem in this case.

The first method is to solve the quadratic equation obtained by multiplying out the equilibrium expression:

$$y^2 + (1.76 \times 10^{-5})y - (1.76 \times 10^{-8}) = 0$$

Using the quadratic formula gives

$$y = 1.24 \times 10^{-4} \text{ M} = [\text{H}_3\text{O}^+] = [\text{CH}_3\text{COO}^-]$$

Because  $y \gg 10^{-7} \text{ M}$ , neglecting water ionization in setting up the problem is justified.

$$\text{pH} = -\log_{10} (1.24 \times 10^{-4}) = 3.91$$

$$\text{percentage ionized} = \frac{1.24 \times 10^{-4} \text{ M}}{0.00100 \text{ M}} \times 100\% = 12.4\%$$

The other approach to solving the problem is to use successive approximations (see Appendix C). Begin by neglecting  $y$  in the denominator (relative to 0.00100), which gives

$$\frac{y^2}{0.00100} = 1.76 \times 10^{-5}$$

$$y = 1.33 \times 10^{-4} \text{ M}$$

This is just what we do in Example 15.6. Now, continue by reinserting this *approximate* value of  $y$  into the *denominator* and then recalculate  $y$ :

$$\frac{y^2}{0.00100 - 0.00133} = 1.76 \times 10^{-5}$$

$$y^2 = 1.53 \times 10^{-8}$$

$$y = 1.33 \times 10^{-4} \text{ M}$$

If we insert this new value of  $y$  into the denominator and iterate the calculation once again, we obtain  $1.24 \times 10^{-4} \text{ M}$ , the same value produced by the quadratic formula. We terminate the iteration process when two successive results for  $y$  agree to the desired number of significant figures.

**Related Problems: 31, 32**

The method of successive approximations is often faster to apply than the quadratic formula. Keep in mind that the accuracy of a result is limited both by the accuracy of the input data (values of  $K_a$  and initial concentrations) and by the fact that solutions are not ideal. It is pointless to calculate equilibrium concentrations to any degree of accuracy higher than 1% to 3%.

### 15.4.2 Weak Bases

There is a perfect parallel between the behavior of weak bases and weak acids. The definition and description of weak acids, the existence of  $K_a$ , and the production of  $\text{H}_3\text{O}^+(aq)$  ion when they are dissolved in water can be applied directly to weak bases, the existence of  $K_b$ , and the production of  $\text{OH}^-(aq)$  ion. A **weak base** such as ammonia reacts only partially with water to produce  $\text{OH}^-(aq)$ :

The  $K_b$  of a weak base is smaller than 1, and the weaker the base, the smaller the  $K_b$ . If the  $K_b$  of a compound is smaller than  $1 \times 10^{-14}$ , that compound is ineffective as a base in aqueous solution.

The analogy to weak acids continues in the calculation of the aqueous equilibria of weak bases, as the following example shows.

#### EXAMPLE 15.8

Calculate the pH of a solution made by dissolving 0.0100 mol of  $\text{NH}_3$  in enough water to give 1.000 L of solution at  $25^\circ\text{C}$ . The  $K_b$  for ammonia is  $1.8 \times 10^{-5}$ .

#### Solution

Set up the table of the changes in concentrations that occur as the reaction goes to equilibrium, neglecting the small contribution to  $[\text{OH}^-]$  from the autoionization of water:

	$\text{H}_2\text{O}(\ell) + \text{NH}_3(aq)$	$\rightleftharpoons$	$\text{NH}_4^+(aq)$	$+ \text{OH}^-(aq)$
Initial concentration (M)	0.0100		0	$\approx 0$
Change in concentration (M)	$-y$		$+y$	$+y$
Equilibrium concentration (M)	$0.0100 - y$		$y$	$y$

Substitution into the equilibrium expression gives

$$\frac{y^2}{0.0100 - y} = K_b = 1.8 \times 10^{-5}$$

which can be solved for  $y$  by either the quadratic formula or the method of successive approximations to obtain:

$$y = 4.15 \times 10^{-4} \text{ M} = [\text{OH}^-]$$

The product of  $[\text{H}_3\text{O}^+]$  and  $[\text{OH}^-]$  is always  $K_w$ . Hence,

$$[\text{H}_3\text{O}^+] = \frac{K_w}{[\text{OH}^-]} = \frac{1.0 \times 10^{-14}}{4.15 \times 10^{-4}} = 2.4 \times 10^{-11} \text{ M}$$

$$\text{pH} = -\log_{10} (2.4 \times 10^{-11}) = 10.62$$

The pH is greater than 7, as expected for a solution of a base.

**Related Problems:** 35, 36

### 15.4.3 Hydrolysis

Most of the acids considered up to now have been uncharged species with the general formula HA. In the Brønsted–Lowry picture there is no reason why the acid should be an electrically neutral molecule. When  $\text{NH}_4\text{Cl}$ , a salt, dissolves

**FIGURE 15.14** Proof that ammonium chloride is an acid. (a) A solution of sodium hydroxide, with the pink color of phenolphthalein indicating its basic character. (b and c) As aqueous ammonium chloride is added, a neutralization reaction takes place and the solution turns colorless from the bottom up.

in water,  $\text{NH}_4^+$  ions are present. Some of these ionize by transferring hydrogen ions to water in a straightforward Brønsted–Lowry acid–base reaction:

$\text{NH}_4^+$  acts as an acid here, just as acetic acid did in Examples 15.6 and 15.7. Because  $K_a$  is much smaller than 1, only a small amount of  $\text{H}_3\text{O}^+$  is generated.  $\text{NH}_4^+$  is a weak acid, but it is nonetheless an acid, and a solution of ammonium chloride has a pH below 7 (Fig. 15.14).

**Hydrolysis** is the label for the reaction of a substance with water. This term is applied especially to a reaction in which the pH changes from 7 upon dissolving a salt (in this case,  $\text{NH}_4\text{Cl}$ ) in water. There is no need for any special description of hydrolysis. The hydrolysis reaction that takes place when  $\text{NH}_4\text{Cl}$  dissolves in water is completely described as a Brønsted–Lowry reaction in which water acts as a base and  $\text{NH}_4^+$  acts as an acid to give a pH below 7. In parallel fashion, dissolving a salt whose anion is a weak base produces a basic solution. This too is a case of hydrolysis; it is simply another Brønsted–Lowry acid–base reaction, with water acting now as an acid (a hydrogen ion donor).

Two salts that give basic solutions are sodium acetate and sodium fluoride. When these salts dissolve in water, they furnish acetate ( $\text{CH}_3\text{COO}^-$ ) and fluoride ( $\text{F}^-$ ) ions, respectively, both of which act as Brønsted–Lowry bases,

causing the  $\text{OH}^-$  concentration to increase and give a pH above 7.

#### EXAMPLE 15.9

Suppose 0.100 mol of  $\text{NaCH}_3\text{COO}$  is dissolved in enough water to make 1.00 L of solution. What is the pH of the solution?

(Continued)

**Solution**

The  $K_a$  for  $\text{CH}_3\text{COOH}$ , the conjugate acid of  $\text{CH}_3\text{COO}^-$ , is  $1.76 \times 10^{-5}$ . Therefore,  $K_b$  for the acetate ion is

$$\frac{[\text{CH}_3\text{COOH}][\text{OH}^-]}{[\text{CH}_3\text{COO}^-]} = K_b = \frac{K_w}{K_a} = 5.7 \times 10^{-10}$$

The equilibrium here is

$\text{H}_2\text{O}(\ell) + \text{CH}_3\text{COO}^-(aq) \rightleftharpoons \text{CH}_3\text{COOH}(aq) + \text{OH}^-(aq)$			
Initial concentration (M)	0.100	0	$\approx 0$
Change in concentration (M)	$-y$	$+y$	$+y$
Equilibrium concentration (M)	$0.100 - y$	$y$	$y$

Substitution into the equilibrium expression gives

$$\frac{y^2}{0.100 - y} = K_b = 5.7 \times 10^{-10}$$

$$y = 7.5 \times 10^{-6} \text{ M} = [\text{OH}^-]$$

Note that  $y$  is small relative to 0.100 and fairly large relative to  $10^{-7}$ .

$$[\text{H}_3\text{O}^+] = \frac{K_w}{[\text{OH}^-]} = \frac{1.0 \times 10^{-14}}{7.5 \times 10^{-6}} = 1.3 \times 10^{-9} \text{ M}$$

$$\text{pH} = 8.89$$

**Related Problems: 41, 42**

Hydrolysis does not occur with all ions, only with those that are conjugate acids of weak bases or conjugate bases of weak acids. Chloride ion is the conjugate base of the strong acid HCl and consequently is ineffective as a base, unlike  $\text{F}^-(aq)$  and  $\text{CH}_3\text{COO}^-(aq)$ . Its interaction with water would therefore scarcely change the  $\text{OH}^-(aq)$  concentration. So, a solution of NaCl is neutral, whereas a solution of NaF is slightly basic.

## 15.5 Buffer Solutions

A **buffer solution** maintains relatively constant pH upon small additions of acid or base. Typically, a buffer solution contains a weak acid and its conjugate weak base in approximately equal concentrations. Buffer solutions play important roles in controlling the solubility of ionic compounds in solution (see Chapter 16) and in maintaining the pH in biochemical and physiological processes. Many life processes are sensitive to pH and require regulation within a small range of  $\text{H}_3\text{O}^+$  and  $\text{OH}^-$  concentrations. Organisms have built-in buffers to protect them against large changes in pH. Human blood has a pH near 7.4, which is maintained by a combination of carbonate, phosphate, and protein buffer systems. Conditions that drive blood pH below 7.0 or above 7.8 lead quickly to death.

**FIGURE 15.15** Formic acid,  $\text{HCOOH}$ , is the simplest carboxylic acid, with only a hydrogen atom attached to the  $-\text{COOH}$  group.

### 15.5.1 Calculations of Buffer Action

Consider a typical weak acid, formic acid ( $\text{HCOOH}$ ) (Fig. 15.15), and its conjugate base, formate ion ( $\text{HCOO}^-$ ). The latter can be obtained by dissolving a

salt such as sodium formate (NaHCOO) in water. The acid–base equilibrium established between these species is given by

with an acid ionization constant

$$\frac{[\text{H}_3\text{O}^+][\text{HCOO}^-]}{[\text{HCOOH}]} = K_a = 1.77 \times 10^{-4}$$

Section 15.2 describes the pH of a solution containing only a weak acid (such as HCOOH) or only a weak base (such as HCOO<sup>−</sup>). Suppose now that the weak acid and its conjugate base are *both* present initially. The resulting calculations resemble closely the calculation of Example 14.15, in which equilibrium was established from an initial mixture containing both reactants and products.

### EXAMPLE 15.10

Suppose 1.00 mol of HCOOH and 0.500 mol of NaHCOO are added to water and diluted to 1.00 L. Calculate the pH of the solution.

#### Solution

	HCOOH(aq)	+ H <sub>2</sub> O(ℓ)	⇌	H <sub>3</sub> O <sup>+</sup> (aq)	+ HCOO <sup>−</sup> (aq)
Initial concentration (M)	1.00			≈ 0	0.500
Change in concentration (M)	<u>−y</u>			<u>+y</u>	<u>+y</u>
Equilibrium concentration (M)	1.00 − y			y	0.500 + y

The equilibrium expression is

$$\frac{y(0.500 + y)}{1.00 - y} = K_a = 1.77 \times 10^{-4}$$

Because  $y$  is likely to be small relative to 1.00 and to 0.500, we write the approximate expression

$$\frac{y(0.500)}{1.00} \approx 1.77 \times 10^{-4}$$

$$y \approx 3.54 \times 10^{-4} \text{ M} = [\text{H}_3\text{O}^+]$$

A glance verifies that  $y$  is indeed small relative to 1.00 and 0.500. Then

$$\text{pH} = -\log_{10}(3.54 \times 10^{-4}) = 3.45$$

**Related Problems:** 43, 44

To understand how buffer solutions work, let's write the equilibrium expression for the ionization of a weak acid HA in the form

$$[\text{H}_3\text{O}^+] = K_a \frac{[\text{HA}]}{[\text{A}^-]}$$

The concentration of hydronium ion depends on the ratio of the concentration of the weak acid to the concentration of its conjugate base. The key to effective buffer action is to keep these concentrations nearly equal and fairly large. Adding a small amount of base to an effective buffer takes away only a few percent of the HA molecules by converting them into A<sup>−</sup> ions and adds only a few percent to the amount of A<sup>−</sup> originally present. The ratio [HA]/[A<sup>−</sup>] decreases,

but only very slightly. Added acid consumes a small fraction of the base  $A^-$  to generate a bit more HA. The ratio  $[HA]/[A^-]$  now increases, but again the change is only slight. Because the concentration of  $H_3O^+$  is tied directly to this ratio, it changes only slightly. The following example illustrates buffer action quantitatively.

### EXAMPLE 15.11

Suppose 0.10 mol of a strong acid such as HCl is added to the solution in Example 15.10. Calculate the pH of the resulting solution.

#### Solution

The strong acid HCl ionizes essentially completely in dilute aqueous solution. Initially assume that *all* the hydrogen ions from HCl are taken up by formate ions to produce formic acid, some of which ionizes back to formate ion and  $H_3O^+$ . This is simply a way of describing one possible route by which equilibrium is approached and does not define the sequence of reactions that actually occurs. The position of the final equilibrium does not depend on the route by which it is attained.

Because 0.10 mol of HCl reacts with an equal number of moles of  $HCOO^-$ , the concentrations of  $HCOO^-$  and  $HCOOH$  *before* ionization are

$$[HCOO^-]_0 = 0.50 - 0.10 = 0.40 \text{ M}$$

$$[HCOOH]_0 = 1.00 + 0.10 = 1.10 \text{ M}$$

The table to calculate the concentrations at equilibrium is

$HCOOH(aq) + H_2O(l) \rightleftharpoons H_3O^+(aq) + HCOO^-(aq)$			
Initial concentration (M)	1.10	$\approx 0$	0.40
Change in concentration (M)	$-y$	$+y$	$+y$
Equilibrium concentration (M)	$1.10 - y$	$y$	$0.40 + y$

The equilibrium expression then becomes

$$\frac{y(0.40 + y)}{1.10 - y} = 1.77 \times 10^{-4}$$

Because  $y$  is again likely to be small relative to both 0.40 and 1.10,

$$y \approx \left( \frac{1.10}{0.40} \right) (1.77 \times 10^{-4}) = 4.9 \times 10^{-4}$$

$$\text{pH} = 3.31$$

Even though 0.10 mol of a strong acid was added, the pH changed only slightly, from 3.45 to 3.31. In contrast, the same amount of acid added to a liter of pure water would change the pH from 7 to 1.

**Related Problems: 45, 46**

Note that we solved this problem by first performing a stoichiometric (limiting reactant) calculation and then an equilibrium calculation. A similar strategy works if a strong base such as  $OH^-$  is added instead of a strong acid. The base reacts with formic acid to produce formate ions. Adding 0.10 mol of  $OH^-$  to the  $HCOOH/HCOO^-$  buffer of Example 15.10 increases the pH only to 3.58. In the absence of the buffer system, the same base would raise the pH to 13.00.

In any buffer there is competition between the tendency of the acid to donate hydrogen ions to water (increasing the acidity) and the tendency of the base to

accept hydrogen ions from water (increasing the basicity). The resulting pH depends on the magnitude of  $K_a$ . If  $K_a$  is large relative to  $10^{-7}$ , the acid ionization will win out and acidity will increase, as in the  $\text{HCOOH}/\text{HCOO}^-$  buffer. A basic buffer (with  $\text{pH} > 7$ ) can be prepared by working with an acid–base pair with  $K_a$  smaller than  $10^{-7}$ . In this case the net reaction produces  $\text{OH}^-$ , and we must use  $K_b$  to determine the equilibrium state. A typical example is the  $\text{NH}_4^+/\text{NH}_3$  buffer prepared by mixing ammonium chloride with ammonia.

### EXAMPLE 15.12

Calculate the pH of a solution made by adding 0.100 mol of  $\text{NH}_4\text{Cl}$  and 0.200 mol of  $\text{NH}_3$  to water and diluting to 1.000 L.  $K_a$  for  $\text{NH}_4^+$  is  $5.6 \times 10^{-10}$ .

#### Solution

Because  $K_a \ll 10^{-7}$  for  $\text{NH}_4^+$  (equivalently,  $K_b \gg 10^{-7}$  for  $\text{NH}_3$ ), the net reaction is production of  $\text{OH}^-$  ions. Therefore, the equilibrium is written to show the net transfer of hydrogen ions from water to  $\text{NH}_3$ :

	$\text{H}_2\text{O}(\ell) + \text{NH}_3(\text{aq})$	$\rightleftharpoons$	$\text{NH}_4^+(\text{aq}) + \text{OH}^-(\text{aq})$
Initial concentration (M)	0.200		0.100      0
Change in concentration (M)	$-y$		$+y$ $+y$
Equilibrium concentration (M)	$0.200 - y$		$0.100 + y$ $y$

The equilibrium expression is

$$\frac{y(0.100 + y)}{0.200 - y} = K_b = \frac{K_w}{K_a} = 1.8 \times 10^{-5}$$

If  $y$  is small relative to the original concentrations of both  $\text{NH}_3$  and  $\text{NH}_4^+$ , then

$$\frac{y(0.100)}{0.200} \approx 1.8 \times 10^{-5}$$

$$y \approx \left( \frac{0.200}{0.100} \right) (1.8 \times 10^{-5}) = 3.6 \times 10^{-5} \ll 0.100, 0.200$$

$$[\text{H}_3\text{O}^+] = \frac{1.0 \times 10^{-14}}{[\text{OH}^-]} = \frac{1.0 \times 10^{-14}}{3.6 \times 10^{-5}} = 2.8 \times 10^{-10} \text{ M}$$

$$\text{pH} = -\log_{10} (2.8 \times 10^{-10}) = 9.55$$

## 15.5.2 Designing Buffers

Control of pH is vital in synthetic and analytical chemistry, just as it is in living organisms. Procedures that work well at a pH of 5 may fail when the concentration of hydronium ion in the solution is raised tenfold to make the pH 4. Fortunately, it is possible to prepare buffer solutions that maintain the pH close to any desired value by the proper choice of a weak acid and the ratio of its concentration to that of its conjugate base. Let's see how to choose the best conjugate acid–base system and how to calculate the required acid–base ratio.

In Examples 15.10, 15.11, and 15.12, the equilibrium concentrations of acid and base in the buffer systems were close to the initial concentrations. When this

is the case, the calculation of pH is simplified greatly, because for either an acidic or a basic buffer,

$$K_a = \frac{[\text{H}_3\text{O}^+][\text{A}^-]}{[\text{HA}]} \approx \frac{[\text{H}_3\text{O}^+][\text{A}^-]_0}{[\text{HA}]_0}$$

$$[\text{H}_3\text{O}^+] \approx \frac{[\text{HA}]_0}{[\text{A}^-]_0} K_a$$

and the pH is given by

$$\text{pH} \approx \text{p}K_a - \log_{10} \frac{[\text{HA}]_0}{[\text{A}^-]_0} \quad [15.7]$$

We obtained Equation 15.7 by taking the logarithm and changing sign. It is easy to verify that this simple equation gives the correct result for the three preceding examples. However, it must be used with some care because it is only approximate. It is valid only when *both*  $[\text{H}_3\text{O}^+]$  and  $[\text{OH}^-]$  are small relative to  $[\text{HA}]_0$  and  $[\text{A}^-]_0$ ; this means the extent of ionization must be small.

We can use this expression relating pH to  $\text{p}K_a$  to design buffers with a specific value of pH. In an optimal buffer the acid and its conjugate base are purposely very nearly equal in concentration; if the difference in concentrations is too great, the buffer is less resistant to the effects of adding acid or base. To select a buffer system, we choose an acid with a  $\text{p}K_a$  as close as possible to the desired pH. Then we adjust the concentrations of acid and conjugate base to give exactly the desired pH.

### EXAMPLE 15.13

Design a buffer system with pH 4.60.

#### Solution

From Table 15.2, the  $\text{p}K_a$  for acetic acid is 4.75, so the  $\text{CH}_3\text{COOH}/\text{CH}_3\text{COO}^-$  buffer is a suitable one. The concentrations required to give the desired pH are related by

$$\text{pH} = 4.60 = \text{p}K_a - \log_{10} \frac{[\text{CH}_3\text{COOH}]_0}{[\text{CH}_3\text{COO}^-]_0}$$

$$\log_{10} \frac{[\text{CH}_3\text{COOH}]_0}{[\text{CH}_3\text{COO}^-]_0} = \text{p}K_a - \text{pH} = 4.75 - 4.60 = 0.15$$

$$\frac{[\text{CH}_3\text{COOH}]_0}{[\text{CH}_3\text{COO}^-]_0} = 10^{0.15} = 1.4$$

We can establish this ratio by dissolving 0.100 mol of sodium acetate and 0.140 mol of acetic acid in water and diluting to 1.00 L, or 0.200 mol of  $\text{NaCH}_3\text{COO}$  and 0.280 mol of  $\text{CH}_3\text{COOH}$  in the same volume, and so on. As long as the ratio of the concentrations is 1.4, the solution will be buffered at approximately pH 4.60.

**Related Problems: 47, 48, 49, 50**

The preceding example shows that the *absolute* concentrations of acid and conjugate base in a buffer are much less important than is their ratio in determining the pH. Nonetheless, the absolute concentrations do affect the capacity of the solution to resist changes in pH when acid or base is added. The higher the concentrations of buffering species, the smaller the change in pH when a fixed amount of a strong acid or base is added. In Example 15.10 a change in buffer concentrations from 1.00 M and 0.500 M to 0.500 M and 0.250 M does not alter the original pH of 3.45 because the ratio of acid to base concentrations is unchanged. The pH after 0.100 mol of HCl is added does change to the value 3.15 rather than 3.31. The buffer at lower concentration is less resistant to pH

**FIGURE 15.16** Addition of a given volume of base to buffered and unbuffered solutions causes a much greater change in the pH of the unbuffered solution. Of the two buffered solutions, the one with higher buffer concentration resists pH changes more effectively. The red line represents 100 mL of a buffer that is 0.1 M in both  $\text{CH}_3\text{COOH}$  and  $\text{CH}_3\text{COO}^-$ ; the blue line represents the same volume of a buffer that is 1.0 M in both components.

change (Fig. 15.16). The buffering capacity of *any* buffer solution is exhausted if enough strong acid (or strong base) is added to use up the original amount of weak base (or weak acid) through chemical reaction.

## 15.6 Acid–Base Titration Curves

Section 11.3 describes an acid–base titration as the addition of carefully metered volumes of a basic solution of known concentration to an acidic solution of unknown concentration—or the addition of acid to base—to reach an *endpoint* at which the unknown solution has been completely neutralized. The endpoint is signaled by the color change of an indicator or by a sudden rise or fall in pH. The pH of the reaction mixture changes continuously over the course of an acid–base titration, but changes abruptly only near the endpoint. A graph of the pH versus the volume  $V$  of titrating solution added is a **titration curve**. Its shape depends on the value of  $K_a$  and on the concentrations of the acid and base reacting. The concepts and tools of acid–base equilibria predict the exact shapes of titration curves when these quantities are all known. The same concepts allow  $K_a$  and the concentration of the unknown solution to be calculated from an experimental titration curve. Here we examine three categories of titration and determine the titration curve for each: strong acid reacting with strong base, weak acid reacting with strong base, and strong acid reacting with weak base. Titrations of a weak acid with a weak base (and the reverse) are not useful for analytical purposes.

### 15.6.1 Titration of a Strong Acid with a Strong Base

The addition of a strong base to a strong acid (or the reverse) is the simplest type of titration. The chemical reaction is the neutralization:

Suppose a solution of 100.0 mL (0.1000 L) of 0.1000 M HCl is titrated with 0.1000 M NaOH. What does the titration curve look like? The curve can be measured experimentally, and the result is shown in Figure 15.17. We can also

**FIGURE 15.17** A titration curve for the titration of a strong acid by a strong base. The curve shown is for 100.0 mL of 0.1000 M HCl titrated with 0.1000 M NaOH.

construct the curve theoretically by calculating the pH of the reaction mixture at many different points during the addition of the NaOH solution and plotting the results. The following example illustrates the theoretical procedure.

**1.  $V = 0$  mL NaOH added**

Initially,  $[\text{H}_3\text{O}^+] = 0.1000$  M, so the pH is 1.000. The number of moles of  $\text{H}_3\text{O}^+$  present initially is

$$\begin{aligned} n_{\text{H}_3\text{O}^+} &= [\text{H}_3\text{O}^+](\text{volume}) = (0.1000 \text{ mol L}^{-1})(0.1000 \text{ L}) \\ &= 1.000 \times 10^{-2} \text{ mol} \end{aligned}$$

**2.  $V = 30.00$  mL NaOH added**

30.00 mL of 0.1000 M NaOH solution contains

$$(0.1000 \text{ mol L}^{-1})(0.03000 \text{ L}) = 3.000 \times 10^{-3} \text{ mol OH}^-$$

This reacts with (and neutralizes) an equal number of moles of the  $\text{H}_3\text{O}^+$  ion present initially and reduces  $n_{\text{H}_3\text{O}^+}$  to

$$n_{\text{H}_3\text{O}^+} = (1.000 \times 10^{-2} - 3.000 \times 10^{-3}) \text{ mol} = 7.00 \times 10^{-3} \text{ mol}$$

In addition—and this is very important to remember—the volume of the titration mixture has increased from 100.0 to 130.0 mL (that is, from 0.1000 to 0.1300 L). The concentration of  $\text{H}_3\text{O}^+$  at this point in the titration is

$$\begin{aligned} [\text{H}_3\text{O}^+] &= \frac{n_{\text{H}_3\text{O}^+}}{V_{\text{tot}}} = \frac{7.00 \times 10^{-3} \text{ mol}}{0.1300 \text{ L}} = 0.0538 \text{ M} \\ \text{pH} &= 1.27 \end{aligned}$$

**3.  $V = 100.00$  mL NaOH added**

This is called the **equivalence point**, that point in the titration at which the number of moles of base added equals the number of moles of acid

originally present. The volume of base added up to the equivalence point is the **equivalent volume**,  $V_e$ . At the equivalence point in the titration of a strong acid with a strong base, the concentrations of  $\text{OH}^-$  and  $\text{H}_3\text{O}^+$  must be equal and the pH 7.0 due to the autoionization of water. At this point the solution is simply a nonhydrolyzing salt (in this case, NaCl) in water. The pH is 7 at the equivalence point only in the titration of a strong acid with a strong base (or vice versa). The pH at the equivalence point differs from 7 if the titration involves a weak acid or weak base.

#### 4. $V = 100.05 \text{ mL NaOH added}$

Beyond the equivalence point,  $\text{OH}^-$  is added to a neutral unbuffered solution. The  $\text{OH}^-$  concentration can be found from the number of moles of  $\text{OH}^-$  added after the equivalence point has been reached. The volume beyond the equivalence point at this stage is 0.05 mL, or  $5 \times 10^{-5} \text{ L}$ . (This is the volume of approximately one drop of solution added from the buret.) The number of moles of  $\text{OH}^-$  in this volume is

$$(0.1000 \text{ mol L}^{-1})(5 \times 10^{-5} \text{ L}) = 5 \times 10^{-6} \text{ mol}$$

Meanwhile, the total volume of the titration mixture is

$$0.1000 \text{ L HCl solution} + 0.10005 \text{ L NaOH solution} = 0.20005 \text{ L solution}$$

Therefore, the concentration of  $\text{OH}^-$  is

$$[\text{OH}^-] = \frac{\text{moles OH}^-}{\text{total volume}} = \frac{5 \times 10^{-6} \text{ mol}}{0.20005 \text{ L}} = 2.5 \times 10^{-5} \text{ M}$$

$$[\text{H}_3\text{O}^+] = 4 \times 10^{-10} \text{ M}; \text{pH} = 9.4$$

As the titration curve shows (see Fig. 15.17), the pH increases dramatically in the immediate vicinity of the equivalence point:  $[\text{H}_3\text{O}^+]$  changes by four orders of magnitude between 99.98 mL and 100.02 mL NaOH! Any indicator whose color changes between pH = 5.0 and pH = 9.0 therefore signals the endpoint of the titration to an accuracy of  $\pm 0.02 \text{ mL}$  in 100.0 mL, or  $\pm 0.02\%$ . The titration **endpoint**, the experimentally measured volume at which the indicator changes color, is then almost identical to the equivalence point, the theoretical volume at which the chemical amount of added base equals that of acid present originally.

The titration of a strong base by a strong acid is entirely parallel. In this case the pH starts at a higher value and *drops* through a pH of 7 at the equivalence point. The roles of acid and base, and of  $\text{H}_3\text{O}^+$  and  $\text{OH}^-$ , are reversed in the equations already given.

### 15.6.2 Titration of a Weak Acid with a Strong Base

We turn now to the titration of a weak acid with a strong base (the titration of a weak base with a strong acid is analogous). The equivalence point has the same meaning as for a strong acid titration. At the equivalence point, the number of moles of base added (in volume  $V_e$ ) is equal to the number of moles of acid originally present (in volume  $V_0$ ). So, once again

$$c_0 V_0 = c_t V_e$$

where  $c_0$  is the original weak acid concentration and  $c_t$  is the  $\text{OH}^-$  concentration in the titrating solution.

The calculation of the titration curve differs from the strong acid–strong base case in that now equilibrium (reflected in the  $K_a$  of the weak acid) enters

**FIGURE 15.18** A titration curve for the titration of a weak acid by a strong base. The curve shown in red is for 100.0 mL of 0.1000 M  $\text{CH}_3\text{COOH}$  titrated with 0.1000 M  $\text{NaOH}$ . For comparison, the dashed blue line shows the titration curve for a strong acid of the same amount and concentration as presented in Figure 15.17.

the picture. As an example, consider the titration of 100.0 mL of a 0.1000 M solution of acetic acid ( $\text{CH}_3\text{COOH}$ ) with 0.1000 M  $\text{NaOH}$ . For this titration,

$$\begin{aligned} V_e &= \frac{c_0}{c_t} V_0 = \left( \frac{0.1000 \text{ M}}{0.1000 \text{ M}} \right) (100.0 \text{ mL}) \\ &= 100.0 \text{ mL} \end{aligned}$$

There are four distinct ranges in the titration; each corresponds to a type of calculation that we have illustrated already. Figure 15.18 shows pH versus volume for this titration, and the following paragraphs outline the calculation of four typical points on the curve.

**1.  $V = 0$  mL  $\text{NaOH}$  added**

At the beginning of the titration—before any  $\text{NaOH}$  is added—the problem is simply the ionization of a weak acid, considered in Section 15.4. A calculation analogous to those of Examples 15.6 and 15.7 gives a pH of 2.88.

**2.  $0 < V < V_e$**

In this range the acid has been partially neutralized by added  $\text{NaOH}$  solution. Because  $\text{OH}^-$  is a stronger base than acetate ion, it reacts almost completely with the acid originally present:

$$K = \frac{1}{K_b} = \frac{K_a}{K_w} = 2 \times 10^9 \gg 1$$

As a specific example, suppose that 30.00 mL of 0.1000 M  $\text{NaOH}$  has been added. The 30.00 mL  $\text{NaOH}$  contains

$$(0.1000 \text{ mol L}^{-1})(0.03000 \text{ L}) = 3.000 \times 10^{-3} \text{ mol OH}^-$$

and the original solution contained

$$(0.1000 \text{ mol L}^{-1})(0.1000 \text{ L}) = 1.000 \times 10^{-2} \text{ mol CH}_3\text{COOH}$$

The neutralization reaction generates one  $\text{CH}_3\text{COO}^-$  ion for every  $\text{OH}^-$  ion added. Hence,  $3.000 \times 10^{-3} \text{ mol}$  of  $\text{CH}_3\text{COO}^-$  ions is generated. The amount of acetic acid that remains unreacted is

$$1.000 \times 10^{-2} - 3.000 \times 10^{-3} = 7.00 \times 10^{-3} \text{ mol}$$

Because the total volume is now 130.0 mL (or 0.1300 L), the nominal concentrations after reaction are

$$[\text{CH}_3\text{COOH}] \approx \frac{7.00 \times 10^{-3} \text{ mol}}{0.1300 \text{ L}} = 5.38 \times 10^{-2} \text{ M}$$

$$[\text{CH}_3\text{COO}^-] \approx \frac{3.00 \times 10^{-3} \text{ mol}}{0.1300 \text{ L}} = 2.31 \times 10^{-2} \text{ M}$$

This is merely a buffer solution containing acetic acid at a concentration of  $5.38 \times 10^{-2} \text{ M}$  and sodium acetate at a concentration of  $2.31 \times 10^{-2} \text{ M}$ . Because the  $K_a$  for acetic acid is larger than  $10^{-7}$ , hydronium ion (not hydroxide ion) predominates, and this is an acidic buffer. The pH can be found from the procedure used in Example 15.10 or, more approximately from Equation 15.7:

$$\text{pH} \approx \text{p}K_a - \log_{10} \frac{[\text{CH}_3\text{COOH}]_0}{[\text{CH}_3\text{COO}^-]_0} = 4.75 - \log_{10} \frac{5.38 \times 10^{-2}}{2.31 \times 10^{-2}} = 4.38$$

This region of the titration shows clearly the buffering action of a mixture of a weak acid with its conjugate base. At the half-equivalence point  $V = V_e/2$ ,  $[\text{CH}_3\text{COOH}]_0 = [\text{CH}_3\text{COO}^-]_0$ , which corresponds to an equimolar buffer; at this point  $\text{pH} \approx \text{p}K_a$ . On either side of this point the pH rises relatively slowly as the NaOH solution is added.

### 3. $V = V_e$

At the equivalence point,  $c_t V_e$  mol of  $\text{OH}^-$  has been added to the same number of moles of  $\text{CH}_3\text{COOH}$ . An identical solution could have been prepared simply by adding  $c_t V_e = 1.000 \times 10^{-2} \text{ mol}$  of the base  $\text{CH}_3\text{COO}^-$  (in the form of  $\text{NaCH}_3\text{COO}$ ) to 0.2000 L of water. The pH at the equivalence point corresponds to the hydrolysis of  $\text{CH}_3\text{COO}^-$ :

as considered in Example 15.9. At the equivalence point the pH is 8.73.

Note that in the titration of a weak acid by a strong base the equivalence point comes not at pH 7 but at a higher (more basic) value. By the same token, the equivalence point in the titration of a weak base by a strong acid occurs at a pH lower than 7.

### 4. $V > V_e$

Beyond the equivalence point,  $\text{OH}^-(aq)$  is added to a solution of the base  $\text{CH}_3\text{COO}^-$ . The  $[\text{OH}^-]$  comes almost entirely from the hydroxide ion added beyond the equivalence point; very little comes from the reaction of the  $\text{CH}_3\text{COO}^-$  with water. Beyond  $V_e$ , the pH for the titration of a weak acid by a strong base is very close to that for a strong acid by a strong base.

The equivalent volume  $V_e$  is readily determined in the laboratory by using an indicator that changes color near pH 8.7, the pH at the equivalence point of the acetic acid titration. A suitable choice would be phenolphthalein, which changes from colorless to red over a pH range from 8.2 to 10.0. The slope of pH versus

volume of strong base is less steep near the equivalence point for a weak acid than it is for a strong acid, so determination of the equivalent volume—and of the unknown weak acid concentration—is somewhat less accurate.

The following example shows how to determine concentrations and ionization constants for unknown acids and bases from titrations.

### EXAMPLE 15.14

A volume of 50.00 mL of a weak acid of unknown concentration is titrated with a 0.1000 M solution of NaOH. The equivalence point is reached after 39.30 mL of NaOH solution has been added. At the half-equivalence point (19.65 mL) the pH is 4.85. Calculate the original concentration of the acid and its ionization constant  $K_a$ .

#### Solution

The number of moles of acid originally present,  $c_0V_0$ , is equal to the number of moles of base added at the equivalence point,  $c_tV_e$ , so

$$c_0 = \frac{V_e}{V_0} c_t = \frac{39.50 \text{ mL}}{50.00 \text{ mL}} \times 0.100 \text{ M} = .0786 \text{ M}$$

This is the original concentration of acid.

At the half-equivalence point,

$$\text{pH} = 4.85 \approx \text{p}K_a$$

$$K_a = 10^{-4.85} = 1.4 \times 10^{-5}$$

The unknown acid could be propionic acid,  $\text{CH}_3\text{CH}_2\text{COOH}$  (see Table 15.2).

**Related Problems: 61, 62**

## 15.7 Polyprotic Acids

So far, we have only considered acids that are monoprotic. A molecule of a **monoprotic acid** can donate a single hydrogen ion to an acceptor molecule. A molecule of a **polyprotic acid** can donate two or more hydrogen ions to acceptors. Sulfuric acid is a familiar and important example. It reacts in two stages; first

to give the hydrogen sulfate ion, and then

**FIGURE 15.19** The indicator phenolphthalein is pink in basic solution (*left*). When dry ice (solid carbon dioxide) is placed in the bottom of the beaker (*right*), it dissolves to form carbonic acid. This neutralizes the base in solution, and causes the indicator to change to its colorless form characteristic of an acid solution.

The hydrogen sulfate ion is amphoteric, meaning that it is a base in the first reaction (with conjugate acid  $\text{H}_2\text{SO}_4$ ) and an acid in the second (with conjugate base  $\text{SO}_4^{2-}$ ). In its first ionization  $\text{H}_2\text{SO}_4$  is a strong acid, but the product of that ionization ( $\text{HSO}_4^-$ ) is a weak acid. So, the  $\text{H}_3\text{O}^+$  produced in a solution of  $\text{H}_2\text{SO}_4$  comes primarily from the first ionization, and the solution has a pH close to that of a monoprotic strong acid of the same concentration. But when this solution reacts with a strong base, its neutralizing power is twice that of a monoprotic acid of the same concentration, because each mole of sulfuric acid can react with and neutralize two moles of hydroxide ion.

### 15.7.1 Weak Polyprotic Acids

Weak polyprotic acids ionize in two or more stages. Examples are carbonic acid ( $\text{H}_2\text{CO}_3$ ), formed from solvated  $\text{CO}_2$  (carbonated water; Fig. 15.19), and phosphoric acid ( $\text{H}_3\text{PO}_4$ ). Carbonic acid can give up one hydrogen ion to form  $\text{HCO}_3^-$  (hydrogen carbonate ion) or two hydrogen ions to form  $\text{CO}_3^{2-}$  (carbonate ion). Phosphoric acid ionizes in three stages, giving successively  $\text{H}_2\text{PO}_4^-$ ,  $\text{HPO}_4^{2-}$ , and  $\text{PO}_4^{3-}$ .

Two simultaneous equilibria are involved in the ionization of a diprotic acid such as  $\text{H}_2\text{CO}_3$ :<sup>2</sup>

$$\frac{[\text{H}_3\text{O}^+][\text{HCO}_3^-]}{[\text{H}_2\text{CO}_3]} = K_{a1} = 4.3 \times 10^{-7}$$

and

$$\frac{[\text{H}_3\text{O}^+][\text{CO}_3^{2-}]}{[\text{HCO}_3^-]} = K_{a2} = 4.8 \times 10^{-11}$$

We emphasize two important points at the outset:

1. The  $[\text{H}_3\text{O}^+]$  in the two ionization equilibria are one and the same.
2.  $K_{a2}$  is invariably smaller than  $K_{a1}$  because the negative charge left behind by the loss of a hydrogen ion in the first ionization causes the second hydrogen ion to be more tightly bound.

Exact calculations of simultaneous equilibria can be complicated. They simplify considerably when the original acid concentration is not too small and the ionization constants  $K_{a1}$  and  $K_{a2}$  differ substantially in magnitude (by a factor of 100 or more). The latter condition is almost always satisfied. Under such conditions, the two equilibria can be treated sequentially, as in the following example.

### EXAMPLE 15.15

Calculate the equilibrium concentrations of  $\text{H}_2\text{CO}_3$ ,  $\text{HCO}_3^-$ ,  $\text{CO}_3^{2-}$ , and  $\text{H}_3\text{O}^+$  in a saturated aqueous solution of  $\text{CO}_2$ , in which the original concentration of  $\text{H}_2\text{CO}_3$  is 0.034 M.

#### Solution

The  $\text{H}_3\text{O}^+$  arises both from the ionization of  $\text{H}_2\text{CO}_3$  and from the subsequent ionization of  $\text{HCO}_3^-$ , but because  $K_{a1} \gg K_{a2}$  it is reasonable to ignore the contribution of  $[\text{H}_3\text{O}^+]$  from the second ionization (as well as from the autoionization of water). These approximations will be checked later in the calculation.

If  $y$  mol  $\text{L}^{-1}$  of  $\text{H}_2\text{CO}_3$  ionizes, the following approximations apply:

	$\text{H}_2\text{CO}_3(aq) + \text{H}_2\text{O}(\ell) \rightleftharpoons \text{H}_3\text{O}^+(aq) + \text{HCO}_3^-(aq)$		
Initial concentration (M)	0.034	$\approx 0$	0
Change in concentration (M)	$-y$	$+y$	$+y$
Equilibrium concentration (M)	$0.034 - y$	$y$	$y$

(Continued)

<sup>2</sup>An accurate description of carbonic acid and solvated  $\text{CO}_2$  is somewhat more complicated than indicated here. In fact, most of the dissolved  $\text{CO}_2$  remains as  $\text{CO}_2(aq)$ , and only a small fraction actually reacts with water to give  $\text{H}_2\text{CO}_3(aq)$ . However, we will indicate by  $[\text{H}_2\text{CO}_3]$  the total concentration of both of these species. Approximately 0.034 mol of  $\text{CO}_2$  dissolves per liter of water at 25°C and atmospheric pressure.

where equating both  $[\text{HCO}_3^-]$  and  $[\text{H}_3\text{O}^+]$  to  $y$  involves the assumption that the subsequent ionization of  $\text{HCO}_3^-$  has only a small effect on its concentration. Then the first ionization equilibrium can be written as

$$\frac{[\text{H}_3\text{O}^+][\text{HCO}_3^-]}{[\text{H}_2\text{CO}_3]} = K_{a1}$$

$$\frac{y^2}{0.034 - y} = 4.3 \times 10^{-7}$$

Solving this equation for  $y$  gives

$$y = 1.2 \times 10^{-4} \text{ M} = [\text{H}_3\text{O}^+] = [\text{HCO}_3^-]$$

$$[\text{H}_2\text{CO}_3] = 0.034 - y = 0.034 \text{ M}$$

The second equilibrium can be written as

$$\frac{[\text{H}_3\text{O}^+][\text{CO}_3^{2-}]}{[\text{HCO}_3^-]} = K_{a2} = \frac{(1.2 \times 10^{-4})[\text{CO}_3^{2-}]}{1.2 \times 10^{-4}} = 4.8 \times 10^{-11}$$

$$[\text{CO}_3^{2-}] = 4.8 \times 10^{-11} \text{ M}$$

The concentration of the base produced in the second ionization,  $[\text{CO}_3^{2-}]$ , is numerically equal to  $K_{a2}$ .

Now we must check the validity of the assumptions. Because

$$[\text{CO}_3^{2-}] = 4.8 \times 10^{-11} \text{ M} \ll 1.2 \times 10^{-4} \text{ M} = [\text{HCO}_3^-]$$

we were justified in ignoring the effect of the second ionization on the concentrations of  $\text{HCO}_3^-$  and  $\text{H}_3\text{O}^+$ . The additional concentration of  $\text{H}_3\text{O}^+$  furnished by  $\text{HCO}_3^-$  is only  $4.8 \times 10^{-11} \text{ M}$ . Finally,  $[\text{H}_3\text{O}^+]$  is much larger than  $10^{-7} \text{ M}$ , so neglecting the water autoionization was also justified.

**Related Problems: 63, 64**

**FIGURE 15.20** Phosphoric acid,  $\text{H}_3\text{PO}_4$ , is a triprotic acid that is used in the manufacture of phosphate fertilizers and in the food industry.

For a triprotic acid such as  $\text{H}_3\text{PO}_4$  (Fig. 15.20), the concentration of the base ( $\text{PO}_4^{3-}$ ) resulting from the third ionization could have been calculated in a similar manner.

An analogous procedure applies to the reactions of a base that can accept two or more hydrogen ions. In a solution of sodium carbonate ( $\text{Na}_2\text{CO}_3$ ), the carbonate ion reacts with water to form first  $\text{HCO}_3^-$  and then  $\text{H}_2\text{CO}_3$ :

$$\frac{[\text{OH}^-][\text{HCO}_3^-]}{[\text{CO}_3^{2-}]} = K_{b1} = \frac{K_w}{K_{a2}} = 2.1 \times 10^{-4}$$

$$\frac{[\text{OH}^-][\text{H}_2\text{CO}_3]}{[\text{HCO}_3^-]} = K_{b2} = \frac{K_w}{K_{a1}} = 2.3 \times 10^{-8}$$

In this case  $K_{b1} \gg K_{b2}$ , so essentially all the  $\text{OH}^-$  arises from the first reaction.

The ensuing calculation of the concentrations of species present is just like that in Example 15.15.

### 15.7.2 Effect of pH on Solution Composition

Changing the pH of a solution shifts the positions of all acid–base equilibria, including those involving polyprotic acids. Acid–base equilibrium expressions

and equilibrium constants are used to calculate the amount of the change. For example, the two equilibria that apply to solutions containing  $\text{H}_2\text{CO}_3$ ,  $\text{HCO}_3^-$ , and  $\text{CO}_3^{2-}$  can be written as

$$\frac{[\text{HCO}_3^-]}{[\text{H}_2\text{CO}_3]} = \frac{K_{a1}}{[\text{H}_3\text{O}^+]} \quad \frac{[\text{CO}_3^{2-}]}{[\text{HCO}_3^-]} = \frac{K_{a2}}{[\text{H}_3\text{O}^+]}$$

At a given pH, the right sides are known and the relative amounts of the three carbonate species can be calculated. This is illustrated by the following example.

### EXAMPLE 15.16

Calculate the fraction of carbonate present as  $\text{H}_2\text{CO}_3$ ,  $\text{HCO}_3^-$ , and  $\text{CO}_3^{2-}$  at pH 10.00.

#### Solution

At this pH,  $[\text{H}_3\text{O}^+] = 1.0 \times 10^{-10}$  M, and the values of  $K_{a1}$  and  $K_{a2}$  for the preceding equations are used to find

$$\frac{[\text{HCO}_3^-]}{[\text{H}_2\text{CO}_3]} = \frac{4.3 \times 10^{-7}}{1.0 \times 10^{-10}} = 4.3 \times 10^3$$

$$\frac{[\text{CO}_3^{2-}]}{[\text{HCO}_3^-]} = \frac{4.8 \times 10^{-11}}{1.0 \times 10^{-10}} = 0.48$$

It is most convenient to rewrite these ratios with the same species (say,  $\text{HCO}_3^-$ ) in the denominator. The first equation becomes

$$\frac{[\text{H}_2\text{CO}_3]}{[\text{HCO}_3^-]} = \frac{1}{4.3 \times 10^3} = 2.3 \times 10^{-4}$$

The fraction of each species present is obtained by dividing the concentration of each species by the sum of the three concentrations. For  $\text{H}_2\text{CO}_3$  this gives

$$\text{fraction H}_2\text{CO}_3 = \frac{[\text{H}_2\text{CO}_3]}{[\text{H}_2\text{CO}_3] + [\text{HCO}_3^-] + [\text{CO}_3^{2-}]}$$

This can be simplified by dividing numerator and denominator by  $[\text{HCO}_3^-]$  and substituting the ratios that have already been calculated:

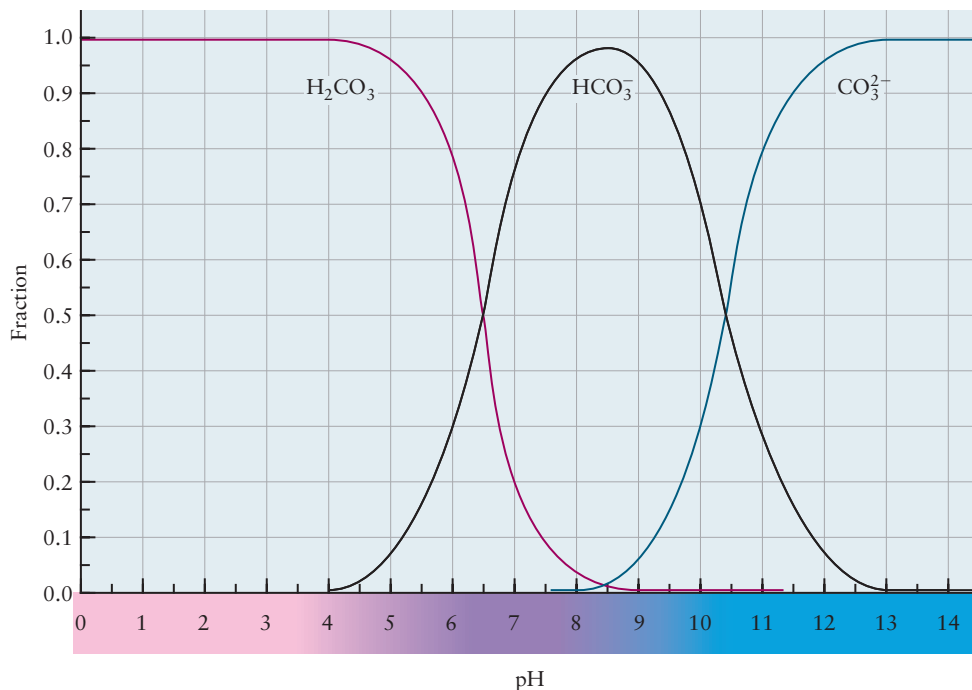

$$\begin{aligned} \text{fraction H}_2\text{CO}_3 &= \frac{[\text{H}_2\text{CO}_3]/[\text{HCO}_3^-]}{([\text{H}_2\text{CO}_3]/[\text{HCO}_3^-]) + 1 + ([\text{CO}_3^{2-}]/[\text{HCO}_3^-])} \\ &= \frac{2.3 \times 10^{-4}}{2.3 \times 10^{-4} + 1 + 0.48} = 1.6 \times 10^{-4} \end{aligned}$$

In the same way the fractions of  $\text{HCO}_3^-$  and  $\text{CO}_3^{2-}$  present are calculated to be 0.68 and 0.32, respectively.

**Related Problems:** 67, 68

Repeating the calculation of Example 15.16 at a series of different pH values gives the graph shown in Figure 15.21. At high pH,  $\text{CO}_3^{2-}$  predominates, and at low pH,  $\text{H}_2\text{CO}_3$  is the major species. At intermediate pH (near pH 8, the approximate pH of seawater), the hydrogen carbonate ion  $\text{HCO}_3^-$  is most prevalent. The variation in composition of sedimentary rocks from different locations can be traced back to the effect of pH on solution composition. Sediments containing carbonates were formed from alkaline (high-pH) lakes and oceans in which  $\text{CO}_2$  was present mainly as  $\text{CO}_3^{2-}$  ion. Sediments deposited from waters with intermediate pH are hydrogen carbonates or mixtures between carbonates and hydrogen carbonates. An example of the latter is trona

**FIGURE 15.21** The equilibrium fractions of  $\text{H}_2\text{CO}_3$ ,  $\text{HCO}_3^-$  and  $\text{CO}_3^{2-}$  that are present in aqueous solution at different values of the pH. (See cautionary footnote in Section 15.7.1 on page 646.)

( $2\text{Na}_2\text{CO}_3 \cdot \text{NaHCO}_3 \cdot 2\text{H}_2\text{O}$ ), an ore from the western United States that is an important source of both carbonates of sodium. Acidic waters did not deposit carbonates, but instead released  $\text{CO}_2(\text{g})$  to the atmosphere.

## 15.8 Organic Acids and Bases: Structure and Reactivity

One of the goals of chemistry is to understand the relationship between *structure* and *function*. How does the molecular structure of a compound (including its attached functional groups) affect its chemical reactivity? As an example of the exploration of structure–function relationships, we consider here the trends in acid strength in organic compounds. This extends the earlier discussion of acid strength in inorganic acids (see Section 15.3) and illustrates the usefulness of chemical concepts such as electronegativity and resonance in predicting reactivity. This section depends on the thermodynamic description in Section 14.3.

Table 15.2 lists a number of organic acids with  $\text{p}K_{\text{a}}$  values in aqueous solution between 0 (strong acid) and 14 (weak acid). Almost all of them are carboxylic acids with the characteristic  $-\text{COOH}$  functional group, which can donate a proton to a water solvent molecule by breaking the  $\text{O}-\text{H}$  bond to form a negative ion and  $\text{H}^+$ . Acid ionization constants can be defined for many other functional groups besides carboxylic acids, because many organic reactions involve the transfer of hydrogen ions or catalysis by acids or bases. Consequently these acid ionization constants provide important information about reactivity of the compounds.

Aqueous solutions can be used to describe acidity only in compounds with values of the  $\text{p}K_{\text{a}}$  between about 14 and 0. Values much greater than 14 mean that there is negligible ionization in aqueous solution, and values much less than 0 mean that ionization is essentially complete. Because our goal is a scale of *relative* acidities, we can use information from nonaqueous solvents as well as from water. In a sufficiently basic solvent, even a very weak acid will show some

## CONNECTION TO BIOLOGY

## Buffered Blood Plasma

Both the interiors of cells and the fluids that surround them must be maintained at relatively constant pH because the activities of enzymes (biological catalysts, see Section 18.8) are markedly pH dependent. The phosphate buffer system ( $\text{HPO}_4^{2-}/\text{H}_2\text{PO}_4^-$ ) is one of the systems that stabilize pH within cells whereas the bicarbonate buffer system ( $\text{HCO}_3^-/\text{H}_2\text{CO}_3$ ) stabilizes pH in fluids, including blood. The bicarbonate buffer system in blood is particularly interesting for a number of reasons. First, the  $\text{p}K_a$  of carbonic acid is 3.57 at physiological temperatures ( $37^\circ\text{C}$ ), which is far removed from the desired pH of 7.4, so it would appear that it would be a poor choice for this application. What makes it work is the tight coupling of the buffer system with the dissolution equilibrium of  $\text{CO}_2$  in plasma. Not only does this coupling provide an additional source of carbonic acid but it also provides a mechanism for the dynamic regulation of a number of metabolic reactions through changes in respiration rates. Finally, both pH and the concentration of dissolved  $\text{CO}_2$  enhance and regulate the delivery of  $\text{O}_2$  from the lungs to tissues via the capillaries. Let's examine each of these issues in turn.

We can use Equation 15.7 (often called the Henderson–Hasselbalch equation in biochemistry) to calculate the buffering capacity (the quantity of acid or base added that changes the pH by 1 unit) of the bicarbonate system in plasma

$$\text{pH} = 7.4 = 3.57 - \log \frac{[\text{H}_2\text{CO}_3]}{[\text{HCO}_3^-]}$$

so the ratio of bicarbonate to carbonic acid is about 6800 in plasma under normal physiological conditions. The concentration of bicarbonate in blood is one of several indicators of acid–base imbalance and it is generally measured as part of an electrolyte panel in routine blood tests; a typical value is 20 mM. The carbonic acid concentration under these conditions is only about  $3 \mu\text{M}$ . Using the approach developed in Example 15.8, we calculate the buffering capacity of this system to be only  $2.7 \mu\text{M}$  with respect to added  $\text{OH}^-$ , which is a typical  $\text{OH}^-$  concentration in plasma. The system would have essentially no buffering capacity were it not coupled to the equilibrium established between gas phase and dissolved  $\text{CO}_2$  as represented by the following reactions,

in which (aq) refers to the plasma phase. The equilibrium constant for the second reaction is rather small under normal physiological conditions (in mammals) but it provides the additional source of carbonic acid needed to make a viable buffer system. We can combine the equilibrium constants for the simultaneous reactions using the method developed in Section 14.4 to get

$$K_a K_h = \frac{[\text{H}^+][\text{HCO}_3^-]}{[\text{CO}_2(\text{aq})]} = \frac{[\text{H}^+][\text{HCO}_3^-]}{(P_{\text{CO}_2})/K}$$

in which  $P_{\text{CO}_2}$  and  $K$  are the partial pressure and Henry's law constant of  $\text{CO}_2$ . We can rearrange this equation to get

$$\text{pH} = \text{p}K_a + \text{p}K_h + \frac{K[\text{HCO}_3^-]}{(P_{\text{CO}_2})}$$

$\text{p}K_a = 3.57$  and  $\text{p}K_h = 2.52$  so the first two terms in the Henderson–Hasselbalch equation for the coupled reactions yield an initial  $\text{pH} = 6.1$ , which is still much lower than the desired value of 7.4 but within the range considered acceptable, and certainly much better than what could be accomplished using the bicarbonate buffer system alone. This coupled buffer system is an open system in which the total carbonic acid pool available for buffering is largely provided by dissolved  $\text{CO}_2$ . The Henry's law constant for  $\text{CO}_2$  in plasma at  $37^\circ\text{C}$  is about  $2 \text{ L atm mol}^{-1}$  so the concentration of dissolved  $\text{CO}_2$  at the typical partial pressure found in the lungs (40 torr) is about 1.2 mM, which provides an adequate concentration of acid to ensure sufficient buffering capacity.

Rapidly metabolizing tissues, such as muscle, produce large quantities of  $\text{CO}_2$  and hydrogen ions, which are both heterotropic effectors that promote the release of oxygen from the oxygenated form of hemoglobin. One of the mechanisms by which this occurs is through the formation of salt bridges, ionic bonds between amino acids that stabilize certain protein structures over others. Low pH leads to the formation of salt bridges by protonating the side chain of the amino acid histidine, which binds electrostatically to the deprotonated carboxylate group of the amino acid aspartate in the same chain, resulting in a conformational change that favors the quaternary structure (see Section 7.6) of deoxyhemoglobin, thus promoting the release of  $\text{O}_2$ .  $\text{CO}_2$  produces a similar effect, though indirectly, through the second and third reactions listed above. The regulation of  $\text{O}_2$  binding through these mechanisms is referred to as the Bohr effect (named after Christian Bohr, the father of Neils Bohr), which has at least two important physiological consequences. First, it enhances the total fraction of bound oxygen that can be delivered by hemoglobin as it

moves from  $P_{O_2} \approx 100$  torr in the lungs to  $P_{O_2} \approx 30$  torr in tissues. Only about 66% of the oxygen stored in hemoglobin is available to be transferred if the pH is the same in both environments. This fraction increases to 77% at pH 7.2 (characteristic of actively metabolizing tissues) with no  $CO_2$  present, and to 88% at pH 7.2 with a  $CO_2$  partial pressure of 40 torr. In addition to increasing the overall quantity of  $O_2$  available, heterotropic regulation provides a mechanism to respond differentially to cells undergoing metabolism at different rates. Figure C15.1 shows that lowering the pH dramatically increases the amount of oxygen transferred. The curves all shift to the right, indicating a smaller fraction of bound oxygen at typical partial pressures found in venous blood. Increasing the partial pressure of  $CO_2$  has the same effect as shown by the pair of curves labeled pH 7.4 (no  $CO_2$ ) and pH 7.4 (40 torr  $CO_2$ ).

Regulating pH is vital to all cells because many cellular processes are catalyzed by enzymes, the activities of

which depend strongly on pH. Coupling of the bicarbonate buffer system in blood to  $CO_2$  provides a mechanism for controlling pH through respiration. Increases in the plasma hydrogen ion concentration shift the equilibrium toward carbonic acid, which ultimately produces gaseous  $CO_2$  in the reverse of the series of reactions listed earlier. pH can be restored to the desired value by increasing the rate of respiration, which removes  $CO_2(g)$  and shifts the equilibria back to the right. It is possible to overdo it, however. Hyperventilation (breathing faster and/or deeper than normal) can remove such large amounts of  $CO_2$  that the pH rises to unhealthy levels, causing symptoms such as dizziness or fainting. Sudden exposure to high altitudes, for example during skiing and mountain climbing, can also cause hyperventilation. Adaptation to high altitudes is accomplished, in part, by excreting bicarbonate through the kidneys, thus shifting the equilibria to the right and increasing pH.

**FIGURE C15.1** The effect of pH on the fraction of protein that is oxygenated, plotted as a function of the  $O_2$  partial pressure. (Adapted from Reginald H. Garrett and Charles M. Grisham, *Biochemistry*, 4e, figure 14.5, p. 474, Boston: Brooks/Cole, Cengage Learning, 2010; © Cengage Learning)

ionization; in a sufficiently acidic solvent, even a very strong acid will be only partially ionized. This allows an extension of the  $pK_a$  scale above 14 and below 0, provided we consistently think of it as only a relative scale. We thus generalize our earlier definition of  $K_a$ , which was limited to aqueous solvents, to describe acid ionization in a general solvent:

Our assumption is that the *difference* in  $pK_a$  values for two different acids in a given solvent

$$pK_a - pK'_a = -\log_{10}(K_a/K'_a)$$

depends only weakly on the particular solvent chosen, even though the actual  $pK_a$  values are very sensitive to the solvent. If this is the case, we can extend the  $pK_a$  scale beyond the range that comes from measurements of pH in aqueous solution. The result is given in Table 15.4.

TABLE 15.4

## Acidities of Organic Compounds

Acid	$pK_a$	Conjugate Base
$\text{CH}_3\text{—CH}_3$	50	$\text{CH}_3\text{—}\ddot{\text{C}}\text{H}_2^-$
$\text{CH}_4$	49	$:\text{CH}_3^-$
$\text{CH}_2=\text{CH}_2$	44	$\text{CH}_2=\ddot{\text{C}}\text{H}^-$
$\text{C}_6\text{H}_6$	43	$\text{C}_6\text{H}_5^-$
$\text{C}_6\text{H}_5\text{CH}_3$	41	$\text{C}_6\text{H}_5\ddot{\text{C}}\text{H}_2^-$
$\text{CH}_3\text{CH}_2\text{NH}_3^+$	35	$\text{CH}_3\text{CH}_2\text{NH}_2$
$(\text{C}_6\text{H}_5)_3\text{CH}$	32	$(\text{C}_6\text{H}_5)_3\ddot{\text{C}}^-$
$\text{HC}\equiv\text{CH}$	25	$\text{HC}\equiv\ddot{\text{C}}^-$
$\text{CH}_3\text{COCH}_3$	20	$\text{CH}_3\text{CO}\ddot{\text{C}}\text{H}_2^-$
$(\text{CH}_3)_3\text{C}\ddot{\text{O}}\text{H}$	18	$(\text{CH}_3)_3\text{C}\ddot{\text{O}}:^-$
$\text{C}_2\text{H}_5\ddot{\text{O}}\text{H}$	16	$\text{C}_2\text{H}_5\ddot{\text{O}}:^-$
$\text{H}_2\ddot{\text{O}}$	15.7	$\text{H}\ddot{\text{O}}:^-$

A thermodynamic analysis shows that this difference in  $pK_a$  values is related to the difference in the standard Gibbs free energy changes for the two reactions:

$$\Delta G^\circ - \Delta G'^{\circ} = -RT(\ln K_a - \ln K'_a) = 2.3 RT(pK'_a - pK_a) \quad [15.8]$$

The factor 2.3 appears when we relate the natural logarithm to the base 10 logarithm. The difference in standard Gibbs free energy changes can be separated into one contribution arising from standard enthalpy changes and one from absolute entropy changes:

$$\Delta G^\circ - \Delta G'^{\circ} = \Delta H^\circ - \Delta H'^{\circ} - T(\Delta S^\circ - \Delta S'^{\circ})$$

If we change the structure of an organic acid, what will be the effect on the  $pK_a$ ? In general, modest structural changes such as the replacement of a functional group have only small effects on the entropy change of ionization, and most of the influence comes through changes in the enthalpy change of ionization. The quantitative magnitude of this effect is calculated in the following example.

### EXAMPLE 15.17

How large a change in energy (or enthalpy) of reaction is needed for an acid ionization to lower the  $pK_a$  by one unit at 25°C? Assume that the entropy of ionization is unchanged. (We use unprimed variables to indicate the reaction with the lower  $pK_a$ , or higher  $K_a$ .)

#### Solution

The entropy of ionization is unchanged, so  $\Delta S^\circ = \Delta S'^{\circ}$ , and  $\Delta H^\circ - \Delta H'^{\circ} = \Delta G^\circ - \Delta G'^{\circ}$ . If the change in  $pK_a$  is 1.00, then the change in Gibbs free energy of reaction is

$$\begin{aligned} \Delta G^\circ - \Delta G'^{\circ} &= -RT(\ln K_a - \ln K'_a) \\ &= 2.3 RT(pK'_a - pK_a) = 2.3 RT(-1) \\ &= 2.3(8.315 \text{ J mol}^{-1} \text{ K}^{-1})(298 \text{ K})(-1) \\ &= -5700 \text{ J mol}^{-1} = -5.7 \text{ kJ mol}^{-1} \end{aligned}$$

If we assume that this change in Gibbs free energy is entirely due to a change in enthalpy, then one unit of  $pK_a$  change corresponds to a lowering of the enthalpy of the products relative to the reactants by 5.7 kJ mol<sup>-1</sup>. (Note that the lowering the energy of the products in the acid ionization reaction relative to the reactants increases the  $K_a$  and lowers the  $pK_a$ .)

**Related Problems:** 69, 70

The sign of the effect is clear from Example 15.17: If a change in structure of a molecule lowers its  $pK_a$  (making it a stronger acid), then the energy change for the acid ionization must be lowered. Another way to say this is that the effect of the structural change is to lower the energy of the conjugate base relative to that of the original acid, in other words, to increase the stability of the conjugate base.

An exploration of structure–function relations that lie behind the data in Table 15.4 must examine the effects of changes in molecular structure on the relative energetic stability of acid and conjugate base. Here we focus on the importance of resonance in Lewis dot structures in lowering the energy of the conjugate base.

Let's consider why the acidity of carboxylic acids is considerably greater than that of alcohols. For example, the  $pK_a$  of acetic acid,  $\text{CH}_3\text{COOH}$ , is considerably lower than that of ethanol,  $\text{CH}_3\text{CH}_2\text{OH}$  (4.8 versus 16). Some of this may be due to the “inductive effect” of substituting an electronegative O atom for two H atoms. But, inductive effects do not typically cause such large changes (more than 11 units of pH). An alternative explanation is found in the concept of resonance stabilization, which was introduced in Section 3.9 and discussed

in the context of organic molecules in Section 7.4. A single Lewis diagram can be drawn for the conjugate base of ethanol:

On the other hand, the conjugate base of acetic acid is represented by a resonance hybrid of two Lewis diagrams:

The possibility of more than one resonance form stabilizes the acetate ion and contributes to the greater acidity of acetic acid.

A second example of resonance stabilization affecting acidity arises in a comparison of phenols and alcohols. Phenol (also called carboic acid) has a  $pK_a$  of 10, whereas the  $pK_a$  values for typical alcohols range from 16 to 18. The reason for this difference is the greater stability of the conjugate base (the phenoxide ion,  $\text{C}_6\text{H}_5\text{O}^-$ ) due to the spreading out of the negative charge over the aromatic ring. Several different resonance forms contribute to the stability of the phenoxide ion.

It is important to consider both the reactant and the product when you make these arguments. The reactant acid phenol has two resonance structures, so is itself stabilized by resonance. If a reactant acid is resonance stabilized, that will favor the reactants in the acid ionization equilibrium, making it less acidic. But the phenoxide ion product has three resonance structures, so shows an even larger resonance stabilization. Thus, on the whole, phenol is made more acidic by virtue of the resonance stabilization of the conjugate base product.

As you consider the effect of resonance stabilization on acid strength, or the effect of the electronegativity on oxoacid strength (see Section 15.3.1), it is important to keep in mind the caution “all other factors being equal.” A beginning student might fallaciously argue that HF would be more acidic than HCl because F is more electronegative than Cl. The  $-\text{X}-\text{O}-\text{H}$  series are similar enough in the other important factors that one gets reasonable predictions based on electronegativity arguments alone.

Finally, the free energy of solvation of the ions in solution also plays a key role in acid strength. The solvation of an ion involves both a lowering in energy and a change in entropy as polar water molecules rearrange themselves around, and potentially hydrogen bond to, the newly formed anion  $\text{A}^-$ . The free energy of solvation of small ions in water (also called the free energy of hydration) ranges from  $-200$  to  $-400 \text{ kJ mol}^{-1}$  for singly charged ions.

### EXAMPLE 15.18

By using resonance Lewis diagrams, predict which will be the stronger acid:  $\text{H}_2\text{SO}_3$  or  $\text{H}_2\text{SO}_4$  (consider the first acid ionization), all other factors being equal.

(Continued)

**Solution**

There are two resonance Lewis structures for the conjugate base of  $\text{H}_2\text{SO}_3$ ,  $\text{HSO}_3^-$ :

The conjugate base of  $\text{H}_2\text{SO}_4$ ,  $\text{HSO}_4^-$ , has three equivalent resonance structures.

The extra stabilization, resulting from three rather than two resonance structures, of the conjugate base makes  $\text{H}_2\text{SO}_4$  the stronger acid.

**Related Problems:** 69, 70

## 15.9 A DEEPER LOOK Exact Treatment of Acid–Base Equilibria

Sections 15.4 and 15.5 outline methods for calculating equilibria involving weak acids, bases, and buffer solutions. There we assume that the amount of hydronium ion (or hydroxide ion) resulting from the ionization of water can be neglected in comparison with that produced by the ionization of dissolved acids or bases. In this section, we replace that approximation by a treatment of acid–base equilibria that is exact, within the limits of the mass-action law. This approach leads to somewhat more complicated equations, but it serves several purposes. It has great practical importance in cases in which the previous approximations no longer hold, such as very weak acids or bases or very dilute solutions. It includes as special cases the various aspects of acid–base equilibrium considered earlier. Finally, it provides a foundation for treating amphoteric equilibrium later in this section.

Consider a general case in which the initial concentration of a weak acid HA is called  $c_a$ , and the initial concentration of its conjugate base (which for simplicity is assumed to come from the salt NaA) is  $c_b$ . In solution there will be five dissolved species: HA,  $\text{A}^-$ ,  $\text{Na}^+$ ,  $\text{H}_3\text{O}^+$ , and  $\text{OH}^-$ . It is necessary to write down and solve five independent equations that relate the equilibrium concentrations of these species to the initial concentrations  $c_a$  and  $c_b$  and to  $K_a$ , the acid ionization constant of HA. The first equation is simply

$$[\text{Na}^+] = c_b \quad (\text{a})$$

reflecting the fact that the  $\text{Na}^+(aq)$  from the dissolved salt is a spectator ion that does not take part in the acid–base equilibrium. Next there are two equilibrium relations:

$$[\text{H}_3\text{O}^+][\text{OH}^-] = K_w \quad (\text{b})$$

$$\frac{[\text{H}_3\text{O}^+][\text{A}^-]}{[\text{HA}]} = K_a \quad (\text{c})$$

The fourth relation is one of stoichiometry, or conservation of “A-material”:

$$c_a + c_b = [\text{HA}] + [\text{A}^-] \quad (\text{d})$$

The original A-material was introduced either as acid or as base, with a total concentration of  $c_a + c_b$ . When equilibrium is reached, some redistribution has doubtless occurred, but the *total* concentration,  $[\text{HA}] + [\text{A}^-]$ , must be the same. The fifth and final relation results from charge balance. The solution must be electrically neutral, so the total amount of positive charge must be equal to the total amount of negative charge:

$$[\text{Na}^+] + [\text{H}_3\text{O}^+] = [\text{A}^-] + [\text{OH}^-] \quad (\text{e})$$

These five independent equations completely determine the five unknown concentrations. To solve them, begin by substituting (a) into (e) and solving for  $[\text{A}^-]$ :

$$[\text{A}^-] = c_b + [\text{H}_3\text{O}^+] - [\text{OH}^-] \quad (\text{e}')$$

Next, insert (e') into (d) and solve for  $[\text{HA}]$ :

$$[\text{HA}] = c_a + c_b - [\text{A}^-] = c_a - [\text{H}_3\text{O}^+] + [\text{OH}^-] \quad (\text{d}')$$

Next, substitute both (d') and (e') into (c) to find

$$\frac{[\text{H}_3\text{O}^+](c_b + [\text{H}_3\text{O}^+] - [\text{OH}^-])}{(c_a - [\text{H}_3\text{O}^+] + [\text{OH}^-])} = K_a \quad (\text{c}')$$

There are two ways to proceed with the general equation (c'). First, we can set up the exact solution for  $[\text{H}_3\text{O}^+]$ , a procedure that is useful for very weak acids or bases or for very dilute solutions. Or, we can reduce (c') in various limits to cases already considered.

For the exact solution, eliminate  $[\text{OH}^-]$  in (c') by using (b). This gives

$$\frac{[\text{H}_3\text{O}^+] \left( c_b + [\text{H}_3\text{O}^+] - \frac{K_w}{[\text{H}_3\text{O}^+]} \right)}{\left( c_a - [\text{H}_3\text{O}^+] + \frac{K_w}{[\text{H}_3\text{O}^+]} \right)} = K_a$$

The numerator and denominator are multiplied by  $[\text{H}_3\text{O}^+]$  and the fraction is cleared by moving the denominator to the right side:

$$[\text{H}_3\text{O}^+](c_b[\text{H}_3\text{O}^+] + [\text{H}_3\text{O}^+]^2 - K_w) = K_a(c_a[\text{H}_3\text{O}^+] - [\text{H}_3\text{O}^+]^2 + K_w)$$

This can be rewritten as

$$[\text{H}_3\text{O}^+]^3 + (c_b + K_a)[\text{H}_3\text{O}^+]^2 - (K_w + c_a K_a)[\text{H}_3\text{O}^+] - K_a K_w = 0$$

This is a cubic equation for  $[\text{H}_3\text{O}^+]$ , which can be solved with a calculator. The concentrations of  $\text{OH}^-$ ,  $\text{A}^-$ , and  $\text{HA}$  can then be found by successive substitutions into (b), (e'), and (d').

Alternatively, the general equation (c') can be examined in various limits. In an acidic buffer (as in Examples 15.10 and 15.11), if it can be assumed that  $[\text{H}_3\text{O}^+] \gg [\text{OH}^-]$ , then (c') simplifies to

$$\frac{[\text{H}_3\text{O}^+](c_b + [\text{H}_3\text{O}^+])}{(c_a - [\text{H}_3\text{O}^+])} = K_a$$

which is exactly the equation used in those examples. If, in addition,  $c_b = 0$ , the weak-acid ionization limit of Examples 15.6 and 15.7 is reached. In a basic buffer, if it can be assumed that  $[\text{OH}^-] \gg [\text{H}_3\text{O}^+]$ , then (c') simplifies to

$$\frac{(K_w/[\text{OH}^-])(c_b - [\text{OH}^-])}{(c_a + [\text{OH}^-])} = K_a$$

Here (b) was used to substitute for  $[\text{H}_3\text{O}^+]$  where it multiplies the whole expression. This can be rewritten as

$$\frac{[\text{OH}^-](c_a + [\text{OH}^-])}{(c_b - [\text{OH}^-])} = \frac{K_w}{K_a} = K_b$$

which is exactly the equation used in Example 15.12. If no acid is present initially ( $c_a = 0$ ), this expression reduces to the weak-base ionization limits of Examples 15.8 and 15.9. The general approach includes all of the previous calculations as special cases.

Unless conditions require the use of the exact solution, approximate equations are preferable because they are easier to apply and provide greater physical insight. If a calculation (ignoring water autoionization) of the ionization of a weak acid gives a concentration of  $\text{H}_3\text{O}^+$  smaller than  $10^{-6}$  M or if a calculation of base ionization gives a concentration of  $\text{OH}^-$  smaller than  $10^{-6}$  M, then we have to use the more exact treatment. For buffer solutions, a pH near 7 does not necessarily mean that water ionization is important, unless the acid or base concentration becomes very small.

### EXAMPLE 15.19

Calculate the pH of a  $1.00 \times 10^{-5}$  M solution of  $\text{HCN}(aq)$ . The  $K_a$  of  $\text{HCN}(aq)$  is  $6.17 \times 10^{-10}$ .

#### Solution

Suppose the autoionization of water is ignored and the method of Examples 15.6 and 15.7 is used. This gives  $[\text{H}_3\text{O}^+] = 7.9 \times 10^{-8}$  M, which of course makes no sense, because it is *lower* than the concentration of hydronium ion in pure water.  $\text{HCN}$  is a very weak acid, but it is nonetheless an acid, not a base.

So, we have to use the exact cubic equation for  $[\text{H}_3\text{O}^+]$ , inserting into it the proper coefficients and taking  $c_a = 1.00 \times 10^{-5}$  and  $c_b = 0$ . This gives

$$[\text{H}_3\text{O}^+]^3 + 6.17 \times 10^{-10}[\text{H}_3\text{O}^+]^2 - 1.617 \times 10^{-14}[\text{H}_3\text{O}^+] - 6.17 \times 10^{-24} = 0$$

Unfortunately, there is no method as simple as the quadratic formula to solve a cubic equation. The easiest way to solve this equation is to try a series of values for  $[\text{H}_3\text{O}^+]$  on the left side, varying them to obtain a result as close as possible to 0 (see Appendix C). It is safe to assume that the final answer will be slightly larger than  $1 \times 10^{-7}$ , so the initial guesses should be of that magnitude. Carrying out the procedure gives

$$[\text{H}_3\text{O}^+] = 1.27 \times 10^{-7} \text{ M} \qquad \text{pH} = 6.90$$

**Related Problems: 71, 72**

### 15.9.1 Amphoteric Equilibria

A second situation in which an exact analysis of acid–base equilibrium is useful occurs when an amphoteric species is dissolved in water. The hydrogen carbonate ion ( $\text{HCO}_3^-$ ) is amphoteric because it can act as an acid in the equilibrium

or as a base in the equilibrium

If sodium hydrogen carbonate ( $\text{NaHCO}_3$ ) is dissolved in water, there is a competition between the tendency of  $\text{HCO}_3^-$  to accept hydrogen ions and to donate them. Because  $K_{b2} > K_{a2}$ , there should be more production of  $\text{OH}^-$  than of  $\text{H}_3\text{O}^+$ , so the solution should be basic.

In an exact treatment of this equilibrium, there are six unknown concentrations—those of  $\text{Na}^+$ ,  $\text{H}_2\text{CO}_3$ ,  $\text{HCO}_3^-$ ,  $\text{CO}_3^{2-}$ ,  $\text{OH}^-$ , and  $\text{H}_3\text{O}^+$ . Two equilibrium equations were already presented, and a third relates  $[\text{OH}^-]$  and  $[\text{H}_3\text{O}^+]$  to  $K_w$ . If  $[\text{HCO}_3^-]_0$  is the original concentration of  $\text{NaHCO}_3$ , then from stoichiometry

$$[\text{HCO}_3^-]_0 = [\text{HCO}_3^-] + [\text{H}_2\text{CO}_3] + [\text{CO}_3^{2-}]$$

because the total amount of carbonate material is conserved. Any reduction in  $[\text{HCO}_3^-]$  must be compensated by a corresponding increase in either  $[\text{H}_2\text{CO}_3]$  or  $[\text{CO}_3^{2-}]$ . Next we use the principle of conservation of charge. The positively charged species present are  $\text{Na}^+$  and  $\text{H}_3\text{O}^+$ , and the negatively charged species are  $\text{HCO}_3^-$ ,  $\text{CO}_3^{2-}$ , and  $\text{OH}^-$ . Because there is overall charge neutrality,

$$[\text{Na}^+] + [\text{H}_3\text{O}^+] = [\text{HCO}_3^-] + 2[\text{CO}_3^{2-}] + [\text{OH}^-]$$

where the coefficient 2 for  $[\text{CO}_3^{2-}]$  arises because each carbonate ion is doubly charged. In addition, the  $\text{Na}^+$  concentration is unchanged, so

$$[\text{Na}^+] = [\text{HCO}_3^-]_0$$

In principle, these six equations can be solved simultaneously to calculate the exact  $[\text{H}_3\text{O}^+]$  for an arbitrary initial concentration of  $\text{HCO}_3^-$ . The result is complex and gives little physical insight. Instead, we give only a simpler, approximate solution, which is sufficient in the cases considered here. Subtracting the carbonate balance equation from the charge balance equation gives

$$[\text{H}_3\text{O}^+] = [\text{CO}_3^{2-}] - [\text{H}_2\text{CO}_3] + [\text{OH}^-]$$

The three equilibrium expressions are used to rewrite this as

$$[\text{H}_3\text{O}^+] = K_{a2} \frac{[\text{HCO}_3^-]}{[\text{H}_3\text{O}^+]} - \frac{[\text{H}_3\text{O}^+][\text{HCO}_3^-]}{K_{a1}} + \frac{K_w}{[\text{H}_3\text{O}^+]}$$

where  $[\text{CO}_3^{2-}]$  and  $[\text{H}_2\text{CO}_3]$  have been eliminated in favor of  $[\text{HCO}_3^-]$ .

Multiplying by  $K_{a1}[\text{H}_3\text{O}^+]$  gives

$$K_{a1}[\text{H}_3\text{O}^+]^2 + [\text{HCO}_3^-][\text{H}_3\text{O}^+]^2 = K_{a1}K_{a2}[\text{HCO}_3^-] + K_{a1}K_w$$

$$[\text{H}_3\text{O}^+]^2 = \frac{K_{a1}K_{a2}[\text{HCO}_3^-] + K_{a1}K_w}{K_{a1} + [\text{HCO}_3^-]}$$

This equation still contains two unknown quantities,  $[\text{H}_3\text{O}^+]$  and  $[\text{HCO}_3^-]$ . Because both  $K_{a2}$  and  $K_{b2}$  are small,  $[\text{HCO}_3^-]$  should be close to its original value,  $[\text{HCO}_3^-]_0$ . If  $[\text{HCO}_3^-]$  is set equal to  $[\text{HCO}_3^-]_0$ , this becomes

$$[\text{H}_3\text{O}^+]^2 \approx \frac{K_{a1}K_{a2}[\text{HCO}_3^-]_0 + K_{a1}K_w}{K_{a1} + [\text{HCO}_3^-]_0}$$

which can be solved for  $[\text{H}_3\text{O}^+]$ . In many cases of interest,  $[\text{HCO}_3^-]_0 \gg K_{a1}$ , and  $K_{a2}[\text{HCO}_3^-]_0 \gg K_w$ . When this is so, the expression simplifies to

$$[\text{H}_3\text{O}^+]^2 \approx K_{a1}K_{a2}$$

$$[\text{H}_3\text{O}^+] \approx \sqrt{K_{a1}K_{a2}}$$

$$\text{pH} \approx \frac{1}{2} (\text{p}K_{a1} + \text{p}K_{a2})$$

so the pH of such a solution is the average of the  $\text{p}K_a$  values for the two ionizations.

### EXAMPLE 15.20

What is the pH of a solution that is 0.100 M in  $\text{NaHCO}_3$ ?

#### Solution

First, the two assumptions are checked:

$$[\text{HCO}_3^-]_0 = 0.100 \gg 4.3 \times 10^{-7} = K_{a1}$$

$$[\text{HCO}_3^-]_0 K_{a2} = 4.8 \times 10^{-12} \gg 1.0 \times 10^{-14} = K_w$$

so both are satisfied. Therefore,

$$[\text{H}_3\text{O}^+] = \sqrt{K_{a1}K_{a2}} = 4.5 \times 10^{-9} \text{ M}$$

$$\text{pH} = 8.34$$

and the solution is basic, as expected.

## 15.9.2 Titration of a Polyprotic Acid

A polyprotic acid has more than one equivalence point. The first equivalence point occurs when the volume  $V_{e1}$  of base added is sufficient to remove one hydrogen ion from each acid molecule,  $V_{e2}$  is the volume sufficient to remove two hydrogen ions from each, and so forth. A diprotic acid shows two equivalence points, and a triprotic acid, three. The equivalent volumes are related to each other by

$$V_{e1} = \frac{1}{2} V_{e2} = \frac{1}{3} V_{e3}$$

Figure 15.22 shows a titration curve for triprotic phosphoric acid. The three equivalence points are at 100.0 mL, 200.0 mL, and 300.0 mL. Calculating the pH as a function of the volume of added base presents no new complications beyond those already considered. The initial pH is given by a calculation analogous to that of Example 15.15, and the pH in the flat regions between equivalence points is obtained by a buffer calculation like that for a diprotic acid. For

**FIGURE 15.22** A titration curve for the titration of a polyprotic acid (phosphoric acid) by a strong base. The curve shown is for 100.0 mL of 0.1000 M  $\text{H}_3\text{PO}_4$  titrated with 0.1000 M NaOH. No clear third equivalence point is seen at 300 mL because  $K_a$  for  $\text{HPO}_4^{2-}$  is not much greater than  $K_a$  for  $\text{H}_2\text{O}$  in aqueous solution.

example, the pH after addition of 50.0 mL of base is that of an equimolar  $\text{H}_3\text{PO}_4/\text{H}_2\text{PO}_4^-$  buffer (subsequent ionization of  $\text{H}_2\text{PO}_4^-$  can be ignored). Finally, the pH at the first equivalence point is that for a solution of  $\text{NaH}_2\text{PO}_4$  and uses the amphoteric equilibria equations presented earlier in this section ( $\text{PO}_4^{3-}$  can be ignored in this case). The pH at the second equivalence point is an amphoteric equilibrium in which  $\text{HPO}_4^{2-}$  is in equilibrium with  $\text{H}_2\text{PO}_4^-$  and with  $\text{PO}_4^{3-}$ .

## CHAPTER SUMMARY

According to the Brønsted–Lowry model, acid–base chemistry encompasses a broad range of reactions in which protons are donated by species called the acid and accepted by species called the base. These reactions play key roles in situations that include industrial manufacturing processes, ordinary household substances, and the life-sustaining reactions in living systems. In aqueous solutions, all acids and bases react with the water in which they are dissolved. An acid increases the concentration of the hydronium ion  $\text{H}_3\text{O}^+$  above its value in pure water, which is controlled by the ion product constant of water. A base increases the concentration of the hydroxide ion  $\text{OH}^-$  above the value it takes in pure water, due to the ion product constant of water. The concentration of the hydronium ion is conveniently expressed by pH, and that of the hydroxide by pOH. These quantities are related as  $\text{pH} + \text{pOH} = 14$  by the ion product constant of water. Some acids and bases dissociate completely in solution to produce concentrations of hydronium and hydroxide equivalent to the concentration of

parent acid or base with which the solutions were prepared. These are called strong acids and bases, and reactions of their solutions are completely described by the laws of stoichiometry. Most acids and bases dissociate only partially, so we must use the principles of chemical equilibrium to describe the concentration of hydronium and hydroxide in their solutions. These are the weak acids and bases, and description of their reactions requires methods of stoichiometry combined with methods of equilibrium. Acid–base neutralization reactions produce water and salts as their products. These reactions can be followed quantitatively and precisely by titration, as a means to determine the amount of acid or base in an unknown sample. The Brønsted–Lowry model does not require acids and bases to be neutral molecules. Positive and negative ions dissolved in water can react with the water as either Brønsted–Lowry acids or bases. When the salt of a weak acid is dissolved in water, hydrolysis of the anion produces the undissociated acid, and the solution is basic. Similarly, hydrolysis of the salt of a weak base produces an acidic solution. In both cases the pH is calculated by equilibrium methods. An especially interesting situation arises when a weak acid is dissolved along with one of its salts. The combination of weak acid equilibrium and hydrolysis—called a buffer solution—keeps the pH of the solution constant as small amounts of acid are added. This stabilization mechanism is extremely important in biochemical and biological situations, where success of various reactions depends critically on keeping pH constant. The extent of all these acid–base reactions can be correlated with the structures of their molecules. The extent of reaction is governed by the equilibrium constant, which in turn depends on the standard Gibbs free energy of formation of the reactants and products, which depends on their molecular structure.

## CONCEPTS AND SKILLS

### Section 15.1 – Classifications of Acids and Bases

*Define acids and bases in the Brønsted–Lowry and Lewis models and provide several examples of their reactions with a solvent (Problems 1–12).*

- In the Brønsted–Lowry model acids are proton donors, and bases are proton acceptors. Acid–base reactions are proton transfer reactions.
- In the Lewis model acids are electron pair acceptors, and bases are electron pair donors. Acid–base reactions are electron pair transfer reactions that lead to the formation of new chemical bonds.

### Section 15.2 – Properties of Acids and Bases in Aqueous Solutions: The Brønsted–Lowry Scheme

*Define the pH function and convert between pH and  $[H_3O^+]$  (Problems 13–16).*

- The autoionization of water produces free hydronium and hydroxide ions whose concentrations in liquid water obey the ion product expression for water:
  - $[H_3O^+][OH^-] = K_w = 10^{-14}$  for pure water at 25°C
  - $[H_3O^+] = [OH^-] = 10^{-7}$  M
- Strong acids and bases dissociate essentially completely in aqueous solution and increase the concentrations of hydronium and hydroxide ions, respectively.
- The pH function  $pH = -\log [H_3O^+]$  is a convenient way to express the concentration of hydronium ions over a very large range of values. The pH value tells us at a glance the nature of the solution:  $pH < 7$  is an acidic solution;  $pH > 7$  is a basic solution;  $pH = 7$  is a neutral solution.

**Section 15.3 – Acid and Base Strength**

State the relationship between the ionization constant for an acid or base and the strength of that acid or base.

- For the reaction of an acid with water  $\text{HA}(aq) + \text{H}_2\text{O}(\ell) \longrightarrow \text{H}_3\text{O}^+(aq) + \text{A}^-(aq)$ 
  - $([\text{H}_3\text{O}^+][\text{A}^-])/[\text{HA}] = K_a$  [15.4]
  - Strong acids have  $K_a > 1$ , with large  $[\text{H}_3\text{O}^+]$  at equilibrium.
- For the reaction of a base with water  $\text{B}(aq) + \text{H}_2\text{O}(\ell) \longrightarrow \text{BH}^+(aq) + \text{OH}^-(aq)$ 
  - $([\text{BH}^+][\text{OH}^-])/[\text{B}] = K_b$
  - Strong bases have  $K_b < 1$ , with large  $[\text{OH}^-]$  at equilibrium.

State the relationship between the ionization constant for an acid and that for its conjugate base (Problems 21–22).

- For a conjugate acid–base pair  $K_a K_b = K_w$ . Stronger conjugate acids have weaker conjugate bases and vice versa.

Describe how the strengths of oxoacids relate to their molecular structure and bonding.

- The strength of oxoacids containing the structural unit  $\text{X—O—H}$  increases as electronegativity of X increases. As X withdraws electron density from the H atom to the O—X bond, it becomes easier to break the O—H bond and release  $\text{H}^+$ .

Explain how indicators allow the pH of a solution to be estimated (Problems 25–26).

- An indicator is a weak organic acid ( $\text{HIn}$ ) that has a different color from its conjugate base ( $\text{In}^-$ ). As the pH of the solution changes, the ratio of  $[\text{HIn}]$  to  $[\text{In}^-]$  changes according to the acid ionization equilibrium expression  $K_a = ([\text{H}_3\text{O}^+][\text{In}^-])/[\text{HIn}]$  and the color of the solution changes accordingly.

**Section 15.4 – Equilibria Involving Weak Acids and Bases**

Formulate the equilibrium expression for the ionization of a weak acid or base, and use it to determine the pH and the fraction ionized (Problems 27–36).

- For a weak acid  $\text{HA}(aq) + \text{H}_2\text{O}(\ell) \longrightarrow \text{H}_3\text{O}^+(aq) + \text{A}^-(aq)$  the equilibrium expression is
  - $K_a = ([\text{H}_3\text{O}^+][\text{A}^-])/[\text{HA}]$
  - let  $x = [\text{H}_3\text{O}^+] = [\text{A}^-]$
  - then  $x^2/([\text{HA}] - x) = K_a$
  - If  $K_a$  is very small and the initial concentration of  $\text{HA} \geq 0.05 \text{ M}$ , use the approximation  $x^2/[\text{HA}] = K_a$ .
  - Otherwise, use the quadratic equation or the method of successive approximations.
- For a weak base  $\text{B}(aq) + \text{H}_2\text{O}(\ell) \longrightarrow \text{BH}^+(aq) + \text{OH}^-(aq)$  the equilibrium expression is
  - $([\text{BH}^+][\text{OH}^-])/[\text{B}] = K_b$
  - Follow the same procedures as for the weak acid.
- Hydrolysis is the reaction of the salt of a weak base or the salt of a weak acid with water.
  - The cation of a weak base acts as an acid to form the conjugate base and produce an acidic solution.
  - The anion of a weak acid acts as a base to form the conjugate acid and produce a basic solution.
- For all conjugate acid–base pairs  $K_b = K_w/K_a$ .

### Section 15.5 – Buffer Solutions

Explain the behavior of a buffer solution. Calculate its pH from the concentrations of its conjugate acid–base pair (Problems 43–46).

- A buffer solution contains either a weak acid and its salt, or a weak base and its salt, both in appreciable amounts. Adding a small amount of acid or base only slightly alters the ratio of the acid or base to its salt. Keeping this ratio nearly constant resists changes in pH when either acid or base is added.
- The pH in a buffer solution given by these approximate equations is valid when the equilibrium concentrations of the acid and its conjugate base are close to their initial concentrations:

$$[\text{H}_3\text{O}^+] = \frac{[\text{HA}]_0}{[\text{A}^-]_0} K_a$$

$$\text{pH} \approx \text{p}K_a - \log_{10} \frac{[\text{HA}]_0}{[\text{A}^-]_0} \quad [15.7]$$

- To describe the response of a buffer to an added acid or base, follow the procedures demonstrated in Example 15.11.

Design a buffer system to produce and maintain a particular pH (Problems 47–50).

- The method is based on the equation for the pH of a buffer solution. Choose an acid with a  $\text{p}K_a$  as close as possible to the desired pH. Then adjust the ratio of the concentrations of the acid and its conjugate base to produce the desired pH. The method is illustrated in Example 15.13.

### Section 15.6 – Acid–Base Titration Curves

Calculate the pH at any stage in the titration of a strong acid or base by a strong base or acid (Problems 51–52).

- Titration curves for strong acids by strong bases and vice versa have four regions determined by the amount of titrant that has been added. In each of these regions the pH can be calculated by procedures of stoichiometry and definitions of solution concentration.
  - Before any titrant is added: The initial concentration of the starting acid or base determines the pH.
  - Before the equivalence point: Calculate the number of moles of acid or base remaining and divide by the total volume to calculate the concentration and determine the pH.
  - At the equivalence point:  $\text{pH} = 7$ .
  - After the equivalence point: Calculate the number of moles of excess acid or base and divide by the total volume to calculate the concentration and determine the pH.
- The choice of indicator is not critical in strong acid–strong base titrations since the slope of the transition at the equivalence point is very steep.

Calculate the pH at any stage in the titration of a weak acid or base by a strong base or acid (Problems 53–62).

- Titration curves for weak acids by strong bases and vice versa also have four regions identified by the amount of titrant that has been added. Calculating the pH in each of these requires consideration of equilibria in the solution, and each corresponds to a standard type of calculation illustrated in the chapter.
  - Before any titrant is added: This is simply the ionization of a weak acid or base, as described in Examples 15.6 and 15.7.

- Before the equivalence point: This is a buffer solution, as described in Example 15.10.
- At the equivalence point: This is a hydrolysis problem. All of the initial acid or base has been converted to a salt, which hydrolyzes back to the acid or base, so the  $\text{pH} \neq 7$ . See Example 15.9.
- After the equivalence point: The problem is very close to the titration of a strong acid or base. Calculate the number of moles of excess acid or base added and divide by the total volume to obtain the concentration and the pH.
- The choice of indicator is critical in weak acid–strong base and weak base–strong acid titrations because the slope of the transition is not so steep and the pH of the equivalence point can be very different from 7.  $\text{p}K_a$  (indicator)  $\approx$  pH at the equivalence point.)

### Section 15.7 – Polyprotic Acids

*Calculate the concentrations of all the species present in a solution of a weak polyprotic acid (Problems 63–68).*

- If the initial acid concentration is not too small and the first ionization constant  $K_{a1}$  is about 100 times larger than the second ionization constant  $K_{a2}$ , the two equilibria can be treated sequentially. Set up the equilibrium expression for the first dissociation. Assume  $y$  moles of acid dissociate to produce  $y$  moles of the hydronium ion and  $y$  moles of the first conjugate base. Calculate  $y$ . Set up the equilibrium expression for the second dissociation. Assume that the equilibrium concentrations of hydronium ion and the first conjugate base take the value  $y$  determined from the first step, and calculate the equilibrium concentration of the conjugate base produced in the second ionization. The details are illustrated in Example 15.15.

### Section 15.8 – Organic Acids and Bases: Structure and Reactivity

*Use structure–function relations to predict effects of substitutions on relative strengths of organic acids (Problems 69, 70).*

- The strength of an organic acid increases with the stability of its conjugate base anion. Any structural change that increases the stability of the conjugate base increases the strength of the organic acid. A structural change that increases the stability of the acid decreases the strength of the acid.
  - If several resonance structures are possible for the anion, its stability is increased.
  - Predicting acid strength based on simple arguments involving electronegativity or resonance should adhere to the caution “all other factors being equal.”

### Section 15.9 – A Deeper Look . . . Exact Treatment of Acid–Base Equilibria

*Outline the procedure for the exact treatment of acid–base equilibrium and use it to find the pH of a very dilute solution of a weak acid or base (Problems 71, 72).*

- For a weak acid, the dissolved species are HA,  $\text{A}^-$ ,  $\text{H}_3\text{O}^+$ , and  $\text{OH}^-$ . The amount of hydronium produced by dissociation of water cannot be neglected compared to the amount produced by the dissociated acid. The concentrations of these four dissolved species must be determined from four independent equations, which are then solved simultaneously.
  - Equilibrium expression for dissociation of the acid  $\frac{[\text{H}_3\text{O}^+][\text{A}^-]}{[\text{HA}]} = K_a$
  - Ion product of water  $[\text{H}_3\text{O}^+][\text{OH}^-] = K_w$

- Conservation of the anion of the acid:  $c_a = [\text{HA}] + [\text{A}^-]$
- Charge balance for electrical neutrality of the solution  $[\text{H}_3\text{O}^+] = [\text{A}^-] + [\text{OH}^-]$
- Detailed procedures for solving these equations simultaneously are illustrated in Example 15.19.

Calculate the pH at selected points in the titration of a polyprotic acid (Problems 73, 74).

- A polyprotic acid has multiple equivalent points at which the equivalent volumes of titrant are related as  $V_{e1} = \frac{1}{2} V_{e2} = \frac{1}{3} V_{e3}$ .
- The initial pH before titration begins is calculated by treating the first two equilibria sequentially as in Example 15.15.
- Between equivalence points pH is calculated as for a buffer involving a diprotic acid.
- The pH at each equivalence point is calculated as for an amphoteric equilibrium.
- Detailed procedures are outlined in Figure 15.22.

## CUMULATIVE EXERCISE

**FIGURE 15.23** The effect of acid rain on a stand of trees in the Great Smoky Mountains of the United States.

### Acid Rain

Acid rain is a major environmental problem throughout the industrialized world. One major source is the burning of fossil fuels containing sulfur (coal, oil, and natural gas). The sulfur dioxide released into the air dissolves in water or, more seriously, may be oxidized further to sulfur trioxide. The  $\text{SO}_3$  dissolves in water to form sulfuric acid:

The net effect is to increase the acidity of the rain, which damages trees (Fig. 15.23), kills fish in lakes, dissolves stone, and corrodes metal.

- A sample of rainwater is tested for acidity by using two indicators. Addition of methyl orange to half of the sample gives a yellow color, and addition of methyl red to the other half gives a red color. Estimate the pH of the sample.
- The pH in acid rain can range down to 3 or even lower in heavily polluted areas. Calculate the concentrations of  $\text{H}_3\text{O}^+$  and  $\text{OH}^-$  in a raindrop at pH 3.30 at 25°C.
- When  $\text{SO}_2$  dissolves in water to form sulfurous acid,  $\text{H}_2\text{SO}_3(\text{aq})$ , that acid can donate a hydrogen ion to water. Write a balanced chemical equation for this reaction, and identify the stronger Brønsted–Lowry acid and base in the equation.
- Ignore the further ionization of  $\text{HSO}_3^-$ , and calculate the pH of a solution whose initial concentration of  $\text{H}_2\text{SO}_3$  is  $4.0 \times 10^{-4}$  M. (*Hint*: Use the quadratic equation in this case.)
- Now suppose that all the dissolved  $\text{SO}_2$  from part (d) has been oxidized further to  $\text{SO}_3$ , so that  $4.0 \times 10^{-4}$  mol of  $\text{H}_2\text{SO}_4$  is dissolved per liter. Calculate the pH in this case. (*Hint*: Because the first ionization of  $\text{H}_2\text{SO}_4$  is that of a strong acid, the concentration of  $\text{H}_3\text{O}^+$  can be written as  $4.0 \times 10^{-4}$  plus the unknown amount of dissociation from  $\text{HSO}_4^-(\text{aq})$ .)
- Lakes have a natural buffering capacity, especially in regions where limestone gives rise to dissolved calcium carbonate. Write an equation for the

effect of a small amount of acid rain containing sulfuric acid if it falls into a lake containing carbonate ( $\text{CO}_3^{2-}$ ) ions. Discuss how the lake will resist further pH changes. What happens if a large excess of acid rain is deposited?

- (g) A sample of 1.00 L of rainwater known to contain only sulfurous (and not sulfuric) acid is titrated with 0.0100 M NaOH. The equivalence point of the  $\text{H}_2\text{SO}_3/\text{HSO}_3^-$  titration is reached after 31.6 mL has been added. Calculate the original concentration of sulfurous acid in the sample, again ignoring any effect of  $\text{SO}_3^{2-}$  on the equilibria.
- (h) Calculate the pH at the half-equivalence point, after 15.8 mL has been added. (*Hint:* Use the quadratic equation.)

### Answers

- (a) 4.4 to 4.8
- (b)  $[\text{H}_3\text{O}^+] = 5.0 \times 10^{-4} \text{ M}$ ;  $[\text{OH}^-] = 2.0 \times 10^{-11} \text{ M}$
- (c)  $\text{H}_2\text{SO}_3(\text{aq}) + \text{H}_2\text{O}(\ell) \rightleftharpoons \text{HSO}_3^-(\text{aq}) + \text{H}_3\text{O}^+(\text{aq})$ . The stronger acid is  $\text{H}_3\text{O}^+$ , and the stronger base is  $\text{HSO}_3^-$ .
- (d) The pH is 3.41.
- (e) The pH is 3.11.
- (f) The  $\text{H}_3\text{O}^+$  in the sulfuric acid solution reacts according to  $\text{H}_3\text{O}^+(\text{aq}) + \text{CO}_3^{2-}(\text{aq}) \rightleftharpoons \text{HCO}_3^-(\text{aq}) + \text{H}_2\text{O}(\ell)$ . The  $\text{HSO}_4^-$  in the sulfuric acid reacts according to  $\text{HSO}_4^-(\text{aq}) + \text{CO}_3^{2-}(\text{aq}) \rightleftharpoons \text{SO}_4^{2-}(\text{aq}) + \text{HCO}_3^-(\text{aq})$ . This gives rise to a  $\text{HCO}_3^-/\text{CO}_3^{2-}$  buffer that can resist further changes in pH. An excess of acid rain overwhelms the buffer and leads to the formation of  $\text{H}_2\text{CO}_3$ .
- (g)  $3.16 \times 10^{-4} \text{ M}$
- (h) The pH is 3.81.

## PROBLEMS

Answers to problems whose numbers are red appear in Appendix G. Problems that are more challenging are indicated with asterisks.

### 15.1 Classifications of Acids and Bases

- Which of the following can act as Brønsted–Lowry acids? Give the formula of the conjugate Brønsted–Lowry base for each of them.
  - $\text{Cl}^-$
  - $\text{HSO}_4^-$
  - $\text{NH}_4^+$
  - $\text{NH}_3$
  - $\text{H}_2\text{O}$
- Which of the following can act as Brønsted–Lowry bases? Give the formula of the conjugate Brønsted–Lowry acid for each of them.
  - $\text{F}^-$
  - $\text{SO}_4^{2-}$
  - $\text{O}^{2-}$
  - $\text{OH}^-$
  - $\text{H}_2\text{O}$
- Lemon juice contains citric acid ( $\text{C}_6\text{H}_8\text{O}_7$ ). What species serves as a base when lemon juice is mixed with baking soda (sodium hydrogen carbonate) during the preparation of some lemon cookies?
- A treatment recommended in case of accidental swallowing of ammonia-containing cleanser is to drink large amounts of diluted vinegar. Write an equation for the chemical reaction on which this procedure depends.
- An important step in many industrial processes is the slaking of lime, in which water is added to calcium oxide to make calcium hydroxide.
  - Write the balanced equation for this process.
  - Can this be considered a Lewis acid–base reaction? If so, what is the Lewis acid and what is the Lewis base?
- Silica ( $\text{SiO}_2$ ) is an impurity that must be removed from a metal oxide or sulfide ore when the ore is being reduced to elemental metal. To do this, lime ( $\text{CaO}$ ) is added. It reacts with the silica to form a slag of calcium silicate ( $\text{CaSiO}_3$ ), which can be separated and removed from the ore.
  - Write the balanced equation for this process.
  - Can this be considered a Lewis acid–base reaction? If so, what is the Lewis acid and what is the Lewis base?

7. Chemists working with fluorine and its compounds sometimes find it helpful to think in terms of acid–base reactions in which the fluoride ion ( $F^-$ ) is donated and accepted.

- (a) Would the acid in this system be the fluoride donor or fluoride acceptor?  
 (b) Identify the acid and base in each of these reactions:

8. Researchers working with glasses often think of acid–base reactions in terms of oxide donors and oxide acceptors. The oxide ion is  $O^{2-}$ .

- (a) In this system, is the base the oxide donor or the oxide acceptor?  
 (b) Identify the acid and base in each of these reactions:

9. Identify each of the following oxides as an acid or base anhydride. Write the chemical formula and give the name of the acid or base formed upon reaction with water.

- (a)  $MgO$  (b)  $Cl_2O$   
 (c)  $SO_3$  (d)  $Cs_2O$

10. Write the chemical formula and give the name of the anhydride corresponding to each of the following acids or bases, and identify it as an acid or base anhydride.

- (a)  $H_3AsO_4$  (b)  $H_2MoO_4$   
 (c)  $RbOH$  (d)  $H_2SO_3$

11. Tin(II) oxide is amphoteric. Write balanced chemical equations for its reactions with an aqueous solution of hydrochloric acid and with an aqueous solution of sodium hydroxide. (Note: The hydroxide complex ion of tin(II) is  $[Sn(OH)_3]^-$ .)  
 12. Zinc oxide is amphoteric. Write balanced chemical equations for its reactions with an aqueous solution of hydrochloric acid and with an aqueous solution of sodium hydroxide. (Note: The hydroxide complex ion of zinc is  $[Zn(OH)_4]^{2-}$ .)

## 15.2 Properties of Acids and Bases in Aqueous Solutions: The Brønsted–Lowry Scheme

13. The concentration of  $H_3O^+$  in a sample of wine is  $2.0 \times 10^{-4}$  M. Calculate the pH of the wine.  
 14. The concentration of  $OH^-$  in a solution of household bleach is  $3.6 \times 10^{-2}$  M. Calculate the pH of the bleach.  
 15. The pH of normal human urine is in the range of 5.5 to 6.5. Compute the range of the  $H_3O^+$  concentration and the range of the  $OH^-$  concentration in normal urine.

16. The pH of normal human blood is in the range of 7.35 to 7.45. Compute the range of the concentration of  $H_3O^+$  and the range of the  $OH^-$  concentration in normal blood.

17. The  $pK_w$  of seawater at  $25^\circ C$  is 13.776. This differs from the usual  $pK_w$  of 14.00 at this temperature because dissolved salts make seawater a nonideal solution. If the pH in seawater is 8.00, what are the concentrations of  $H_3O^+$  and  $OH^-$  in seawater at  $25^\circ C$ ?

18. At body temperature ( $98.6^\circ F = 37.0^\circ C$ ),  $K_w$  has the value  $2.4 \times 10^{-14}$ . If the pH of blood is 7.4 under these conditions, what are the concentrations of  $H_3O^+$  and  $OH^-$ ?

19. When placed in water, potassium starts to react instantly and continues to react with great vigor. On the basis of this information, select the better of the following two equations to represent the reaction.

State the reason for your choice.

20. Molecules of *t*-butyl chloride,  $(CH_3)_3CCl$ , react very slowly when mixed with water at low pH to give *t*-butyl alcohol,  $(CH_3)_3COH$ . When the pH is raised, the reaction takes place rapidly. Write an equation or equations to explain these facts.

## 15.3 Acid and Base Strength

21. Ephedrine ( $C_{10}H_{15}ON$ ) is a base that is used in nasal sprays as a decongestant.

(a) Write an equation for its equilibrium reaction with water.

(b) The  $K_b$  for ephedrine is  $1.4 \times 10^{-4}$ . Calculate the  $K_a$  for its conjugate acid.

(c) Is ephedrine a weaker or a stronger base than ammonia?

22. Niacin ( $C_5H_4NCOOH$ ), one of the B vitamins, is an acid.

(a) Write an equation for its equilibrium reaction with water.

(b) The  $K_a$  for niacin is  $1.5 \times 10^{-5}$ . Calculate the  $K_b$  for its conjugate base.

(c) Is the conjugate base of niacin a stronger or a weaker base than pyridine,  $C_5H_5N$ ?

23. Use the data in Table 15.2 to determine the equilibrium constant for the reaction.

Identify the stronger Brønsted–Lowry acid and the stronger Brønsted–Lowry base.

24. Use the data in Table 15.2 to determine the equilibrium constant for the reaction

Identify the stronger Brønsted–Lowry acid and the stronger Brønsted–Lowry base.

25. (a) Which is the stronger acid—the acidic form of the indicator bromocresol green or the acidic form of methyl orange?  
 (b) A solution is prepared in which bromocresol green is green and methyl orange is orange. Estimate the pH of this solution.
26. (a) Which is the stronger base—the basic form of the indicator cresol red or the basic form of thymolphthalein?  
 (b) A solution is prepared in which cresol red is red and thymolphthalein is colorless. Estimate the pH of this solution.

### 15.4 Equilibria Involving Weak Acids and Bases

27. Aspirin is acetylsalicylic acid,  $\text{HC}_9\text{H}_7\text{O}_4$ , which has a  $K_a$  of  $3.0 \times 10^{-4}$ . Calculate the pH of a solution made by dissolving 0.65 g of acetylsalicylic acid in water and diluting to 50.0 mL.
28. Vitamin C is ascorbic acid ( $\text{HC}_6\text{H}_7\text{O}_6$ ), for which  $K_a$  is  $8.0 \times 10^{-5}$ . Calculate the pH of a solution made by dissolving a 500-mg tablet of pure vitamin C in water and diluting to 100 mL.
29. (a) Calculate the pH of a 0.20 M solution of benzoic acid at 25°C.  
 (b) How many moles of acetic acid must be dissolved per liter of water to obtain the same pH as that from part (a)?
30. (a) Calculate the pH of a 0.35 M solution of propionic acid at 25°C.  
 (b) How many moles of formic acid must be dissolved per liter of water to obtain the same pH as that from part (a)?
31. Iodic acid ( $\text{HIO}_3$ ) is fairly strong for a weak acid, having a  $K_a$  equal to 0.16 at 25°C. Compute the pH of a 0.100 M solution of  $\text{HIO}_3$ .
32. At 25°C, the  $K_a$  of pentafluorobenzoic acid ( $\text{C}_6\text{F}_5\text{COOH}$ ) is 0.033. Suppose 0.100 mol of pentafluorobenzoic acid is dissolved in 1.00 L of water. What is the pH of this solution?
33. Papaverine hydrochloride ( $\text{papH}^+\text{Cl}^-$ ) is a drug used as a muscle relaxant. It is a weak acid. At 25°C, a 0.205 M solution of  $\text{papH}^+\text{Cl}^-$  has a pH of 3.31. Compute the  $K_a$  of the  $\text{papH}^+$  ion.
34. The unstable weak acid 2-germaacetic acid ( $\text{GeH}_3\text{COOH}$ ) is derived structurally from acetic acid ( $\text{CH}_3\text{COOH}$ ) by having a germanium atom replace one of the carbon atoms. At 25°C, a 0.050 M solution of 2-germaacetic acid has a pH of 2.42. Compute the  $K_1$  of 2-germaacetic acid and compare it with that of acetic acid.
35. Morphine is a weak base for which  $K_b$  is  $8 \times 10^{-7}$ . Calculate the pH of a solution made by dissolving 0.0400 mol of morphine in water and diluting to 600.0 mL.
36. Methylamine is a weak base for which  $K_b$  is  $4.4 \times 10^{-4}$ . Calculate the pH of a solution made by dissolving 0.070 mol of methylamine in water and diluting to 800.0 mL.
37. The pH at 25°C of an aqueous solution of hydrofluoric acid, HF, is 2.13. Calculate the concentration of HF in this solution, in moles per liter.
38. The pH at 25°C of an aqueous solution of sodium cyanide ( $\text{NaCN}$ ) is 11.50. Calculate the concentration of  $\text{CN}^-$  in this solution, in moles per liter.
39. You have 50.00 mL of a solution that is 0.100 M in acetic acid, and you neutralize it by adding 50.00 mL of a solution that is 0.100 M in sodium hydroxide. The pH of the resulting solution is not 7.00. Explain why. Is the pH of the solution greater than or less than 7?
40. A 75.00-mL portion of a solution that is 0.0460 M in  $\text{HClO}_4$  is treated with 150.00 mL of 0.0230 M  $\text{KOH}(aq)$ . Is the pH of the resulting mixture greater than, less than, or equal to 7.0? Explain.
41. Suppose a 0.100 M solution of each of the following substances is prepared. Rank the pH of the resulting solutions from lowest to highest:  $\text{NH}_4\text{Br}$ ,  $\text{NaOH}$ ,  $\text{KI}$ ,  $\text{NaCH}_3\text{COO}$ ,  $\text{HCl}$ .
42. Suppose a 0.100 M solution of each of the following substances is prepared. Rank the pH of the resulting solutions from lowest to highest:  $\text{KF}$ ,  $\text{NH}_4\text{I}$ ,  $\text{HBr}$ ,  $\text{NaCl}$ ,  $\text{LiOH}$ .

### 15.5 Buffer Solutions

43. “Tris” is short for tris(hydroxymethyl)aminomethane. This weak base is widely used in biochemical research for the preparation of buffers. It offers low toxicity and a  $pK_b$  (5.92 at 25°C) that is convenient for the control of pH in clinical applications. A buffer is prepared by mixing 0.050 mol of tris with 0.025 mol of  $\text{HCl}$  in a volume of 2.00 L. Compute the pH of the solution.
44. “Bis” is short for bis(hydroxymethyl)aminomethane. It is a weak base that is closely related to tris (see problem 43) and has similar properties and uses. Its  $pK_b$  is 8.8 at 25°C. A buffer is prepared by mixing 0.050 mol of bis with 0.025 mol of  $\text{HCl}$  in a volume of 2.00 L (the same proportions as in the preceding problem). Compute the pH of the solution.
45. (a) Calculate the pH in a solution prepared by dissolving 0.050 mol of acetic acid and 0.020 mol of sodium acetate in water and adjusting the volume to 500 mL.  
 (b) Suppose 0.010 mol of  $\text{NaOH}$  is added to the buffer from part (a). Calculate the pH of the solution that results.

46. Sulfanilic acid ( $\text{NH}_2\text{C}_6\text{H}_4\text{SO}_3\text{H}$ ) is used in manufacturing dyes. It ionizes in water according to the equilibrium equation

A buffer is prepared by dissolving 0.20 mol of sulfanilic acid and 0.13 mol of sodium sulfanilate ( $\text{NaNH}_2\text{C}_6\text{H}_4\text{SO}_3$ ) in water and diluting to 1.00 L.

- (a) Compute the pH of the solution.  
 (b) Suppose 0.040 mol of HCl is added to the buffer. Calculate the pH of the solution that results.
47. A physician wishes to prepare a buffer solution at  $\text{pH} = 3.82$  that efficiently resists changes in pH yet contains only small concentrations of the buffering agents. Determine which one of the following weak acids, together with its sodium salt, would probably be best to use: *m*-chlorobenzoic acid,  $K_a = 1.04 \times 10^{-4}$ ; *p*-chlorocinnamic acid,  $K_a = 3.89 \times 10^{-5}$ ; 2,5-dihydroxybenzoic acid,  $K_a = 1.08 \times 10^{-3}$ ; or acetoacetic acid,  $K_a = 2.62 \times 10^{-4}$ . Explain.
48. Suppose you were designing a buffer system for imitation blood and wanted the buffer to maintain the blood at the realistic pH of 7.40. All other things being equal, which buffer system would be preferable:  $\text{H}_2\text{CO}_3/\text{HCO}_3^-$  or  $\text{H}_2\text{PO}_4^-/\text{HPO}_4^{2-}$ ? Explain.
49. You have at your disposal an ample quantity of a solution of 0.0500 M NaOH and 500 mL of a solution of 0.100 M formic acid ( $\text{HCOOH}$ ). How much of the NaOH solution should be added to the acid solution to produce a buffer of pH 4.00?
50. You have at your disposal an ample quantity of a solution of 0.100 M HCl and 400 mL of a solution of 0.0800 M NaCN. How much of the HCl solution should be added to the NaCN solution to produce a buffer of pH 9.60?

### 15.6 Acid–Base Titration Curves

51. Suppose 100.0 mL of a 0.3750 M solution of the strong base  $\text{Ba}(\text{OH})_2$  is titrated with a 0.4540 M solution of the strong acid  $\text{HClO}_4$ . The neutralization reaction is

Compute the pH of the titration solution before any acid is added, when the titration is 1.00 mL short of the equivalence point, when the titration is at the equivalence point, and when the titration is 1.00 mL past the equivalence point. (Note: Each mole of  $\text{Ba}(\text{OH})_2$  gives *two* moles of  $\text{OH}^-$  in solution.)

52. A sample containing 26.38 mL of 0.1439 M HBr is titrated with a solution of NaOH having a molarity of 0.1219 M. Compute the pH of the titration solution before any base is added, when the titration is 1.00 mL short of the equivalence point, when the titration is at the equivalence point, and when the titration is 1.00 mL past the equivalence point.
53. A sample containing 50.00 mL of 0.1000 M hydrazoic acid ( $\text{HN}_3$ ) is being titrated with 0.1000 M sodium hydroxide. Compute the pH before any base is added, after the addition of 25.00 mL of the base, after the addition of 50.00 mL of the base, and after the addition of 51.00 mL of the base.
54. A sample of 50.00 mL of 0.1000 M aqueous solution of chloroacetic acid,  $\text{CH}_2\text{ClCOOH}$  ( $K_1 = 1.4 \times 10^{-3}$ ), is titrated with a 0.1000 M NaOH solution. Calculate the pH at the following stages in the titration, and plot the titration curve: 0, 5.00, 25.00, 49.00, 49.90, 50.00, 50.10, and 55.00 mL NaOH.
55. The base ionization constant of ethylamine ( $\text{C}_2\text{H}_5\text{NH}_2$ ) in aqueous solution is  $K_b = 6.41 \times 10^{-4}$  at  $25^\circ\text{C}$ . Calculate the pH for the titration of 40.00 mL of a 0.1000 M solution of ethylamine with 0.1000 M HCl at the following volumes of added HCl: 0, 5.00, 20.00, 39.90, 40.00, 40.10, and 50.00 mL.
56. Ammonia is a weak base with a  $K_b$  of  $1.8 \times 10^{-5}$ . A 140.0-mL sample of a 0.175 M solution of aqueous ammonia is titrated with a 0.106 M solution of the strong acid HCl. The reaction is

Compute the pH of the titration solution before any acid is added, when the titration is at the half-equivalence point, when the titration is at the equivalence point, and when the titration is 1.00 mL past the equivalence point.

57. Sodium benzoate, the sodium salt of benzoic acid, is used as a food preservative. A sample containing solid sodium benzoate mixed with sodium chloride is dissolved in 50.0 mL of 0.500 M HCl, giving an acidic solution (benzoic acid mixed with HCl). This mixture is then titrated with 0.393 M NaOH. After the addition of 46.50 mL of the NaOH solution, the pH is found to be 8.2. At this point, the addition of one more drop (0.02 mL) of NaOH raises the pH to 9.3. Calculate the mass of sodium benzoate ( $\text{NaC}_6\text{H}_5\text{COO}$ ) in the original sample. (Hint: At the equivalence point, the *total* number of moles of acid [here HCl] equals the *total* number of moles of base [here, both NaOH and  $\text{NaC}_6\text{H}_5\text{COO}$ ].)

58. An antacid tablet (such as Tums or Roloids) weighs 1.3259 g. The only acid-neutralizing ingredient in this brand of antacid is  $\text{CaCO}_3$ . When placed in 12.07 mL of 1.070 M HCl, the tablet fizzes merrily as  $\text{CO}_2(\text{g})$  is given off. After all of the  $\text{CO}_2$  has left the solution, an indicator is added, followed by 11.74 mL of 0.5310 M NaOH. The indicator shows that at this point the solution is definitely basic. Addition of 5.12 mL of 1.070 M HCl makes the solution acidic again. Then 3.17 mL of the 0.5310 M NaOH brings the titration exactly to an endpoint, as signaled by the indicator. Compute the percentage by mass of  $\text{CaCO}_3$  in the tablet.
59. What is the mass of diethylamine,  $(\text{C}_2\text{H}_5)_2\text{NH}$ , in 100.0 mL of an aqueous solution if it requires 15.90 mL of 0.0750 M HCl to titrate it to the equivalence point? What is the pH at the equivalence point if  $K_b = 3.09 \times 10^{-4}$ ? What would be a suitable indicator for the titration?
60. A chemist who works in the process laboratory of the Athabasca Alkali Company makes frequent analyses of ammonia recovered from the Solvay process for making sodium carbonate. What is the pH at the equivalence point if she titrates the aqueous ammonia solution (approximately 0.10 M) with a strong acid of comparable concentration? Select an indicator that would be suitable for the titration.
61. If 50.00 mL of a 0.200 M solution of the weak base *N*-ethyl-morpholine ( $\text{C}_6\text{H}_{13}\text{NO}$ ) is mixed with 8.00 mL of 1.00 M HCl and then diluted to a final volume of 100.0 mL with water, the result is a buffer with a pH of 7.0. Compute the  $K_b$  of *N*-ethylmorpholine.
62. The sodium salt of cacodylic acid, a weak acid, has the formula  $\text{NaO}_2\text{As}(\text{CH}_3)_2 \cdot 3\text{H}_2\text{O}$ . Its molar mass is 214.02 g  $\text{mol}^{-1}$ . A solution is prepared by mixing 21.40 g of this substance with enough water to make 1.000 L of solution. Then 50.00 mL of the sodium cacodylate solution is mixed with 29.55 mL of 0.100 M HCl and enough water to bring the volume to a total of 100.00 mL. The pH of the solution is 6.00. Determine the  $K_a$  of cacodylic acid.

### 15.7 Polyprotic Acids

63. Arsenic acid ( $\text{H}_3\text{AsO}_4$ ) is a weak triprotic acid. Given the three acid ionization constants from Table 15.2 and an initial concentration of arsenic acid (before ionization) of 0.1000 M, calculate the equilibrium concentrations of  $\text{H}_3\text{AsO}_4$ ,  $\text{H}_2\text{AsO}_4^-$ ,  $\text{HAsO}_4^{2-}$ ,  $\text{AsO}_4^{3-}$ , and  $\text{H}_3\text{O}^+$ .
64. Phthalic acid ( $\text{H}_2\text{C}_8\text{H}_4\text{O}_4$ , abbreviated  $\text{H}_2\text{Ph}$ ) is a diprotic acid. Its ionization in water at 25°C takes place in two steps:

If 0.0100 mol of phthalic acid is dissolved per liter of water, calculate the equilibrium concentrations of  $\text{H}_2\text{Ph}$ ,  $\text{HPh}^-$ ,  $\text{Ph}^{2-}$ , and  $\text{H}_3\text{O}^+$ .

65. A solution as initially prepared contains 0.050 mol  $\text{L}^{-1}$  of phosphate ion ( $\text{PO}_4^{3-}$ ) at 25°C. Given the three acid ionization constants from Table 15.2, calculate the equilibrium concentrations of  $\text{PO}_4^{3-}$ ,  $\text{HPO}_4^{2-}$ ,  $\text{H}_2\text{PO}_4^-$ ,  $\text{H}_3\text{PO}_4$ , and  $\text{OH}^-$ .
66. Oxalic acid ionizes in two stages in aqueous solution:

Calculate the equilibrium concentrations of  $\text{C}_2\text{O}_4^{2-}$ ,  $\text{HC}_2\text{O}_4^-$ ,  $\text{H}_2\text{C}_2\text{O}_4$ , and  $\text{OH}^-$  in a 0.10 M solution of sodium oxalate ( $\text{Na}_2\text{C}_2\text{O}_4$ ).

67. The pH of a normal raindrop is 5.60. Compute the concentrations of  $\text{H}_2\text{CO}_3(\text{aq})$ ,  $\text{HCO}_3^-(\text{aq})$ , and  $\text{CO}_3^{2-}(\text{aq})$  in this raindrop if the total concentration of dissolved carbonates is  $1.0 \times 10^{-5}$  mol  $\text{L}^{-1}$ .
68. The pH of a drop of acid rain is 4.00. Compute the concentrations of  $\text{H}_2\text{CO}_3(\text{aq})$ ,  $\text{HCO}_3^-(\text{aq})$ , and  $\text{CO}_3^{2-}(\text{aq})$  in the acid raindrop if the total concentration of dissolved carbonates is  $3.6 \times 10^{-5}$  mol  $\text{L}^{-1}$ .

### 15.8 Organic Acids and Bases: Structure and Reactivity

69. Which will be the stronger acid: propene ( $\text{CH}_2=\text{CHCH}_3$ ) or propane ( $\text{C}_3\text{H}_8$ )? Explain by using resonance Lewis structures.
70. Predict, using resonance Lewis dot structures, which will be the stronger base,  $\text{HSO}_3^-$  or  $\text{HSO}_4^-$ . Give a thermodynamic argument for how an equilibrium constant of a reaction might be affected if the reactant, rather than the product, is resonance stabilized.

### 15.9 A Deeper Look . . . Exact Treatment of Acid–Base Equilibria

71. Thiamine hydrochloride (vitamin  $\text{B}_1$  hydrochloride,  $\text{HC}_{12}\text{-H}_{17}\text{ON}_4\text{SCL}_2$ ) is a weak acid with  $K_a = 3.4 \times 10^{-7}$ . Suppose  $3.0 \times 10^{-5}$  g of thiamine hydrochloride is dissolved in 1.00 L of water. Calculate the pH of the resulting solution. (*Hint*: This is a sufficiently dilute solution that the autoionization of water cannot be neglected.)
72. A sample of vinegar contains 40.0 g of acetic acid ( $\text{CH}_3\text{COOH}$ ) per liter of solution. Suppose 1.00 mL is removed and diluted to 1.00 L, and 1.00 mL of *that* solution is removed and diluted to 1.00 L. Calculate the pH of the resulting solution. (*Hint*: This is a sufficiently dilute solution that the autoionization of water cannot be neglected.)

\*87. The  $K_a$  for acetic acid drops from  $1.76 \times 10^{-5}$  at  $25^\circ\text{C}$  to  $1.63 \times 10^{-5}$  at  $50^\circ\text{C}$ . Between the same two temperatures,  $K_w$  increases from  $1.00 \times 10^{-14}$  to  $5.47 \times 10^{-14}$ . At  $50^\circ\text{C}$  the density of a 0.10 M solution of acetic acid is 98.81% of its density at  $25^\circ\text{C}$ . Will the pH of a 0.10 M solution of acetic acid in water increase, decrease, or remain the same when it is heated from  $25^\circ\text{C}$  to  $50^\circ\text{C}$ ? Explain.

88. Calculate the pH of a solution that is prepared by dissolving 0.23 mol of hydrofluoric acid (HF) and 0.57 mol of hypochlorous acid (HClO) in water and diluting to 3.60 L. Also, calculate the equilibrium concentrations of HF,  $\text{F}^-$ , HClO, and  $\text{ClO}^-$ . (*Hint:* The pH will be determined by the stronger acid of this pair.)

89. For each of the following compounds, indicate whether a 0.100 M aqueous solution is acidic ( $\text{pH} < 7$ ), basic ( $\text{pH} > 7$ ), or neutral ( $\text{pH} = 7$ ): HCl,  $\text{NH}_4\text{Cl}$ ,  $\text{KNO}_3$ ,  $\text{Na}_3\text{PO}_4$ ,  $\text{NaCH}_3\text{COO}$ .

\*90. Calculate  $[\text{H}_3\text{O}^+]$  in a solution that contains 0.100 mol of  $\text{NH}_4\text{CN}$  per liter.

91. Discuss the justification for this statement: “Although one does not normally regard  $\text{NH}_4^+$  as an acid, it is actually only slightly weaker as an acid than hydrocyanic acid, HCN, in aqueous solution.”

\*92. Imagine that you want to do physiological experiments at a pH of 6.0 and the organism with which you are working is sensitive to most available materials other than a certain weak acid,  $\text{H}_2\text{Z}$ , and its sodium salts.  $K_{a1}$  and  $K_{a2}$  for  $\text{H}_2\text{Z}$  are  $3 \times 10^{-1}$  and  $5 \times 10^{-7}$ . You have available 1.0 M aqueous  $\text{H}_2\text{Z}$  and 1.0 M NaOH. How much of the NaOH solution should be added to 1.0 L of the acid solution to give a buffer at  $\text{pH} = 6.0$ ?

93. A buffer solution is prepared by mixing 1.00 L of 0.050 M pentafluorobenzoic acid ( $\text{C}_6\text{F}_5\text{COOH}$ ) and 1.00 L of 0.060 M sodium pentafluorobenzoate ( $\text{NaC}_6\text{F}_5\text{COO}$ ). The  $K_a$  of this weak acid is 0.033. Determine the pH of the buffer solution.

94. A chemist needs to prepare a buffer solution with  $\text{pH} = 10.00$  and has both  $\text{Na}_2\text{CO}_3$  and  $\text{NaHCO}_3$  in pure crystalline form. What mass of each should be dissolved in 1.00 L of solution if the combined mass of the two salts is to be 10.0 g?

95. Which of these procedures would *not* make a  $\text{pH} = 4.75$  buffer?

- (a) Mix 50.0 mL of 0.10 M acetic acid and 50.0 mL of 0.10 M sodium acetate.  
 (b) Mix 50.0 mL of 0.20 M acetic acid and 50.0 mL of 0.10 M NaOH.

(c) Start with 50.0 mL of 0.20 M acetic acid and add a solution of strong base until the pH equals 4.75.

(d) Start with 50.0 mL of 0.20 M HCl and add a solution of strong base until the pH equals 4.75.

(e) Start with 100.0 mL of 0.20 M sodium acetate and add 50.0 mL of 0.20 M HCl.

96. It takes 4.71 mL of 0.0410 M NaOH to titrate a 50.00-mL sample of flat (no  $\text{CO}_2$ ) GG's Cola to a pH of 4.9. At this point the addition of one more drop (0.02 mL) of NaOH raises the pH to 6.1. The only acid in GG's Cola is phosphoric acid. Compute the concentration of phosphoric acid in this cola. Assume that the 4.71 mL of base removes only the first hydrogen from the  $\text{H}_3\text{PO}_4$ ; that is, assume that the reaction is

\*97. Sodium carbonate exists in various crystalline forms with different amounts of water of crystallization, including  $\text{Na}_2\text{CO}_3$ ,  $\text{Na}_2\text{CO}_3 \cdot 10\text{H}_2\text{O}$ , and others. The water of crystallization can be driven off by heating; the amount of water removed depends on the temperature and duration of heating.

A sample of  $\text{Na}_2\text{CO}_3 \cdot 10\text{H}_2\text{O}$  had been heated inadvertently, and it was not known how much water had been removed. A 0.200-g sample of the solid that remained after the heating was dissolved in water, 30.0 mL of 0.100 M NaOH was added, and the  $\text{CO}_2$  formed was removed. The solution was acidic; 6.4 mL of 0.200 M NaOH was needed to neutralize the excess acid. What fraction of the water had been driven from the  $\text{Na}_2\text{CO}_3 \cdot 10\text{H}_2\text{O}$ ?

98. An aqueous solution of sodium carbonate,  $\text{Na}_2\text{CO}_3$ , is titrated with strong acid to a point at which two  $\text{H}^+$  ions have reacted with each carbonate ion. (a) If 20.0 mL of the carbonate solution reacts with just 40.0 mL of 0.50 M acid, what is the molarity of the carbonate solution? (b) If the solution contains 5.0 percent by mass sodium carbonate, what is the density of the solution? (c) Suppose that you wanted to prepare a liter of an identical solution by starting with crystalline sodium carbonate decahydrate,  $\text{Na}_2\text{CO}_3 \cdot 10\text{H}_2\text{O}$ , rather than with solid  $\text{Na}_2\text{CO}_3$  itself. How much of this substance would you need?

99. Three flasks, labeled A, B, and C, contained aqueous solutions of the same pH. It was known that one of the solutions was  $1.0 \times 10^{-3}$  M in nitric acid, one was  $6 \times 10^{-3}$  M in formic acid, and one was  $4 \times 10^{-2}$  M in the salt formed by the weak organic base aniline with hydrochloric acid ( $\text{C}_6\text{H}_5\text{NH}_3\text{Cl}$ ). (Formic acid is monoprotic.) (a) Describe a procedure for identifying the solutions. (b) Compare qualitatively (on the basis of the preceding information) the strengths of nitric and formic acids with each other and with the acid strength of the anilinium ion,  $\text{C}_6\text{H}_5\text{NH}_3^+$ . (c) Show how the information given may be used to derive values for  $K_a$  for formic acid and  $K_b$  for aniline. Derive these values.

100. Novocain, the commonly used local anesthetic, is a weak base with  $K_b = 7 \times 10^{-6}$  M. (a) If you had a 0.0200 M solution of Novocain in water, what would be the approximate concentration of  $\text{OH}^-$  and the pH? (b) Suppose that you wanted to determine the concentration of Novocain in a solution that is about 0.020 M by titration with 0.020 M HCl. Calculate the expected pH at the equivalence point.
101. A 0.1000 M solution of a weak acid, HA, requires 50.00 mL of 0.1000 M NaOH to titrate it to its equivalence point. The pH of the solution is 4.50 when only 40.00 mL of the base has been added.
- (a) Calculate the ionization constant  $K_a$  of the acid.  
 (b) Calculate the pH of the solution at the equivalence point.
102. The chief chemist of Victory Vinegar Works, Ltd., interviews two chemists for employment. He states, "Quality control requires that our high-grade vinegar contain  $5.00 \pm 0.01\%$  acetic acid by mass. How would you analyze our product to ensure that it meets this specification?"

Anne Dalton says, "I would titrate a 50.00-mL sample of the vinegar with 1.000 M NaOH, using phenolphthalein to detect the equivalence point to within  $\pm 0.02$  mL of base."

Charlie Cannizzarro says, "I would use a pH meter to determine the pH to  $\pm 0.01$  pH units and interface it with a computer to print out the mass percentage of acetic acid."

Which candidate did the chief chemist hire? Why?

103. Phosphonocarboxylic acid

effectively inhibits the replication of the herpes virus. Structurally, it is a combination of phosphoric acid and acetic acid. It can donate three protons. The equilibrium constant values are  $K_{a1} = 1.0 \times 10^{-2}$ ,  $K_{a2} = 7.8 \times 10^{-6}$ , and  $K_{a3} = 2.0 \times 10^{-9}$ . Enough phosphonocarboxylic acid is added to blood (pH 7.40) to make its total concentration  $1.0 \times 10^{-5}$  M. The pH of the blood does not change. Determine the concentrations of all four forms of the acid in this mixture.

104. Egg whites contain dissolved carbon dioxide and water, which react together to give carbonic acid ( $\text{H}_2\text{CO}_3$ ). In the few days after an egg is laid, it loses carbon dioxide through its shell. Does the pH of the egg white increase or decrease during this period?
105. If you breathe too rapidly (hyperventilate), the concentration of dissolved  $\text{CO}_2$  in your blood drops. What effect does this have on the pH of the blood?
106. A reference book states that a saturated aqueous solution of potassium hydrogen tartrate is a buffer with a pH of 3.56. Write two chemical equations that show the buffer action of this solution. (Tartaric acid is a diprotic acid with the formula  $\text{H}_2\text{C}_4\text{H}_4\text{O}_6$ . Potassium hydrogen tartrate is  $\text{KHC}_4\text{H}_4\text{O}_6$ .)
- \* 107. Glycine, the simplest amino acid, has both an acid group and a basic group in its structure ( $\text{H}_2\text{N}-\text{CH}_2-\text{COOH}$ ). In aqueous solution it exists predominantly as a self-neutralized species called a zwitterion ( $\text{H}_3\text{N}^+-\text{CH}_2-\text{COO}^-$ ). The zwitterion therefore behaves both as an acid and as a base, according to the equilibria at  $25^\circ\text{C}$ :

Calculate the pH of a 0.10 M aqueous solution of glycine at  $25^\circ\text{C}$ . (*Hint*: You may need to take account of the autoionization of water.)

- \* 108. Consider the two following nitrophenol structures:

*p*-nitrophenol

*m*-nitrophenol

Predict which will be the stronger acid. (*Hint*: Consider possible resonance structures analogous to those given in the text for phenol.)

## CUMULATIVE PROBLEMS

- 109.** Use the data from Table 15.1, together with Le Châtelier's principle, to decide whether the autoionization of water is exothermic or endothermic.
- 110.** Baking soda (sodium hydrogen carbonate,  $\text{NaHCO}_3$ ) is used in baking because it reacts with acids in foods to form carbonic acid ( $\text{H}_2\text{CO}_3$ ), which in turn decomposes to water and carbon dioxide. In a batter the carbon dioxide appears as gas bubbles that cause the bread or cake to rise.
- (a) A rule of thumb in cooking is that  $\frac{1}{2}$  teaspoon baking soda is neutralized by 1 cup of sour milk. The acid component of sour milk is lactic acid ( $\text{HC}_3\text{H}_5\text{O}_3$ ). Write an equation for the neutralization reaction.
- (b) If the density of baking soda is  $2.16 \text{ g cm}^{-3}$ , calculate the concentration of lactic acid in the sour milk, in moles per liter. Take  $1 \text{ cup} = 236.6 \text{ mL} = 48 \text{ teaspoons}$ .
- (c) Calculate the volume of carbon dioxide that is produced at 1 atm pressure and  $350^\circ\text{F}$  ( $177^\circ\text{C}$ ) from the reaction of  $\frac{1}{2}$  teaspoon of baking soda.
- 111.** Boric acid,  $\text{B}(\text{OH})_3$ , is an acid that acts differently from the usual Brønsted–Lowry acids. It reacts with water according to
- $$\text{B}(\text{OH})_3(aq) + 2 \text{H}_2\text{O}(\ell) \rightleftharpoons \text{B}(\text{OH})_4^-(aq) + \text{H}_3\text{O}^+(aq)$$
- $$K_a = 5.8 \times 10^{-10}$$
- (a) Draw Lewis structures for  $\text{B}(\text{OH})_3$  and  $\text{B}(\text{OH})_4^-$ . Can these be described as Lewis acids or Lewis bases?
- (b) Calculate the pH of a 0.20 M solution of  $\text{B}(\text{OH})_3(aq)$ .

Sodium acetate crystals ( $\text{NaC}_2\text{H}_3\text{O}_2$ ) form quickly in a supersaturated solution when a small speck of solute is added.

Dissolution and precipitation are chemical reactions by which solids pass into and out of solution. A brief introduction and several examples appear in Section 11.2. These reactions involve equilibria between dissolved species and species in the solid state, and so are described by the general principles of chemical equilibrium in Chapter 14. These reactions rank alongside acid–base reactions in practical importance. The dissolution and reprecipitation of solids permit chemists to isolate single products from reaction mixtures and to purify impure solid samples. Understanding the mechanisms of these reactions helps engineers prevent formation of deposits in water processing and distribution systems and helps doctors reduce the incidence of painful kidney stones. Dissolution and precipitation control the formation of mineral deposits and profoundly affect the ecologies of rivers, lakes, and oceans.

The theme of this chapter is to understand how to manipulate solubility equilibria in order to control the maximum concentration of particular ionic solids in the solution. In the first section we present the general aspects of the equilibria that govern the extent of dissolution and precipitation reactions. In the remaining sections we develop the quantitative descriptions for these equilibria, including the effects of adding more solutes, adding acids or bases, and adding ligands that can bind to dissolved metal ions to form complex ions.

## 16.1 The Nature of Solubility Equilibria

### 16.1.1 General Features of Solubility Equilibria

Solubility equilibria resemble the equilibria between volatile liquids (or solids) and their vapors in a closed container. In both cases, particles from a condensed phase tend to escape and spread through a larger, but limited, volume. In both cases, equilibrium is a dynamic compromise in which the rate of escape of particles from the condensed phase is equal to their rate of return. In a vaporization–condensation equilibrium, we assumed that the vapor above the condensed phase was an ideal gas. The analogous starting assumption for a dissolution–precipitation reaction is that the solution above the undissolved solid is an ideal solution. A solution in which sufficient solute has been dissolved to establish a dissolution–precipitation equilibrium between the solid substance and its dissolved form is called a **saturated solution**.

Le Châtelier’s principle applies to these equilibria, as it does to all equilibria. One way to exert a stress on a solubility equilibrium is to change the amount of solvent. Adding solvent reduces the concentration of dissolved substance; more solid then tends to dissolve to restore the concentration of the dissolved substance to its equilibrium value. If an excess of solvent is added so that all of the solid dissolves, then obviously the solubility equilibrium ceases to exist and the solution is *unsaturated*. In a vaporization–condensation equilibrium, this corresponds to the complete evaporation of the condensed phase. Removing solvent from an already saturated solution forces additional solid to precipitate in order to maintain a constant concentration. A volatile solvent is often removed by simply letting a solution stand uncovered until the solvent evaporates. When sufficient solvent has evaporated, the solid forms as crystals on the bottom and sides of the container (Fig. 16.1).

Controlled precipitation by manipulating solubility is a widely used technique for purifying reaction products in synthetic chemistry. Side reactions can generate significant amounts of impurities; other impurities may enter with the starting materials, and catalysts (introduced to increase the reaction rates) must be removed from the final products. Running a reaction may take only hours, but the *workup* (separation of crude product) and subsequent purification may require weeks. **Recrystallization**, one of the most powerful methods for purifying solids, relies on differences between the solubilities of the desired substance and its contaminants. An impure product is dissolved and reprecipitated, repeatedly if necessary, with careful control of the factors that influence solubility. Manipulating solubility requires an understanding of the equilibria that exist between an undissolved substance and its solution.

In recrystallization a solution begins to deposit a compound when it is brought to the point of saturation with respect to that compound. In dissolution the solvent attacks the solid and solvent molecules **solvate** each new solute molecule as it is released from the dissolving solid. In precipitation the reverse occurs: Solute-to-solute attractions are reestablished as the solute leaves the solution. Often, solute-to-solvent attractions persist right through the process of precipitation, and solvent incorporates itself into the solid. When lithium sulfate

**FIGURE 16.1** The beaker contains an aqueous solution of  $\text{K}_2\text{PtCl}_4$ , a substance used as a starting material in the synthesis of anticancer drugs. It is loosely covered to keep out dust and allowed to stand. As the water evaporates, the solution becomes saturated and deposits solid  $\text{K}_2\text{PtCl}_4$  in the form of long, needle-like red crystals.

(Li<sub>2</sub>SO<sub>4</sub>) precipitates from water, it brings with it into the solid one molecule of water per formula unit:

Such loosely bound solvent is known as solvent of crystallization (Fig. 2.1). Dissolving and then reprecipitating a compound may thus furnish material that has a different chemical formula and a different mass. Consequently, recrystallization processes for purification of reaction products must be planned carefully.

Dissolution–precipitation reactions frequently come to equilibrium slowly. Days or even weeks of shaking a solid in contact with a solvent may be required before the solution becomes saturated. Moreover, solutions sometimes become **supersaturated**, a state in which the concentration of dissolved solid exceeds its equilibrium value and the solid remains in solution rather than form a precipitate. This state is analogous to superheating a pure liquid above its boiling point or supercooling it below its freezing point. A supersaturated solution may persist for months or years and require extraordinary measures to be brought to equilibrium by precipitating the solid, although thermodynamics shows that the possibility for equilibrium is there all along. Precipitation from a supersaturated solution is a spontaneous process, but its rate may be slow. The generally sluggish approach to equilibrium in dissolution–precipitation reactions is quite the opposite of the rapid rates at which acid–base reactions reach equilibrium.

### 16.1.2 The Solubility of Ionic Solids

The **solubility** of a substance in a solvent is defined as the greatest amount (expressed either in grams or in moles) that will dissolve in equilibrium in a specified volume of solvent at a particular temperature. Although solvents other than water are used in many applications, aqueous solutions are the most important and are the exclusive concern here. Salts show a wide range of solubilities in water (Fig. 16.2). Silver perchlorate (AgClO<sub>4</sub>) dissolves to the remarkable extent of about 5570 g (or almost 27 mol) per liter of water at 25°C, but at the same temperature only about 0.0018 g (or  $1.3 \times 10^{-5}$  mol) of silver chloride (AgCl) dissolves per liter of water. Many salts with even lower solubilities are known. Solubilities often depend strongly on temperature (Fig. 16.3). Most dissolution reactions for ionic solids are endothermic (heat is absorbed), so by Le Châtelier's principle the solubility increases with increasing temperature.

**FIGURE 16.2** Vastly different quantities of different compounds will dissolve in 1 L of water at 20°C. Clockwise from the front are borax, potassium permanganate, lead(II) chloride, sodium phosphate decahydrate, calcium oxide, and potassium dichromate.

© Cengage Learning/Leon Lewandowski

**FIGURE 16.3** Most solubilities increase with increasing temperature, but some decrease. Note that the changes are not always smooth because different solid hydrates form over different temperature ranges.

**FIGURE 16.4** A yellow precipitate of lead iodide forms when a drop of KI solution is added to a solution of  $\text{Pb}(\text{NO}_3)_2$ .

Those dissolution reactions that are exothermic (such as for  $\text{CaSO}_4$ ) show the opposite behavior.

Although all ionic compounds dissolve to some extent in water, those having solubilities (at 25°C) of less than  $0.1 \text{ g L}^{-1}$  are called *insoluble*. Those having solubilities of more than  $10 \text{ g L}^{-1}$  are *soluble*, and the intermediate cases ( $0.1$  to  $10 \text{ g L}^{-1}$ ) are said to be *slightly soluble*. Fortunately, it is not necessary to memorize long lists of solubility data. Table 16.1 lists some generalizations concerning groups of salts and gives enough factual data to support good predictions about precipitation or dissolution in thousands of situations of practical importance. Knowing the solubilities of ionic substances, even in these qualitative terms, provides a way to predict the courses of numerous reactions. For example, when a solution of KI is added to one of  $\text{Pb}(\text{NO}_3)_2$ ,  $\text{K}^+$  and  $\text{NO}_3^-$  ions are brought into contact, as are  $\text{Pb}^{2+}$  and  $\text{I}^-$  ions. From the table,  $\text{KNO}_3$  is a soluble salt but  $\text{PbI}_2$  is insoluble; therefore, a precipitate of  $\text{PbI}_2$  will appear (Fig. 16.4).

TABLE 16.1

## Solubilities of Ionic Compounds in Water

Anion	Soluble <sup>†</sup>	Slightly Soluble	Insoluble
NO <sub>3</sub> <sup>-</sup> (nitrate)	All	—	—
CH <sub>3</sub> COO <sup>-</sup> (acetate)	Most	—	Be(CH <sub>3</sub> COO) <sub>2</sub>
ClO <sub>3</sub> <sup>-</sup> (chlorate)	All	—	—
ClO <sub>4</sub> <sup>-</sup> (perchlorate)	Most	KClO <sub>4</sub>	—
F <sup>-</sup> (fluoride)	Group I, AgF, BeF <sub>2</sub>	SrF <sub>2</sub> , BaF <sub>2</sub> , PbF <sub>2</sub>	MgF <sub>2</sub> , CaF <sub>2</sub>
Cl <sup>-</sup> (chloride)	Most	PbCl <sub>2</sub>	AgCl, Hg <sub>2</sub> Cl <sub>2</sub>
Br <sup>-</sup> (bromide)	Most	PbBr <sub>2</sub> , HgBr <sub>2</sub>	AgBr, Hg <sub>2</sub> Br <sub>2</sub>
I <sup>-</sup> (iodide)	Most	—	AgI, Hg <sub>2</sub> I <sub>2</sub> , PbI <sub>2</sub> , HgI <sub>2</sub>
SO <sub>4</sub> <sup>2-</sup> (sulfate)	Most	CaSO <sub>4</sub> , Ag <sub>2</sub> SO <sub>4</sub> , Hg <sub>2</sub> SO <sub>4</sub>	SrSO <sub>4</sub> , BaSO <sub>4</sub> , PbSO <sub>4</sub>
S <sup>2-</sup> (sulfide)	Groups I and II, (NH <sub>4</sub> ) <sub>2</sub> S	—	Most
CO <sub>3</sub> <sup>2-</sup> (carbonate)	Group I, (NH <sub>4</sub> ) <sub>2</sub> CO <sub>3</sub>	—	Most
SO <sub>3</sub> <sup>2-</sup> (sulfite)	Group I, (NH <sub>4</sub> ) <sub>2</sub> SO <sub>3</sub>	—	Most
PO <sub>4</sub> <sup>3-</sup> (phosphate)	Group I, (NH <sub>4</sub> ) <sub>3</sub> PO <sub>4</sub>	—	Most
OH <sup>-</sup> (hydroxide)	Group I, Ba(OH) <sub>2</sub>	Sr(OH) <sub>2</sub> , Ca(OH) <sub>2</sub>	Most

<sup>†</sup>Soluble compounds are defined as those that dissolve to the extent of 10 or more grams per liter; slightly soluble compounds, 0.1 to 10 grams per liter; and insoluble compounds, less than 0.1 gram per liter at room temperature.

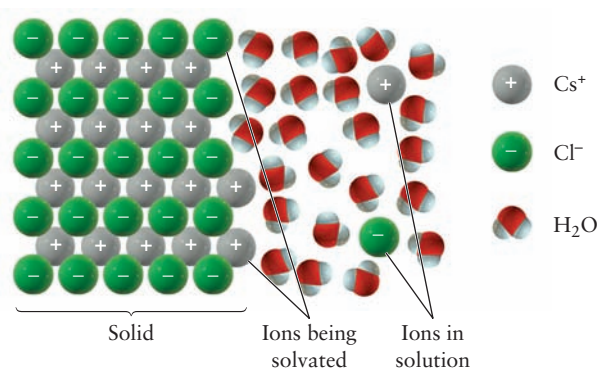

## 16.2 Ionic Equilibria between Solids and Solutions

When an ionic solid such as CsCl dissolves in water, it breaks up into ions that move apart from each other and become solvated by water molecules (*aquated*, or *hydrated*; Fig. 16.5). The aquated ions are shown in the chemical equation for the solubility equilibrium. Thus,

shows that the dissolved particles are ions. For a highly soluble salt (such as CsCl), the concentrations of the ions in a saturated aqueous solution are so large that the solution is nonideal. There is much association among the ions in solution, resulting in temporary pairs of oppositely charged ions and in larger clusters as well. In such cases the simple type of equilibrium expression developed in Sections 14.2 and 14.3 does not apply; therefore, we restrict our attention to sparingly soluble and “insoluble” salts, for which the concentrations in

**FIGURE 16.5** The dissolution of the ionic solid CsCl in water. Note the different solvation patterns of positive and negative ions. Water molecules arrange themselves so that the atoms with partial negative charges (oxygen) point toward the positively charged Cs<sup>+</sup> ions. The water molecules form hydrogen bonds to the Cl<sup>-</sup> anions, so the O—H—Cl atoms lie nearly in a straight line.

a saturated solution are  $0.1 \text{ mol L}^{-1}$  or less—low enough that the interactions among the solvated ions are relatively small.

The sparingly soluble salt silver chloride, for example, establishes the following equilibrium when placed in water:

The equilibrium law for this reaction (written by following the rules for heterogeneous equilibria from Sections 14.2 and 14.3) is

$$[\text{Ag}^+][\text{Cl}^-] = K_{\text{sp}}$$

where the subscript “sp,” standing for “**solubility product**,” distinguishes the  $K$  as referring to the dissolution of a slightly soluble ionic solid in water. Note that we have omitted the subscript eq for simplicity; the concentrations in this and all equilibrium constant expressions to follow are equilibrium ones. At  $25^\circ\text{C}$ ,  $K_{\text{sp}}$  has the numerical value  $1.6 \times 10^{-10}$  for silver chloride. In the AgCl solubility product expression, the concentrations of the two ions produced are raised to

TABLE 16.2

Solubility Product Constants  $K_{\text{sp}}$  at  $25^\circ\text{C}$ **Iodates**

$\text{AgIO}_3$	$[\text{Ag}^+][\text{IO}_3^-] = 3.1 \times 10^{-8}$

$\text{CuCl}$	$[\text{Cu}^+][\text{Cl}^-] = 1.0 \times 10^{-6}$
$\text{Hg}_2\text{Cl}_2$	$[\text{Hg}_2^{2+}][\text{Cl}^-]^2 = 1.2 \times 10^{-18}$

**Bromides**

$\text{AgBr}$	$[\text{Ag}^+][\text{Br}^-] = 7.7 \times 10^{-13}$
$\text{CuBr}$	$[\text{Cu}^+][\text{Br}^-] = 4.2 \times 10^{-8}$
$\text{Hg}_2\text{Br}_2$	$[\text{Hg}_2^{2+}][\text{Br}^-]^2 = 1.3 \times 10^{-21}$

**Iodides**

$\text{AgI}$	$[\text{Ag}^+][\text{I}^-] = 1.5 \times 10^{-16}$
$\text{CuI}$	$[\text{Cu}^+][\text{I}^-] = 5.1 \times 10^{-12}$
$\text{PbI}_2$	$[\text{Pb}^{2+}][\text{I}^-]^2 = 8.5 \times 10^{-9}$
$\text{Hg}_2\text{I}_2$	$[\text{Hg}_2^{2+}][\text{I}^-]^2 = 1.2 \times 10^{-28}$

**Hydroxides**

$\text{AgOH}$	$[\text{Ag}^+][\text{OH}^-] = 1.5 \times 10^{-8}$
$\text{Al}(\text{OH})_3$	$[\text{Al}^{3+}][\text{OH}^-]^3 = 3.7 \times 10^{-15}$
$\text{Fe}(\text{OH})_3$	$[\text{Fe}^{3+}][\text{OH}^-]^3 = 1.1 \times 10^{-36}$
$\text{Fe}(\text{OH})_2$	$[\text{Fe}^{2+}][\text{OH}^-]^2 = 1.6 \times 10^{-14}$
$\text{Mg}(\text{OH})_2$	$[\text{Mg}^{2+}][\text{OH}^-]^2 = 1.2 \times 10^{-11}$
$\text{Mn}(\text{OH})_2$	$[\text{Mn}^{2+}][\text{OH}^-]^2 = 2.0 \times 10^{-13}$
$\text{Zn}(\text{OH})_2$	$[\text{Zn}^{2+}][\text{OH}^-]^2 = 4.5 \times 10^{-17}$

the first power because their coefficients are 1 in the chemical equation. Solid AgCl does not appear in the equilibrium expression; the amount of pure solid AgCl does not affect the equilibrium as long as *some* is present. If no solid is present, the system is not in a state of equilibrium, and the product of the two ion concentrations does not obey the solubility equilibrium expression.

### 16.2.1 Solubility and $K_{sp}$

The molar solubility of a salt in water is not the same as its solubility product constant, but a simple relation often exists between them. For example, let's define  $S$  as the molar solubility of AgCl(s) in water at 25°C. Then, from stoichiometry,  $[Ag^+] = [Cl^-] = S$  is the molarity of either ion at equilibrium. Hence,

$$[Ag^+][Cl^-] = S^2 = K_{sp} = 1.6 \times 10^{-10}$$

Taking the square roots of both sides of the equation gives

$$S = 1.26 \times 10^{-5} \text{ M}$$

which rounds off to  $1.3 \times 10^{-5}$  M. This is the molar solubility of AgCl in water. It is converted to a gram solubility by multiplying by the molar mass of AgCl:

$$(1.26 \times 10^{-5} \text{ mol L}^{-1})(143.3 \text{ g mol}^{-1}) = 1.8 \times 10^{-3} \text{ g L}^{-1}$$

Therefore,  $1.8 \times 10^{-3}$  g of AgCl dissolves per liter of water at 25°C.

Solubility product constants (like solubilities) can be sensitive to temperature. At 100°C the  $K_{sp}$  for silver chloride is  $2.2 \times 10^{-8}$ ; hot water dissolves about 12 times as much silver chloride as does water at 25°C. Refer to Table 16.2 for the solubility product constants at 25°C of a number of important sparingly soluble salts. The temperature dependence of equilibrium constants is discussed in detail in Chapter 14, Section 14.7.3.

#### EXAMPLE 16.1

The  $K_{sp}$  of calcium fluoride is  $3.9 \times 10^{-11}$ . Calculate the concentrations of calcium and fluoride ions in a saturated solution of  $CaF_2$  at 25°C, and determine the solubility of  $CaF_2$  in grams per liter.

#### Solution

The solubility equilibrium is

and the expression for the solubility product is

$$[Ca^{2+}][F^-]^2 = K_{sp}$$

The concentration of fluoride ion is squared because it has a coefficient of 2 in the chemical equation.

If  $S$  mol of  $CaF_2$  dissolves in 1 L, the equilibrium concentration of  $Ca^{2+}$  will be  $[Ca^{2+}] = S$ . The concentration of  $F^-$  will be  $[F^-] = 2S$ , because each mole of  $CaF_2$  produces *two* moles of fluoride ions. Therefore,

$$[Ca^{2+}][F^-]^2 = S \times (2S)^2 = 4S^3 = K_{sp} = 3.9 \times 10^{-11}$$

Solving for  $S^3$  gives

$$S^3 = \frac{1}{4}(3.9 \times 10^{-11})$$

Taking the cube roots of both sides of this equation gives

$$S = 2.1 \times 10^{-4}$$

The equilibrium concentrations are therefore

$$[Ca^{2+}] = S = 2.1 \times 10^{-4} \text{ M}$$

$$[F^-] = 2S = 4.3 \times 10^{-4} \text{ M}$$

Because the molar mass of  $CaF_2$  is  $78.1 \text{ g mol}^{-1}$ , the gram solubility is

$$\begin{aligned} \text{gram solubility} &= (2.1 \times 10^{-4} \text{ mol L}^{-1})(78.1 \text{ g mol}^{-1}) \\ &= 0.017 \text{ g L}^{-1} \end{aligned}$$

**Related Problems: 7, 8, 9, 10, 11, 12**

It is possible to reverse the procedure just outlined, of course, and determine the value of  $K_{sp}$  from measured solubilities, as the following example illustrates.

### EXAMPLE 16.2

Silver chromate ( $\text{Ag}_2\text{CrO}_4$ ) is a red solid that dissolves in water to the extent of  $0.029 \text{ g L}^{-1}$  at  $25^\circ\text{C}$ . Estimate its  $K_{sp}$  and compare your estimate with the value in Table 16.2.

#### Solution

The molar solubility is calculated from the gram solubility and the molar mass of silver chromate ( $331.73 \text{ g mol}^{-1}$ ):

$$\text{molar solubility} = \frac{0.029 \text{ g L}^{-1}}{331.73 \text{ g mol}^{-1}} = 8.74 \times 10^{-5} \text{ mol L}^{-1}$$

An extra significant digit is carried in this intermediate result to avoid round-off errors. Because each mole of  $\text{Ag}_2\text{CrO}_4$  that

dissolves gives *two* moles of silver ion, the concentration of  $\text{Ag}^+(aq)$  is

$$[\text{Ag}^+] = 2 \times 8.74 \times 10^{-5} \text{ M} = 1.75 \times 10^{-4} \text{ M}$$

and that of  $\text{CrO}_4^{2-}$  is simply  $8.74 \times 10^{-5} \text{ M}$ . The solubility product constant is then

$$\begin{aligned} K_{sp} &= [\text{Ag}^+]^2[\text{CrO}_4^{2-}] = (1.75 \times 10^{-4})^2 \times (8.74 \times 10^{-5}) \\ &= 2.7 \times 10^{-12} \end{aligned}$$

This estimate is about 42% greater than the tabulated value,  $1.9 \times 10^{-12}$ . The text below explains this discrepancy. See also Section 16.5.

**Related Problems: 13, 14, 15, 16**

Computing  $K_{sp}$  from a solubility and solubility from  $K_{sp}$  is valid if the solution is ideal and if there are no side reactions that reduce the concentrations of the ions after they enter solution. If such reactions are present, they cause higher solubilities than are predicted from the  $K_{sp}$  expression. For example, the solubility computed for  $\text{PbSO}_4(s)$  at  $25^\circ\text{C}$  from its  $K_{sp}$  is  $0.032 \text{ g L}^{-1}$ , whereas that measured experimentally is  $0.0425 \text{ g L}^{-1}$ . The difference is caused by the presence of species other than  $\text{Pb}^{2+}(aq)$  in solution, such as  $\text{PbOH}^+(aq)$ . Further discussion of these side reactions is deferred to Section 16.5.

## 16.3 Precipitation and the Solubility Product

So far, we have considered only cases in which a single slightly soluble salt attains equilibrium with its component ions in water. The relative concentrations of the cations and anions in such solutions echo their relative numbers of moles in the original salt. Thus, when  $\text{AgCl}$  is dissolved, equal numbers of moles of  $\text{Ag}^+(aq)$  and  $\text{Cl}^-(aq)$  ions result, and when  $\text{Ag}_2\text{SO}_4$  is dissolved, twice as many moles of  $\text{Ag}^+(aq)$  ions as  $\text{SO}_4^{2-}(aq)$  are produced. A solubility product relationship such as

$$[\text{Ag}^+][\text{Cl}^-] = K_{sp}$$

is more general than this, however, and continues in force even if the relative number of moles of the two ions in solution differ from those in the pure solid compound. Such a situation often results when two solutions are mixed to give a precipitate or when another salt is present that contains an ion common to the salt under consideration.

### 16.3.1 Precipitation from Solution

Suppose a solution is prepared by mixing one soluble salt, such as  $\text{AgNO}_3$ , with a solution of a second, such as  $\text{NaCl}$ . Will a precipitate of very slightly soluble

**FIGURE 16.6** Some solid silver chloride is in contact with a solution containing  $\text{Ag}^+(aq)$  and  $\text{Cl}^-(aq)$  ions. If a solubility equilibrium exists, then the product  $Q$  of the concentrations of the ions  $[\text{Ag}^+] \times [\text{Cl}^-]$  is a constant,  $K_{sp}$  (curved line). When  $Q$  exceeds  $K_{sp}$ , solid silver chloride tends to precipitate until equilibrium is attained. When  $Q$  is less than  $K_{sp}$ , additional solid tends to dissolve. If no solid is present,  $Q$  remains less than  $K_{sp}$ . The red and blue arrows represent the path toward equilibrium for a 1:1 salt like  $\text{AgCl}$ ; the system moves along a path with slope = 1.

silver chloride form? The answer is found by examining the reaction quotient  $Q$  that was defined in Section 14.6. The initial reaction quotient  $Q_0$ , when the mixing of the solutions is complete but before any reaction occurs, is

$$Q_0 = [\text{Ag}^+]_0[\text{Cl}^-]_0$$

If  $Q_0 < K_{sp}$ , no solid silver chloride can appear. On the other hand, if  $Q_0 > K_{sp}$ , solid silver chloride precipitates until the reaction quotient  $Q$  reaches  $K_{sp}$  (Fig. 16.6).

### EXAMPLE 16.3

An emulsion of silver chloride for photographic film is prepared by adding a soluble chloride salt to a solution of silver nitrate. Suppose 500 mL of a solution of  $\text{CaCl}_2$  with a chloride ion concentration of  $8.0 \times 10^{-6} \text{ M}$  is added to 300 mL of a 0.0040 M solution of  $\text{AgNO}_3$ . Will a precipitate of  $\text{AgCl}(s)$  form when equilibrium is reached?

#### Solution

The “initial concentrations” to be used in calculating  $Q_0$  are those *before* reaction but *after* dilution through mixing the two solutions. The initial concentration of  $\text{Ag}^+(aq)$  after dilution from 300 mL to 800 mL of solution is

$$[\text{Ag}^+]_0 = 0.00400 \text{ M} \times \left( \frac{300 \text{ mL}}{800 \text{ mL}} \right) = 0.0015 \text{ M}$$

and that of  $\text{Cl}^-(aq)$  is

$$[\text{Cl}^-]_0 = 8.0 \times 10^{-6} \text{ M} \times \left( \frac{500 \text{ mL}}{800 \text{ mL}} \right) = 5.0 \times 10^{-6} \text{ M}$$

The initial reaction quotient is

$$Q_0 = [\text{Ag}^+]_0[\text{Cl}^-]_0 = (0.0015)(5.0 \times 10^{-6}) = 7.5 \times 10^{-9}$$

Because  $Q_0 > K_{sp}$ , a precipitate of silver chloride appears at equilibrium, although there may be too little to detect visually. Another possible precipitate, calcium nitrate, is far too soluble to form in this experiment (see Table 16.1).

**Related Problems:** 17, 18, 19, 20

The equilibrium concentrations of ions after the mixing of two solutions to give a precipitate are most easily calculated by supposing that the reaction first goes to completion (consuming one type of ion) and that subsequent dissolution of the solid restores some of that ionic species to solution—just the approach used in Example 15.11 for the addition of a strong acid to a buffer solution.

**EXAMPLE 16.4**

Calculate the equilibrium concentrations of silver and chloride ions resulting from the precipitation reaction of Example 16.3.

**Solution**

In this case the silver ion is clearly in excess; therefore, the chloride ion is the limiting reactant. If all of it were used up to make solid AgCl, the concentration of the remaining silver ion would be

$$[\text{Ag}^+] = 0.0015 - 5.0 \times 10^{-6} = 0.0015 \text{ M}$$

Set up the equilibrium calculation as

	$\text{AgCl}(s) \rightleftharpoons \text{Ag}^+(aq) + \text{Cl}^-(aq)$	
Initial concentration (M)	0.0015	0
Change in concentration (M)	$+y$	$+y$
Equilibrium concentration (M)	$0.0015 + y$	$y$

so that the equilibrium expression is

$$(0.0015 + y)y = K_{\text{sp}} = 1.6 \times 10^{-10}$$

This quadratic equation can be solved using the quadratic formula function on your calculator but *only* if it carries 10 significant figures. It can be solved more easily by making the approximation that  $y$  is much smaller than 0.0015; the equation therefore simplifies to

$$0.0015y \approx 1.6 \times 10^{-10}$$

$$y \approx 1.1 \times 10^{-7} \text{ M} = [\text{Cl}^-]$$

The assumption about the size of  $y$  was justified. The concentration of silver ion is

$$[\text{Ag}^+] = 0.0015 \text{ M}$$

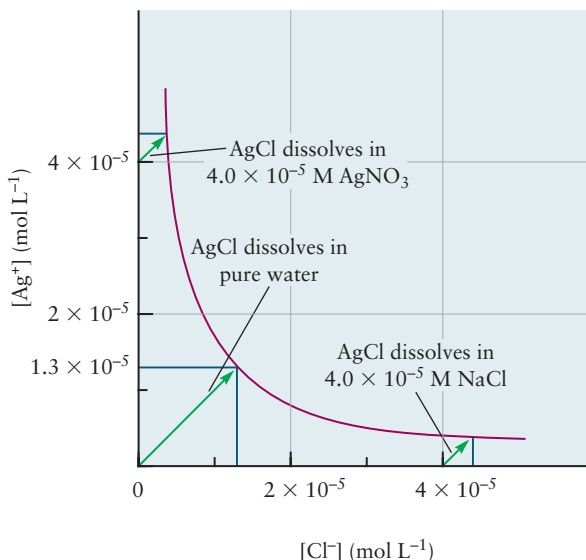

**Related Problems: 21, 22, 23, 24**

### 16.3.2 The Common-Ion Effect

Suppose a small amount of NaCl(s) is added to a saturated solution of AgCl. What happens? Sodium chloride is quite soluble in water and dissolves to form  $\text{Na}^+(aq)$  and  $\text{Cl}^-(aq)$  ions, raising the concentration of chloride ion. The quantity  $Q_0 = [\text{Ag}^+][\text{Cl}^-]$  then exceeds the  $K_{\text{sp}}$  of silver chloride, and silver chloride precipitates until the concentrations of  $\text{Ag}^+(aq)$  and  $\text{Cl}^-(aq)$  are sufficiently reduced that the solubility product expression once again is satisfied.

The same equilibrium may be approached from the other direction. The amount of AgCl(s) that can dissolve in a solution of sodium chloride is less than the amount that could dissolve in the same volume of pure water. Because  $[\text{Ag}^+][\text{Cl}^-] = K_{\text{sp}}$ , a graph of the equilibrium concentration of silver ion against chloride concentration has the form of a hyperbola (Fig. 16.7). The presence of excess  $\text{Cl}^-(aq)$  reduces the concentration of  $\text{Ag}^+(aq)$  permitted, and the solubility of AgCl(s) is reduced. In the same way, the prior presence of  $\text{Ag}^+(aq)$  in the solvent (for example, when an attempt is made to dissolve AgCl in water that already contains  $\text{AgNO}_3$ ) reduces the amount of  $\text{Cl}^-(aq)$  permitted at equilibrium and also reduces the solubility of AgCl. This is referred to as the **common-ion effect**: If the solution and the solid salt to be dissolved in it have an ion in common, then the solubility of the salt is depressed.

**FIGURE 16.7** The presence of a dissolved common ion reduces the solubility of a salt in solution. As the AgCl dissolves, the concentrations of the ions follow the paths shown by the green arrows until they reach the red equilibrium curve. The molar solubilities are proportional to the lengths of the blue lines:  $1.3 \times 10^{-5} \text{ mol L}^{-1}$  for AgCl in pure water, but only  $0.37 \times 10^{-5} \text{ mol L}^{-1}$  in either  $4.0 \times 10^{-5} \text{ M AgNO}_3$  or  $4.0 \times 10^{-5} \text{ M NaCl}$ .

Let's examine the quantitative consequences of the common-ion effect. Suppose an excess of  $\text{AgCl}(s)$  is added to 1.00 L of a 0.100 M NaCl solution and the solubility is again determined. If  $S$  mol of AgCl dissolves per liter, the concentration of  $\text{Ag}^+(aq)$  will be  $S \text{ mol L}^{-1}$  and that of  $\text{Cl}^-(aq)$  will be

$$[\text{Cl}^-] = 0.100 + S$$

because the chloride ion comes from two sources: the 0.100 M NaCl and the dissolution of AgCl. The expression for the solubility product is written as

$$[\text{Ag}^+][\text{Cl}^-] = S(0.100 + S) = K_{\text{sp}} = 1.6 \times 10^{-10}$$

The solubility of  $\text{AgCl}(s)$  in this solution must be smaller than it is in pure water, which is much smaller than 0.100. That is,

$$S < 1.3 \times 10^{-5} \ll 0.100$$

Thus,  $(0.100 + S)$  can be approximated by 0.100 (as in Example 16.4), giving

$$(0.100)S \approx 1.6 \times 10^{-10}$$

$$S \approx 1.6 \times 10^{-9}$$

This is indeed much smaller than 0.100, so the approximation was a very good one. Therefore, at equilibrium,

$$[\text{Ag}^+] = S = 1.6 \times 10^{-9} \text{ M}$$

$$[\text{Cl}^-] = 0.100 \text{ M}$$

The gram solubility of AgCl in this example is

$$(1.6 \times 10^{-9} \text{ mol L}^{-1})(143.3 \text{ g mol}^{-1}) = 2.3 \times 10^{-7} \text{ g L}^{-1}$$

The solubility of AgCl in 0.100 M NaCl is lower than that in pure water by a factor of about 8000.

**EXAMPLE 16.5**

What is the gram solubility of  $\text{CaF}_2(s)$  in a 0.100 M solution of NaF?

**Solution**

Again, the molar solubility is denoted by  $S$ . The only source of the  $\text{Ca}^{2+}(aq)$  in the solution at equilibrium is the dissolution of  $\text{CaF}_2$ , whereas the  $\text{F}^{-}(aq)$  has two sources, the  $\text{CaF}_2$  and the NaF. Hence,

	$\text{CaF}_2(s) \rightleftharpoons \text{Ca}^{2+}(aq)$	+	$2 \text{F}^{-}(aq)$
Initial concentration (M)	0		0.100
Change in concentration (M)	+ $S$		+ $2S$
Equilibrium concentration (M)	$S$		$0.100 + 2S$

If  $0.100 + 2S$  is approximated as 0.100, then

$$[\text{Ca}^{2+}][\text{F}^{-}]^2 = K_{\text{sp}}$$

$$S(0.100)^2 = 3.9 \times 10^{-11}$$

$$S = 3.9 \times 10^{-9}$$

Clearly,

$$2S = 7.8 \times 10^{-9} \ll 0.100$$

so the assumption was justified. The gram solubility of  $\text{CaF}_2$  is

$$(3.9 \times 10^{-9} \text{ mol L}^{-1})(78.1 \text{ g mol}^{-1}) = 3.0 \times 10^{-7} \text{ g L}^{-1}$$

and the solubility in this case is reduced by a factor of 50,000.

**Related Problems: 25, 26, 27, 28**

## 16.4 The Effects of pH on Solubility

Some solids are only weakly soluble in water but dissolve readily in acidic solutions. Copper and nickel sulfides from ores, for example, can be brought into solution with strong acids, a fact that aids greatly in the separation and recovery of these valuable metals in their elemental forms. The effect of pH on solubility is shown dramatically in the damage done to buildings and monuments by acid rain (Fig. 16.8). Both marble and limestone are made up of small crystals of calcite ( $\text{CaCO}_3$ ), which dissolves to only a limited extent in “natural” rain (with a pH of about 5.6) but dissolves much more extensively as the rainwater becomes more acidic. The reaction

causes this increase. This section examines the role of pH in solubility.

### 16.4.1 Solubility of Hydroxides

One direct effect of pH on solubility occurs with the metal hydroxides. The concentration of  $\text{OH}^{-}$  appears explicitly in the expression for the solubility product of such compounds. Thus, for the dissolution of  $\text{Zn}(\text{OH})_2(s)$ ,

**FIGURE 16.8** The calcium carbonate in marble and limestone is very slightly soluble in neutral water. Its solubility is much greater in acidic water. Objects carved of these materials dissolve relatively rapidly in areas where rain, snow, or fog is acidified from air pollution. Shown here is the damage to a marble statue of George Washington between 1935 (left) and 1994 (right).

the solubility product expression is

$$[\text{Zn}^{2+}][\text{OH}^-]^2 = K_{\text{sp}} = 4.5 \times 10^{-17}$$

As the solution is made more acidic, the concentration of hydroxide ion decreases, causing an increase in the concentration of  $\text{Zn}^{2+}(\text{aq})$  ion. Zinc hydroxide is thus more soluble in acidic solution than in pure water.

### EXAMPLE 16.6

Compare the solubility of  $\text{Zn}(\text{OH})_2$  in pure water with that in a solution buffered at pH 6.00.

#### Solution

In pure water the usual solubility product calculation applies:

$$\begin{aligned} [\text{Zn}^{2+}] &= S & [\text{OH}^-] &= 2S \\ S(2S)^2 &= 4S^3 = K_{\text{sp}} = 4.5 \times 10^{-17} \\ S &= 2.2 \times 10^{-6} \text{ M} = [\text{Zn}^{2+}] \end{aligned}$$

so the solubility is  $2.2 \times 10^{-6} \text{ mol L}^{-1}$ , or  $2.2 \times 10^{-4} \text{ g L}^{-1}$ .  
Using

$$[\text{OH}^-] = 2S = 4.5 \times 10^{-6} \text{ M}$$

the resulting solution is found to have pH 8.65.

In the second case it is assumed that the solution is buffered sufficiently that the pH remains 6.00 after dissolution of the zinc hydroxide. Then

$$\begin{aligned} [\text{OH}^-] &= 1.0 \times 10^{-8} \text{ M} \\ [\text{Zn}^{2+}] &= \frac{K_{\text{sp}}}{[\text{OH}^-]^2} = \frac{4.5 \times 10^{-17}}{(1.0 \times 10^{-8})^2} = 0.45 \text{ M} \end{aligned}$$

so that  $0.45 \text{ mol L}^{-1}$ , or  $45 \text{ g L}^{-1}$ , should dissolve in this case. When ionic concentrations are this high, the simple form of the solubility expression will likely break down, but the qualitative conclusion is still valid:  $\text{Zn}(\text{OH})_2$  is far more soluble at pH 6.00 than in pure water.

**Related Problems:** 31, 32

## 16.4.2 Solubility of Salts of Bases

Metal hydroxides can be described as salts of a strong base, the hydroxide ion. The solubility of salts in which the anion is a different weak or strong base is

also affected by pH. For example, consider a solution of a slightly soluble fluoride, such as calcium fluoride. The solubility equilibrium is

As the solution is made more acidic, some of the fluoride ion reacts with hydronium ion through

Because this is just the reverse of the acid ionization of HF, its equilibrium constant is the reciprocal of  $K_a$  for HF, or  $1/(3.5 \times 10^{-4}) = 2.9 \times 10^3$ . As acid is added, the concentration of fluoride ion is reduced, so the calcium ion concentration must increase to maintain the solubility product equilibrium for  $\text{CaF}_2$ . As a result, the solubility of fluoride salts increases in acidic solution. The same applies to other ionic substances in which the anion is a weak or a strong base. By contrast, the solubility of a salt such as  $\text{AgCl}$  is only very slightly affected by a decrease in pH. The reason is that HCl is a strong acid, so  $\text{Cl}^{-}$  is ineffective as a base. The reaction

occurs to a negligible extent in acidic solution.

## 16.5 Complex Ions and Solubility

(a)

(b)

**FIGURE 16.9** (a) From left to right, crystals of  $\text{Cu}(\text{NH}_3)_4\text{SO}_4$ ,  $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ , and  $\text{CuSO}_4$ . (b) Aqueous solutions of copper sulfate containing (left) and not containing (right) ammonia.

A transition-metal ion may form a **coordination complex** in solution or in the solid state; in the complex the metal ion is surrounded by a group of anions or neutral molecules called **ligands**. (See Section 8.2.) The interaction involves the sharing by the metal ion of a lone pair on each ligand molecule, giving a partially covalent bond with that ligand. Such complexes often have strikingly deep colors. When exposed to gaseous ammonia, greenish white crystals of copper sulfate ( $\text{CuSO}_4$ ) give a deep blue crystalline solid with the chemical formula  $[\text{Cu}(\text{NH}_3)_4]\text{SO}_4$  (Fig. 16.9). The anions in the solid are still sulfate ions ( $\text{SO}_4^{2-}$ ) but the cations are now **complex ions**, or coordination complexes of the central  $\text{Cu}^{2+}$  ion with four ammonia molecules, each coordination complex is represented by the molecular formula  $\text{Cu}(\text{NH}_3)_4^{2+}$ . The ammonia molecules in this complex are called ammine ligands. They coordinate to the copper ion through their lone-pair electrons (Fig. 16.10), acting as Lewis bases toward the metal ion, the Lewis acid. When the solid is dissolved in water, the deep blue color remains. This is evidence that the complex persists in water, because when ordinary  $\text{CuSO}_4$  (without ammonia ligands) is dissolved in water, a much paler blue color results (see Fig. 16.9b).

Here we explore the effects of the formation of complex ions on equilibria in aqueous solutions. The microscopic structure and bonding in these complexes is presented in Chapter 8.

### 16.5.1 Complex-Ion Equilibria

When silver ions are dissolved in an aqueous ammonia solution, doubly coordinated silver–ammonia complexes, shown in Figure 16.11, form in two stepwise reactions:

TABLE 16.3

## Formation Constants of Coordination Complexes in Aqueous Solution

	$K_f$	$K_1$	$K_2$	$K_3$	$K_4$	$K_5$	$K_6$
<b>Ammines</b>							
$\text{Ag}(\text{NH}_3)_2^+$	$1.7 \times 10^7$	$2.1 \times 10^3$	$8.2 \times 10^3$				
$\text{Co}(\text{NH}_3)_6^{2+}$	$2.5 \times 10^4$	$1.0 \times 10^2$	32	8.5	4.4	1.1	0.18
$\text{Cu}(\text{NH}_3)_4^{2+}$	$1.1 \times 10^{12}$	$1.0 \times 10^4$	$2 \times 10^3$	$5 \times 10^2$	90		
$\text{Ni}(\text{NH}_3)_6^{2+}$	$8 \times 10^{-7}$	$5 \times 10^2$	$1.3 \times 10^2$	40	12	3.3	0.8
$\text{Zn}(\text{NH}_3)_4^{2+}$	$5 \times 10^8$	$1.5 \times 10^2$	$1.8 \times 10^2$	$2 \times 10^2$	90		
<b>Chlorides</b>							
$\text{AgCl}_2^-$	$1.8 \times 10^5$	$1.7 \times 10^3$	$1.0 \times 10^2$				
$\text{FeCl}_4^-$	0.14	28	4.5	0.1	$1.1 \times 10^2$		
$\text{HgCl}_4^{2-}$	$1.2 \times 10^{15}$	$5.5 \times 10^6$	$3 \times 10^6$	7	10		
$\text{PbCl}_4^{2-}$	25	40	1.5	0.8	0.5		
$\text{SnCl}_4^{2-}$	30	32	5.4	0.6	0.3		
<b>Hydroxides</b>							
$\text{Co}(\text{OH})_3^-$	$3 \times 10^{10}$	$4 \times 10^4$	1	$8 \times 10^5$			
$\text{Cu}(\text{OH})_4^{2-}$	$3 \times 10^{18}$	$1 \times 10^7$	$5 \times 10^6$	$2 \times 10^3$	30		
$\text{Ni}(\text{OH})_3^-$	$2 \times 10^{11}$	$9 \times 10^4$	$4 \times 10^3$	$6 \times 10^2$			
$\text{Pb}(\text{OH})_3^-$	$4 \times 10^{14}$	$7 \times 10^7$	$1.1 \times 10^3$	$5 \times 10^3$			
$\text{Zn}(\text{OH})_4^{2-}$	$5 \times 10^{14}$	$2.5 \times 10^4$	$8 \times 10^6$	70	33		

FIGURE 16.10 The structure of  $\text{Cu}(\text{NH}_3)_4^{2+}$ .FIGURE 16.11 The structure of  $\text{Ag}(\text{NH}_3)_2^+$ .

$$\frac{[\text{Ag}(\text{NH}_3)_2^+]}{[\text{Ag}(\text{NH}_3)^+][\text{NH}_3]} = K_2 = 8 \times 10^3$$

If these two chemical equations are added (and their corresponding equilibrium laws are multiplied), the result is

$$\frac{[\text{Ag}(\text{NH}_3)_2^+]}{[\text{Ag}^+][\text{NH}_3]^2} = K_f = K_1 K_2 = 1.7 \times 10^7$$

where  $K_f$  is the **formation constant** of the full complex ion  $\text{Ag}(\text{NH}_3)_2^+$ . Table 16.3 lists formation constants for a representative selection of complex ions. The larger the formation constant  $K_f$ , the more stable the corresponding complex ion (for ions with the same number of ligands).

Because  $K_1$  and  $K_2$  of the  $\text{Ag}(\text{NH}_3)_2^+$  complex ion are both large, a silver salt dissolved in water that contains a high concentration of ammonia will be primarily in the form of the complex ion  $[\text{Ag}(\text{NH}_3)_2]^+$  at equilibrium.

## EXAMPLE 16.7

Suppose 0.100 mol of  $\text{AgNO}_3$  is dissolved in 1.00 L of a 1.00 M solution of  $\text{NH}_3$ . Calculate the concentrations of the  $\text{Ag}^+$  and  $\text{Ag}(\text{NH}_3)_2^+$  ions present at equilibrium.

**Solution**

Suppose that most of the  $\text{Ag}^+$  is present as  $\text{Ag}(\text{NH}_3)_2^+$  (this will be checked later). Then

$$[\text{Ag}(\text{NH}_3)_2^+]_0 = 0.100 \text{ M}$$

$$[\text{NH}_3]_0 = 1.00 \text{ M} - (2 \times 0.100) \text{ M} = 0.80 \text{ M}$$

(Continued)

after each silver ion has become complexed with two ammonia molecules. The two stages of the dissociation of the  $\text{Ag}(\text{NH}_3)_2^+$  ion are the reverse reaction of the complexation, so their equilibrium constants are the reciprocals of  $K_2$  and  $K_1$ , respectively:

If  $y$  mol  $\text{L}^{-1}$  of  $\text{Ag}(\text{NH}_3)_2^+$  dissociates at equilibrium according to the first equation (and not many of the  $\text{Ag}(\text{NH}_3)^+$  dissociate via the second equation).

$\text{Ag}(\text{NH}_3)_2^+(aq) \rightleftharpoons \text{Ag}(\text{NH}_3)^+(aq) + \text{NH}_3(aq)$			
Initial concentration (M)	0.100	0	0.80
Change in concentration (M)	$-y$	$+y$	$+y$
Equilibrium concentration (M)	$0.100 - y$	$y$	$0.80 + y$

then the first equilibrium expression becomes

$$\frac{y(0.80 + y)}{0.100 - y} = \frac{1}{K_2} = \frac{1}{8.2 \times 10^3}$$

$$y = 1.5 \times 10^{-5} \text{ M} = [\text{Ag}(\text{NH}_3)^+]$$

We can then calculate the concentration of free  $\text{Ag}^+$  ions from the equilibrium law for the second step of the dissociation of the complex ion:

$$\frac{[\text{Ag}^+][\text{NH}_3]}{[\text{Ag}(\text{NH}_3)^+]} = \frac{1}{K_1}$$

$$\frac{[\text{Ag}^+](0.80)}{1.5 \times 10^{-5}} = \frac{1}{2.1 \times 10^3}$$

$$[\text{Ag}^+] = 9 \times 10^{-9} \text{ M}$$

It is clear that the original assumption was correct, and most of the silver present is tied up in the  $\text{Ag}(\text{NH}_3)_2^+$  complex.

**Related Problems: 35, 36**

**FIGURE 16.12** The thiosulfate ion (top) looks structurally similar to the sulfate ion  $\text{SO}_4^{2-}$  (bottom), but has one oxygen atom replaced by a sulfur atom. It is prepared, however, by the reaction of elemental sulfur with the sulfite ion ( $\text{SO}_3^{2-}$ ).

There is a close similarity between the working of Example 16.7 and an acid–base calculation. The first step (the assumption that the reaction goes to completion and is followed by a small amount of back dissociation) is analogous to the procedure for dealing with the addition of a small amount of a strong acid to a solution of a weak base. The subsequent calculation of the successive dissociation steps resembles the calculation of polyprotic acid equilibria in Example 15.15. The only difference is that in complex-ion equilibria it is conventional to work with formation constants, which are the inverse of the dissociation constants used in acid–base equilibria.

The formation of coordination complexes can have a large effect on the solubility of a compound in water. Silver bromide is only very weakly soluble in water,

but addition of thiosulfate ion ( $\text{S}_2\text{O}_3^{2-}$ ) (Figure 16.12) to the solution allows the complex ion  $\text{Ag}(\text{S}_2\text{O}_3)_2^{3-}$  to form:

**FIGURE 16.13** An illustration of the effect of complex ion formation on solubility. Each test tube contains 2.0 g AgBr, but the one on the left also contains dissolved thiosulfate ion, which forms a complex ion with  $\text{Ag}^+$ . Almost none of the white solid AgBr has dissolved in pure water, but almost all of it has dissolved in the solution containing thiosulfate.

© Cengage Learning/Leon Levandowski

This greatly increases the solubility of the silver bromide (Fig. 16.13). The formation of this complex ion is an important step in the development of photographic images; thiosulfate ion is a component of the fixer that brings silver bromide into solution from the unexposed portion of the film.

### EXAMPLE 16.8

Calculate the solubility of AgBr in a 1.00 M aqueous solution of ammonia.

#### Solution

We tentatively assume that almost all the silver that dissolves is complexed as  $\text{Ag}(\text{NH}_3)_2^+$  (this will be checked later). The overall reaction is then

Note that this is the sum of the two reactions

so its equilibrium constant is the product  $K_{\text{sp}}K_{\text{f}} = 1.3 \times 10^{-5}$ .

If  $S \text{ mol L}^{-1}$  of AgBr dissolves, then

$$S = [\text{Br}^-] \approx [\text{Ag}(\text{NH}_3)_2^+]$$

$$[\text{NH}_3] = 1.00 - 2S$$

because 2 mol of  $\text{NH}_3$  is used up for each mole of complex formed. The equilibrium expression is

$$\frac{S^2}{(1.00 - 2S)^2} = K_{\text{sp}}K_{\text{f}} = 1.3 \times 10^{-5}$$

$$S = 3.6 \times 10^{-3} \text{ M} = [\text{Ag}(\text{NH}_3)_2^+] = [\text{Br}^-]$$

To check the original assumption, calculate the concentration of free silver ion:

$$[\text{Ag}^+] = \frac{K_{\text{sp}}}{[\text{Br}^-]} = \frac{K_{\text{sp}}}{S} = 2.1 \times 10^{-10} \ll [\text{Ag}(\text{NH}_3)_2^+]$$

verifying that almost all the silver is complexed. The solubility is therefore  $3.6 \times 10^{-3} \text{ mol L}^{-1}$ , significantly greater than the solubility in pure water:

$$\text{solubility in pure water} = \sqrt{K_{\text{sp}}} = 8.8 \times 10^{-7} \text{ mol L}^{-1}$$

**Related Problems:** 39, 40

Another interesting effect of complex ions on solubilities is illustrated by the addition of iodide ion to a solution containing mercury(II) ion. After a moderate amount of iodide ion has been added, an orange precipitate forms (Fig. 16.14) through the reaction

With further addition of iodide ion, however, the orange solid redissolves because complex ions form:

© Cengage Learning/Leon Lewandowski

**FIGURE 16.14** The “orange tornado” is a striking demonstration of the effects of complex ions on solubility. A solution is prepared with an excess of  $\text{I}^-(aq)$  over  $\text{Hg}^{2+}(aq)$  so that the  $\text{Hg}^{2+}$  is complexed as  $\text{HgI}_3^-$  and  $\text{HgI}_4^{2-}$ . A magnetic stirrer is used to create a vortex in the solution. Addition of a solution containing  $\text{Hg}^{2+}$  down the center of the vortex then causes the orange solid  $\text{HgI}_2$  to form in a layer at the edges of the vortex, giving the tornado effect.

In the same way, silver chloride will dissolve in a concentrated solution of sodium chloride by forming soluble  $\text{AgCl}_2^-$  complex ions. Complex ion formation affects solubility in the opposite direction from the common-ion effect of Section 16.3.

## 16.5.2 Acidity and Amphoterism of Complex Ions

When dissolved in water, many metal ions increase the acidity of the solution. The iron(III) ion is an example: Each dissolved  $\text{Fe}^{3+}$  ion is strongly solvated by six water molecules, leading to a complex ion  $\text{Fe}(\text{H}_2\text{O})_6^{3+}$ . This complex ion can act as a Brønsted–Lowry acid, donating hydrogen ions to the solvent, water:

Metal ion hydrolysis fits into the general scheme of the Brønsted–Lowry acid–base reaction.

### EXAMPLE 16.9

Calculate the pH of a solution that is 0.100 M in  $\text{Fe}(\text{NO}_3)_3$ .

#### Solution

The iron(III) is present as  $\text{Fe}(\text{H}_2\text{O})_6^{3+}$ , which reacts as a weak acid:

with  $K_a$  equal to  $7.7 \times 10^{-3}$ . If  $y$  mol  $\text{L}^{-1}$  of  $[\text{Fe}(\text{H}_2\text{O})_6]^{3+}$  reacts, then (neglecting the ionization of water itself)

$$[\text{H}_3\text{O}^+] = [\text{Fe}(\text{H}_2\text{O})_5\text{OH}^{2+}] = y$$

$$[\text{Fe}(\text{H}_2\text{O})_6^{3+}] = 0.100 - y$$

The equilibrium expression has the form

$$\frac{y^2}{0.100 - y} = 7.7 \times 10^{-3}$$

$$y = 2.4 \times 10^{-2} \text{ M} = [\text{H}_3\text{O}^+]$$

so the pH is 1.62. Solutions of iron(III) salts are strongly acidic.

**Related Problems:** 43, 44

**TABLE 16.4**

pH of 0.1 M Aqueous Metal Nitrate Solutions at 25°C

Metal Nitrate	pH
$\text{Fe}(\text{NO}_3)_3$	1.6
$\text{Pb}(\text{NO}_3)_2$	3.6
$\text{Cu}(\text{NO}_3)_2$	4.0
$\text{Zn}(\text{NO}_3)_2$	5.3
$\text{Ca}(\text{NO}_3)_2$	6.7
$\text{NaNO}_3$	7.0

Another acceptable way to write the reaction that makes iron(III) solutions acidic is

in which the specific mention of the six waters of hydration is now omitted. The  $\text{FeOH}^{2+}$  complex ions are brown, but  $\text{Fe}^{3+}$  ions are almost colorless. This reaction occurs to a sufficient extent to make a solution of  $\text{Fe}(\text{NO}_3)_3$  in water pale brown. When strong acid is added, the equilibrium is driven back to the left and the color fades. Table 16.4 gives values of the pH for 0.1 M solutions of several metal ions. Those that form strong complexes with hydroxide ion have low pH

**FIGURE 16.15** The acidity of metal ions is illustrated by the vigorous reaction of anhydrous  $\text{AlCl}_3$  with water to generate hydrated aluminum oxides,  $\text{HCl}(aq)$ , and heat. The  $\text{HCl}$  turns the indicator, bromocresol red, to its red acid form.

© Cengage Learning/Leon Lewandowski

(Fig. 16.15), whereas those that do not form such complexes give neutral solutions (pH 7).

Different cations behave differently as water ligands are replaced by hydroxide ions in an increasingly basic solution. A particularly interesting example is  $\text{Zn}^{2+}$ . It forms a series of hydroxo complex ions:

In the Brønsted–Lowry theory, a polyprotic acid,  $\text{Zn}(\text{H}_2\text{O})_4^{2+}(aq)$ , donates hydrogen ions in succession to make all the product ions. The second product,  $\text{Zn}(\text{OH})_2$ , is amphoteric; it can react as either acid or base. It is only slightly soluble in pure water (its  $K_{\text{sp}}$  is only  $1.9 \times 10^{-17}$ ). If enough acid is added to solid  $\text{Zn}(\text{OH})_2$ , the  $\text{OH}^-$  ligands are removed, forming the soluble  $\text{Zn}^{2+}$  ion; if enough base is added,  $\text{OH}^-$  ligands attach to form the soluble  $\text{Zn}(\text{OH})_4^{2-}$  (zincate) ion. Thus,  $\text{Zn}(\text{OH})_2$  is soluble in strongly acidic or strongly basic solutions but is only slightly soluble at intermediate pH values (Fig. 16.16). This amphoterism can be used to separate  $\text{Zn}^{2+}$  from other cations that do not share the property. For example,  $\text{Mg}^{2+}$  adds a maximum of two  $\text{OH}^-$  ions to form  $\text{Mg}(\text{OH})_2$ , a sparingly soluble hydroxide. Further addition of  $\text{OH}^-$  does not lead to the formation of new complex ions. If a mixture of  $\text{Mg}^{2+}$  and  $\text{Zn}^{2+}$  ions is made sufficiently basic, the  $\text{Mg}^{2+}$  precipitates as  $\text{Mg}(\text{OH})_2$  but the zinc remains in solution as  $\text{Zn}(\text{OH})_4^{2-}$ , allowing the two to be separated. In the same way, aluminum is separated from iron industrially by dissolving solid  $\text{Al}(\text{OH})_3$  in strong base as  $\text{Al}(\text{OH})_4^-(aq)$  while  $\text{Fe}(\text{OH})_3$  remains as a precipitate.

## 16.6

### A DEEPER LOOK

## Selective Precipitation of Ions

**FIGURE 16.16** Zinc hydroxide is insoluble in water (center) but dissolves readily in acid (left) and base (right). The indicator used is bromocresol red, which turns from red to yellow in acidic solution.

© Cengage Learning/Leon Lewandowski

One way to analyze a mixture of ions in solution is to separate the mixture into its components by exploiting the differences in the solubilities of compounds containing the ions. To separate silver ions from lead ions, for example, a search is made for compounds of these elements that (1) have a common anion and (2) have widely different solubilities. The chlorides  $\text{AgCl}$  and  $\text{PbCl}_2$  are two such compounds, for which the solubility equilibria are

Lead chloride is far more soluble in water than is silver chloride. Consider a solution that is 0.10 M in both  $\text{Ag}^+$  and  $\text{Pb}^{2+}$ . Is it possible to add enough  $\text{Cl}^-$  to precipitate almost all the  $\text{Ag}^+$  ions but leave all the  $\text{Pb}^{2+}$  ions in solution? If so, a quantitative separation of the two species can be achieved.

For  $\text{Pb}^{2+}$  to remain in solution, its reaction quotient must remain smaller than  $K_{\text{sp}}$ :  $Q = [\text{Pb}^{2+}][\text{Cl}^-]^2 < K_{\text{sp}}$ . Inserting  $K_{\text{sp}}$  and the concentration of  $\text{Pb}^{2+}$  gives

$$[\text{Cl}^-]^2 < \frac{K_{\text{sp}}}{[\text{Pb}^{2+}]} = \frac{2.4 \times 10^{-4}}{0.10} = 2.4 \times 10^{-3}$$

The square root of this is

$$[\text{Cl}^-] < 4.9 \times 10^{-2} \text{ M}$$

Thus, as long as the chloride ion concentration remains smaller than 0.049 M, no  $\text{PbCl}_2$  should precipitate. To reduce the *silver* ion concentration in solution as far as possible (that is, to precipitate out as much silver chloride as possible), the chloride ion concentration should be kept as high as possible without exceeding 0.049 M. If exactly this concentration of  $\text{Cl}^-$  (aq) is chosen, then at equilibrium,

$$[\text{Ag}^+] = \frac{K_{\text{sp}}}{[\text{Cl}^-]} = \frac{1.6 \times 10^{-10}}{0.049} = 3.3 \times 10^{-9} \text{ M}$$

At that concentration of  $\text{Cl}^-$ , the concentration of  $\text{Ag}^+$  has been reduced to  $3.3 \times 10^{-9}$  from the original concentration of 0.10 M. In other words, only about three  $\text{Ag}^+$  ions in  $10^8$  remain in solution, but all the  $\text{Pb}^{2+}$  ions are left in solution. A nearly perfect separation of the two ionic species has been achieved.

This calculation gave the optimal theoretical separation factor for the two ions. In practice it is necessary to keep the chloride concentration lower. If  $[\text{Cl}^-]$  is ten times smaller, or 0.0049 M, about three  $\text{Ag}^+$  ions in  $10^7$  remain in solution with the  $\text{Pb}^{2+}$ . This is 10 times more  $\text{Ag}^+$  than if  $[\text{Cl}^-] = 0.049 \text{ M}$ , but the separation of  $\text{Ag}^+$  from  $\text{Pb}^{2+}$  is still very good.

Figure 16.17 shows graphically how ions can be separated based on solubility. The relation between the concentration of  $\text{Pb}^{2+}$  and  $\text{Cl}^-$  ions in contact with solid  $\text{PbCl}_2$

$$[\text{Pb}^{2+}] = \frac{K_{\text{sp}}}{[\text{Cl}^-]^2}$$

can be rewritten in a useful form by taking the common logarithms of both sides:

$$\log_{10}[\text{Pb}^{2+}] = -2 \log_{10}[\text{Cl}^-] + \log_{10}K_{\text{sp}}$$

**FIGURE 16.17** To separate a mixture of  $\text{Ag}^+$  and  $\text{Pb}^{2+}$  ions, a chloride ion concentration is selected that gives a  $\text{Pb}^{2+}$  concentration below the equilibrium curve for  $\text{PbCl}_2$  (so all  $\text{Pb}^{2+}$  remains in solution) but well above the equilibrium curve for  $\text{Ag}^+$ . As a result, nearly all the  $\text{Ag}^+$  precipitates as  $\text{AgCl}$ . If  $[\text{Pb}^{2+}]_0 = [\text{Ag}^+]_0 = 0.1 \text{ M}$ , then the maximum  $[\text{Cl}^-]$  is found by tracing the horizontal red line and then dropping the vertical red line to find  $[\text{Cl}^-] = 0.049 \text{ M}$ . The concentration of  $\text{Ag}^+$  still in solution is found by tracing the horizontal blue line from the intersection of the  $[\text{Cl}^-]$  line of the  $\text{AgCl}$  equilibrium curve back to the vertical axis where  $[\text{Ag}^+] = 3.3 \times 10^{-9} \text{ M}$ .

That is, a graph of  $\log_{10} [\text{Pb}^{2+}]$  against  $\log_{10} [\text{Cl}^-]$  is a straight line with slope  $-2$ . The corresponding graph for the  $\text{AgCl}$  solubility equilibrium has slope  $-1$ .

$$\log_{10}[\text{Ag}^+] = -\log_{10}[\text{Cl}^-] + \log_{10}K_{\text{sp}}$$

If the concentration of  $\text{Cl}^-$  and the initial concentrations of the metal ions correspond to a point that lies between the two lines in Figure 16.17, then  $\text{AgCl}$  precipitates but  $\text{PbCl}_2$  does not.

### 16.6.1 Metal Sulfides

Controlling the solubility of metal sulfides has important applications. According to Table 16.2, most metal sulfides are very slightly soluble in water; only a very small amount of a compound such as  $\text{ZnS}(s)$  will dissolve in water. Although it is tempting to write the resulting equilibrium as

in analogy with the equilibria for other weakly soluble salts, this is misleading, because  $\text{S}^{2-}$ , like  $\text{O}^{2-}$ , is a very strong base (stronger than  $\text{OH}^-$ ) and reacts almost quantitatively with water.

The value of  $K_{\text{b}}$  for this reaction is on the order of  $10^5$ ; this means essentially no  $\text{S}^{2-}$  is present in aqueous solution. The net dissolution reaction is found by adding the two preceding equations,

for which the equilibrium constant is

$$[\text{Zn}^{2+}][\text{OH}^-][\text{HS}^-] = K \approx 2 \times 10^{-25}$$

Table 16.5 gives values of the equilibrium constants for comparable reactions of other metal sulfides. As the pH decreases, the concentration of  $\text{OH}^-$  decreases. At the same time, the concentration of  $\text{HS}^-$  also decreases as the equilibrium

shifts to the right upon addition of  $\text{H}_3\text{O}^+$ . If both  $[\text{OH}^-]$  and  $[\text{HS}^-]$  decrease, then  $[\text{Zn}^{2+}]$  must increase in order to maintain a constant value for the product of the three concentrations. As a result, the solubility of  $\text{ZnS}(s)$  increases as the pH of the solution decreases. Other metal sulfides behave the same way, becoming more soluble in acidic solution.

A quantitative calculation of metal sulfide solubility requires treating several simultaneous equilibria, as the following example illustrates.

**TABLE 16.5**

Equilibrium Constants for Metal Sulfide Dissolution at 25°C

Metal Sulfide	$K^\dagger$
CuS	$5 \times 10^{-37}$
PbS	$3 \times 10^{-28}$
CdS	$7 \times 10^{-28}$
SnS	$9 \times 10^{-27}$
ZnS	$2 \times 10^{-25}$
FeS	$5 \times 10^{-19}$
MnS	$3 \times 10^{-14}$

$^\dagger K$  is the equilibrium constant for the reaction  $\text{MS}(s) + \text{H}_2\text{O}(\ell) \rightleftharpoons \text{M}^{2+}(aq) + \text{OH}^-(aq) + \text{HS}^-(aq)$ .

**FIGURE 16.18** Hydrogen sulfide,  $\text{H}_2\text{S}$ , is a poisonous, foul-smelling gas. When dissolved in water, it gives a weak acid, hydrosulfuric acid.

#### EXAMPLE 16.10

In a solution that is saturated with  $\text{H}_2\text{S}$  (see Fig. 16.18),  $[\text{H}_2\text{S}]$  is fixed at 0.1 M. Calculate the molar solubility of  $\text{FeS}(s)$  in such a solution if it is buffered at pH 3.0.

#### Solution

If the pH is 3.0, then

$$[\text{OH}^-] = 1 \times 10^{-11} \text{ M}$$

(Continued)

In addition, the acid ionization of  $\text{H}_2\text{S}$  must be considered:

Substitution of  $[\text{H}_2\text{S}] = 0.1 \text{ M}$  for a saturated solution and  $[\text{H}_3\text{O}^+] = 1 \times 10^{-3} \text{ M}$  (at pH 3.0) into the equilibrium expression for this reaction gives

$$\frac{[\text{H}_3\text{O}^+][\text{HS}^-]}{[\text{H}_2\text{S}]} = \frac{[1 \times 10^{-3}][\text{HS}^-]}{0.1} = K_a = 9.1 \times 10^{-8}$$

$$[\text{HS}^-] = 9 \times 10^{-6} \text{ M}$$

where  $K_a$  came from Table 15.2. For the reaction

the equilibrium constant from Table 16.3 is

$$[\text{Fe}^{2+}][\text{HS}^-][\text{OH}^-] = 5 \times 10^{-19}$$

Substituting the values of  $[\text{HS}^-]$  and  $[\text{OH}^-]$  and solving for  $[\text{Fe}^{2+}]$  give

$$[\text{Fe}^{2+}](9 \times 10^{-6})(1 \times 10^{-11}) = 5 \times 10^{-19}$$

$$[\text{Fe}^{2+}] = 6 \times 10^{-3} \text{ M}$$

Hence,  $6 \times 10^{-3} \text{ mol}$  of FeS dissolves per liter under these conditions.

**Related Problems: 55, 56**

By adjusting the pH through appropriate choice of buffers, as in Example 16.10, conditions can be selected so that metal ions of one element remain entirely in solution, whereas those of a second element in the mixture precipitate almost entirely as solid metal sulfide (Fig. 16.19). Such a procedure is important for separating metal ions in qualitative analysis.

**FIGURE 16.19** These sulfides are insoluble at pH 1, so they can be separated out of a mixture containing other, more soluble sulfides. From left to right, they are PbS,  $\text{Bi}_2\text{S}_3$ , CuS, CdS,  $\text{Sb}_2\text{S}_3$ ,  $\text{SnS}_2$ ,  $\text{As}_2\text{S}_3$ , and HgS. The precipitates occupy the lower part of the test tubes; in the 2nd and 6th from the left, the precipitate appears as a dispersion of fine particles. The colored bands observed at each meniscus are refracted images of the colored solids at the bottom of each tube.

## CHAPTER SUMMARY

Dissolution–precipitation reactions involve equilibrium between a substance in its solid form and molecules or ions of that same substance dissolved in solution. This equilibrium is described by the mass action law, so knowledge of the equilibrium constant permits manipulation of the concentrations in solution through the principles described in Chapter 14. Numerous separation and purification procedures are based on such manipulations. The significance of these dissolution–precipitation equilibria in practical applications is comparable to that of acid–base reactions. Solutions of slightly soluble solids are said to be saturated when the dissolved concentration is at equilibrium with the solid. In accordance with Le Châtelier’s principle, if the solution goes to a state of

supersaturation, it will return to equilibrium by precipitating solid out of solution. Similarly, according to Le Châtelier, solubility can be increased by increasing temperature for an endothermic dissolution reaction, or by decreasing temperature for an exothermic dissolution reaction. Solubility is greatly influenced by the presence of other species to the solution, through the way they shift the equilibrium concentration of the dissolved solid species. This general principle explains the common ion effect and the influence of pH on solubility.

## CONCEPTS AND SKILLS

### Section 16.1 – The Nature of Solubility Equilibria

*Discuss the dynamical processes that lead to solubility equilibria (Problems 1–4).*

- When a solid substance is in contact with a solution in which this same substance is dissolved, molecules of the substance pass back and forth between the solid and dissolved states, just as molecules move between a liquid and its vapor. When the rate of passage from the solid into the solution is equal to the rate of the reverse passage from solution into the solid, a state of dissolution–precipitation equilibrium exists. At equilibrium, the solution is saturated and cannot accommodate more solute. The solubility  $S$  of a substance is the greatest amount that will dissolve in a specified volume of solvent at a specified temperature, and is expressed in  $\text{g L}^{-1}$  or  $\text{mol L}^{-1}$ . The solubility depends on temperature. In accordance with Le Châtelier's principle, solubility will increase with temperature if the dissolution reaction is endothermic, and decrease as temperature increases if the reaction is exothermic. A nonequilibrium supersaturated state can exist temporarily, in which the concentration of dissolved species exceeds the equilibrium concentration. The solution can return to equilibrium by precipitation of the excess dissolved species.

### Section 16.2 – Ionic Equilibria between Solids and Solutions

*Relate the solubilities of sparingly soluble salts in water to their solubility product constants (Problems 5–16).*

- Slightly soluble ionic solids dissociate in solution to establish equilibrium with the dissolved cations and ions. The equilibrium expression is written in accordance with the stoichiometry of the compound. The solid does not appear in the equilibrium expression because it is in its standard state which has activity  $a = 1$ .
  - $\text{AB}(s) \rightleftharpoons \text{A}^+(aq) + \text{B}^-(aq)$
  - $K_{\text{sp}} = [\text{A}^+][\text{B}^-] = S^2$  if  $S$  is the molar solubility and the solid is dissolved in pure water.
  - $\text{AB}_2(s) \rightleftharpoons \text{A}^+(aq) + 2\text{B}^-(aq)$
  - $K_{\text{sp}} = [\text{A}^+][\text{B}^-]^2 = 4S^3$ , and so on, for different stoichiometric ratios if the solid is dissolved in pure water.

### Section 16.3 – Precipitation and the Solubility Product

*Use the reaction quotient to predict whether a precipitate will form when two solutions are mixed, and then calculate the equilibrium concentrations that result (Problems 17–24).*

- At any point in the reaction for the dissolution of the  $\text{AB}(s)$  above  $Q = [\text{A}^+][\text{B}^-]$ . When  $Q > K_{\text{sp}}$ , a precipitate will form. Assume the reaction goes to completion and consumes all of one ion (the limiting reagent). Subsequent dissolution restores some of that ion to establish equilibrium between the precipitate and the solution. See Examples 16.3 and 16.4.

Calculate the solubility of a sparingly soluble salt in a solution that contains a given concentration of a common ion (Problems 25–30).

- The common ion effect describes the equilibrium of a solid with a solution that already contains some ions of the same type as one of those in the solid. No matter what the source of the ions, the total concentration of each in the solution must obey the equilibrium expression. The concentration of the “common ion” at equilibrium is the sum of its concentration initially present and the additional amount produced in the dissolution of the solid. Substitute this total concentration in the equilibrium expression and calculate the solubility at equilibrium. See Example 16.5.

### Section 16.4 – The Effects of pH on Solubility

Determine the dependence on pH of the solubility of a salt of a weak base (Problems 31–34).

- Solubility of metal hydroxides increases at lower pH because the acid present ties up hydroxide ions in solution and so shifts the dissolution equilibrium to the right. Solubility of salts in which the anion is a weak base increases at lower pH because the hydronium ion in solution consumes the anion and so shifts the dissolution equilibrium to the right.

### Section 16.5 – Complex Ions and Solubility

Calculate the concentrations of molecular and ionic species in equilibrium with complex ions (Problems 35–38).

- The equilibrium expression relates the concentration of the complex ion and the concentration of the species that participate in its formation to the formation constant  $K_f$  for the ion. Set up the equilibrium expression by writing the total concentration of each species as the sum of its concentration initially present and the additional amount produced in formation of the complex ion, and solve for the resulting equilibrium concentration. See Example 16.7.

Determine the effect of complex ion formation on the solubility of sparingly soluble salts containing a common cation (Problems 39–40).

- Suppose a sparingly soluble salt such as AgCl is already in equilibrium with a solution. Adding a new reactant that forms a soluble complex with  $\text{Ag}^+$  ions will consume the free  $\text{Ag}^+$  ions in the solution. By Le Châtelier’s principle this will drive the dissolution equilibrium to the right and increase the solubility of AgCl above its value in pure water. The resulting equilibrium is the sum of the dissolution–precipitation reaction and the complex formation reaction, and the resulting equilibrium constant is the product  $K_{sp}K_f$ . See Example 16.8.

Calculate the pH of aqueous solutions containing metal cations (Problems 41–46).

- Many metal cations are highly solvated in aqueous solutions to form complex ions that function as Brønsted–Lowry acids by donating protons to the solution. If the acid dissociation constant  $K_a$  is known for the complex ion, the equilibrium concentration of  $\text{H}_3\text{O}^+$  and the pH are readily calculated. See Example 16.9.

### Section 16.6 – A Deeper Look . . . Selective Precipitation of Ions

Specify the optimal conditions for separating two elements based on the differing solubilities of their ionic compounds (Problems 49–56.)

- Identify compounds of the two elements that have a common anion and widely different solubilities. Add enough of the common anion to precipitate all of the less soluble compound and leave the more soluble compound in solution. The maximum amount that can be added is determined by keeping

the reaction quotient  $Q$  for the more soluble compound below its  $K_{sp}$  value. The quantitative degree of separation depends on the relative magnitudes of the  $K_{sp}$  values. This method is illustrated in Figure 16.17.

## CUMULATIVE EXERCISE

### Carbonate Minerals in Fresh Water and Seawater

The carbonates (see Fig. 16.20) are among the most abundant and important minerals in the earth's crust. When these minerals come into contact with fresh water or seawater, solubility equilibria are established that greatly affect the chemistry of the natural waters. Calcium carbonate ( $\text{CaCO}_3$ ), the most important natural carbonate, makes up limestone and other forms of rock such as marble. Other carbonate minerals include dolomite,  $\text{CaMg}(\text{CO}_3)_2$ , and magnesite,  $\text{MgCO}_3$ . These compounds are sufficiently soluble that their solutions are nonideal, so calculations based on solubility product expressions are only approximate.

- The rare mineral nesquehonite contains  $\text{MgCO}_3$  together with water of hydration. A sample containing 21.7 g of nesquehonite is acidified and heated, and the volume of  $\text{CO}_2(\text{g})$  produced is measured to be 3.51 L at  $0^\circ\text{C}$  and  $P = 1$  atm. Assuming all the carbonate has reacted to form  $\text{CO}_2$ , give the chemical formula for nesquehonite.
- Write a chemical equation and a solubility product expression for the dissolution of dolomite in water.
- In a sufficiently basic solution, the carbonate ion does not react significantly with water to form hydrogen carbonate ion. Calculate the solubility (in grams per liter) of limestone (calcium carbonate) in a 0.10 M solution of sodium hydroxide. Use the  $K_{sp}$  from Table 16.2.
- In a strongly basic 0.10 M solution of  $\text{Na}_2\text{CO}_3$ , the concentration of  $\text{CO}_3^{2-}$  is 0.10 M. What is the gram solubility of limestone in this solution? Compare your answer with that for part (c).
- In a mountain lake having a pH of 8.1, the total concentration of carbonate species,  $[\text{CO}_3^{2-}] + [\text{HCO}_3^-]$ , is measured to be  $9.6 \times 10^{-4}$  M, whereas the concentration of  $\text{Ca}^{2+}$  is  $3.8 \times 10^{-4}$  M. Calculate the concentration of  $\text{CO}_3^{2-}$  in this lake, using  $K_a = 4.8 \times 10^{-11}$  for the acid ionization of  $\text{HCO}_3^-$  to  $\text{CO}_3^{2-}$ . Is the lake unsaturated, saturated, or supersaturated with respect to  $\text{CaCO}_3$ ?
- Will acid rainfall into the lake increase or decrease the solubility of limestone rocks in the lake's bed?
- Seawater contains a high concentration of  $\text{Cl}^-$  ions, which form weak complexes with calcium, such as the ion pair  $\text{CaCl}^+$ . Does the presence of such complexes increase or decrease the equilibrium solubility of  $\text{CaCO}_3$  in seawater?

**FIGURE 16.20** Carbonate minerals. Calcite (*left*) and aragonite (*middle*) are both  $\text{CaCO}_3$ , and smithsonite (*right*) is  $\text{ZnCO}_3$ .

**Answers****PROBLEMS**

Answers to problems whose numbers are red appear in Appendix G. Problems that are more challenging are indicated with asterisks.

**16.1 The Nature of Solubility Equilibria**

- Gypsum has the formula  $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ . Plaster of Paris has the chemical formula  $\text{CaSO}_4 \cdot \frac{1}{2}\text{H}_2\text{O}$ . In making wall plaster, water is added to plaster of Paris and the mixture then hardens into solid gypsum. How much water (in liters, at a density of  $1.00 \text{ kg L}^{-1}$ ) should be added to 25.0 kg of plaster of Paris to turn it into gypsum, assuming no loss from evaporation?
- A 1.00-g sample of magnesium sulfate is dissolved in water, and the water is then evaporated away until the residue is bone dry. If the temperature of the water is kept between  $48^\circ\text{C}$  and  $69^\circ\text{C}$ , the solid that remains weighs 1.898 g. If the experiment is repeated with the temperature held between  $69^\circ\text{C}$  and  $100^\circ\text{C}$ , however, the solid has a mass of 1.150 g. Determine how many waters of crystallization per  $\text{MgSO}_4$  there are in each of these two solids.
- The following graph shows the solubility of KBr in water in units of grams of KBr per 100 g of  $\text{H}_2\text{O}$ . If 80 g of KBr is added to 100 g of water at  $10^\circ\text{C}$  and the mixture is heated slowly, at what temperature will the last KBr dissolve?

- Figure 16.3 shows the solubility of  $\text{AgNO}_3$  in water in units of moles of  $\text{AgNO}_3$  per kilogram of  $\text{H}_2\text{O}$ . If 255 g of  $\text{AgNO}_3$  is added to 100 g of water at  $95^\circ\text{C}$  and cooled slowly, at what temperature will the solution become saturated?

**16.2 Ionic Equilibria between Solids and Solutions**

- Iron(III) sulfate,  $\text{Fe}_2(\text{SO}_4)_3$ , is a yellow compound that is used as a coagulant in water treatment. Write a balanced chemical equation and a solubility product expression for its dissolution in water.
- Lead antimonate,  $\text{Pb}_3(\text{SbO}_4)_2$ , is used as an orange pigment in oil-based paints and in glazes. Write a balanced chemical equation and a solubility product expression for its dissolution in water.
- Thallium(I) iodate ( $\text{TlIO}_3$ ) is only slightly soluble in water. Its  $K_{\text{sp}}$  at  $25^\circ\text{C}$  is  $3.07 \times 10^{-6}$ . Estimate the solubility of thallium(I) iodate in water in units of grams per 100.0 mL of water.
- Thallium thiocyanate (TISCN) is only slightly soluble in water. Its  $K_{\text{sp}}$  at  $25^\circ\text{C}$  is  $1.82 \times 10^{-4}$ . Estimate the solubility of thallium thiocyanate in units of grams per 100.0 mL of water.
- Potassium perchlorate,  $\text{KClO}_4$ , has a  $K_{\text{sp}}$  at  $25^\circ\text{C}$  of  $1.07 \times 10^{-2}$ . Compute its solubility in grams per liter of solution.
- Ammonium hexachloroplatinate(IV),  $(\text{NH}_4)_2(\text{PtCl}_6)$ , is one of the few sparingly soluble ammonium salts. Its  $K_{\text{sp}}$  at  $20^\circ\text{C}$  is  $5.6 \times 10^{-6}$ . Compute its solubility in grams per liter of solution.
- The solubility product constant of mercury(I) iodide is  $1.2 \times 10^{-28}$  at  $25^\circ\text{C}$ . Estimate the concentration of  $\text{Hg}_2^{2+}$  and  $\text{I}^-$  in equilibrium with solid  $\text{Hg}_2\text{I}_2$ .
- The solubility product constant of  $\text{Hg}_2\text{Cl}_2$  is  $2 \times 10^{-18}$  at  $25^\circ\text{C}$ . Estimate the concentration of  $\text{Hg}_2^{2+}$  and  $\text{Cl}^-$  in equilibrium with solid  $\text{Hg}_2\text{Cl}_2$  at  $25^\circ\text{C}$ .
- The solubility of silver chromate ( $\text{Ag}_2\text{CrO}_4$ ) in 500 mL of water at  $25^\circ\text{C}$  is 0.0129 g. Calculate its solubility product constant.

14. At 25°C, 400 mL of water can dissolve 0.00896 g of lead iodate,  $\text{Pb}(\text{IO}_3)_2$ . Calculate  $K_{\text{sp}}$  for lead iodate.
15. At 100°C, water dissolves  $1.8 \times 10^{-2}$  g of  $\text{AgCl}$  per liter. Compute the  $K_{\text{sp}}$  of  $\text{AgCl}$  at this temperature.
16. A mass of 0.017 g of silver dichromate ( $\text{Ag}_2\text{Cr}_2\text{O}_7$ ) will dissolve in 300 mL of water at 25°C. Calculate the solubility product constant  $K_{\text{sp}}$  of silver dichromate.
27. The solubility product of nickel(II) hydroxide,  $\text{Ni}(\text{OH})_2$ , at 25°C is  $K_{\text{sp}} = 1.6 \times 10^{-16}$ .

- (a) Calculate the molar solubility of  $\text{Ni}(\text{OH})_2$  in pure water at 25°C.
- (b) Calculate the molar solubility of  $\text{Ni}(\text{OH})_2$  in 0.100 M  $\text{NaOH}$ .

28. Silver arsenate ( $\text{Ag}_3\text{AsO}_4$ ) is a slightly soluble salt having a solubility product of  $K_{\text{sp}} = 1.0 \times 10^{-22}$  at 25°C for the equilibrium

- (a) Calculate the molar solubility of silver arsenate in pure water at 25°C.
- (b) Calculate the molar solubility of silver arsenate in 0.10 M  $\text{AgNO}_3$ .

### 16.3 Precipitation and the Solubility Product

17. A solution of barium chromate ( $\text{BaCrO}_4$ ) is prepared by dissolving  $6.3 \times 10^{-3}$  g of this yellow solid in 1.00 L of hot water. Will solid barium chromate precipitate upon cooling to 25°C, according to the solubility product expression? Explain.
18. A solution is prepared by dissolving 0.090 g of  $\text{PbI}_2$  in 1.00 L of hot water and cooling the solution to 25°C. Will solid precipitate result from this process, according to the solubility product expression? Explain.
19. A solution is prepared by mixing 250.0 mL of  $2.0 \times 10^{-3}$  M  $\text{Ce}(\text{NO}_3)_3$  and 150.0 mL of  $10 \times 10^{-2}$  M  $\text{KIO}_3$  at 25°C. Determine whether  $\text{Ce}(\text{IO}_3)_3(\text{s})$  ( $K_{\text{sp}} = 1.9 \times 10^{-10}$ ) tends to precipitate from this mixture.
20. Suppose 100.0 mL of a 0.0010 M  $\text{CaCl}_2$  solution is added to 50.0 mL of a  $6.0 \times 10^{-5}$  M  $\text{NaF}$  solution at 25°C. Determine whether  $\text{CaF}_2(\text{s})$  ( $K_{\text{sp}} = 3.9 \times 10^{-11}$ ) tends to precipitate from this mixture.
21. Suppose 50.0 mL of a 0.0500 M solution of  $\text{Pb}(\text{NO}_3)_2$  is mixed with 40.0 mL of a 0.200 M solution of  $\text{NaIO}_3$  at 25°C. Calculate the  $[\text{Pb}^{2+}]$  and  $[\text{IO}_3^-]$  when the mixture comes to equilibrium. At this temperature,  $K_{\text{sp}}$  for  $\text{Pb}(\text{IO}_3)_2$  is  $2.6 \times 10^{-13}$ .
22. Silver iodide ( $\text{AgI}$ ) is used in place of silver chloride for the fastest photographic film because it is more sensitive to light and can therefore form an image in a very short exposure time. A silver iodide emulsion is prepared by adding 6.60 L of 0.10 M  $\text{NaI}$  solution to 1.50 L of 0.080 M  $\text{AgNO}_3$  solution at 25°C. Calculate the concentration of silver ion remaining in solution when the mixture comes to equilibrium and its chemical amount relative to the amount present initially.
23. When 50.0 mL of 0.100 M  $\text{AgNO}_3$  and 30.0 mL of 0.0600 M  $\text{Na}_2\text{CrO}_4$  are mixed, a precipitate of silver chromate ( $\text{Ag}_2\text{CrO}_4$ ) is formed. The solubility product  $K_{\text{sp}}$  of silver chromate in water at 25°C is  $1.9 \times 10^{-12}$ . Calculate the  $[\text{Ag}^+]$  and  $[\text{CrO}_4^{2-}]$  remaining in solution at equilibrium.
24. When 40.0 mL of 0.0800 M  $\text{Sr}(\text{NO}_3)_2$  and 80.0 mL of 0.0500 M  $\text{KF}$  are mixed, a precipitate of strontium fluoride ( $\text{SrF}_2$ ) is formed. The solubility product  $K_{\text{sp}}$  of strontium fluoride in water at 25°C is  $2.8 \times 10^{-9}$ . Calculate the  $[\text{Sr}^{2+}]$  and  $[\text{F}^-]$  remaining in solution at equilibrium.
25. Calculate the solubility (in  $\text{mol L}^{-1}$ ) of  $\text{CaF}_2(\text{s})$  at 25°C in a 0.040 M aqueous solution of  $\text{NaF}$ .
26. Calculate the mass of  $\text{AgCl}$  that can dissolve in 100 mL of 0.150 M  $\text{NaCl}$  solution.
29. A saturated solution of  $\text{Mg}(\text{OH})_2$  at 25°C is prepared by equilibrating solid  $\text{Mg}(\text{OH})_2$  with water. Concentrated  $\text{NaOH}$  is then added until the solubility of  $\text{Mg}(\text{OH})_2$  is 0.0010 times that in  $\text{H}_2\text{O}$  alone. (Ignore the change in volume resulting from the addition of  $\text{NaOH}$ .) The solubility product  $K_{\text{sp}}$  of  $\text{Mg}(\text{OH})_2$  is  $1.2 \times 10^{-11}$  at 25°C. Calculate the concentration of hydroxide ion in the solution after the addition of the  $\text{NaOH}$ .
30. A saturated solution of  $\text{BaF}_2$  at 25°C is prepared by equilibrating solid  $\text{BaF}_2$  with water. Powdered  $\text{NaF}$  is then dissolved in the solution until the solubility of  $\text{BaF}_2$  is 1.0% of that in  $\text{H}_2\text{O}$  alone. The solubility product  $K_{\text{sp}}$  of  $\text{BaF}_2$  is  $1.7 \times 10^{-6}$  at 25°C. Calculate the concentration of fluoride ion in the solution after addition of the powdered  $\text{NaF}$ .

### 16.4 The Effects of pH on Solubility

31. Compare the molar solubility of  $\text{AgOH}$  in pure water with that in a solution buffered at pH 7.00. Note the difference between the two: When  $\text{AgOH}$  is dissolved in pure water, the pH does not remain at 7.
32. Compare the molar solubility of  $\text{Mg}(\text{OH})_2$  in pure water with that in a solution buffered at pH 9.00.
33. For each of the following ionic compounds, state whether the solubility will increase, decrease, or remain unchanged as a solution at pH 7 is made acidic.
- (a)  $\text{PbI}_2$       (b)  $\text{AgOH}$       (c)  $\text{Ca}_3(\text{PO}_4)_2$
34. For each of the following ionic compounds, state whether the solubility will increase, decrease, or remain unchanged as a solution at pH 7 is made acidic.
- (a)  $\text{SrCO}_3$       (b)  $\text{Hg}_2\text{Br}_2$       (c)  $\text{MnS}$

### 16.5 Complex Ions and Solubility

35. Suppose 0.10 mol of  $\text{Cu}(\text{NO}_3)_2$  and 1.50 mol of  $\text{NH}_3$  are dissolved in water and diluted to a total volume of 1.00 L. Calculate the concentrations of  $\text{Cu}(\text{NH}_3)_4^{2+}$  and of  $\text{Cu}^{2+}$  at equilibrium.
36. The formation constant of the  $\text{TlCl}_4^-$  complex ion is  $1 \times 10^{18}$ . Suppose 0.15 mol of  $\text{Tl}(\text{NO}_3)_3$  is dissolved in 1.00 L of a 0.50 M solution of  $\text{NaCl}$ . Calculate the concentration at equilibrium of  $\text{TlCl}_4^-$  and of  $\text{Tl}^{3+}$ .

37. The organic compound “18-crown-6” binds alkali metals in aqueous solution by wrapping around and enfolding the ion. It presents a niche that nicely accommodates the  $K^+$  ion but is too small for the  $Rb^+$  ion and too large for the  $Na^+$  ion. The values of the equilibrium constants show this:

An aqueous solution is initially 0.0080 M in 18-crown-6(aq) and also 0.0080 M in  $K^+(aq)$ . Compute the equilibrium concentration of free  $K^+$ . (“Free” means not tied up with the 18-crown-6.) Compute the concentration of free  $Na^+$  if the solution contains 0.0080 M  $Na^+(aq)$  instead of  $K^+(aq)$ .

38. The organic compound 18-crown-6 (see preceding problem) also binds strongly with the alkali metal ions in methanol.

In methanol solution the equilibrium constant is  $1.41 \times 10^6$ . A similar reaction with  $Cs^+$  has an equilibrium constant of only  $2.75 \times 10^4$ . A solution is made (in methanol) containing 0.020 mol  $L^{-1}$  each of  $K^+$  and  $Cs^+$ . It also contains 0.30 mol  $L^{-1}$  of 18-crown-6. Compute the equilibrium concentrations of both the uncomplexed  $K^+$  and the uncomplexed  $Cs^+$ .

39. Will silver chloride dissolve to a significantly greater extent in a 1.00 M NaCl solution than in pure water due to the possible formation of  $AgCl_2^-$  ions? Use data from Tables 16.2 and 16.3 to provide a quantitative answer to this question. What will happen in a 0.100 M NaCl solution?
40. Calculate how many grams of silver chloride will dissolve in 1.0 L of a 1.0 M  $NH_3$  solution through formation of the complex ion  $Ag(NH_3)_2^+$ .
41. The pH of a 0.2 M solution of  $CuSO_4$  is 4.0. Write chemical equations to explain why a solution of this salt is neither basic [from the reaction of  $SO_4^{2-}(aq)$  with water] nor neutral, but acidic.
42. Will a 0.05 M solution of  $FeCl_3$  be acidic, basic, or neutral? Explain your answer by writing chemical equations to describe any reactions taking place.
43. The acid ionization constant for  $Co(H_2O)_6^{2+}(aq)$  is  $3 \times 10^{-10}$ . Calculate the pH of a 0.10 M solution of  $Co(NO_3)_2$ .
44. The acid ionization constant for  $Fe(H_2O)_6^{2+}(aq)$  is  $3 \times 10^{-6}$ . Calculate the pH of a 0.10 M solution of  $Fe(NO_3)_2$ , and compare it with the pH of the corresponding iron(III) nitrate solution from Example 16.9.
45. A 0.15 M aqueous solution of the chloride salt of the complex ion  $Pt(NH_3)_4^{2+}$  is found to be weakly acidic with a pH of 4.92. This is initially puzzling because the  $Cl^-$  ion

in water is not acidic and  $NH_3$  in water is *basic*, not acidic. Finally, it is suggested that the  $Pt(NH_3)_4^{2+}$  ion as a group donates hydrogen ions. Compute the  $K_a$  of this acid, assuming that just one hydrogen ion is donated.

46. The pH of a 0.10 M solution of  $Ni(NO_3)_2$  is 5.0. Calculate the acid ionization constant of  $Ni(H_2O)_6^{2+}(aq)$ .
47.  $K_{sp}$  for  $Pb(OH)_2$  is  $4.2 \times 10^{-15}$ , and  $K_f$  for  $Pb(OH)_3^-$  is  $4 \times 10^{14}$ . Suppose a solution whose initial concentration of  $Pb^{2+}(aq)$  is 1.00 M is brought to pH 13.0 by addition of solid NaOH. Will solid  $Pb(OH)_2$  precipitate, or will the lead be dissolved as  $Pb(OH)_3^-(aq)$ ? What will be  $[Pb^{2+}]$  and  $[Pb(OH)_3^-]$  at equilibrium? Repeat the calculation for an initial  $Pb^{2+}$  concentration of 0.050 M. (*Hint*: One way to solve this problem is to *assume* that  $Pb(OH)_2(s)$  is present and calculate  $[Pb^{2+}]$  and  $[Pb(OH)_3^-]$  that would be in equilibrium with the solid. If the sum of these is less than the original  $[Pb^{2+}]$ , the remainder can be assumed to have precipitated. If not, there is a contradiction and we must assume that *no*  $Pb(OH)_2(s)$  is present. In this case we can calculate  $[Pb^{2+}]$  and  $[Pb(OH)_3^-]$  directly from  $K_f$ .)
48.  $K_{sp}$  from  $Zn(OH)_2$  is  $4.5 \times 10^{-17}$ , and  $K_f$  for  $Zn(OH)_4^{2-}$  is  $5 \times 10^{14}$ . Suppose a solution whose initial concentration of  $Zn^{2+}(aq)$  is 0.010 M is brought to pH 14.0 by addition of solid NaOH. Will solid  $Zn(OH)_2$  precipitate, or will the zinc be dissolved as  $Zn(OH)_4^{2-}(aq)$ ? What will be  $[Zn^{2+}]$  and  $[Zn(OH)_4^{2-}]$  at equilibrium? Repeat the calculation at pH 13 for an initial  $Zn^{2+}$  concentration of 0.10 M. See the hint in problem 47.

## 16.6 A Deeper Look . . . Selective Precipitation of Ions

49. An aqueous solution at 25°C is 0.10 M in both  $Mg^{2+}$  and  $Pb^{2+}$  ions. We wish to separate the two kinds of metal ions by taking advantage of the different solubilities of their oxalates,  $MgC_2O_4$  and  $PbC_2O_4$ .
- What is the highest possible oxalate ion concentration that allows only one solid oxalate salt to be present at equilibrium? Which ion is present in the solid— $Mg^{2+}$  or  $Pb^{2+}$ ?
  - What fraction of the less soluble ion still remains in solution under the conditions of part (a)?
50. An aqueous solution at 25°C is 0.10 M in  $Ba^{2+}$  and 0.50 M in  $Ca^{2+}$  ions. We wish to separate the two by taking advantage of the different solubilities of their fluorides,  $BaF_2$  and  $CaF_2$ .
- What is the highest possible fluoride ion concentration that allows only one solid fluoride salt to be present at equilibrium? Which ion is present in the solid— $Ba^{2+}$  or  $Ca^{2+}$ ?
  - What fraction of the less soluble ion still remains in solution under the conditions of part (a)?
51. The cations in an aqueous solution that contains 0.100 M  $Hg_2(NO_3)_2$  and 0.0500 M  $Pb(NO_3)_2$  are to be separated by taking advantage of the difference in the solubilities of their iodides. The  $K_{sp}$  of  $PbI_2$  and of  $Hg_2I_2$  are given in Table 16.2. What should be the concentration of iodide ion for the best separation? In the “best” separation, one of the cations should remain entirely in solution and the other should precipitate as fully as possible.

52. The cations in an aqueous solution that contains 0.150 M  $\text{Ba}(\text{NO}_3)_2$  and 0.0800 M  $\text{Ca}(\text{NO}_3)_2$  are to be separated by taking advantage of the difference in the solubilities of their sulfates.  $K_{\text{sp}}(\text{BaSO}_4) = 1.1 \times 10^{-10}$  and  $K_{\text{sp}}(\text{CaSO}_4) = 2.4 \times 10^{-5}$ . What should be the concentration of sulfate ion for the best separation?
53. Calculate the  $[\text{Zn}^{2+}]$  in a solution that is in equilibrium with  $\text{ZnS}(s)$  and in which  $[\text{H}_3\text{O}^+] = 1.0 \times 10^{-5}$  M and  $[\text{H}_2\text{S}] = 0.10$  M.
54. Calculate the  $[\text{Cd}^{2+}]$  in a solution that is in equilibrium with  $\text{CdS}(s)$  and in which  $[\text{H}_3\text{O}^+] = 1.0 \times 10^{-3}$  M and  $[\text{H}_2\text{S}] = 0.10$  M.
55. What is the highest pH at which 0.10 M  $\text{Fe}^{2+}$  will remain entirely in a solution that is saturated with  $\text{H}_2\text{S}$  at a concentration of  $[\text{H}_2\text{S}] = 0.10$  M? At this pH, what would be the concentration of  $\text{Pb}^{2+}$  in equilibrium with solid  $\text{PbS}$  in this solution?
56. What is the highest pH at which 0.050 M  $\text{Mn}^{2+}$  will remain entirely in a solution that is saturated with  $\text{H}_2\text{S}$  at a concentration of  $[\text{H}_2\text{S}] = 0.10$  M? At this pH, what would be the concentration of  $\text{Cd}^{2+}$  in equilibrium with solid  $\text{CdS}$  in this solution?

## ADDITIONAL PROBLEMS

57. Write a chemical equation for the dissolution of mercury(I) chloride in water, and give its solubility product expression.
- \*58. Magnesium ammonium phosphate has the formula  $\text{MgNH}_4\text{PO}_4 \cdot 6\text{H}_2\text{O}$ . It is only slightly soluble in water (its  $K_{\text{sp}}$  is  $2.3 \times 10^{-13}$ ). Write a chemical equation and the corresponding equilibrium law for the dissolution of this compound in water.
59. Soluble barium compounds are poisonous, but barium sulfate is routinely ingested as a suspended solid in a “barium cocktail” to improve the contrast in X-ray images. Calculate the concentration of dissolved barium per liter of water in equilibrium with solid barium sulfate.
60. A saturated aqueous solution of silver perchlorate ( $\text{AgClO}_4$ ) contains 84.8% by mass  $\text{AgClO}_4$ , but a saturated solution of  $\text{AgClO}_4$  in 60% aqueous perchloric acid contains only 5.63% by mass  $\text{AgClO}_4$ . Explain this large difference using chemical equations.
61. Suppose 140 mL of 0.0010 M  $\text{Sr}(\text{NO}_3)_2$  is mixed with enough 0.0050 M  $\text{NaF}$  to make 1.00 L of solution. Will  $\text{SrF}_2(s)$  ( $K_{\text{sp}} = 2.8 \times 10^{-9}$ ) precipitate at equilibrium? Explain.
62. The concentration of calcium ion in a town’s supply of drinking water is 0.0020 M. (This water is referred to as hard water because it contains such a large concentration of  $\text{Ca}^{2+}$ .) Suppose the water is to be fluoridated by the addition of  $\text{NaF}$  for the purpose of reducing tooth decay. What is the maximum concentration of fluoride ion that can be achieved in the water before precipitation of  $\text{CaF}_2$  begins? Will the water supply attain the level of fluoride ion recommended by the U.S. Public Health Service, about  $5 \times 10^{-5}$  M (1 mg fluorine per liter)?
63. Suppose that 150 mL of 0.200 M  $\text{K}_2\text{CO}_3$  and 100 mL of 0.400 M  $\text{Ca}(\text{NO}_3)_2$  are mixed together. Assume that the volumes are additive, that  $\text{CaCO}_3$  is completely insoluble, and that all other substances that might be formed are soluble. Calculate the mass of  $\text{CaCO}_3$  precipitated, and calculate the concentrations in the final solution of the four ions that were present initially.
64. The solubility of  $\text{CaCO}_3$  in water is about 7 mg  $\text{L}^{-1}$ . Show how one can calculate the solubility product of  $\text{BaCO}_3$  from this information and from the fact that when sodium carbonate solution is added slowly to a solution containing equimolar concentrations of  $\text{Ca}^{2+}$  and  $\text{Ba}^{2+}$ , no  $\text{CaCO}_3$  is formed until about 90% of the  $\text{Ba}^{2+}$  has been precipitated as  $\text{BaCO}_3$ .
65. It is sometimes asserted that carbonates are soluble in strong acids because a gas is formed that escapes ( $\text{CO}_2$ ). Suppose that  $\text{CO}_2$  were extremely soluble in water (as, for example, ammonia is) and therefore it did not leave the site of the reaction, but that otherwise, its chemistry was unchanged. Would calcium carbonate be soluble in strong acids? Explain.
66. The solubility products of  $\text{Fe}(\text{OH})_3$  and  $\text{Ni}(\text{OH})_2$  are about  $10^{-36}$  and  $6 \times 10^{-18}$ , respectively. Find the approximate pH range suitable for the separation of  $\text{Fe}^{3+}$  and  $\text{Ni}^{2+}$  by precipitation of  $\text{Fe}(\text{OH})_3$  from a solution initially 0.01 M in each ion, as follows: (a) Calculate the lowest pH at which all but 0.1% of the  $\text{Fe}^{3+}$  will be precipitated as  $\text{Fe}(\text{OH})_3$ ; (b) calculate the highest pH possible without precipitation of  $\text{Ni}(\text{OH})_2$ .
67. The two solids  $\text{CuBr}(s)$  and  $\text{AgBr}(s)$  are only very slightly soluble in water:  $K_{\text{sp}}(\text{CuBr}) = 4.2 \times 10^{-8}$  and  $K_{\text{sp}}(\text{AgBr}) = 7.7 \times 10^{-13}$ . Some  $\text{CuBr}(s)$  and  $\text{AgBr}(s)$  are both mixed into a quantity of water that is then stirred until it is saturated with respect to both solutes. Next, a small amount of  $\text{KBr}$  is added and dissolves completely. Compute the ratio of  $[\text{Cu}^+]$  to  $[\text{Ag}^+]$  after the system reestablishes equilibrium.
- \*68. The two salts  $\text{BaCl}_2$  and  $\text{Ag}_2\text{SO}_4$  are both far more soluble in water than either  $\text{BaSO}_4$  ( $K_{\text{sp}} = 1.1 \times 10^{-10}$ ) or  $\text{AgCl}$  ( $K_{\text{sp}} = 1.6 \times 10^{-10}$ ) at 25°C. Suppose 50.0 mL of 0.040 M  $\text{BaCl}_2(aq)$  is added to 50.0 mL of 0.020 M  $\text{Ag}_2\text{SO}_4(aq)$ . Calculate the concentrations of  $\text{SO}_4^{2-}(aq)$ ,  $\text{Cl}^-(aq)$ ,  $\text{Ba}^{2+}(aq)$ , and  $\text{Ag}^+(aq)$  that remain in solution at equilibrium.
69. The Mohr method is a technique for determining the amount of chloride ion in an unknown sample. It is based on the difference in solubility between silver chloride ( $\text{AgCl}$ ;  $K_{\text{sp}} = 1.6 \times 10^{-10}$ ) and silver chromate ( $\text{Ag}_2\text{CrO}_4$ ;  $K_{\text{sp}} = 1.9 \times 10^{-12}$ ). In using this method, one adds a small amount of chromate ion to a solution with unknown chloride concentration. By measuring the volume of  $\text{AgNO}_3$

added before the appearance of the red silver chromate, one can determine the amount of  $\text{Cl}^-$  originally present. Suppose we have a solution that is 0.100 M in  $\text{Cl}^-$  and 0.00250 M in  $\text{CrO}_4^{2-}$ . If we add 0.100 M  $\text{AgNO}_3$  solution drop by drop, will  $\text{AgCl}$  or  $\text{Ag}_2\text{CrO}_4$  precipitate first? When  $\text{Ag}_2\text{CrO}_4(s)$  first appears, what fraction of the  $\text{Cl}^-$  originally present remains in solution?

70. Oxide ion, like sulfide ion, is a strong base. Write an equation for the dissolution of  $\text{CaO}$  in water and give its equilibrium constant expression. Write the corresponding equation for the dissolution of  $\text{CaO}$  in an aqueous solution of a strong acid, and relate its equilibrium constant to the previous one.
71. Water that has been saturated with magnesia ( $\text{MgO}$ ) at  $25^\circ\text{C}$  has a pH of 10.16. Write a balanced chemical equation for the equilibrium between  $\text{MgO}(s)$  and the ions it furnishes in aqueous solution, and calculate the equilibrium constant at  $25^\circ\text{C}$ . What is the solubility, in moles per liter, of  $\text{MgO}$  in water?
72. To 1.00 L of a 0.100 M  $\text{AgNO}_3$  solution is added an excess of sodium chloride. Then 1.00 L of 0.500 M  $\text{NH}_3(aq)$  is added. Finally, sufficient nitric acid is added until the pH of the resulting solution is 1.0. Write balanced equations for the reactions that take place (if any) at each of three steps in this process.
73. Only about 0.16 mg of  $\text{AgBr}(s)$  will dissolve in 1.0 L of water (this volume of solid is smaller than the head of a pin). In a solution of ammonia that contains 0.10 mol ammonia per liter of water, there are about 555 water molecules for every molecule of ammonia. However, more than 400 times as much  $\text{AgBr}$  (68 mg) will dissolve in this solution as in plain water. Explain how such a tiny change in the composition of the solution can have such a large effect on the solubility of  $\text{AgBr}$ .
- \*74. (a) Calculate the solubility of calcium oxalate ( $\text{CaC}_2\text{O}_4$ ) in 1.0 M oxalic acid ( $\text{H}_2\text{C}_2\text{O}_4$ ) at  $25^\circ\text{C}$ , using the two acid ionization constants for oxalic acid from Table 15.2 and the solubility product  $K_{\text{sp}} = 2.6 \times 10^{-9}$  for  $\text{CaC}_2\text{O}_4$ .

- (b) Calculate the solubility of calcium oxalate in pure water at  $25^\circ\text{C}$ .
- (c) Account for the difference between the results of (a) and (b).

- \*75. When 6 M  $\text{HCl}$  is added to solid  $\text{CdS}$ , some of the solid dissolves to give the complex ion  $\text{CdCl}_4^{2-}(aq)$ .
- (a) Write a balanced equation for the reaction that occurs.
- (b) Use data from Tables 15.2 and 16.5 and the formation constant of  $\text{CdCl}_4^{2-}$  ( $K_f = 8 \times 10^2$ ) to calculate the equilibrium constant for the reaction of part (a).
- (c) What is the molar solubility of  $\text{CdS}$  per liter of 6 M  $\text{HCl}$ ?
- \*76. Using data from Table 16.3, calculate the concentrations of  $\text{Hg}^{2+}(aq)$ ,  $\text{HgCl}^+(aq)$ , and  $\text{HgCl}_2(aq)$  that result when 1.00 L of a 0.100 M  $\text{Hg}(\text{NO}_3)_2$  solution is mixed with an equal volume of a 0.100 M  $\text{HgCl}_2$  solution. (*Hint:* Use the analogy with amphoteric equilibria discussed in Section 10.8.)
- \*77. Calculate the concentration of  $\text{Cu}^{2+}(aq)$  in a solution that contains 0.020 mol of  $\text{CuCl}_2$  and 0.100 mol of  $\text{NaCN}$  in 1.0 L.

(*Hint:* Do not overlook the reaction of  $\text{CN}^-$  with water to give  $\text{HCN}$ .)

78. An aqueous solution of  $\text{K}_2[\text{Pt}(\text{OH})_6]$  has a pH greater than 7. Explain this fact by writing an equation showing the  $\text{Pt}(\text{OH})_6^{2-}$  ion acting as a Brønsted–Lowry base and accepting a hydrogen ion from water.
79. In Example 16.9 we included only the first acid dissociation  $K_{a1}$  of a 0.100 M aqueous solution of  $\text{Fe}(\text{H}_2\text{O})_6^{3+}$ . Subsequent dissociation can also occur, with  $K_{a2} = 2.0 \times 10^{-5}$ , to give  $\text{Fe}(\text{H}_2\text{O})_4(\text{OH})_2^+$ .
- (a) Calculate the concentration of  $\text{Fe}(\text{H}_2\text{O})_4(\text{OH})_2^+$  at equilibrium. Does the pH change significantly when this second dissociation is taken into account?
- (b) We can describe the same reaction as the dissociation of a complex ion  $\text{Fe}(\text{OH})_2^+$  to  $\text{Fe}^{3+}$  and two  $\text{OH}^-$  ions. Calculate  $K_f$ , the formation constant for  $\text{Fe}(\text{OH})_2^+$ .

## CUMULATIVE PROBLEMS

80. The volume of a certain saturated solution is greater than the sum of the volumes of the water and salt from which it is made. Predict the effect of increased pressure on the solubility of this salt.
81. Codeine has the molecular formula  $\text{C}_{18}\text{H}_{21}\text{NO}_3$ . It is soluble in water to the extent of 1.00 g per 120 mL of water at room temperature and 1.00 g per 60 mL of water at  $80^\circ\text{C}$ . Compute the molal solubility (in mol  $\text{kg}^{-1}$ ) at both temperatures, taking the density of water to be fixed at  $1.00 \text{ g cm}^{-3}$ . Is the dissolution of codeine in water endothermic or exothermic?
82. Suppose 1.44 L of a saturated solution of strontium carbonate ( $\text{SrCO}_3$ ) in boiling water at  $100^\circ\text{C}$  is prepared. The

solution is then strongly acidified and shaken to drive off all the gaseous  $\text{CO}_2$  that forms. The volume of this gas (at a temperature of  $100^\circ\text{C}$  and a partial pressure of 0.972 atm) is measured to be 0.20 L (200 mL).

- (a) Calculate the molar solubility of  $\text{SrCO}_3$  in water at  $100^\circ\text{C}$ .
- (b) Estimate the solubility product constant  $K_{\text{sp}}$  of  $\text{SrCO}_3$  at this temperature.
- (c) Explain why the actual  $K_{\text{sp}}$  at this temperature may be lower than you predicted in part (b).
83. A buffer is prepared by adding 50.0 mL of 0.15 M  $\text{HNO}_3(aq)$  to 100.0 mL of 0.12 M  $\text{NaHCOO}(aq)$  (sodium formate). Calculate the solubility of  $\text{CaF}_2(s)$  in this solution.

A lightning strike contains about  $10^{20}$  electrons.

Electrochemistry is the branch of chemistry concerned with the interconversion of chemical and electrical energy through oxidation–reduction reactions. Electrons are transferred between two half-reactions through external electrical circuits, in contrast to solution-phase redox reactions discussed in Section 11.4. Energy produced by spontaneous chemical reactions may be converted to electrical energy; conversely, electrical energy can be used to drive chemical reactions that are not normally spontaneous. Electrochemistry is historically a vital field, primarily for its important industrial applications. Bulk commodity chemicals, such as chlorine, and most metals are produced using large-scale electrochemical processes. In addition, considerable efforts have been directed toward preventing the corrosion (electrochemically triggered oxidation) of metals, for example, alloy-based structural materials of pervasive importance in vehicles, ships, airplanes, buildings, and bridges. Another important practical application has been the development of batteries, which produce electrical energy from spontaneous redox reactions in electrochemical cells.

The field of electrochemistry is much broader than is represented by its industrial applications alone, and it has been transformed into a molecular science over the past forty years or so. Considerable insight into the molecular nature of electrochemical reactions has been provided by new techniques that couple electrochemical approaches with spectroscopic techniques and computational methods. The oxidation and reduction of single molecules have been detected and studied using the scanning electrochemical microscope, an analog of the scanning tunneling microscope described in Chapter 1, for example. Electrochemical methods are now widely used in medical diagnostics, where they routinely measure very low concentrations of molecules of clinical significance; current detection limits are the attomole ( $10^{-18}$  mol) level, which is about a million molecules. Finally, the current national interest in alternative energy provides enormous opportunities for research and development in electrochemistry. Solar energy conversion, fuel cells, and energy storage are technologies that rely on electrochemical transformations that occur at the molecular level. Electrochemistry has already made and will undoubtedly continue to make important contributions to developing improved energy technologies. New experimental and theoretical understanding of electrochemical processes at the molecular level, along with the opportunities to apply these methods to technological problems of global importance, make it a particularly exciting time to learn about the field.

We begin our discussion of electrochemistry by reviewing redox reactions in aqueous solution, introducing the components of electrochemical cells, and distinguishing galvanic cells from electrolytic cells. We recommend that you review the procedure in Section 11.4 for balancing redox reactions before continuing on to the next section, in which we discuss electrochemical processes from both thermodynamic and molecular points of view, as well as a variety of applications.

## 17.1 Electrochemical Cells

Electrochemical reactions interconvert chemical and electrical energy through coupled redox reactions in which, generally, the oxidation and reduction half-reactions are separated in space in an **electrochemical cell**. Each half-reaction occurs on or near the surface of an **electrode**, and the electrons produced at the electrode where oxidation is occurring are transferred to the other electrode by a wire. The half of the electrochemical cell in which reduction occurs is also connected to the half of the electrochemical cell where oxidation occurs by an ionic conductor to allow ions to move between the solutions surrounding the electrodes, so that they remain electrically neutral overall. Each is called a **half-cell**. The Gibbs free energy made available in a spontaneous reaction in a **galvanic cell** can be converted into electrical energy, which can be used to do work. Conversely, electrical work done *on* the system by an external power supply in an **electrolytic cell** provides a source of free energy to drive redox reactions that are not normally spontaneous. Perhaps the most powerful characteristic of electrochemistry is its ability to control reversible chemical reactions by supplying or extracting electrical energy; this ability enables both very large-scale industrial chemical technologies (making chlorine from salt water or extracting metals from their ores) as well as very sensitive schemes for chemical analysis (sub-picogram sensitivity for clinical applications).

### 17.1.1 Galvanic Cells

Let's begin by considering the following redox reaction

**FIGURE 17.1** A metallic copper anode reacts to give a blue solution containing copper(II) ions as silver ions plate out on a silver cathode in a galvanic cell. Typically ammeters assume positive charge carriers, so point opposite to the electron flow.

© Cengage Learning/Charles D. Winters

which was first discussed in Section 11.4 and illustrated in Figure 11.13. It is clear from the figure in Chapter 11 that copper metal has been oxidized to form copper ions (which are responsible for the blue color), and silver ions have been reduced to silver metal, which appears in the form of the tree-like structures seen coating the wire. The reaction may be written as the sum of two half-reactions:

which makes it clear that copper metal has been oxidized (it has lost electrons) and silver ions have been reduced (they have gained electrons). Let's now run the same reaction in a galvanic cell, like the one shown in the photograph in Figure 17.1 and also illustrated schematically in Figure 17.2.

The beaker on the left contains a strip of copper metal immersed in an aqueous solution of  $\text{Cu}(\text{NO}_3)_2$ , while the beaker on the right contains a strip of silver metal immersed in an aqueous solution of  $\text{AgNO}_3$ . A wire connects the two metal electrodes, allowing electrons to flow between them, and the ionic conductor connecting the cells in this case is called a **salt bridge** (an ionic solution such as  $\text{NaNO}_3$  stabilized in a gel or prevented from leaving the bridge by porous plugs on each end). Copper has still been oxidized (as evidenced by the blue color of the  $\text{Cu}^{2+}(aq)$  ions in Fig. 17.1), and silver ions have still been reduced (as could be determined by weighing the silver electrode). The difference, however, is that the energy of the electrons being transferred through the wire in the galvanic cell is available to do work (run an electric motor, for example). The **ammeter** shown in the figure measures the magnitude and the direction of the electrical current that flows between the electrodes (in this case the electrons flow from the copper to the silver electrode).

Electrochemists have defined a standard terminology and notation that applies to both galvanic and electrolytic cells. The **anode** is always the electrode at which oxidation occurs, and the **cathode** is always the electrode at which reduction occurs; these names were coined by Michael Faraday, along with many other terms used in electrochemistry. The components of electrochemical cells are represented by a shorthand notation, which, for the cell just described, is written as

**FIGURE 17.2** A schematic of the galvanic cell shown in Figure 17.1. Electrons flow from the copper electrode to the silver electrode through an external circuit and the current is measured with an ammeter. Anions migrate toward the copper electrode and cations move toward the silver electrode in the respective solutions with sodium and nitrate ions moving through the salt bridge to maintain electrical neutrality.

in which the single vertical lines represent phase boundaries (between the metal electrodes and the electrolyte solution in this example) and the double lines represent the salt bridge. The oxidation (anode) half-reaction is always written on the left, by convention, irrespective of whether the cell is a galvanic cell or an electrolytic cell. Species in aqueous solution are written immediately adjacent to the double line. Commas are used to indicate the presence of different components in the same phase, an aqueous solution of hydrochloric acid being represented as  $|\text{H}^+, \text{Cl}^-|$ , for example. Finally, unless otherwise indicated, you may assume that all reactions are carried out in aqueous solution and that the shorthand notation used for the ions  $\text{H}^+$ ,  $\text{Ag}^+$ , and  $\text{Cl}^-$  implies that we mean  $\text{H}^+(aq)$ ,  $\text{Ag}^+(aq)$ , and  $\text{Cl}^-(aq)$ , respectively.

### 17.1.2 Electrolytic Cells

The galvanic cell reaction described above is spontaneous because the Gibbs free energy change for the reaction as written is negative. This thermodynamic driving force can be related to an electrostatic driving force as follows. We showed in Section 3.3 that systems composed of charged particles spontaneously seek states of the lowest electrostatic potential energy just like mechanical systems spontaneously seek states of the lowest mechanical potential energy. Electrons being transferred in a galvanic cell reaction spontaneously move from a region of higher electrostatic potential energy on the anode to a region of lower electrostatic potential energy on the cathode, in the same way that water flows downhill. Electrons will flow from the anode to the cathode until the potential energies of the electrons in both half-cells are equal to one another, at which point the system has reached equilibrium; there is no longer any electrostatic driving force for the reaction.

Galvanic cell reactions occur spontaneously as written; consequently, their reverse reactions are not spontaneous. The reverse reactions can be made to occur by applying an external driving force that increases the electrostatic potential energies of electrons on the cathode side of the reaction until they are higher than those on the anode side. The external driving force is provided by a power supply in electrolytic cells. Electrons flow in the opposite direction, the species being oxidized when the cell was operating as a galvanic cell is now being reduced, and the electrode originally serving as the anode becomes the cathode and vice versa.

#### EXAMPLE 17.1

The final step in the production of magnesium from seawater is the electrolysis of *molten* magnesium chloride, with the overall reaction

Write equations for the half-reactions occurring at the anode and at the cathode, and identify the direction in which electrons flow through the external circuit.

#### Solution

Oxidation, the loss of electrons, occurs at the anode, by the half-reaction

Reduction, the gain of electrons, occurs at the cathode, by the half-reaction

Electrons released at the anode, where chlorine is liberated, travel through the external circuit to the cathode, where molten magnesium is produced.

#### Related Problems: 1, 2

It is customary in electrochemistry to measure the difference between the **electrostatic potential** of the electrons at the cathode and the anode rather than the differences in their electrostatic potential energy. The electrostatic potential of a positively charged particle or a negatively charged particle at a particular point in space (or in your electrochemical cell) is typically given the symbol  $\Phi$ , but in electrochemistry it is often given the symbol  $E$ . This is confusing because  $E$  is also often used for energy, so we will describe electrostatic potential using the symbol  $\Phi$ , then introduce the change in notation afterward when you have a good understanding of the difference between electrostatic potential and electrostatic potential energy.

The SI unit for potential is the volt:  $1 \text{ V} = 1 \text{ J C}^{-1}$ . The change in the potential energy of a particle of a unit positive test charge ( $+1 \text{ C}$ ) that results from a change in potential of  $+1 \text{ V}$  is given by

$$\Delta E_p = q\Delta\Phi = (1 \text{ C})(1 \text{ V}) = 1 \text{ J}$$

where  $q$  is the charge on the particle. Of course, if the moving particle is an electron,  $q$  is negative, so the change in potential energy is negative when the electron moves through the same potential difference  $\Delta\Phi$  of  $+1 \text{ V}$ . Using the formula above, in MKS units, the change in potential energy of an electron of charge  $-1.6 \times 10^{-19} \text{ C}$  when it moves through a potential difference of  $+1 \text{ V}$  is

$$\Delta E_p = q\Delta\Phi = -e(\Delta\Phi) = (-1.6 \times 10^{-19} \text{ C})(+1 \text{ V}) = -1.6 \times 10^{-19} \text{ J}$$

The energy unit eV is particularly convenient, since the above result is  $-1 \text{ eV}$ . You can conclude that if you stretch a wire between the positive and negative terminals of a  $9 \text{ V}$  battery, an electron would flow from the negative terminal to the positive terminal, thus increasing its electrostatic potential, corresponding to changing its potential energy by  $-9 \text{ eV}$ . For an electron, uphill in electrostatic potential is downhill in potential energy. It is customary in electrochemical applications to replace the symbol for a change in electrostatic potential  $\Delta\Phi$  by  $\Delta E$ , but this  $E$  is not energy, it is electrostatic potential. You can readily tell which  $E$  is which since energy would typically have units of joules, J, or electron volts, eV, and electrostatic potential is given in units of volts, V, where  $1 \text{ V} = 1 \text{ J C}^{-1}$ . Thus if you use eV as your unit of energy, in this case electrostatic potential energy, and V for your unit of electrostatic potential, an electron moving through an electrostatic potential difference  $\Delta E$  of  $+1 \text{ V}$  has undergone a change in potential energy  $\Delta E_p$  of  $-1 \text{ eV}$ .

The electrostatic driving force in electrochemistry is expressed in terms of the potential, rather than the potential energy. Electrons spontaneously move from regions of higher potential energy to regions of lower potential energy, as discussed earlier, or from more negative to more positive potentials. Spontaneous processes are those for which  $\Delta E_p < 0$  or  $\Delta E > 0$  (the latter is the change in electrostatic potential in volts). These are equivalent statements, but you should be alert to the fact that the signs are opposites of one another and that spontaneous processes are characterized by *increases* in the potential, in contrast to what you have been used to seeing for spontaneous processes expressed in terms of changes in thermodynamic variables. We connect the two driving forces in the next section. A **voltmeter** measures the potential differences between two half-cells, the result being the **cell potential** (or voltage) as discussed later. Reversing the direction of a spontaneous process requires the application of an external potential that is greater in magnitude and opposite in sign to the potential of the spontaneous reaction. External potentials can be applied by inserting a power supply or a battery in the circuit of an electrolytic cell as shown in Figure 17.3.

**FIGURE 17.3** The spontaneous reaction in the galvanic cell shown in Figure 17.2 can be reversed by the application of an external potential from a power supply connected into the circuit as shown schematically. The power supply is in the off position in the figure; the meter would read either voltage or current during operation.

### 17.1.3 Faraday's Laws

Alessandro Volta discovered the galvanic cell in 1800 and constructed a “battery of cells” consisting of a number of platelets of silver and zinc that were separated from one another by porous strips of paper saturated with a salt solution. This voltaic pile, as it was then known, demonstrated that electricity could be produced by chemical reactions. By 1807, Sir Humphry Davy had prepared elemental sodium and potassium using a battery to electrolyze their respective hydroxides, demonstrating that electricity could drive chemical reactions. Michael Faraday was the first to demonstrate quantitative relationships between the amount of charge that flowed and the quantities of materials produced or consumed in electrochemical reactions, from which he asserted the fundamental duality of these processes: “the electricity which decomposes, and that which is evolved by the decomposition of, a certain quantity of matter, are alike.” Faraday arranged a series of electrochemical cells through which the same amount of charge was passed and measured the quantities of the materials produced or consumed. The relationships he discovered are known as **Faraday's laws**, which we state as follows:

1. The mass of a given substance that is produced or consumed in an electrochemical reaction is proportional to the quantity of electric charge passed.
2. Equivalent masses<sup>1</sup> of different substances are produced or consumed in electrochemical reactions by a given quantity of electric charge passed.

These laws, which summarize the stoichiometry of electrochemical processes, were discovered by Michael Faraday in 1833, more than half a century before the electron was discovered and the nature of electricity was understood on the atomic scale. Faraday also measured, for the first time, the charge to mass ratio of the hydrogen ion, long before its chemical nature had been definitively established, by measuring the amount of charge required to generate 1 g of hydrogen gas. The value he obtained (about 1000 times smaller than  $e/m_e$ ) provided a benchmark against which J. J. Thomson would later compare the charge

<sup>1</sup>The electron had not yet been discovered at the time of Faraday's experiments and so he was only able to assert that there were “equivalent masses” produced or consumed when a certain amount of charge was passed. The modern definition of the equivalent mass of an element or a compound in a redox reaction is its molar mass divided by the number of moles of electrons transferred per mole of substance in the corresponding half-reaction.

to mass ratio of the electron and conclude that “the charge on the electron must be very large or the mass of the electron must be very small, compared to the hydrogen ion.”

Let's express Faraday's laws in modern terms and relate the changes in masses observed to the charge that flows in electrochemical experiments. The magnitude of the charge on a single electron (expressed in coulombs) has been very accurately determined to be

$$|-e| = e = 1.602176565 \times 10^{-19} \text{ C}$$

so the magnitude of the charge of one mole of electrons is equal to

$$\begin{aligned} Q &= (6.02214129 \times 10^{23})(1.602176565 \times 10^{-19} \text{ C}) \\ &= 96,485.34 \text{ C} \end{aligned}$$

which is an enormously large quantity of charge. Here we have introduced the symbol  $Q = Ne$  for the magnitude of charge that flowed in the electrochemical cell. It is equal to the absolute value of the charge on an electron multiplied by the total number of electrons that were transferred during the electrochemical reaction. The magnitude of the charge per mole of electrons has been given a special name and symbol, the **Faraday constant**,

$$F = 96,485.34 \text{ C mol}^{-1}$$

in recognition of the central importance of the mole concept in chemistry.

We typically measure the total magnitude of charge passed in electrochemical experiments by measuring the current and the time. The **electric current** is the amount of charge that flows through a circuit per second, measured in the SI base unit, the ampere (A). The coulomb (C), a derived unit, is defined as the total magnitude of charge transferred by 1 A of current flowing for one second.

$$1 \text{ C} = (1 \text{ A})(1 \text{ s}) \quad [17.1]$$

We can use Equation 17.1 to calculate the total magnitude, or amount, of charge that has passed when a current of  $I$  amperes has flowed for  $t$  seconds as

$$Q = It$$

or express the number of moles of electrons  $n$  transferred as

$$n = \frac{It}{96,485 \text{ C mol}^{-1}}$$

We can calculate the number of moles (and therefore the number of grams) of reactants consumed and products formed in electrochemical reactions if we know how many electrons are transferred in a particular reaction and how many moles of electrons have passed through the cell. Suppose, for example, that we have a zinc–silver galvanic cell in which the anode half-reaction is

and the cathode half-reaction is

Each mole of electrons produced arises from the oxidation of 1/2 mol of zinc metal (because each Zn atom gives up two electrons) and causes the reduction of 1 mol of silver ions. From the molar masses of silver and zinc, we calculate that  $(65.38)/2 = 32.69$  g of zinc is dissolved at the anode, and 107.87 g of silver is deposited at the cathode. The same relationships hold if the cell is operated as an electrolytic cell, but in that case silver is dissolved and zinc is deposited.

**EXAMPLE 17.2**

An electrolytic cell is constructed in which the silver ions in silver chloride are reduced to silver at the cathode and copper is oxidized to  $\text{Cu}^{2+}(\text{aq})$  at the anode. A current of 0.500 A is passed through the cell for 101 minutes. Calculate the mass of copper dissolved and the mass of silver deposited.

**Solution**

$$t = (101 \text{ min})(60 \text{ s min}^{-1}) = 6.06 \times 10^3 \text{ s}$$

The number of moles of electrons passed through the circuit during this time is given by

$$n = \frac{(0.500 \text{ C s}^{-1})(6.06 \times 10^3 \text{ s})}{96,485 \text{ C mol}^{-1}} = 3.14 \times 10^{-2} \text{ mol } e^{-}$$

The half-cell reactions are

so the masses of silver deposited and copper dissolved are

$$\text{mass Ag} = (3.14 \times 10^{-2} \text{ mol } e^{-}) \times \left( \frac{1 \text{ mol Ag}}{1 \text{ mol } e^{-}} \right) \times (107.87 \text{ g mol}^{-1})$$

$$\text{mass Ag} = 3.39 \text{ g Ag deposited}$$

$$\text{mass Cu} = (3.14 \times 10^{-2} \text{ mol } e^{-}) \times \left( \frac{1 \text{ mol Cu}}{2 \text{ mol } e^{-}} \right) \times (63.55 \text{ g mol}^{-1})$$

$$\text{mass Cu} = 0.998 \text{ g Cu dissolved}$$

**Related Problems: 3, 4, 5, 6**

## 17.2 Cell Potentials and the Gibbs Free Energy

We discussed pressure–volume work in Chapters 12 and 13 and, in particular, demonstrated that the maximum work done by the system occurs for reversible processes. We now consider a different kind of work, **electrical work**, which is fundamental in electrochemistry, and we investigate its properties. We showed earlier that the change in the potential energy  $\Delta E_p$  associated with the transfer of one electron through a potential difference  $\Delta\Phi$  equals  $-e\Delta\Phi$ . If  $N$  electrons are transferred, then  $\Delta E_p = -Ne\Delta\Phi$ . Using  $Ne = Q$  gives

$$\Delta E_p = -Q\Delta\Phi = -nF\Delta\Phi$$

where  $n$  is the number of moles of electrons transferred, and, because the electrons are negatively charged, the charge  $Q$  on  $n$  moles of electrons equals  $-nF$  (where  $F$  is Faraday's constant).

Throughout this text we will refer to the difference in the potential  $\Delta\Phi$  as the cell potential difference  $\Delta E_{\text{cell}}$  so the change in the potential energy is written as

$$\Delta E_p = -Q\Delta E_{\text{cell}} = -nF\Delta E_{\text{cell}}$$

where  $\Delta E_{\text{cell}}$  is measured in volts and  $\Delta E_p$  is measured in joules. The change in the potential energy of the electrons is defined as the **electrical work**,  $w_{\text{elec}}$ , done

on the electrons. (In a galvanic cell running spontaneously,  $w_{\text{elec}}$  is a negative number since the cell is doing net work on the surroundings.)

$$w_{\text{elec}} = \Delta E_p = -Q\Delta E_{\text{cell}} = -nF\Delta E_{\text{cell}} \quad [17.2]$$

where  $\Delta E_{\text{cell}} = E_{\text{cathode}} - E_{\text{anode}}$  (because the final location of the electrons is at the cathode, where they execute the reduction reaction, and their initial location is at the anode, where they are produced in the oxidation reaction). One would typically measure the voltage difference  $\Delta E_{\text{cell}}$  before connecting the wire between the two half cells. (Some texts simply use  $E_{\text{cell}}$ , but since this is a potential difference we retain the symbol  $\Delta$ .)

Work is done *on* the system when electrons move from regions of more positive potentials to regions of more negative potentials (increasing their potential energy) and work is done *by* the system when electrons move from regions of more negative potentials to regions of more positive potentials (decreasing their potential energy). The cell potential  $\Delta E_{\text{cell}}$  is positive for galvanic cells, which can produce electrical work, and negative for electrolytic cells in which electrical work is done *on* the system by an external power supply.

### EXAMPLE 17.3

A 6.00 V battery delivers a steady current of 1.25 A for a period of 1.50 hours. Calculate the total magnitude of charge  $Q$ , in coulombs, that passes through the circuit and the electrical work done *by* the battery.

#### Solution

Recalling that  $1 \text{ A} = 1 \text{ C s}^{-1}$  and  $1 \text{ V} = 1 \text{ J C}^{-1}$  we calculate the total magnitude of charge

$$\begin{aligned} Q &= It = (1.25 \text{ C s}^{-1})(1.50 \text{ hr})(3600 \text{ s hr}^{-1}) \\ &= 6750 \text{ C} \end{aligned}$$

and the electrical work done *on* the battery (noting that electrons have a negative charge, and flow spontaneously uphill in cell potential) is

$$\begin{aligned} w_{\text{elec}} &= -Q\Delta E_{\text{cell}} = -(6750 \text{ C})(6.00 \text{ J C}^{-1}) \\ &= -4.05 \times 10^4 \text{ J} \end{aligned}$$

This is the work done *on* the battery, so the work done *by* the battery is the negative of this quantity, or +40.5 kJ.

The change in the Gibbs free energy not only predicts the direction of spontaneous change but is also equal to the reversible work done (other than pressure–volume work) on the system at constant temperature and pressure, which we identify as the electrical work  $w_{\text{elec}}$  as follows:

$$w_{\text{elec,rev}} = \Delta G \quad (\text{at constant } P \text{ and } T) \quad [17.3]$$

This equation shows that if the electrochemical reaction has a negative  $\Delta G$ , then  $w_{\text{elec}}$  is negative and the electrochemical cell can do net work on the surroundings.

We derive this result beginning with the definition of the Gibbs free energy function  $G$ :

$$G = H - TS = U + PV - TS$$

For processes occurring at constant pressure  $P$  and constant temperature  $T$  (the usual case in electrochemical cells),

$$\Delta G = \Delta U + P\Delta V - T\Delta S$$

The first law of thermodynamics is

$$\Delta U = q + w$$

which may be rewritten as

$$\Delta U = q + w_{\text{elec}} - P\Delta V$$

to explicitly identify electrical work  $w_{\text{elec}}$  and pressure–volume work, which is  $-P_{\text{ext}}\Delta V = -P\Delta V$  at constant internal pressure. Substituting for  $\Delta U$  into the equation for the change in the Gibbs free energy gives

$$\Delta G = q + w_{\text{elec}} - P\Delta V + P\Delta V - T\Delta S = q + w_{\text{elec}} - T\Delta S$$

For electrochemical reactions that are run reversibly (which is rather easy to achieve in practice by controlling the current)

$$q = q_{\text{rev}} = T\Delta S$$

allowing us to show that reversible electrical work is equal to the change in the Gibbs free energy

$$w_{\text{elec,rev}} = \Delta G$$

The change in the Gibbs free energy of the system is negative for a galvanic cell, so  $w_{\text{elec}}$  is negative and there is net electrical work done *by* the system. Energy, in the form of useful electrical work, is extracted *from* the system and made available to do work *on* the surroundings. The opposite is true for electrolytic cells. Work is done *on* the system, increasing its Gibbs free energy, most commonly as an increase in the potential energy of the electrons. The maximum work done on the surroundings ( $-w_{\text{elec}}$ ) by a galvanic cell is done when the cell is made to operate reversibly, because it is working against the maximum possible opposing force at all times, just like for reversible  $PV$  work. Cells operating irreversibly (in other words, with large currents permitted to flow) produce less electrical work than those operating reversibly.

The electrical work  $w_{\text{elec}}$  is also equal to the product of the charge transferred and the difference in the electrostatic potential, which can be calculated as follows

$$w_{\text{elec,rev}} = \Delta G = -nF\Delta E_{\text{cell}}$$

for  $n$  moles of electrons moving through a potential difference  $\Delta E_{\text{cell}}$ . Galvanic cells, for which  $\Delta E_{\text{cell}} > 0$ , can produce electrical work, whereas electrolytic cells, for which  $\Delta E_{\text{cell}} < 0$ , consume electrical work.

### 17.2.1 Standard States and Standard Cell Potentials

Recall from Chapters 12 and 14 that the *standard states* of chemical substances are defined at 1 atm pressure and at a specified temperature. Electrochemists use *activities* (see Section 14.3) to define standard states, the standard states of gases and solutes being defined at unit activity. Recall that the standard state for solutes is defined to be a *hypothetical* state in which the solute concentration is 1 M, but the solute behaves as if it were ideal. The potential of the standard hydrogen electrode (SHE), the primary reference electrode used in electrochemistry (see Section 17.2.2), is defined under conditions of unit activity for the hydrogen ions in solution as well as unit activity for the hydrogen gas in equilibrium with the electrolyte. We specify concentrations in molarity in this chapter, but alert you that 1 M is not unit activity when reading more advanced treatments of the subject. The standard free energy change  $\Delta G^\circ$  for a reaction in which all reactants and products are in their standard states can be calculated

from a table of standard free energies of formation  $\Delta G_f^\circ$  of the reactants and the products (see Appendix D). We have shown that the cell potential is related to the change in the Gibbs free energy for reversible processes, allowing us to define a **standard cell potential**  $\Delta E_{\text{cell}}^\circ$  as

$$\Delta G^\circ = -nF\Delta E_{\text{cell}}^\circ \quad (\text{reversible}) \quad [17.4]$$

in which all reactants and products are in their standard states (gases at 1 atm pressure, solutes at 1 M concentration, pure metals in their most stable states and at a specified temperature). It is important to note that the condition of reversibility implies that no current is flowing. Standard cell potentials are measured using voltmeters having extremely high internal resistance to ensure that this is the case; these potentials are also referred to as *open-circuit* potentials. Standard cell potentials are intrinsic electrical properties of electrochemical cells that can be calculated from the associated standard free energy changes  $\Delta G^\circ$  using Equation 17.4. Conversely, and perhaps more importantly,  $\Delta G^\circ$  (and hence equilibrium constants) for a variety of chemical reactions can be determined simply by measuring the standard cell potentials ( $\Delta E_{\text{cell}}^\circ$ ) for reactions that can be carried out by electrochemical means. Many tabulated equilibrium constants have, in fact, been measured using electrochemical methods because they are more convenient and, often, more accurate than other methods. For example, the concentrations of ions in solutions of sparingly soluble salts (see Section 16.1) are quite low but can be readily determined by measuring cell potentials.

#### EXAMPLE 17.4

A  $\text{Zn}^{2+}|\text{Zn}$  half-cell is connected to a  $\text{Cu}^{2+}|\text{Cu}$  half-cell to make a galvanic cell, in which  $[\text{Zn}^{2+}] = [\text{Cu}^{2+}] = 1.00 \text{ M}$ . The cell potential at  $25^\circ\text{C}$  is measured to be  $\Delta E_{\text{cell}}^\circ = 1.10 \text{ V}$ , which corresponds to the overall cell reaction

Calculate  $\Delta G^\circ$  for this reaction under the given conditions.

#### Solution

$$\begin{aligned} \Delta G^\circ &= -nF\Delta E_{\text{cell}}^\circ \\ &= -(2.00 \text{ mol})(96,485 \text{ C mol}^{-1})(1.10 \text{ V}) \\ &= -2.12 \times 10^5 \text{ J} = -212 \text{ kJ} \end{aligned}$$

**Related Problems: 11, 12**

### 17.2.2 Standard Reduction Potentials

We could tabulate cell potentials for every conceivable electrochemical reaction, but the list would be very long. We can instead construct electrochemical cells in which one half-reaction has been chosen to be our reference half-reaction and then measure the cell potentials that result when this reference half-reaction is coupled to all other half-reactions of interest. This procedure is analogous to the one we used to find the changes in internal energy, enthalpy, entropy, and Gibbs free energy for chemical reactions using the standard energies and enthalpies of formation, absolute entropies, and standard Gibbs free energies of formation.

The primary reference electrode has been chosen, by convention, to be the **standard hydrogen electrode** (SHE), often called the **normal hydrogen electrode** (NHE) by electrochemists. The standard hydrogen electrode, as illustrated in Figure 17.4, consists of a platinum electrode immersed in a solution in

Standard hydrogen electrode

**FIGURE 17.4** Schematic of a standard hydrogen electrode.

which  $[\text{H}_3\text{O}^+] = 1 \text{ M}$  (or, more precisely, at a concentration of  $\text{H}_3\text{O}^+$  where  $a_{\text{H}_3\text{O}^+} = 1$ ), under a hydrogen partial pressure  $P_{\text{H}_2} = 1 \text{ atm}$  ( $a_{\text{H}_2} = 1$ ).<sup>2</sup>

Cell potentials for a number of half-reactions have been measured with reference to the SHE, which has been defined to be 0.00 V, and the results tabulated as standard *reduction* potentials by convention (see Appendix E). Half-reactions with positive potentials, with respect to SHE, proceed as reductions whereas half-reactions with negative potentials, with respect to SHE, proceed as oxidations. Standard cell potentials for any electrochemical cell can be calculated from standard reduction potentials using

$$\Delta E_{\text{cell}}^{\circ} = E_{\text{cathode}}^{\circ} - E_{\text{anode}}^{\circ} \quad [17.5]$$

where  $E_{\text{cathode}}^{\circ}$  is the standard reduction potential for the reaction occurring at the cathode (reduction) and  $E_{\text{anode}}^{\circ}$  is the standard reduction potential for the reaction occurring, in reverse, at the anode (oxidation). The procedure for finding standard cell potentials for any cell is simple:

1. Identify the cathode half-reaction.
2. Identify the anode half-reaction.
3.  $\Delta E_{\text{cell}}^{\circ} = E_{\text{cathode}}^{\circ} - E_{\text{anode}}^{\circ}$

If all the reactants and products are in their standard states, reactions for which  $\Delta E_{\text{cell}}^{\circ} > 0$  are spontaneous as written and can be used to construct galvanic cells; those for which  $\Delta E_{\text{cell}}^{\circ} < 0$  are not spontaneous as written and can be driven only by applying an external potential in electrolytic cells. The procedure we just described for finding cell potentials *always works* and can help avoid confusion with sign conventions when working electrochemical problems.

Let's illustrate this procedure for calculating a standard cell potential using the  $\text{Zn}|\text{Zn}^{2+}||\text{Cu}^{2+}|\text{Cu}$  cell described in Example 17.4. The overall reaction is

in which  $\text{Cu}^{2+}(aq)$  is reduced at the cathode and  $\text{Zn}(s)$  is oxidized at the anode. The standard reduction potentials of the two half-reactions obtained from Appendix E are:

and so the standard cell potential for the  $\text{Zn}|\text{Zn}^{2+}||\text{Cu}^{2+}|\text{Cu}$  cell is

$$\Delta E_{\text{cell}}^{\circ} = E_{\text{cathode}}^{\circ} - E_{\text{anode}}^{\circ} = 0.34 \text{ V} - (-0.76 \text{ V}) = 1.10 \text{ V}$$

in agreement with the value measured in Example 17.4. Note that it is conventional in electrochemistry to write positive potentials without explicitly including the sign.

The standard reduction potentials tabulated in Appendix E are arranged in order, with the most positive potentials at the top and the most negative potentials at the bottom. We can determine immediately by inspection whether a given reaction will be spontaneous or not; galvanic cells are those for which the

<sup>2</sup>Note that some sources measure the standard reduction potentials with respect to a different reference electrode than the SHE; a popular choice was the saturated calomel electrode (SCE), described later in this chapter and depicted as the reference electrode in Figure 17.5. Noting that the reduction potential for the SCE is 0.242 V with respect to the standard SHE reference cell, one need only add 0.242 V to any reduction potential measured with respect to the SCE to convert it to one measured with respect to the SHE.

reduction potential of the cathode half-reaction is more positive (higher on the list) than the reduction potential of the anode half-reaction (lower on the list), as long as both half-cells are in their standard states. (See Section 17.4 for cells not in their standard states.)

The procedure we have just outlined can be used to find cell potentials from standard reduction potentials for any reaction of interest, even those for which it is necessary to multiply one half-reaction by an integer to balance the charge transferred in the overall cell reaction. Let's calculate the cell potential for the  $\text{Cu}|\text{Cu}^{2+}||\text{Ag}^+|\text{Ag}$  cell we introduced at the beginning of the chapter. The reaction is

which we can represent as the sum of the following two half-reactions:

We identify the reduction of  $\text{Ag}^+$  as the cathode half-reaction and calculate the standard cell potential as before:

$$\Delta E_{\text{cell}}^{\circ} = E_{\text{cathode}}^{\circ} - E_{\text{anode}}^{\circ} = 0.799 \text{ V} - 0.34 \text{ V} = 0.459 \text{ V}$$

Note that we did *not* multiply the standard reduction potential for the half-reaction  $\text{Ag}^+(aq) + e^- \longrightarrow \text{Ag}(s)$  by 2 when calculating the standard cell potential because potentials are intensive quantities that do not depend upon the quantity of material involved. The cell potential is simply the difference in the potentials of the two half-reactions. The change in potential energy, on the other hand, or that of any other extensive thermodynamic property of interest, does depend on the quantity of material involved. The change in the Gibbs free energy of the system discussed previously, for example, is

$$\Delta G^{\circ} = -nF\Delta E_{\text{cell}}^{\circ} = (-2 \text{ mol})(96,485 \text{ C mol}^{-1})(0.459 \text{ V}) = -88.6 \text{ kJ}$$

The negative  $\Delta G^{\circ}$  indicates the reaction would proceed spontaneously (given that the solutes are at standard state concentrations). The work done *on* the system,  $w_{\text{elec}}$  is negative, so the electrical work done *by* the cell is 88.6 kJ (if the cell were run with an opposing force so it could run close to reversibly).

Suppose we want to find the standard reduction potential for a half-reaction that is not listed in Appendix E. We could write the half-reaction of interest as the sum or difference of a pair of half-reactions tabulated in Appendix E. The number of electrons transferred in the reaction of interest, however, may be different than the numbers of electrons transferred in the standard reactions, and so we must first calculate the Gibbs free energy change for the reaction and then calculate the standard cell potential using Equation 17.4, as illustrated by the following example.

Suppose we want to find the standard reduction potential for the half-reaction

using the following standard reduction potentials from Appendix E.

We calculate the change in the Gibbs free energy for the half-reaction as

$$\begin{aligned}\Delta G_3^\circ &= \Delta G_1^\circ - \Delta G_2^\circ \\ -n_3FE_3^\circ &= -n_1FE_1^\circ - (-n_2FE_2^\circ) = -n_1FE_1^\circ + n_2FE_2^\circ \\ E_3^\circ &= \frac{n_1E_1^\circ - n_2E_2^\circ}{n_3}\end{aligned}$$

The standard reduction potential for the half-reaction

therefore, is

$$E_3^\circ(\text{Cu}^{2+}|\text{Cu}^+) = \frac{(2 \text{ mol})(0.340 \text{ V}) - (1 \text{ mol})(0.522 \text{ V})}{1 \text{ mol}} = 0.158 \text{ V}$$

We can also use the procedure just described to calculate cell potentials for balanced chemical reactions of interest from standard reduction potentials, but the number of electrons in the numerator and the denominator will always be equal to one another and will cancel out; it is easier, therefore, to use the expression defined above:

$$\Delta E_{\text{cell}}^\circ = E_{\text{cathode}}^\circ - E_{\text{anode}}^\circ$$

### EXAMPLE 17.5

An aqueous solution of potassium permanganate ( $\text{KMnO}_4$ ) appears deep purple. The permanganate ion can be reduced to the pale-pink manganese(II) ion ( $\text{Mn}^{2+}$ ) in aqueous acidic solutions. The standard reduction potential of an  $\text{MnO}_4^-|\text{Mn}^{2+}$  half-cell is  $E_{\text{cell}}^\circ = 1.49 \text{ V}$ . Suppose this half-cell is combined with a  $\text{Zn}^{2+}|\text{Zn}$  half-cell in a galvanic cell, with  $[\text{Zn}^{2+}] = [\text{MnO}_4^-] = [\text{Mn}^{2+}] = [\text{H}_3\text{O}^+] = 1 \text{ M}$ .

- Write equations for the reactions at the anode and the cathode.
- Write a balanced equation for the overall cell reaction.
- Calculate the standard cell potential difference,  $\Delta E_{\text{cell}}^\circ$ .

#### Solution

- Permanganate ions will be reduced at the cathode because  $E^\circ(\text{MnO}_4^-|\text{Mn}^{2+}) = 1.49 \text{ V}$  is more positive than  $E^\circ(\text{Zn}^{2+}|\text{Zn}) = -0.76 \text{ V}$ . The balanced half-cell reaction requires the presence of  $\text{H}_3\text{O}^+$  ions and water, giving

The anode half-reaction for the oxidation of Zn is

- The number of electrons delivered to the cathode must equal the number of electrons released by the anode, so the first equation must be multiplied by 2 and the second equation by 5 before adding them together to give the overall reaction:

- The galvanic cell potential is the difference between the standard reduction potential for permanganate (at the cathode) and that for zinc (at the anode):

$$\begin{aligned}\Delta E^\circ &= E^\circ(\text{MnO}_4^-|\text{Mn}^{2+}) - E^\circ(\text{Zn}^{2+}|\text{Zn}) \\ &= 1.49 - (-0.76) = 2.25 \text{ V}\end{aligned}$$

Note that the half-cell potentials are not multiplied by their coefficients (2 and 5) before subtraction. Half-cell potentials are *intensive* properties of a galvanic cell and are therefore independent of the amount of the reacting species.

**Related Problems: 13, 14**

## 17.2.3 Oxidizing and Reducing Agents

Strong **oxidizing agents** are chemical species that are themselves easily reduced. These species are characterized by large positive reduction potentials and appear at the top of the list in Appendix E. Fluorine has the most positive reduction potential listed, and fluorine molecules are extremely eager to accept

electrons to become fluoride ions, as expected from fluorine's large electron affinity and the effective solvation of  $F^-(aq)$ . Other strong oxidizing agents include hydrogen peroxide ( $H_2O_2$ ) and aqueous solutions of permanganate ions ( $MnO_4^-$ ). Strong **reducing agents**, on the other hand, are easily oxidized with very negative reduction potentials, and they are listed near the bottom of the table in Appendix E. The alkali and alkaline earth metals are especially good reducing agents, as expected from their low ionization potentials.

Oxygen itself is a good oxidizing agent in acidic solution at pH 0 because it has a reasonably positive standard reduction potential:

Ozone ( $O_3$ ) is an even stronger oxidizing agent than molecular oxygen, as shown by its more positive half-cell reduction potential in acidic aqueous solution:

The strong oxidizing power of ozone is exploited commercially as a bleach for wood pulp, and as a disinfectant and sterilizing agent for water, where it oxidizes algae and organic impurities but leaves no undesirable residue. The corresponding half-reactions in basic solutions, 1 M  $OH^-$ , are given below. They may be calculated using  $K_w$  and the methods in Section 17.3. Both oxygen and ozone are less effective oxidizing agents in basic solutions than in acidic solutions, as can be seen from their standard reduction potentials at pH 14 (standard basic conditions), which are significantly less positive than those under acidic conditions.

Note that the  $O_2$  and  $O_3$  in these half reactions are gaseous species at a pressure of 1 atm in the standard state.

### 17.2.4 Reduction Potential Diagrams and Disproportionation

We can summarize the half-reactions of copper in a **reduction potential diagram** of the form

in which the species are arranged in sequence with the most oxidized form on the left and the most reduced form on the right. The standard reduction potential for each of the three half-reactions is written above the line that connects the half-reactions. Diagrams like these are very useful in helping us predict which ions are unstable with respect to *disproportionation*, a process in which a pair of ions in the same oxidation state are oxidized and reduced (see Example 11.10). A species will undergo a disproportionation reaction if the reduction potential for the half-reaction connecting the species in the center to the one on the right is more positive than the reduction potential for the half-reaction connecting the species in the center to the one on the left. The disproportionation reaction for  $Cu^+$  is

This reaction is spontaneous at standard conditions (and even at rather small concentrations of  $\text{Cu}^+$ ) with negative  $\Delta G^\circ$  and positive  $\Delta E^\circ$ . It is responsible for the negligible concentrations of  $\text{Cu}^+$  found in aqueous solution. Interestingly enough, most transition metals, in fact, do not form stable  $\text{M}^+$  ions in aqueous solution for this reason. The energy required to further ionize  $\text{M}^+$  (essentially the second ionization energy,  $IE_2$ ) is paid for by the large (in magnitude, as  $\Delta H_{\text{hyd}}$  is negative in sign) energy of hydration of  $\text{M}^{2+}$ , making the disproportionation reaction thermodynamically favorable overall.

### EXAMPLE 17.6

Hydrogen peroxide,  $\text{H}_2\text{O}_2$ , is a possible product of the reduction of oxygen in acidic solution:

It can then be further reduced to water:

(a) Use the half-cell potential just given for the reduction of  $\text{H}_2\text{O}_2$ , together with that given earlier,

to calculate the standard half-cell potential for the reduction of  $\text{O}_2$  to  $\text{H}_2\text{O}_2$  in acidic solution.

(b) Write a reduction potential diagram for  $\text{O}_2$ ,  $\text{H}_2\text{O}_2$ , and  $\text{H}_2\text{O}$ .

(c) Is  $\text{H}_2\text{O}_2$  stable with respect to disproportionation in acidic,  $\text{pH} = 0$ , solution?

#### Solution

(a) The desired half-cell reaction is obtained by *subtracting* the reaction with potential  $E_2^\circ$  from that with potential  $E_1^\circ$ . The half-cell reduction potentials are not subtracted, however,

but rather combined as described earlier in this section. Taking  $n_1 = 4$ ,  $n_2 = 2$ , and  $n_3 = 2$  gives

$$E_3^\circ = \frac{n_1 E_1^\circ - n_2 E_2^\circ}{n_3} = \frac{(4 \text{ mol})(1.229 \text{ V}) - (2 \text{ mol})(1.77 \text{ V})}{2 \text{ mol}} = 0.69 \text{ V}$$

(b) The reduction potential diagram is obtained by omitting the electrons, water, and  $\text{H}_3\text{O}^+$  from the corresponding half-equations:

(c)  $\text{H}_2\text{O}_2$  is thermodynamically unstable to disproportionation in acidic solution because the half-cell potential to its right (1.77 V) is higher than that to its left (0.69 V). The disproportionation of  $\text{H}_2\text{O}_2$  is also spontaneous in neutral solution, but it is slow enough that aqueous solutions of hydrogen peroxide can be stored for a long time without deteriorating, as long as they are kept out of the light.

**Related Problems:** 23, 24, 25, 26

## 17.3 Concentration Effects and the Nernst Equation

Concentrations and pressures are rarely fixed at their standard state values in real-world applications. It is therefore necessary to understand how concentration and pressure affect cell potentials by applying the thermodynamic principles presented in Chapter 14 to electrochemical cells. In Chapter 14, we showed that the free energy change is related to the reaction quotient  $Q$  through

$$\Delta G = \Delta G^\circ + RT \ln Q$$

Combining this equation with

$$\Delta G = -nF\Delta E_{\text{cell}}$$

and

$$\Delta G^\circ = -nF\Delta E_{\text{cell}}^\circ$$

gives

$$-nF\Delta E_{\text{cell}} = -nF\Delta E_{\text{cell}}^{\circ} + RT \ln Q$$

from which we get

$$\Delta E_{\text{cell}} = \Delta E_{\text{cell}}^{\circ} - \frac{RT}{nF} \ln Q \quad [17.6]$$

which is known as the **Nernst equation**.

The Nernst equation can be rewritten in terms of common (base-10) logarithms by using the fact that

$$\ln Q \approx 2.303 \log_{10} Q$$

At 25°C (298.15 K), the combination of constants  $2.303 RT/F$  becomes

$$\begin{aligned} 2.303 \frac{RT}{F} &= (2.303) \frac{(8.315 \text{ J K}^{-1} \text{ mol}^{-1})(298.15 \text{ K})}{96,485 \text{ C mol}^{-1}} \\ &= 0.0592 \text{ J C}^{-1} = 0.0592 \text{ V} \end{aligned}$$

because 1 joule per coulomb is 1 volt. The Nernst equation then becomes

$$\Delta E_{\text{cell}} = \Delta E_{\text{cell}}^{\circ} - \frac{0.0592 \text{ V}}{n} \log_{10} Q \quad (\text{at } 25^{\circ}\text{C}) \quad [17.7]$$

which is its most familiar form, with  $n$  being the number of moles of electrons transferred in the overall chemical reaction as written. We remind you that these measurements are made under conditions in which no current flows and that  $n$  appears only to relate the thermodynamic and electrostatic work to one another. In a galvanic cell made from zinc, aluminum, and their ions, for example

$n = 6$  mol (per mol of stoichiometric reaction as written).

The Nernst equation is used to find the concentration dependence of half-cell potentials, as well.

$$E_{\text{hc}} = E_{\text{hc}}^{\circ} - \frac{0.0592 \text{ V}}{n_{\text{hc}}} \log_{10} Q_{\text{hc}}$$

for the potential of any half-cell reaction at 25°C, where  $n_{\text{hc}}$  is the number of moles of electrons appearing in the half-reaction and  $Q_{\text{hc}}$  is the reaction quotient for the half-cell reaction written as a reduction. Using the  $\text{Zn}^{2+}|\text{Zn}$  half-cell as an example, the half-reaction written as a reduction is

so  $n_{\text{hc}} = 2$  and  $Q_{\text{hc}} = 1/[\text{Zn}^{2+}]$ . The cell potential for an electrochemical cell constructed from two half-cells that are not in their standard states is still calculated as before,  $\Delta E_{\text{cell}} = E_{\text{cathode}} - E_{\text{anode}}$ , but with the standard reduction potentials corrected to reflect the non-standard conditions using the Nernst equation.

**EXAMPLE 17.7**

Suppose the  $\text{Zn}|\text{Zn}^{2+}||\text{MnO}_4^-|\text{Mn}^{2+}$  cell from Example 17.5 is operated at pH 2.00 with  $[\text{MnO}_4^-] = 0.12 \text{ M}$ ,  $[\text{Mn}^{2+}] = 0.0010 \text{ M}$ , and  $[\text{Zn}^{2+}] = 0.015 \text{ M}$ . Calculate the cell potential  $\Delta E_{\text{cell}}$  at  $25^\circ\text{C}$ .

**Solution**

Recall that the overall reaction is

From Example 17.5, for every 5 mol of Zn oxidized (or 2 mol of  $\text{MnO}_4^-$  reduced), 10 mol of electrons pass through the external circuit, so  $n = 10$ . A pH of 2.00 corresponds to a hydronium ion concentration of 0.010 M. To solve this problem, you may either use the Nernst equation, Equation 17.7, directly, with  $n = 10$ , or calculate the potentials for each half-reaction using the Nernst equation and then calculate the cell potential in the usual way. The Nernst equation for a half-reaction is

$$E_{\text{hc}} = E_{\text{hc}}^\circ - \frac{0.0592 \text{ V}}{n_{\text{hc}}} \log_{10} Q_{\text{hc}}$$

Substituting the standard reduction potentials and concentrations given conditions for each half-reaction gives

$$E(\text{MnO}_4^-|\text{Mn}^{2+}) = 1.49 \text{ V} - \frac{0.0592 \text{ V}}{5} \log_{10} \frac{(10^{-3})}{(0.12)(10^{-2})^8} = 1.33 \text{ V}$$

and

$$E(\text{Zn}|\text{Zn}^{2+}) = -0.76 \text{ V} - \frac{0.0592 \text{ V}}{2} \log_{10} \frac{1}{0.015} = -0.814 \text{ V}$$

giving

$$\Delta E_{\text{cell}} = E_{\text{cathode}} - E_{\text{anode}} = 1.33 - (-0.814) = 2.14 \text{ V}$$

**Related Problems:** 27, 28

### 17.3.1 Measuring Equilibrium Constants

Electrochemistry provides a convenient and accurate way to measure equilibrium constants for many solution-phase reactions; cell potentials are directly related to equilibrium constants as follows.

$$\Delta G^\circ = -nF\Delta E_{\text{cell}}^\circ$$

and

$$\Delta G^\circ = -RT \ln K$$

so

$$RT \ln K = nF\Delta E_{\text{cell}}^\circ$$

$$\ln K = \frac{nF}{RT} \Delta E_{\text{cell}}^\circ$$

and

$$\log_{10} K = \frac{n}{0.0592 \text{ V}} \Delta E_{\text{cell}}^\circ \quad (\text{at } 25^\circ\text{C}) \quad [17.8]$$

The same result can be obtained in a slightly different way, by returning to the Nernst equation, which reads (at 25°C),

$$\Delta E_{\text{cell}} = \Delta E_{\text{cell}}^{\circ} - \frac{0.0592 \text{ V}}{n} \log_{10} Q$$

Suppose all species are initially present under standard-state conditions;  $Q = 1$ , so the cell potential  $\Delta E_{\text{cell}}$  is the standard cell potential  $\Delta E_{\text{cell}}^{\circ}$ .  $Q$  increases (or decreases, if  $\Delta E_{\text{cell}}^{\circ} < 0$ ) and  $\Delta E_{\text{cell}}$  decreases (or increases) as the reaction proceeds, with  $\Delta E_{\text{cell}}$  approaching 0 V at equilibrium, at which point

$$\Delta E_{\text{cell}}^{\circ} = \frac{0.0592 \text{ V}}{n} \log_{10} K$$

which is the same as the relationship just obtained. This equation allows us to calculate equilibrium constants from standard cell potentials, as the following example illustrates.

### EXAMPLE 17.8

Calculate the equilibrium constant for the redox reaction

at 25°C using the cell potential calculated in Example 17.5.

#### Solution

$\Delta E_{\text{cell}}^{\circ} = 2.25 \text{ V}$  and  $n = 10$  for this reaction as shown in Examples 17.5 and 17.7. Therefore,

$$\log_{10} K = \frac{n}{0.0592 \text{ V}} \Delta E_{\text{cell}}^{\circ} = \frac{10}{0.0592 \text{ V}} (2.25 \text{ V}) = 380$$

$$K = 10^{380}$$

This overwhelmingly large equilibrium constant reflects the strength of permanganate ion as an oxidizing agent and that of zinc as a reducing agent. No  $\text{MnO}_4^{-}$  ions are present at equilibrium, for all practical purposes.

**Related Problems: 35, 36**

The foregoing example illustrates how equilibrium constants for redox reactions can be measured electrochemically. Related procedures can also be used to measure the solubility product constants of sparingly soluble ionic compounds or the ionization constants of weak acids and bases. The solubility product constant of  $\text{AgCl}$  can be measured electrochemically as follows. An electrochemical cell is constructed in which one half-cell contains solid  $\text{AgCl}$  and  $\text{Ag}$  metal, in equilibrium with a known concentration of  $\text{Cl}^{-}(aq)$  (established with 0.001 M  $\text{NaCl}$ , for example) so that an unknown but definite concentration of  $\text{Ag}^{+}(aq)$  is present. A silver electrode is used so that the half-cell reaction involved is either the reduction of  $\text{Ag}^{+}(aq)$  or the oxidation of  $\text{Ag}$ . This is, in effect, an  $\text{Ag}^{+}|\text{Ag}$  half-cell whose potential is to be determined. The second half-cell can be any cell whose standard reduction potential is accurately known, and its choice is a matter of convenience. The standard hydrogen electrode is the reference cell in the following example.

**EXAMPLE 17.9**

A galvanic cell is constructed from a half-cell containing silver and silver chloride and the SHE in order to determine an unknown concentration of  $\text{Ag}^+$  ions. The cell diagram is

and the unknown concentration of  $\text{Ag}^+$  is represented by  $\text{Ag}^+(\text{? M})$ . The SHE is the anode, and the measured cell potential is  $\Delta E_{\text{cell}} = 0.397 \text{ V}$ . Calculate the silver ion concentration in the cell and  $K_{\text{sp}}$  for  $\text{AgCl}$  at  $25^\circ\text{C}$ .

**Solution**

The half-cell reactions are

$$\Delta E_{\text{cell}}^{\circ} = E^{\circ}(\text{cathode}) - E^{\circ}(\text{anode}) = 0.800 - 0.000 \text{ V} = 0.800 \text{ V}$$

Note that  $n = 2$  for the overall cell reaction, and the reaction quotient simplifies to

$$Q = \frac{[\text{H}_3\text{O}^+]^2}{[\text{Ag}^+]^2 P_{\text{H}_2}} = \frac{1}{[\text{Ag}^+]^2}$$

because  $[\text{H}_3\text{O}^+] = 1 \text{ M}$  and  $P_{\text{H}_2} = 1 \text{ atm}$ . The Nernst equation is

$$\Delta E_{\text{cell}} = \Delta E_{\text{cell}}^{\circ} - \frac{0.0592 \text{ V}}{n} \log_{10} Q$$

$$\log_{10} Q = \frac{n}{0.0592 \text{ V}} (\Delta E_{\text{cell}}^{\circ} - \Delta E_{\text{cell}}) = \frac{2}{0.0592 \text{ V}} (0.800 - 0.397 \text{ V}) = 13.6$$

$$Q = 10^{13.6} = 4 \times 10^{13} = 1/[\text{Ag}^+]^2$$

This can be solved for the silver ion concentration  $[\text{Ag}^+]$  to give

$$[\text{Ag}^+] = 1.6 \times 10^{-7} \text{ M}$$

so that

$$[\text{Ag}^+][\text{Cl}^-] = (1.6 \times 10^{-7})(1.00 \times 10^{-3})$$

$$K_{\text{sp}} = 1.6 \times 10^{-10}$$

**Related Problems: 41, 42**

**17.3.2 pH Meters**

Cell potentials are sensitive to pH if  $\text{H}_3\text{O}^+$  is produced or consumed in either half-cell reaction. A simple cell can be constructed to measure pH as follows:

If the half-cell reactions are written as

(In labeling the first as the cathode we have assumed that the cell with variable  $[\text{H}_3\text{O}^+]$  has an  $\text{H}_3\text{O}^+$  concentration  $< 1 \text{ M}$ .)

then  $n = 2$  and  $Q = [\text{H}_3\text{O}^+(\text{aqueous, variable})]^2$  because the other concentrations and gas pressures are unity. The cell potential calculated using the Nernst equation is (for a cell operating at 25°C)

$$\Delta E_{\text{cell}} = \Delta E_{\text{cell}}^{\circ} - \frac{0.0592 \text{ V}}{n} \log_{10} Q$$

which becomes

$$\begin{aligned} \Delta E_{\text{cell}} &= -\frac{0.0592 \text{ V}}{2} \log_{10} [\text{H}_3\text{O}^+]^2 \\ &= -0.0592 \text{ V} \log_{10} [\text{H}_3\text{O}^+] = (0.0592 \text{ V}) \text{ pH} \end{aligned}$$

because  $\Delta E_{\text{cell}}^{\circ} = 0$ . The measured cell potential is directly proportional to the pH.

We have just described a simple **pH meter**. It is not convenient to bubble hydrogen gas through both the unknown and reference half-cells, however, so a smaller and more portable pair of electrodes is used to replace the hydrogen half-cells. The early commercial pH meters used two electrodes that were dipped into a solution of unknown pH. One of these, called the *indicator electrode* (because it indicates the unknown pH of the analyte), was made of an AgCl-coated silver electrode in contact with an HCl solution of known concentration (i.e., 1.0 M) contained in a glass tube terminated by a thin-walled, bulb-shaped, glass membrane. A pH-dependent potential develops across this thin glass membrane when the glass electrode is immersed in a solution of different, and unknown,  $[\text{H}_3\text{O}^+]$  concentration. See Figure 17.5. The reference electrode used was often the **saturated calomel electrode**, depicted on the right side of Figure 17.5. The overall cell can be represented as

$\text{Ag}|\text{AgCl}|\text{Cl}^-(1.0 \text{ M}), \text{H}_3\text{O}^+(1.0 \text{ M})|\text{glass}|\text{H}_3\text{O}^+(\text{var})||\text{Cl}^-(\text{sat})|\text{Hg}_2\text{Cl}_2(\text{s})|\text{Hg}|\text{Pt}$   
with half-reactions

**FIGURE 17.5** Schematic of an early pH meter.

The standard reduction potential of the first half-reaction can be combined with the reduction potential of the saturated calomel electrode (which is 0.242 V, with the  $\text{Cl}^-(aq)$  fixed by the concentration of the KCl electrolyte, but not equal to 1 M, so not a *standard* reduction potential) to give a constant reference potential  $\Delta E_{\text{ref}}$ . The second reaction is the source of the variable potential in the cell, which corresponds to the free energy of dilution of  $\text{H}_3\text{O}^+$  from a concentration of 1.0 M to an unknown concentration. That potential appears as a junction potential across the thin glass membrane of the indicator electrode. The Nernst equation for the overall cell operated at 25°C can be written as

$$\begin{aligned}\Delta E_{\text{cell}} &= \Delta E_{\text{ref}} - \frac{0.0592 \text{ V}}{1} \log_{10} \frac{[\text{H}_3\text{O}^+(\text{var})]}{1.00} \\ &= \Delta E_{\text{ref}} + (0.0592 \text{ V}) \text{pH}\end{aligned}$$

and the pH of the unknown solution is

$$\text{pH} = \frac{\Delta E_{\text{cell}} - \Delta E_{\text{ref}}}{0.0592 \text{ V}}$$

The glass indicator electrode has a number of advantages over other possible pH electrodes. It responds only to changes in  $[\text{H}_3\text{O}^+]$ , and it does so over a wide range of pH. It is unaffected by strong oxidizing agents that would make hydrogen electrodes unreliable. Highly colored solutions that would render acid–base indicators useless do not interfere with the glass indicator electrode.

Most modern pH meters use a combination probe like the one shown in Figure 17.6, in which the indicator and reference electrodes are housed in one body. You are probably familiar with probes like this one from laboratory courses. Another significant advantage of the combination probe is that it can be miniaturized to permit insertion into individual living cells and probe pH in biological samples.

A number of **ion-selective electrodes** have been developed using similar principles to selectively measure ion concentrations to levels as low as  $10^{-10}$  M. The simplest example of such an electrode would be an Ag/AgCl reference electrode, the potential being sensitive to the  $\text{Cl}^-(aq)$  concentrations in the solution of interest. Modern ion selective electrodes are constructed from polymer membranes that have been tailored to transport only the ions of interest, greatly reducing background and improving sensitivity.

**FIGURE 17.6** A combination pH probe.

## 17.4 Molecular Electrochemistry

The term **molecular electrochemistry** was coined recently to identify a branch of the broader field of electrochemistry that focuses on developing a molecular level understanding of electron transfer processes at electrodes and exploiting the interactions between molecules and electrode surfaces to optimize electrochemical reactions. Fundamental questions of interest include the coupling of electron and proton transfer, especially in biological systems; the way electron transfer reactions initiate bond breaking and formation; the role molecules play in catalyzing electrochemical reactions; and the way redox enzymes work. A wide range of applications is being pursued using this approach as well. The electrochemical synthesis of organic molecules, the development and application of biological sensors to problems of fundamental interest and medical diagnostics, the design of better catalysts for fuel cells, and the application of semiconductor photoelectrochemistry to problems as diverse as organic waste remediation and solar energy conversion are all active areas of research and development in this field. We discuss several of these applications in this section.

### 17.4.1 Electrochemical Organic Synthesis

The large-scale commercial synthesis of organic compounds uses simple starting materials derived from petroleum and converts them into the desired products in reactions that are generally carried out at high temperatures and pressures using catalysts. Many of these reactions use  $\text{H}_2$  and  $\text{O}_2$  to reduce and oxidize hydrocarbons to produce intermediates or the desired products. It is interesting to think about these transformations as redox reactions and to compare the driving force available in the homogeneous gas phase reactions in electrochemical terms. The driving force for the gas phase oxidations and reductions is limited by the potentials for the reduction of oxygen or the oxidation of hydrogen, which is a range of about 1V under standard conditions, which corresponds to a change in the Gibbs free energy of about  $100 \text{ kJ mol}^{-1}$  if one mole of electrons is transferred in the balanced chemical reaction. Synthetic organic reactions carried out electrochemically can be driven by potentials that range between  $-2.5 \text{ V}$  to  $3.5 \text{ V}$ , providing much larger driving forces and the possibility of greater control over the thermodynamics and kinetics of reactions by controlling potential. This approach also has the advantage that it does not rely on powerful, but toxic and potentially dangerous, reducing agents like the alkali metals or oxidizing agents like  $\text{Cl}_2$  or  $\text{Cr}_2\text{O}_7^{2-}$ . It has also been suggested that electrons are probably the least expensive and most widely available redox reagents on a per-mole basis.

The most famous example of a large-scale electrochemical organic synthesis is the Monsanto process for the production of adiponitrile, a precursor for hexamethylene diamine, which is one of the monomers used to make the large-volume commodity chemical nylon. The reaction mechanism is complex, but the following is one of the reactions that produces adiponitrile

which is then reduced in hydrogen to form the hexamethylenediamine monomer. The reaction is carried out in very large electrochemical reactors with steel electrodes coated by a thin film of Cd and the reactants, products, and electrolyte carried in an aqueous solution/organic solvent emulsion. This process produces some 200,000 tons of adiponitrile each year. Electrochemical organic

synthesis has become increasingly popular in recent years for the synthesis of organic molecules on much smaller scales, such as pharmaceuticals, because of its speed and selectivity.

### 17.4.2 Enzyme-Based Electrochemical Sensors

Approximately 5% of the world's population, and nearly 8% of the population of the United States, are diabetic; they are unable either to produce insulin, or to respond to the insulin they do produce to regulate the absorption of glucose, a major source of energy, into cells. Diabetics must keep their blood sugar levels controlled pretty tightly to avoid serious medical problems, some of which are potentially life-threatening. They do so by monitoring their blood sugar several times daily and injecting themselves with synthetic human insulin to regulate glucose uptake. In the prior section on the Nernst equation you learned how the potential difference  $\Delta E$  of an electrochemical cell depends on the concentrations of the species involved. This affords a way to measure glucose concentrations in a blood sample electrochemically.

Glucose sensors monitor either the reduction of glucose by the enzyme glucose dehydrogenase GDH(FAD), or the oxidation of glucose by the enzyme glucose oxidase GOx(FADH<sub>2</sub>), where FAD and FADH<sub>2</sub> are the reduced and oxidized forms of cofactors (see Section 18.8) associated with the enzymes that provide the reducing or oxidizing equivalents in the form of (H<sup>+</sup>, e<sup>-</sup>) pairs. The first reaction is used in test strips; an example is shown in Figure 17.7.

In the particular test strip shown, reduction occurs at the Ag/AgCl reference electrode and oxidation of glucose (in the blood sample) is catalyzed by an enzyme called glucose dehydrogenase (GDH), which converts an alcohol functional group into a ketone (see Section 7.6). The overall set of reactions is summarized as follows.

**FIGURE 17.7** Glucose sensor test strip showing the capillary partially filled with blood, the carbon working electrode and the counter-reference and fill-detection electrodes. The planar electrodes are separated from one another by 50  $\mu\text{m}$ .

Electron transfer from the enzyme to the electrode surface is not very efficient, however, because the enzyme's active site is buried inside the protein and there is no easy path for the electrons to follow. The problem was solved by incorporating molecules called *mediators* into the device that facilitate electron transfer over large distances by a series of efficient electron transfer reactions. The design of the mediators is one part of the clever chemistry referred to earlier.

### 17.4.3 Electrogenerated Chemiluminescence and Cyclic Voltammetry

Electrogenerated chemiluminescence (ECL) has become a very important analytical technique for detecting biologically important molecules, with applications in clinical diagnostics, food and water testing, the detection of biowarfare agents, and basic research. It is very sensitive (picomolar concentrations can be measured) and the response is linearly proportional to concentration. ECL generally results from charge transfer reactions between radical anions and radical cations that produce excited molecular electronic states, which then emit light. The radicals are generated electrochemically, and the series of reactions can be written as

in which A is the oxidized form of an electron acceptor and  $A^{\bullet-}$  is its radical anion formed upon reduction; D is an electron donor and  $D^{\bullet+}$  is its radical cation formed upon oxidation;  $A^*$  is an electronically excited state of A and  $h\nu$  is the energy of the emitted light. The electrochemical generation of the radical anion is illustrated in Figure 17.8a. Using an external voltage source, an electrode may be raised in free energy (by lowering its electric potential) until an electron can transfer from the electrode to the lowest unoccupied molecular orbital (LUMO) of an organic molecule. In this case the molecule is acting as an electron acceptor A. Figure 17.8b depicts what happens when an external voltage source is applied to lower the free energy of an electrode (by raising its electric potential). That allows an electron to transfer from the highest occupied molecular orbital (HOMO) of the molecule, now acting as an electron donor, D, to the electrode. The electron transfer reaction that produces  $A^*$ , which

**FIGURE 17.8** Generation of a radical cation and a radical anion in an ECL experiment. (a) The molecule is acting as an electron acceptor A. The radical anion of A is formed when the electrode potential is made more negative, raising its energy above the LUMO of A. (b) The same molecule is acting as an electron donor D. The radical cation of D is formed when the electrode potential is made more positive, lowering its energy below the HOMO of D.

**FIGURE 17.9** Reaction of  $R^-$  and  $R^+$  to form  $R + R^*$ . The latter is electronically excited, so is the species that emits light in an ECL experiment. Note that if two different molecules are the acceptor and donor, then  $A^-$  is on the left in the reactant side of this figure and  $A^*$  is on the right in the product side of this figure. (One of the paired electrons in  $A^-$  was transferred to the singly occupied orbital in  $D^+$  to form  $D + A^*$ .)

subsequently returns to the ground state  $A$  by emitting a photon, is illustrated in Figure 17.9.

The ECL process is most easily illustrated using a specific example in which we identify the redox potentials of the donor and acceptor using an electrochemical technique known as cyclic voltammetry, and connect them to the absorption and emission spectra of the system. **Cyclic voltammetry** measures the current that flows as the electrode potential is scanned in the forward direction (typically toward more negative potentials) and then in the reverse direction. The cyclic nature of the scan gives the technique its name. Cyclic voltammetry is perhaps the electrochemists' most powerful method for the study of electrochemical processes. It can quickly identify redox active materials and locate the potentials at which various oxidations and reduction reactions occur. Cyclic voltammetry can also provide a great deal of information about the kinetics of electrochemical reactions, but that discussion is beyond the scope of this textbook. The application of cyclic voltammetry to ECL affords us the opportunity to introduce you to the technique at an elementary level as well as to illustrate how ECL experiments are actually carried out. Figure 17.10 shows the cyclic voltammogram of a redox-active dye molecule (PM 567) that has been tailored for ECL applications. The same molecule, in this example, is reduced to form the radical anion and oxidized to form the radical cation.

The potential is set initially to 0 V (measured with respect to SCE in Figure 17.10) and then scanned through a cycle, first toward more negative potentials, then toward more positive potentials, and finally returning to zero. As shown in the voltammogram in Figure 17.10, the current begins to rise as the potential reaches about  $-1.4$  V, signifying the reduction of PM to  $PM^{\bullet-}$  at the cathode as depicted schematically in Figure 17.8a.

**FIGURE 17.10** Cyclic voltammogram for an ECL dye.

**FIGURE 17.11** Absorption and fluorescence spectra of an ECL dye.

The scan is reversed by now using the external voltage source to lower the energy of the electrode (by raising its electric potential) and current begins to flow in the opposite direction as  $\text{PM}^{\bullet-}$  is oxidized back to PM. When the potential is scanned through potentials more positive than about 1 V, PM is oxidized to  $\text{PM}^{\bullet+}$ ; this is depicted schematically in Figure 17.8b. Finally, when the scan is reversed again,  $\text{PM}^{\bullet+}$  may be reduced back to PM. The shapes of these curves contain a great deal of information about the kinetics of the reactions, with the current rising and then falling due to an increase and then a decrease in the rates of diffusion of reactants to the electrode surface. The redox potential for the  $\text{PM}|\text{PM}^{\bullet-}$  couple is located between the two peaks in the absolute value of the wave near  $-1.4$  V, and the redox potential for the  $\text{PM}^{\bullet+}|\text{PM}$  couple is located between the two peaks in the absolute value of the wave near 1 V. We can calculate the maximum amount of energy available to create an excited state, and the energy of the emitted photon from the reaction

as follows. We have associated the potential of the  $\text{PM}^{\bullet+}|\text{PM}$  couple with the HOMO (highest occupied molecular orbital) and that of the  $\text{PM}|\text{PM}^{\bullet-}$  couple with the LUMO (lowest unoccupied molecular orbital), so the energy available is given by the potential difference between the two redox couples times the charge of the electron, giving  $-e\Delta E = 2.4$  eV for this system. Note that this association is a qualitative one, as it neglects the contribution of entropy to the Gibbs free energy. The absorption and fluorescence spectra of PM 567 are shown in Figure 17.11. The peak in the absorption spectrum (violet curve) appears at 514 nm, which corresponds to an energy of about 2.4 eV, so the energy available from the recombination reaction is sufficient to create the excited state. The maximum in the fluorescence spectrum (blue curve) is shifted to somewhat longer wavelengths, as is typical for molecules in solution, appearing at 567 nm.

#### EXAMPLE 17.10

Sketch and interpret the cyclic voltammogram you expect for the  $[\text{Fe}(\text{CN})_6]^{3-}/[\text{Fe}(\text{CN})_6]^{4-}$  redox couple measured with respect to the SHE reference electrode. The standard reduction potential for this system is 0.36 V.

(Continued)

**Solution**

The cyclic voltammogram for this system is sketched above. The potential is set initially at 0.8 V and no current flows. A detectable current begins to flow as the potential is scanned to more negative values, the current beginning to appear at about 0.5 V. The current is due to the reduction of  $[\text{Fe}(\text{CN})_6]^{3-}$  to  $[\text{Fe}(\text{CN})_6]^{4-}$  at the cathode. The current peaks and then declines as the potential is scanned to more negative values. The direction of the potential scan is reversed at about 0 V and a current flowing in the opposite direction begins to appear at about 0.34 V, indicating the re-oxidation of  $[\text{Fe}(\text{CN})_6]^{4-}$  to  $[\text{Fe}(\text{CN})_6]^{3-}$ . The current first increases and then decreases as the potential is scanned to more positive values. The redox potential is determined graphically by locating the midpoint between the two peaks, in this case 0.36 V.

**Related Problems:** 43, 44

**EXAMPLE 17.11**

Suppose that you were asked to synthesize a molecule for use in ECL that emits light at 600 nm and has a redox potential associated with the LUMO located at  $-1.05$  V (with respect to SHE), for compatibility with other requirements in a particular analytical application. (Assume the emission spectrum is not significantly shifted from the absorption spectrum.) What is the redox potential associated with the HOMO?

**Solution**

The energy of a photon is related to its wavelength by  $E = h\nu = hc/\lambda$ , where  $\lambda$  is the wavelength,  $h$  is Planck's constant and  $c$  is the speed of light (see Equations 4.1 and 4.7). Solving for  $E$  gives

$$\begin{aligned} E &= (6.626 \times 10^{-34} \text{ J s})(3 \times 10^8 \text{ m s}^{-1})/(600 \times 10^{-9} \text{ m}) \\ &= 3.3 \times 10^{-19} \text{ J} = 2.06 \text{ eV} \end{aligned}$$

which is equal to the difference in the energies of the two orbitals  $\epsilon_{\text{LUMO}} - \epsilon_{\text{HOMO}}$ . The energy of the LUMO with redox potential  $-1.05$  V is 1.05 eV (with respect to SHE) so the energy of the HOMO must be  $-1.01$  eV with an associated potential located at 1.01 V.

**Related Problems:** 45, 46

## CONNECTION TO BIOLOGY

## ECL in Clinical Assays

We have illustrated the principles of ECL using as an example a molecule that serves as both the electron acceptor and the electron donor. Biological applications of ECL, however, require molecules both that are stable and that show ECL in *aqueous* solution. The discovery of ECL in the water-soluble coordination complex  $\text{Ru}(\text{bpy})_3^{2+}$ , shown in Figure C17.1, was a promising development, but it turned out to be difficult, if not impossible, to find a suitable electron acceptor that could be reduced electrochemically in water. The difficulty arises because potentials more negative than the potential for water reduction are needed to produce species that can reduce  $\text{Ru}(\text{bpy})_3^{3+}$  generated electrochemically by oxidation of  $\text{Ru}(\text{bpy})_3^{2+}$  (see Section 17.8, *A Deeper Look . . . Electrolysis of Water and Aqueous Solutions*). The problem was solved by finding a way to produce reducing species by *oxidation*, using molecules called coreactants that decompose upon oxidation to produce products with the required reducing power, allowing a single applied potential step to initiate both reactions.

The molecule tripropylamine,  $\text{N}(\text{CH}_2\text{CH}_2\text{CH}_3)_3$  abbreviated  $\text{Pr}_2\text{NCH}_2\text{CH}_2\text{CH}_3$ , is a particularly good coreactant for the efficient generation of ECL from  $\text{Ru}(\text{bpy})_3^{2+}$  in aqueous solution.  $\text{Ru}(\text{bpy})_3^{2+}$  and tripropylamine are simultaneously oxidized during a single potential step to produce  $\text{Ru}(\text{bpy})_3^{3+}$  and  $\text{Pr}_2\text{N}(\text{CH}_2\text{CH}_2\text{CH}_3)^{+\bullet}$  respectively. The tripropylamine radical cation then loses a proton to form the strongly reducing free radical species  $\text{Pr}_2\text{N}(\bullet\text{CHCH}_2\text{CH}_3)$ , which reacts with  $\text{Ru}(\text{bpy})_3^{3+}$  to produce an excited state of  $\text{Ru}(\text{bpy})_3^{2+}$  that emits light. The overall sequence is summarized as follows:

ECL is used in a large number of clinically important assays.  $\text{Ru}(\text{bpy})_3^{2+}$  is covalently bound, using different linking molecules, to a probe that binds to target molecules of interest. The target molecules fall into major

classes that include: antigens that trigger an immune response, producing antibodies, and the nucleic acids DNA and RNA. Antibody-based assays are used to measure estrogen and testosterone levels, detect the hepatitis and HIV viruses, and measure insulin levels, for example. Antibodies to a particular antigen are covalently attached to a solid surface, and  $\text{Ru}(\text{bpy})_3^{2+}$ -labeled antibodies and the sample of interest are placed in solution. Any antigen present will be recognized and bound to both the surface-bound antibodies and the solution-phase antibodies, linking them together. A number of schemes have been developed to present these samples to electrode surfaces for ECL analysis, magnetic beads that attach to electrode surfaces or miniature electrodes printed in arrays of small wells, for example. Assays based on the recognition of specific nucleic acid sequences proceed in an analogous way.

ECL has a number of significant advantages over other biological assays. First, the labels are completely stable until the potential is stepped to generate the reactive species. Second, and perhaps most importantly, there is no background emission like that found in fluorescence experiments. Light emission occurs in ECL only when the electrode is stepped through the potential region of interest. Third, it is a very sensitive technique because modern photomultipliers or other detectors can detect single photons. Detection limits for ECL have been demonstrated to be as low as  $10^{-12}$  M, making it among the most sensitive analytical methods available.

FIGURE C17.1  $\text{Ru}(\text{bpy})_3^{2+}$ .

## 17.4.4 Photoelectrochemistry

To understand the transfer of electrons between metals and molecular species, it is helpful to make a qualitative energy level diagram for the electronic energy levels in a metal. Figure 17.12 shows an energy level diagram for copper metal. The energies of the electronic energy levels are plotted along the vertical axis on the left, and the corresponding potentials are plotted along the vertical axis on the right. In Figure 17.12,  $\varepsilon = 0$  is defined as the energy for an electron pulled far from the copper (as in the photoelectric effect in Section 4.4). Later figures in this section show energies and potentials with respect to the potential of a reference electrode (rather than with respect to a free electron's energy). The energies of the orbitals of a copper metal electrode are represented by the solid blocks of color in Figure 17.12. The energy levels of metals are spaced so closely together that they form a continuous *band* of levels (see Section 21.3). The orbitals of bulk metals are constructed from the orbitals of the individual metal atoms using LCAO MO theory, by analogy to the MOs constructed for 1,3-butadiene shown in Figure 6.53. Only half of the four  $\pi$  butadiene orbitals are occupied because each orbital can accommodate two electrons. The same is true for metals; half of the delocalized orbitals are occupied for univalent metals that contribute one electron per atom to form a band. The solid block of color represents the occupied copper orbitals, whereas the unoccupied orbitals are represented by the more transparent block of color. We identify the highest occupied orbital (analogous to the HOMO—highest occupied molecular orbital—in organic chemistry) as the Fermi level with energy  $\varepsilon_F$ . The energy of the Fermi level, for a metal in vacuum, is given by  $\varepsilon_F = -\Phi$ , where  $\Phi$  is the work function of the metal, as defined in our discussion of the photoelectric effect in Section 4.4. The work function of copper is 4.7 eV, so Fig. 17.12 plots the Fermi level at  $-4.7$  eV. Measurements of the absolute potential of SHE give 4.44 V at 25°C, corresponding to an absolute energy of  $-4.44$  eV; this is depicted on the vertical axis on the right. It is typical, however, to measure electrostatic potentials with respect to SHE, so in subsequent figures in this chapter you will see the label 0.0 (SHE) and the potentials of the other electrodes considered will be adjusted to that scale. For example, the Fermi level of copper is at a potential of  $+0.26$  V with respect to SHE, corresponding to being *lower* in energy than SHE by 0.26 eV.

Some metals, called semiconductors, evidence an energetic gap between the highest occupied energy levels in the valence band and the lowest unoccupied levels in the conduction band. The left-hand side of Figure 17.13 shows two energy levels of a molecule or a semiconductor that absorbs light (a **chromophore**)

**FIGURE 17.12** Electrons from the highest occupied metal orbital may be promoted to higher energy levels in the conduction band (light pink region) or given enough energy (black arrow), to be released from the metal (as in the photoelectric effect).

**FIGURE 17.13** Photoexcitation promotes electrons to higher energies (more negative potentials), which make them stronger reducing agents, capable of reducing an acceptor A to  $A^-$ . The vacancies (holes) left behind can now accept electrons, which make them stronger oxidizing agents, capable of oxidizing a donor D to  $D^+$ . The left side of the diagram shows the energy levels in the valence band (VB) of the semiconductor in dark pink, with one representative energy level pulled out so you can see the “hole” created by promoting an electron to an energy level in the conduction band (CB).

along with the redox levels of an electron acceptor A and an electron donor D on the right-hand side of the diagram. The lower energy level in the chromophore is called the HOMO (highest occupied molecular orbital), and the higher energy level is called the LUMO (lowest unoccupied molecular orbital); the corresponding levels in the semiconductor are called the **valence band (VB)** and the **conduction band (CB)**, respectively. We treat the semiconductor bands as if they were molecular orbitals, and we do not consider how the energies of these bands bend as a function of distance from the surface, which is an important consideration in more advanced work. We refer to the energy level splitting as the bandgap for molecular systems as well as semiconductors, for convenience and consistency. Redox potentials (also represented as orbital energy levels) for two different redox reactions,  $A + e^- \rightarrow A^-$  and  $D \rightarrow D^+ + e^-$ , are located on the right-hand side of the diagram; we have chosen the energy levels associated with these reactions to lie between the energy levels of the chromophore for the purpose of this discussion. Values of the potential and the potential energy, referenced to the SHE, are plotted on the two vertical axes; note the direction of increase of each.

Let's use this energy level diagram to understand the mechanism by which light absorption drives redox reactions that are not normally spontaneous. Light absorption promotes electrons from the lower level (the valence band) to the upper level (the conduction band), increasing their potential energy. The potential of these electrons is more negative than when they were in the HOMO, so these excited states have become stronger reducing agents than the ground state of the system. Vacancies (holes) left in the conduction band are now free to accept electrons from other species, making excited states more powerful oxidizing agents than ground states. Photoexcitation, therefore, has created excited states in which the electrons and the holes are simultaneously more strongly reducing and more strongly oxidizing, respectively, than the ground state molecules themselves.

Let's now consider direct photoelectrochemical water splitting by wide bandgap semiconductors such as  $\text{TiO}_2$  or  $\text{SrTiO}_3$ , each with a band gap of about 3 V. When the semiconductor absorbs UV light with an energy greater than 3 eV, an electron can be promoted into the conduction band, leaving a hole in the valence band. The conduction band electron in  $\text{TiO}_2$  can reduce an aqueous proton, as shown in the energy level diagram in Figure 17.14, while the hole accepts an electron as water oxidizes. The net reaction when four electrons are transferred in this way is the sum of two half-reactions:

**FIGURE 17.14** The potential of the conduction band of wide bandgap semiconductors is sufficiently negative to reduce hydrogen ions and that of the valence band sufficiently positive to oxidize water. The low energy edge of the conduction band of  $\text{TiO}_2$  is 0.2 eV higher in energy (lower in electrostatic potential) than NHE.

The overall thermodynamics of the system as well as the stoichiometry of the reaction on the molecular level determines the energy required for the overall reaction. The standard Gibbs free energy of formation of water is

so the light absorbed must provide at least  $237.2 \text{ kJ mol}^{-1}$  to decompose 1 mol of water. A mole of 3 eV photons carries 289 kJ of energy, but the energy absorbed by chromophores is partially degraded into heat, unfortunately, before ultimately being made available to drive the water splitting redox reactions. The net reaction of the two half reactions above is  $2 \text{H}_2\text{O}(\ell) \longrightarrow 2 \text{H}_2(\text{g}) + \text{O}_2(\text{g})$ , but that requires four moles of electrons. The energy required per mole of water split is, as expected:

$$\frac{-nF\Delta E_{\text{cell}}^\circ}{2} = \frac{-(4 \text{ mol})(-1.229)(96.485 \text{ kJ mol}^{-1} \text{ eV}^{-1})}{2} = 237.2 \text{ kJ}$$

Two electrons raised in energy through a potential difference of  $-1.229 \text{ V}$  each would provide enough energy to decompose 1 molecule of water, but there is no molecular mechanism that would produce one oxygen *molecule*, as required. Water splitting, therefore, is a four-electron redox process that proceeds through a series of electron transfer reactions that involve several intermediates.

The energetic considerations discussed above have important consequences for the design of practical systems for photoelectrochemical water splitting. Colloidal semiconductors like  $\text{TiO}_2$  (illustrated in Fig. 17.15) or  $\text{SrTiO}_3$  have become the leading candidates for practical systems. They are more stable than molecular systems, and they have high surface-area-to-volume ratios that support the catalysts required to achieve acceptable reaction rates.

**FIGURE 17.15** Direct photoelectrochemical water splitting by colloidal  $\text{TiO}_2$ , shown with hydrogen and oxygen evolution catalyst particles attached.

The water splitting reaction is thermodynamically allowed, but too slow for practical applications unless hydrogen reduction catalysts, like Pt, and oxidation catalysts, like RuO<sub>2</sub>, are used. The wide bandgap semiconductors used for purposes of illustration are not suitable for practical applications because they absorb radiation only in the ultraviolet region of the spectrum, which accounts for less than 10% of the energy provided by sunlight. In addition, most of the energy of any ultraviolet radiation that is absorbed would be lost as heat; the fraction ultimately available is the ratio of the water oxidation potential energy to the energy of the bandgap, or about 40% (1.229 eV/3 eV). Most of the energy that is lost is due to the fact that the valence band in these wide bandgap materials is much more positive than that required to oxidize water, and so much current research in this area has been devoted to discovering new materials with smaller bandgaps and with valence bands at more negative potentials. Unfortunately, most materials with these properties decompose under illumination because the holes generated oxidize the semiconductors themselves; for example, metal sulfides and metal selenides decompose as

### EXAMPLE 17.12

Would GaAs be a suitable candidate as a semiconductor electrode for direct photoelectrochemical water splitting? The valence band lies at about 0.7 V with respect to SHE and the conduction band lies at -0.7 V with respect to SHE; the band gap is 1.42 eV. Why or why not?

#### Solution

The redox potential of the conduction band is sufficiently negative to reduce H<sup>+</sup> to H<sub>2</sub> but the potential of the valence band is not sufficiently positive to oxidize water.

**Related Problems:** 47, 48

Improving the efficiencies of semiconductor-based solar cells is a topic of great current research interest, motivated both by a desire to more fully understand the basic physical and chemical processes involved as well as to guide the design of practical cells. Wide bandgap semiconductors like TiO<sub>2</sub> and SrTiO<sub>3</sub> have conduction bands with potentials sufficiently negative to reduce water but their valence bands are located at much more positive potentials than necessary to oxidize water, resulting in most of the energy absorbed being lost as heat. Photosynthesis, the process in nature by which solar energy is captured and stored, uses coupled systems to absorb light over a significant wavelength range and efficiently transfer energy to the sites where oxidation reduction reactions occur. Considerable effort is currently being devoted to develop semiconductor-based solar cells that operate using principles inspired by the natural photosynthetic systems. The accompanying *Connection to Energy: Solar Energy Conversion* introduces you to one approach that has been developed to increase the efficiency of direct photoelectrochemical water splitting as well as to generate electricity, using dye-sensitized semiconductor solar cells.

### EXAMPLE 17.13

What properties should you specify for a dye to be used as a sensitizer in a dye-sensitized solar cell used for direct photoelectrochemical water splitting or for generating electricity directly in a cell like the Graetzel cell discussed in the *Connection to Energy: Solar Energy Conversion*?

#### Solution

The LUMO of the dye must lie at higher energy than the conduction band of the semiconductor in order for electron injection to occur; this requirement must be met for both applications.

**Related Problems:** 49, 50

## CONNECTION TO ENERGY

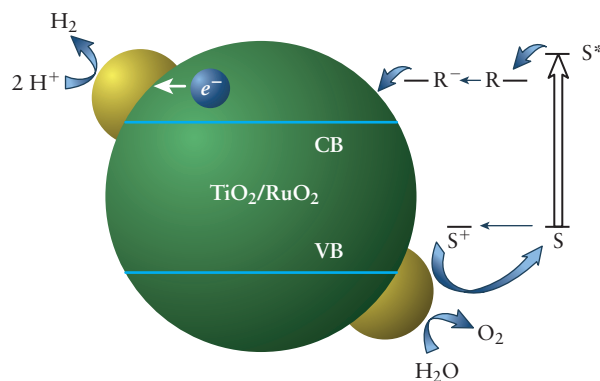

## Solar Energy Conversion

The sun is the ultimate source of energy for the Earth; some of that energy is stored in plants, which provide food and energy for current needs. Plants were also the precursors to fossil fuels, our main source of energy for electrical power generation, transportation, and manufacturing. The finite supply of fossil fuels, combined with a growing population and increasing energy requirements in developing countries, has stimulated tremendous interest in new sources of renewable energy such as solar, wind, and biomass. We describe two approaches to solar energy conversion and storage that are based upon photoelectrochemical reaction schemes: one to produce fuel, the other to produce electricity.

## Artificial Photosynthesis

Photosynthesis, which occurs in plants and some bacteria, converts solar energy into chemical potential energy that is stored in the bonds of carbohydrates. We recover this energy when metabolizing food or from the combustion of fossil fuels or biomass. Sunlight is the source of the Gibbs free energy required to drive these thermodynamically uphill reactions; absorption of a photon provides the energy to excite an electron from a HOMO to a LUMO to drive subsequent redox reactions (see Fig. 17.13). Natural photosynthetic systems are highly organized arrays of molecules that absorb much of the available sunlight and transfer the excitation energy efficiently to the photosynthetic reaction centers that catalyze the redox reactions.

The goal of *artificial photosynthesis* is to design simpler synthetic systems that perform the same functions as natural photosynthesis, the conversion and storage of solar energy as fuel, with a focus on hydrogen. Figure C17.2 shows how the addition of a dye sensitizer and a mediator to the system illustrated in Figure 17.15 enables water splitting at visible wavelengths. The basic idea is fairly straightforward but producing practical devices remains a daunting challenge. Light absorbed by sensitizers generates excited states that can inject electrons into the conduction band of the semiconductor particle, with the electrons ultimately reducing water (beginning with the  $2\text{H}^+ \rightarrow \text{H}_2(\text{g}) + 2\text{e}^-$  half reaction in Fig. 17.14 and again in Fig. C17.2 in shorthand notation not showing the electrons) to generate  $\text{H}_2$  gas that may be stored and used as a fuel. The LUMO of the sensitizer must lie at higher energy than that of the conduction

**FIGURE C17.2** Photoelectrochemical water splitting with addition of a dye sensitizer  $S$  and catalysts.

band to allow electron injection and the redox potential associated with the HOMO must be sufficiently positive to oxidize water. Redox mediators (if used) must have a wider “bandgap” than the sensitizer. Small Pt and  $\text{RuO}_2$  particles (gold spheres) catalyze the reduction and oxidation reactions, respectively. We introduce this single-component model system because it is easy to visualize and illustrates principles that underlie one approach to develop more efficient solar cells.

## Dye-Sensitized Solar Cells

The vast majority of solar cells in current use are Si-based photovoltaic devices in which light absorption excites electron-hole pairs in  $p$ - $n$  junctions (see Section 22.7), generating electrons that flow through external circuits producing electrical work. These cells can be very efficient (more than 20%) but they are also very expensive due to demanding material requirements.

Considerable effort has been devoted to the development of dye-sensitized semiconductor solar cells (DSC) over the past several decades. Research in this area was pioneered in large part by the Swiss physical chemist Michael Grätzel, who has made important contributions to the development of systems for direct water splitting as well as for electricity generation. A schematic of the Grätzel cell is shown in Figure C17.3; it has many of the characteristics of the dye-sensitized semiconductor system discussed earlier. Sensitizing dyes are adsorbed on, or chemically bound to, the surfaces of wide bandgap semiconductor nanoparticles. Light absorbed by the dyes excites electrons into the LUMO from which they are injected into the conduction band of the semiconductor.

FIGURE C17.3 Schematic of a Grätzel cell.

Unlike in the previous example, however, electrons flow through an external circuit where they can do work. The electrons reenter the cell at the cathode and reduce the oxidized form of a redox mediator, which is then oxidized by the hole left behind in the sensitizer. A number of factors have been carefully considered to design cells with conversion efficiencies as high as 12% and projected lifetimes as long as 10 years. The morphology of the semiconductor nanoparticles, the electronic energy level structures of the dye molecules, the coverage of dye molecules on each nanoparticle and the way in which these nanoscopic structures are assembled have been carefully chosen to provide very large surface areas for efficient light absorption and electron injection. Dyes have been synthesized with LUMOs located slightly above the energy of the semiconductor conduction band to ensure efficient injection and with HOMOs located at the lowest possible energies to maximize the fraction of the incident light absorbed as well as to be compatible with the redox potential of the mediator. Examples of sensitizers include derivatives of  $\text{Ru}(\text{bpy})_3$  in which one or more of the bipyridine ligands have been replaced by isothiocyanate ( $-\text{N}=\text{C}=\text{S}$ ) ligands to extend the absorption onset to longer wavelengths, as shown in Figure C17.4. The solar spectrum is represented in the figure by the spectrum of a blackbody at the temperature of the sun to give you a sense of how much of the available radiation is absorbed by these

dyes. The vertical axis is the percent conversion efficiency (incident photons to electrons).

The redox mediator transports electrons from the cathode to the radical cation created by photoexcitation and charge injection, regenerating the ground state of the sensitizer and preventing direct electron-hole pair recombination, an undesirable competing reaction. The relevant reactions are

The iodide/triiodide redox couple has been the mediator of choice because it is sufficiently soluble, does not absorb significant amounts of light, has appropriate redox potentials, rapid dye regeneration kinetics and, most importantly, very slow rates for the direct recombination of the conduction band electrons with triiodide, another undesirable competing reaction. The choice of redox mediator is critical; the performance of the iodide/triiodide couple is unmatched to date but there is considerable interest in finding other mediators that would increase efficiency. The standard reduction potential for the  $\text{I}/\text{I}_3^-$  couple is 0.35 V (SHE) and that of the radical cation is about 1.1 V. The energy difference is lost as heat; designing systems with more closely matched energy levels could greatly improve the efficiencies of these devices.

FIGURE C17.4 Conversion efficiency of molecules used as dye-sensitizers, absorbing photons in the visible and near infrared region of the solar spectrum.

## 17.5 Batteries and Fuel Cells

Batteries and fuel cells are examples of galvanic cells that convert chemical energy into electrical energy, the difference being that batteries carry all of their fuel with them and must be replaced or recharged, whereas fuel cells operate continuously as long as fuel and oxygen are being supplied. You are familiar with the batteries you use in cell phones, laptops, and other consumer products, but applications of batteries and fuel cells for transportation and energy storage are becoming increasingly important as well, driven primarily by energy and environmental concerns. We discuss the chemistry of several of the most common battery systems in current use and introduce you to fuel cells in this section.

### 17.5.1 Batteries

© Cengage Learning/Charles D. Winters

**FIGURE 17.16** Batteries vary in size and chemistry. Shown here are an automobile lead-storage battery, rechargeable nickel–cadmium cells, alkaline cells, and zinc–carbon dry cells.

The origin of the **battery** is lost in history, but it could very well date back some 2000 years. A jar discovered near Baghdad in 1936 has all of the elements needed to generate a voltage, and replicas of the “Baghdad Battery” have produced about 2 V, using common electrolytes available in ancient times, like grape juice. Whether the jar was indeed used to electroplate objects with gold remains a matter of speculation. The development of the modern battery began with the invention of the voltaic pile in 1800, as mentioned earlier. The pile was a collection of galvanic cells (a battery of cells) connected in series (cathode to anode) so that the individual cell voltages added together; enough cells added together could produce a battery that could deliver quite a shock. Modern usage makes no distinction between a single cell and the voltaic pile, and the word *battery* has come to mean the cell itself (Fig. 17.16). Cells that are discarded when their electrical energy has been spent are called **primary cells**, and those that can be recharged are called **secondary cells**.

The most familiar primary cell is the **Leclanché cell** (also called a *zinc–carbon dry cell*) used for flashlights, portable radios, and a host of other purposes. More than five billion such dry cells are used worldwide each year, and estimates place the quantity of zinc consumed for this purpose at more than 30 metric tons per day. The “dry cell” is not really dry at all. Rather, its electrolyte is a moist powder containing ammonium chloride and zinc chloride. Figure 17.17 is a cutaway illustration of a dry cell, which consists of a zinc shell that serves as the anode

**FIGURE 17.17** Leclanché “dry” cell. Electrons produced by oxidation of zinc metal at the anode flow through an external circuit and return at the cathode, where the reduction of  $\text{MnO}_2$  occurs.

(negative terminal) and an axial graphite rod for a cathode (positive terminal), with the rod surrounded by a densely packed layer of graphite and manganese dioxide.

Each of these components performs an interesting and essential function. Oxidation occurs at the zinc anode:

The moist salt mixture (like the salt bridge in Fig. 17.2) enables ion exchange between the sites of the anode and cathode half-reactions to maintain electrical neutrality as electrons flow through the external circuit. Manganese dioxide, the ultimate electron acceptor, is reduced to  $\text{Mn}_2\text{O}_3$  by  $\text{H}_2(g)$ , produced by the reduction of ammonium ions in the following series of reactions:

Mixing powdered graphite with powdered  $\text{MnO}_2$  greatly increases the effective surface area of the cathode, reduces the internal resistance of the cell, and enables currents of several amperes to flow. The overall cell reaction is

The cell components are hermetically sealed (airtight) in a steel shell that is in contact with the zinc anode and thus acts as the negative terminal of the battery. Zinc-carbon dry cells produce 1.5 V when new.

The disadvantage of the Leclanché cell is that the concentration of protons (available as  $\text{NH}_4^{+}(aq)$ ) decreases with time, and the battery's voltage falls as it is used. The zinc anode also corrodes as it oxidizes, and the electrolyte leaks out. The **alkaline dry cell** has largely replaced the Leclanché cell as the dominant primary cell for consumer applications; potassium hydroxide replaces ammonium chloride, and the half-cell reactions are

The overall cell reaction is then

All of the reactants and products in alkaline cells are pure solids or liquids whose concentrations are fixed, and so the cell voltage remains stable over time.

The third primary cell we discuss is the **zinc-mercuric oxide cell** shown in Figure 17.18. It is commonly packaged in the shape of a small button that is convenient for use in automatic cameras, hearing aids, digital calculators, and quartz-electric watches. The anode is a mixture of mercury and zinc, and the cathode is made of steel in contact with solid mercury(II) oxide ( $\text{HgO}$ ). The electrolyte is a 45%  $\text{KOH}$  solution that saturates an absorbent material. The anode half-reaction is the same as that in an alkaline dry cell,

but the cathode half-reaction is now

The overall reaction is

**FIGURE 17.18** A zinc-mercuric oxide dry cell, used in electric watches and cameras.

The voltage (1.34 V) produced by these batteries is very stable over time, which made them especially valuable for use in communication equipment and scientific instruments.

Environmental concerns about mercury led federal regulators to ban their manufacture, however, and they have been replaced by lithium batteries (not lithium-ion batteries, discussed next) for portable electronics applications in cameras, watches, and calculators, for example. Lithium metal is the anode and  $\text{MnO}_2$  is the cathode, with lithium perchlorate dissolved in a mixture of propylene carbonate and 1,2-dimethoxyethane as the electrolyte. The half-cell and overall cell reactions, which produce a nominal battery voltage of 3 V, are:

### 17.5.2 Rechargeable Batteries

Rechargeable batteries have become very important in recent years for use in consumer products and transportation. The lithium-ion battery has become the dominant battery for use in laptops and cell phones. The lead acid battery has long been used in automotive applications with the nickel metal hydride (NiMH) battery having been developed as a rechargeable alternative for applications in hybrids and plug-in electric vehicles. Nickel metal hydride batteries are also popular alternatives to alkaline batteries for consumer applications because they can be recharged; they are manufactured in the same standard sizes. Batteries are recharged by applying an external potential that is greater in magnitude and opposite in sign to the galvanic cell potential, which causes the redox reactions to run in reverse, regenerating the reactants. Not all redox reactions are chemically reversible, however, which limits the choices for constructing rechargeable batteries. The Leclanché cell, for example, is not chemically reversible because the primary products are gases, hydrogen and ammonia, which are irreversibly bound up as water and  $[\text{Zn}(\text{NH}_3)_2]^{2+}(\text{aq})$  ions.

Rechargeable batteries are characterized by their voltages, the maximum current available (sustained for laptops or peak for camera flashes) and the total energy stored. The amount of charge available in a battery before it must be recharged is called its capacity, which for consumer applications has been defined as the maximum current that can be sustained for 20 hours of operation without dropping the voltage below an acceptable value. A 100 watt hour (Whr) battery, for example, will deliver 5 A for 20 hours. The battery in your laptop might have a rating of 3500 mAh, meaning that it will provide 3.5 A for an hour or 1 A for 3.5 hours. The energy available from a battery before it must be recharged is given by the capacity times the voltage, so your laptop might provide  $ItV = (3500 \text{ mAh})(10 \text{ V}) = 35 \text{ J}$  of energy before it needs to be recharged. Battery manufacturers continue to strive to develop batteries that deliver the most energy per unit volume or per-unit weight, depending upon their applications. These quantities are called the volumetric or gravimetric energy densities, measured in units Wh/L or Wh/kg, respectively. Modern Li-ion (see next page) laptop batteries achieve about 200 Wh/kg. Light metals such as lithium and magnesium are the most attractive cations for battery applications with hydroxide being among the most attractive anions. Figure 17.19 shows representative energy densities currently available in various classes of batteries.

The **lead-acid battery** is currently the most widely used rechargeable battery in vehicles. A 12-V lead storage battery consists of six 2.0-V cells (Fig. 17.20) connected in series (cathode to anode) and housed in a hard rubber or plastic case. The anodes in each cell are made of lead grids filled with spongy lead to

**FIGURE 17.19** Ranges of typical energy densities for different classes of batteries.

**FIGURE 17.20** A lead–acid storage battery consists of several cells connected in series. The electrodes are both constructed from lead grids filled with spongy Pb (cathode) and PbO<sub>2</sub> (anode) and the electrolyte is sulfuric acid.

maximize the surface area in contact with the electrolyte; the cathodes are lead grids filled with PbO<sub>2</sub>. The electrolyte is sulfuric acid solution (37% by mass).

Pb is oxidized to Pb<sup>2+</sup> at the anode during discharge, while Pb<sup>4+</sup> in PbO<sub>2</sub> is reduced to Pb<sup>2+</sup> at the cathode; Pb<sup>2+</sup> precipitates as lead sulfate on both electrodes. The half-cell reactions for the galvanic cells are

The anode and cathode have both been largely converted to PbSO<sub>4</sub>(s) when the storage battery is fully discharged, and the concentration of sulfuric acid has fallen, because it is a reactant. Measuring the density of the electrolyte is a quick way to estimate the amount of charge available in the battery because the density of pure sulfuric acid is almost twice the density of water.

The lead–acid battery is recharged by applying a voltage greater than 12 V with the opposite polarity, which returns the battery to its initial state. One of the attractive features of lead–acid batteries is their ability to undergo thousands of charge/discharge cycles before they ultimately fail because PbSO<sub>4</sub> flakes fall off from the electrodes (preventing regeneration of Pb and PbO<sub>2</sub>) or they develop internal short circuits. Lead–acid batteries designed for use in vehicles are not allowed to discharge completely. An alternator driven by the engine charges the battery continuously, or at least intermittently. About  $1.8 \times 10^7$  J can be provided by an average automobile battery before it needs recharging, and currents as large as 100 A are available for the short time needed to start the engine.

A drawback of the lead–acid storage battery is its low energy density, the amount of energy obtainable per kilogram of battery mass. This limitation is not important when a battery is used primarily to start a gasoline-powered automobile, but it precludes the battery's use in vehicles driven by electric motors. The low energy density of the lead–acid battery limits the range of electric vehicles, and it has stimulated electrochemists to develop secondary batteries that have much higher energy densities.

*Lithium-ion batteries* are the most widely used rechargeable batteries for portable electronics and are used in electric cars. They have very high energy densities, due to lithium's low atomic mass, and are much safer than lithium batteries because they do not contain elemental lithium, which is very reactive. The chemistry of the lithium-ion battery is quite interesting, as shown

schematically in Figure 17.21 and summarized by the reactions shown below. Lithium ions shuttle back and forth through an electrolyte between a  $\text{LiCoO}_2$  cathode and a graphite anode represented as  $\text{Li}_y\text{C}_6$  (we represent graphite by the symbol  $\text{C}_6$  to remind you that it is a two-dimensional sheet of benzene rings).

$\text{Li}^+$  ions intercalate (insert) between the atomic planes of these layered structures, and electrons flow through the external circuit to balance charge. Other transition metals are being used in newer versions of this technology, so the general half-cell and the overall cell reactions may be written as:

The simplest way to think of this reaction is to consider what happens when single  $\text{Li}^+$  ions shuttle back and forth. We can represent that situation by the following reactions, with  $\text{M} = \text{Co}$ .

in which an electron occupies an antibonding orbital of one graphite ring to form a (localized) anion for every  $\text{Li}^+$  ion intercalated into graphite. Graphite is oxidized when lithium migrates to the cathode and electrons travel through the external circuit to reduce  $\text{Co(IV)}$  to  $\text{Co(III)}$ .

**FIGURE 17.21** Lithium-ion battery schematic.

Nickel metal hydride (NiMH) batteries have replaced NiCd batteries as the rechargeable battery of choice for consumer applications like flashlights and have also begun to displace lead storage batteries from automotive applications, particularly for hybrid vehicles. The anodes in nickel metal hydride batteries are constructed from a variety of complex rare earth or nickel alloys, the hydrides of which are oxidized at the anode to form the elemental metals. The cathode is  $\text{NiOOH}$  (nickel oxyhydride), at which the nickel is reduced from  $\text{Ni}^{3+}$  to  $\text{Ni}^{2+}$ . The electrolyte is typically  $\text{KOH}$ . The half-cell reactions and overall cell reaction are:

**FIGURE 17.22** Schematic of a sodium-sulfur battery.  $\text{Na}^+$  ions generated by oxidation at the anode also serve to neutralize charge as they migrate through beta-alumina to the cathode.

Another class of interesting batteries with high energy densities uses alkali metals (lithium or sodium) as anodes and sulfur as the electron acceptor. Sulfur does not conduct electricity, so graphite is used as the cathode. These batteries operate at high temperatures because the elements must be liquids for efficient electrical conduction (sulfur melts at  $112^\circ\text{C}$ , lithium at  $186^\circ\text{C}$ , and sodium at  $98^\circ\text{C}$ ). The sodium-sulfur cell (Fig. 17.22), for example, has an optimal operating temperature of  $250^\circ\text{C}$ . The half-cell reactions are

The cathode reaction shown is an oversimplification because sulfide ions react with sulfur to form polysulfides:

but the fundamental principles of the cell operation are the same.

What makes the sodium-sulfur cell possible is a remarkable property of a compound called beta-alumina, which has the composition  $\text{NaAl}_{11}\text{O}_{17}$ . Beta-alumina allows sodium ions to migrate through its structure very easily, but it blocks the passage of polysulfide ions. Therefore, it functions as a semipermeable medium like the membranes used in osmosis (see Section 11.5). This ionic solid electrolyte serves to physically separate the reactants from one another while permitting the transport of the redox-active species  $\text{Na}^+(\text{aq})$ ; the lithium-sulfur battery operates on similar principles.

Sodium-sulfur batteries, with their high energy densities, were originally developed with transportation applications in mind. NiMH batteries have become the current favorite for automotive applications, but the sodium-sulfur battery has found an important application in large-scale energy storage, where the high operating temperatures are less problematic. The city of Presidio, Texas (population ca. 4000), has suffered intermittent power outages over the years because it has been connected to the electric power grid by a single transmission line. The city has recently installed a sodium-sulfur battery that is about the size of a house that will provide up to 4 MW of power for 8 hours, enough to power the entire town overnight. These batteries are also being used in remote locations to store energy generated from wind turbines or photovoltaic systems, making these locations independent of the electric utility grid.

### 17.5.3 Fuel Cells

Fuel cells convert chemical potential energy into electrical energy using coupled redox reactions, like batteries, but they operate as long as they are being supplied with fuel. Batteries carry all of their “fuel” with them and must be replaced or recharged to continue to provide energy. Fuel cells operate using the same oxidation reactions as combustion but are much more efficient, in principle, because different thermodynamic considerations apply. We discuss two classes of fuel cells: polymer electrolyte membrane (PEM) fuel cells that have been developed for transportation and solid oxide fuel cells (SOFC) that are currently the dominant technology for large-scale stationary power generation. We focus on hydrogen fuel cells because of the attractive features they offer, but fuel cells that use methane or methanol as fuels have been developed and may have advantages in certain applications, for example, in areas where natural gas is readily available. However, carbon-based fuels, of course, emit  $\text{CO}_2$  and contribute to climate change (see Section 20.6).

**FIGURE 17.23** Polymer electrolyte membrane (PEM) fuel cell.

The basic components and operation of a PEM fuel cell are shown in Figure 17.23. The hydrogen fuel, entering from the left, is dissociated catalytically and ionized at the anode to produce protons and electrons. The electrons travel through the external circuit, producing work, while the protons move through the membrane toward the cathode. The electrons and protons react catalytically with molecular oxygen at the cathode in a four-electron reduction to produce water.

The overall cell reaction is

with a standard cell potential  $\Delta E_{\text{cell}}^{\circ} = 1.229 \text{ V}$ . The polymer membranes in current use are fluorocarbons (hydrocarbons in which all of the hydrogen atoms have been replaced by fluorine) with sulfonic acid  $-\text{SO}_3\text{H}$  functional groups attached. Protons transfer by hopping between the sulfonic acid side groups, thus moving along and between the polymer chains. The operating temperature of current PEM fuel cells is limited to about  $80^{\circ}\text{C}$  because the polymer membranes must remain hydrated for this proton transfer mechanism to work. Developing alternative membrane materials that transport protons at higher temperatures is an active area of research in materials science and engineering. Increasing the activity and reducing the cost of the oxygen reduction catalysts is also another area of intense current interest. Present generation PEM fuel cells use finely divided Pt nanoparticles supported on carbon substrates. A factor of 10 improvement in oxygen reduction activity has been demonstrated recently by controlling the surface morphology and subsurface electronic structure of platinum nanocrystals that have been alloyed with other metals such as nickel. The surface layer of these particles is pure Pt, which has long been known to be effective at breaking  $\text{O}-\text{O}$  bonds and forming  $\text{O}-\text{H}$  bonds. A subsurface alloy with nominal composition  $\text{PtNi}_3$  alters the electronic structure of the surface layer to make it an even more effective catalyst for oxygen reduction. Collaboration between experimental and computational materials scientists on the development of new catalysts for oxidation–reduction and other important catalytic reactions is a particularly exciting area of current research.

To better understand the attractive characteristics of fuel cells, let's compare the energy available from the hydrogen oxygen PEM fuel cell with that available from the combustion of hydrogen in an internal combustion engine. The relevant reaction for transportation is

because water is produced as a high-temperature exhaust gas. We calculate the maximum work available from combustion as follows:

$$-w_{\max} = \epsilon q_p = (1 - T_l/T_h)q_p$$

where  $\epsilon$  is the Carnot efficiency,  $q_p$  is the heat transferred at constant pressure (supplied to the hot reservoir by the exothermic combustion reaction),  $T_l$  is the temperature of the exhaust gas, and  $T_h$  is the operating temperature of the internal combustion engine. The Carnot efficiency of an internal combustion engine is about 45%, so the maximum theoretical work,  $-w_{\max}$ , available from hydrogen used as a fuel in such an engine is

$$-w_{\max} = (0.4)(241.8 \text{ kJ mol}^{-1}) = +96 \text{ kJ mol}^{-1}$$

Note that we have used the convention in which  $w$  is the work done on the system, so  $-w$ , which has a positive value above, is the work done *on* the surroundings by the engine. The maximum work available if the same reaction is carried out in a fuel cell is  $-w_{\max} = -\Delta G_f^\circ = 228.6 \text{ kJ mol}^{-1}$ , which is more than twice that available, in principle, from the internal combustion engine.  $\Delta G^\circ \approx \Delta H^\circ$  for combustion reactions, so finding ways to capture that energy without suffering the losses imposed by the Carnot efficiency is an important goal. Electric vehicles powered by fuel cells are also significantly more efficient than those powered by internal combustion engines, not only because of the more favorable thermodynamic considerations but also because electric motors are mechanically more efficient than internal combustion engines, the former being about 90% efficient compared with 75% efficiency for the latter. We can compare the so-called “tank-to-wheel” efficiencies of a vehicle powered by a hydrogen fuel cell to one powered by a hydrogen-fueled internal combustion engine by multiplying the work available by the mechanical efficiencies of each engine and taking the ratio.

$$\frac{\text{Overall efficiency fuel cell vehicle}}{\text{Overall efficiency internal combustion engine vehicle}} = \frac{(0.9)(228.6 \text{ kJ mol}^{-1})}{(0.75)(96 \text{ kJ mol}^{-1})} = 2.89$$

The U.S. Department of Energy has been evaluating a fleet of fuel cell vehicles for several years now and reports an average efficiency for the fuel cells in the 53–58% range, which is very close to their target of 60%. (Efficiency is defined as the ratio of the electrical power produced to the heating value of the fuel.) Honda introduced a hydrogen-powered fuel cell car called the FCX Clarity in 2013. Honda reports a tank-to-wheel efficiency of 60%, which is, indeed, about three times higher than that of vehicles powered by internal combustion engines. There are, of course, many practical issues that need to be addressed before vehicles powered by fuel cells are widely deployed, but it is a promising technology and one that clearly illustrates the advantages of capturing chemical energy directly as electrical energy, without the inevitable thermodynamic losses associated with combustion. Electric cars recharged by electricity from solar panels are also a superb option.

Solid oxide fuel cells (SOFC) appear to be the current technology of choice for large-scale stationary power generation, whether to produce backup power for critical applications such as hospitals or for generating power in remote locations that are not served by the electrical power grid. A schematic of an SOFC is shown in Figure 17.24. The electrolytes in these cells are oxide ceramics (see Section 22.2), an important example of which is zirconium oxide ( $\text{ZrO}_2$ ) that has been doped with yttrium oxide,  $\text{Y}_2\text{O}_3$ . Doping replaces some of the  $\text{Zr}^{4+}$  ions with  $\text{Y}^{3+}$  ions, which creates oxide “vacancies” because only three oxide ions per  $\text{Y}^{3+}$  are required for charge neutrality. Oxide ions can move through the lattice at sufficiently high temperatures (1000 °C), which provides

FIGURE 17.24 Solid oxide fuel cell.

a mechanism for ionic conduction. The overall cell reaction for a typical solid oxide fuel cell that uses hydrogen is

when the product is liquid water. The same amount of energy is available from this reaction when the product is steam because the energy stored in the steam is recovered, as it cools to the boiling point, from the enthalpy of condensation, and from cooling the liquid water further to ambient temperatures. The standard cell potentials are similar for both high-temperature and low-temperature products, but the waste heat can be captured in stationary solid oxide fuel cells, unlike those that power vehicles. The intrinsic overall efficiencies of solid oxide fuel cells have been demonstrated to be around 50%, increasing if the steam is used to drive turbines to around 70%, and up to 80% or so if the waste heat is recovered. These systems can be quite large; commercial versions can provide 250 kW to 1 MW of power, which is sufficient for emergency backup at large installations like hospitals.

## 17.6 Corrosion and Corrosion Prevention

The **corrosion** of metals is one of the most significant problems faced by advanced industrial societies (Fig. 17.25). It has been estimated that in the United States alone, the annual cost of corrosion amounts to tens of *billions* of dollars. Effects of corrosion are both visible (the formation of rust on exposed iron surfaces) and invisible (the cracking and resulting loss of strength of metal beneath the surface). The mechanism of corrosion must be understood before processes can be developed for its prevention.

Although corrosion is a serious problem for many metals, we focus on the spontaneous electrochemical reactions of iron. Corrosion can be pictured as a “short-circuited” galvanic cell, in which some regions of the metal surface act as cathodes and others as anodes, and the electric “circuit” is completed by electrons flowing through the iron itself. These electrochemical cells form in

FIGURE 17.25 Rust.

parts of the metal where there are impurities or in regions that are subject to stress. The anode reaction is

Various cathode reactions are possible. In the absence of oxygen (for example, at the bottom of a lake), the corrosion reactions are

These reactions are generally slow and do not cause serious amounts of corrosion. Far more extensive corrosion takes place when the iron is in contact with both oxygen and water. In this case the cathode reaction is

The  $\text{Fe}^{2+}$  ions formed simultaneously at the anode migrate to the cathode, where they are further oxidized by  $\text{O}_2$  to the +3 oxidation state to form rust ( $\text{Fe}_2\text{O}_3 \cdot x\text{H}_2\text{O}$ ), a hydrated form of iron(III) oxide:

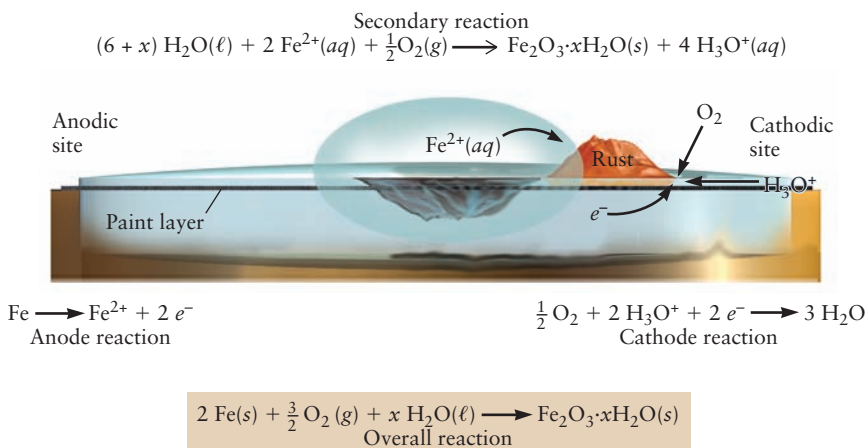

The hydronium ions produced in this reaction allow the corrosion cycle to continue.

When a portion of the paint that protects a piece of iron or steel is chipped off (Fig. 17.26), the exposed area acts as the cathode because it is open to the atmosphere (air and water) and is therefore rich in oxygen, whereas oxygen-poor areas *under* the paint act as anodes. Rust forms on the cathode (the visible, exposed region), and pitting (loss of metal through oxidation of iron and flow of metal ions to the cathode) occurs at the anode. This pitting can lead to loss of structural strength in girders and other supports. The most serious harm done by corrosion is not the visible rusting but the damage done beneath the painted surface.

A number of factors speed corrosion. Dissolved salt provides an electrolyte that improves the flow of charge through solution; a well-known example is the rapid rusting of cars in areas where salt is spread on icy roads. Higher acidity also increases corrosion, as seen by the role of  $\text{H}_3\text{O}^{+}$  as a reactant in the reduction process at the cathode. Acidity is enhanced by the presence of dissolved

FIGURE 17.26 Schematic of iron corrosion. Pitting occurs in the anodic region, and rust appears in the cathodic region. The movement of hydronium ions through the hydrated rust pile is not shown.

CO<sub>2</sub> (which produces H<sub>3</sub>O<sup>+</sup> and HCO<sub>3</sub><sup>-</sup> ions) and by air pollution from oxides of sulfur, which leads to the formation of dissolved sulfuric acid in acid precipitation.

Corrosion of iron can be inhibited in a number of ways. Coatings of paint or plastics obviously protect the metal, but they can crack or suffer other damage, thereby localizing and accentuating the process. An important method of protecting metals arises from the phenomenon of **passivation**, in which a thin metal oxide layer forms on the surface and prevents further electrochemical reactions. Some metals become passivated spontaneously upon exposure to air; aluminum, for example, reacts with oxygen to form a thin protective layer of Al<sub>2</sub>O<sub>3</sub>. Special paints designed to prevent rusting contain potassium dichromate (K<sub>2</sub>Cr<sub>2</sub>O<sub>7</sub>) and lead oxide (Pb<sub>3</sub>O<sub>4</sub>), which cause the superficial oxidation and passivation of iron. Stainless steel is an alloy of iron with chromium in which the chromium leads to passivation and prevents rusting.

A different way of preventing iron corrosion is to use a **sacrificial anode**. A comparison of the standard reduction potentials of iron and magnesium

shows that Mg<sup>2+</sup> is much harder to reduce than Fe<sup>2+</sup> or, conversely, that Mg(s) is more easily oxidized than Fe(s). A piece of magnesium in electrical contact with iron is oxidized in preference to the iron, and the iron is therefore protected. The magnesium is the sacrificial anode, and once it is consumed by oxidation it must be replaced. This method is used to protect ship hulls, bridges, and iron water pipes from corrosion. Magnesium plates are attached at regular intervals along a piece of buried pipe, and it is far easier to replace them periodically than to replace the entire pipe.

## 17.7 Electrometallurgy

**FIGURE 17.27** A specimen of native copper.

© Cengage Learning/Charles D. Winters

The recovery of metals from their sources in the Earth is the science of **extractive metallurgy**, a discipline that draws on chemistry, physics, and engineering for its methods. As a science it is a comparatively recent subject, but its beginnings, which were evidently in the Near East about 6000 years ago, marked the emergence of humanity from the Stone Age. The earliest known metals were undoubtedly gold, silver, and copper because they could be found in their native (elemental) states (Fig. 17.27). Gold and silver were valued for their ornamental uses, but they are too soft to have been made into tools. Iron was also found in elemental form—although rarely—in meteorites.

Most metals in nature are combined with other elements, such as oxygen and sulfur in ores, and chemical processes are required to free them. As Table 17.1 shows, the free energies of formation of most metal oxides are negative, indicating that the reverse reactions, which would yield the free metal and oxygen, have positive free energy changes. Scientists can carry out one of these reverse reactions to obtain the free metal only by coupling it with a second, spontaneous chemical reaction. The greater the cost in free energy, the more difficult the production of the free metal. Thus, silver and gold (at the bottom of Table 17.1) exist in nature as elements, and mercury can be released from its oxide or sulfide ore (cinnabar) merely by moderate heating (see Fig. 1.6). Extracting pure copper, zinc, and iron requires more stringent conditions; the ores of these metals are reduced in chemical reactions at high temperatures, collectively called **pyrometallurgy**. These reactions are carried out in huge furnaces, in which a fuel such as coke (coal from which volatile components have been

TABLE 17.1

Metal Oxides Arranged According to Ease of Reduction

Metal Oxide	Metal	$n^\dagger$	$\Delta G_f^\circ/n^\dagger$ (kJ mol <sup>-1</sup> )	A Method of Production of the Metal
MgO	Mg	2	-285	Electrolysis of MgCl <sub>2</sub>
Al <sub>2</sub> O <sub>3</sub>	Al	6	-264	Electrolysis
TiO <sub>2</sub>	Ti	4	-222	Reaction with Mg

Cr <sub>2</sub> O <sub>3</sub>	Cr	6	-176	Electrolysis, reduction by Al
ZnO	Zn	2	-159	Smelting of ZnS
SnO <sub>2</sub>	Sn	4	-130	Smelting
Fe <sub>2</sub> O <sub>3</sub>	Fe	6	-124	Smelting
NiO	Ni	2	-106	Smelting of nickel sulfides
PbO	Pb	2	-94	Smelting of PbS
CuO	Cu	2	-65	Smelting of CuFeS <sub>2</sub>
HgO	Hg	2	-29	Moderate heating of HgS
Ag <sub>2</sub> O	Ag	2	-6	Found in elemental form
Au <sub>2</sub> O <sub>3</sub>	Au	6	>0	Found in elemental form

<sup>†</sup>The standard free energies of formation of the metal oxides in kJ mol<sup>-1</sup> are adjusted for fair comparison by dividing them by  $n$ , the total decrease in oxidation state required to reduce the metal atoms contained in the oxide to oxidation states of 0. Thus, the reduction of Cr<sub>2</sub>O<sub>3</sub> involves a change in the oxidation state of two chromium atoms from +3 to 0, so  $n = 2 \times 3 = 6$ .

expelled) serves both as the reducing agent and as the source of heat to maintain the required high temperatures. The process, called **smelting**, involves both chemical change and melting. The combustion of carbon

provides the driving force for the overall reaction.

Even smelting is not sufficient to recover the metals at the top of Table 17.1, which have the most negative free energies of formation for their oxides (and for their sulfides as well). These metals have particularly high values of free energy relative to their compounds found in readily available ores. **Electrometallurgy**, or electrolytic production, provides the best ways of recovering such elements from their ores. Electrochemical cells are also used to purify the metals produced by the techniques of pyrometallurgy.

### 17.7.1 Aluminum

Aluminum is the third most abundant element in the Earth's crust (after oxygen and silicon), accounting for 8.2% of the total mass. It occurs most commonly in association with silicon in the aluminosilicates of feldspars and micas and in clays, the products of weathering of these rocks. The most important ore for aluminum production is bauxite, a hydrated aluminum oxide that contains 50% to 60% Al<sub>2</sub>O<sub>3</sub>; 1% to 20% Fe<sub>2</sub>O<sub>3</sub>; 1% to 10% silica; minor concentrations of titanium, zirconium, vanadium, and other transition-metal oxides; and the balance (20% to 30%) water. Bauxite is purified via the **Bayer process**, which takes advantage of the fact that the amphoteric oxide alumina is soluble in strong bases but iron(III) oxide is not. Crude bauxite is dissolved in sodium hydroxide

and separated from hydrated iron oxide and other insoluble impurities by filtration. Pure hydrated aluminum oxide precipitates when the solution is cooled to supersaturation and seeded with crystals of the product:

The water of hydration is removed by calcining at high temperature (1200°C).

Compared with copper, iron, gold, and lead, which were known in antiquity, aluminum is a relative newcomer. Sir Humphry Davy obtained it as an alloy of iron and proved its metallic nature in 1809. It was first prepared in relatively pure form in 1825 by H. C. Oersted through reduction of aluminum chloride with an amalgam of potassium dissolved in mercury

after which the mercury was removed by distillation. Aluminum remained largely a laboratory curiosity until 1886, when Charles Hall in the United States (then a 21-year-old graduate of Oberlin College) and Paul Héroult (a Frenchman of the same age) independently invented an efficient process for its production. In the 1990s the worldwide production of aluminum by the **Hall–Héroult process** was approximately  $1.5 \times 10^7$  metric tons per year.

The Hall–Héroult process involves the cathodic deposition of aluminum, from molten cryolite ( $\text{Na}_3\text{AlF}_6$ ) containing dissolved  $\text{Al}_2\text{O}_3$ , in electrolysis cells (Fig. 17.28). Each cell consists of a rectangular steel box some 6 m long, 2 m wide, and 1 m high, which serves as the cathode, and massive graphite anodes that extend through the roof of the cell into the molten cryolite bath. Enormous currents (50,000 to 100,000 A) are passed through the cell, and as many as one hundred such cells may be connected in series.

Molten cryolite, which is completely dissociated into  $\text{Na}^+$  and  $\text{AlF}_6^{3-}$  ions, is an excellent solvent for aluminum oxide, giving rise to an equilibrium distribution of ions such as  $\text{Al}^{3+}$ ,  $\text{AlF}_2^+$ ,  $\text{AlF}_2^+$ , . . . ,  $\text{AlF}_6^{3-}$ , and  $\text{O}^{2-}$  in the electrolyte. Cryolite melts at 1000°C, but its melting point is lowered by dissolved aluminum oxide, so the operating temperature of the cell is about 950°C. Compared with the melting point of pure  $\text{Al}_2\text{O}_3$  (2050°C), this is a low temperature, and it is the reason the Hall–Héroult process has succeeded. Molten aluminum is somewhat denser than the melt at 950°C and therefore collects at the bottom of the cell, from which it is tapped periodically. Oxygen is the primary anode product, but it reacts with the graphite electrode to produce carbon dioxide. The overall cell reaction is

**FIGURE 17.28** An electrolytic cell used in the Hall–Héroult process for the commercial production of aluminum.

TABLE 17.2

## Densities of Selected Metals

Metal	Density (g cm <sup>-3</sup> ) at Room Conditions
Li	0.534
Na	0.971
Mg	1.738
Al	2.702
Ti	4.54
Zn	7.133
Fe	7.874
Ni	8.902
Cu	8.96
Ag	10.500
Pb	11.35
U	18.95
Au	19.32
Pt	21.45

Aluminum and its alloys have a tremendous variety of applications. Many of these make use of aluminum's low density (Table 17.2), an advantage over iron or steel when weight savings are desirable—such as in the transportation industry, which uses aluminum in vehicles from automobiles to satellites. Aluminum's high electrical conductivity and low density make it useful for electrical transmission lines. For structural and building applications, its resistance to corrosion is an important feature, as is the fact that it becomes stronger at sub-zero temperatures. (Steel and iron sometimes become brittle under these circumstances.) Household products that contain aluminum include foil, soft drink cans, and cooking utensils.

### 17.7.2 Magnesium

Like aluminum, magnesium is an abundant element on the surface of the Earth, but it is not easy to prepare in elemental form. Although ores such as dolomite [CaMg(CO<sub>3</sub>)<sub>2</sub>] and carnallite [KMgCl<sub>3</sub>·6(H<sub>2</sub>O)] exist, the major commercial source of magnesium and its compounds is seawater. Magnesium forms the second most abundant positive ion in the sea, and scientists separate Mg<sup>2+</sup> from the other cations in seawater (Na<sup>+</sup>, Ca<sup>2+</sup>, and K<sup>+</sup>, in particular) by taking advantage of the fact that magnesium hydroxide is the least soluble hydroxide of the group. Economical recovery of magnesium requires a low-cost base to treat large volumes of seawater and efficient methods for separating the Mg(OH)<sub>2</sub>(s) that precipitates from the solution. One base that is used in this way is calcined dolomite, prepared by heating dolomite to high temperatures to drive off carbon dioxide:

The greater solubility of calcium hydroxide ( $K_{\text{sp}} = 5.5 \times 10^{-6}$ ) relative to magnesium hydroxide ( $K_{\text{sp}} = 1.2 \times 10^{-11}$ ) leads to the reaction

The magnesium hydroxide that is produced in this process includes not only the magnesium from the seawater but also that from the dolomite.

An interesting alternative to dolomite as a base for magnesium production is a process used off the coast of Texas (Fig. 17.29). Oyster shells (composed largely of CaCO<sub>3</sub>) are calcined to give lime (CaO), which is added to the seawater to yield magnesium hydroxide. The Mg(OH)<sub>2</sub> slurry (a suspension in water) is washed and filtered in huge nylon filters.

After purification, Mg(OH)<sub>2</sub> can be reacted with carbon dioxide to give magnesium carbonate, used for coating sodium chloride in table salt to prevent caking and for antacid remedies. Another alternative is to add hydrochloric acid to the magnesium hydroxide to neutralize it and yield hydrated magnesium chloride:

After the water is evaporated, the solid magnesium chloride is melted (m.p. 708°C) in a large steel electrolysis cell that holds as much as 10 tons of the molten salt. The steel in the cell acts as the cathode during electrolysis, with graphite anodes suspended from the top. The cell reaction is

The molten magnesium liberated at the cathode floats to the surface and is dipped out periodically, while the chlorine released at the anodes is collected and reacted with steam at high temperatures to produce hydrochloric acid. This is recycled for further reaction with magnesium hydroxide.

**FIGURE 17.29** The production of magnesium hydroxide starts with the addition of lime (CaO) to seawater. Reaction of the magnesium hydroxide with hydrochloric acid produces magnesium chloride, which, after drying, is reduced electrolytically to produce magnesium metal.

Until 1918, elemental magnesium was used mainly in fireworks and flashbulbs, which took advantage of its great reactivity with the oxygen in air and the bright light given off in that reaction (see Fig. 11.11). Since then, many further uses for the metal and its alloys have been developed. Magnesium is even less dense than aluminum and is used in alloys with aluminum to lower density and improve resistance to corrosion under basic conditions. As discussed in Section 17.7, magnesium is used as a sacrificial anode to prevent the oxidation of another metal with which it is in contact. It is also used as a reducing agent to produce other metals such as titanium, uranium, and beryllium from their compounds.

### 17.7.3 Electrorefining and Electroplating

Metals that have been produced by pyrometallurgical methods, such as copper, silver, nickel, and tin, are too impure for many purposes, and **electrorefining** is used to purify them further. Crude metallic copper is cast into slabs, which are used as anodes in electrolysis cells that contain a solution of  $\text{CuSO}_4$  in aqueous  $\text{H}_2\text{SO}_4$ . Thin sheets of pure copper serve as cathodes, and the copper that dissolves at the anodes is deposited in purer form on the cathodes (Fig. 17.30). Impurities that are more easily oxidized than copper, such as nickel, dissolve along with the copper but remain in solution; elements that are less easily oxidized, such as silver and gold, do not dissolve but fall away from the anode as a metallic slime. Periodically, the anode slime and the solution are removed and further processed for recovery of the elements they contain.

A related process is **electroplating**, in which electrolysis is used to plate out a thin layer of a metal on another material, often a second metal. In chrome plating, the piece of metal to be plated is placed in a hot bath of sulfuric acid and chromic acid ( $\text{H}_2\text{CrO}_4$ ) and is made the cathode in an electrolytic cell. As current passes through the cell, chromium is reduced from the +6 oxidation state

**FIGURE 17.30** Electrolytic refining of copper. Many slabs of impure copper (anodes) alternating with thin sheets of pure copper (cathodes) are immersed into a dilute acidic solution of  $\text{CuSO}_4$ . Copper metal oxidized from the impure anodes enters the solution as  $\text{Cu}^{2+}$  ions that migrate to the cathodes where they plate out as copper metal of higher purity.

in chromic acid to elemental chromium and plates out on the cathode. A decorative chromium layer can be as thin as  $2.5 \times 10^{-5}$  cm (corresponding to 2 g of Cr per square meter of surface). Thicker layers ranging up to  $10^{-2}$  cm are found in hard chromium plate, prized for its resistance to wear and used in automobile trim. Steel can be plated with cadmium to improve its resistance to corrosion in marine environments. Gold and silver are used both for decorative plating and (because they are good conductors of electricity) on electronic devices.

#### EXAMPLE 17.14

Suppose a layer of chromium  $3.0 \times 10^{-3}$  cm thick is to be plated onto an automobile bumper with a surface area of  $2.0 \times 10^3$  cm<sup>2</sup>. If a current of 250 A is used, how long must current be passed through the cell to achieve the desired thickness? The density of chromium is  $7.2$  g cm<sup>-3</sup>.

#### Solution

The volume of the Cr is the product of the thickness of the layer and the surface area:

$$\text{volume} = (3.0 \times 10^{-3} \text{ cm})(2.0 \times 10^3 \text{ cm}^2) = 6.0 \text{ cm}^3$$

The mass of chromium is the product of this volume and the density:

$$\text{mass Cr} = (6.0 \text{ cm}^3)(7.2 \text{ g cm}^{-3}) = 43.2 \text{ g}$$

From this, the number of moles of Cr that must be reduced is

$$\frac{43.2 \text{ g}}{52.00 \text{ g mol}^{-1}} = 0.831 \text{ mol Cr}$$

Because Cr is being reduced from oxidation state +6 in  $\text{H}_2\text{CrO}_4$  to 0 in the elemental form, six electrons are required for each atom of Cr deposited. The number of moles of electrons is then

$$0.831 \text{ mol Cr} \times \left( \frac{6 \text{ mol } e^-}{1 \text{ mol Cr}} \right) = 4.98 \text{ mol } e^-$$

$$\text{total magnitude of charge} = (4.98 \text{ mol})(96,485 \text{ C mol}^{-1}) = 4.81 \times 10^5 \text{ C}$$

(Continued)

The required electrolysis time is the total magnitude of charge divided by the current (in amperes):

$$\text{time} = \frac{4.81 \times 10^5 \text{ C}}{250 \text{ C s}^{-1}} = 1.9 \times 10^3 \text{ s} = 32 \text{ min}$$

**Related Problems: 61, 62**

## 17.8 A DEEPER LOOK Electrolysis of Water and Aqueous Solutions

In Section 17.7 we discussed applications of electrolysis in the extraction and purification of metals from their ore sources. We examine here the electrolysis of water and aqueous solutions. Consider first the electrolysis of water using a pair of inert electrodes such as platinum, for which the half-cell reactions are

A practical problem immediately arises. The concentration of  $\text{H}_3\text{O}^+(aq)$  and  $\text{OH}^-(aq)$  ions in pure water at  $25^\circ\text{C}$  is only  $1.0 \times 10^{-7} \text{ M}$ , so the *rate* of electrolysis will be exceedingly small. This practical consideration is put aside for the moment because it does not alter the *thermodynamic* analysis.

The concentration of  $\text{H}_3\text{O}^+$  in pure water at  $25^\circ\text{C}$  is  $1.0 \times 10^{-7} \text{ M}$ , so we must use the Nernst equation to calculate the reduction potentials for each half-reaction as follows:

$$\begin{aligned} E_{\text{cathode}} &= E_{\text{cathode}}^\circ - \frac{0.0592 \text{ V}}{n_{\text{hc}}} \log Q_{\text{hc}} \\ &= 0.00 - \frac{0.0592}{2} \log \frac{P_{\text{H}_2}}{[\text{H}_3\text{O}^+]^2} \end{aligned}$$

If  $\text{H}_2(g)$  is produced at atmospheric pressure, this result simplifies to

$$\begin{aligned} E_{\text{cathode}} &= 0.00 - \frac{0.0592 \text{ V}}{2} \log \frac{1}{(10^{-7})^2} \\ &= -0.414 \text{ V} \end{aligned}$$

The reduction potential for the anode half-reaction

is calculated using the standard reduction potential for that reaction as tabulated in Appendix E:

$$\begin{aligned} E_{\text{anode}} &= E_{\text{anode}}^\circ - \frac{0.0592 \text{ V}}{2} \log \frac{1}{(P_{\text{O}_2})^{1/2} [\text{H}_3\text{O}^+]^2} \\ &= 1.229 \text{ V} - \frac{0.0592 \text{ V}}{2} \log \frac{1}{(10^{-7})^2} \\ &= 0.815 \text{ V} \end{aligned}$$

if  $P_{\text{O}_2} = 1$  atm. The overall cell potential is

$$\Delta E_{\text{cell}} = E_{\text{cathode}} - E_{\text{anode}} = -0.414 - 0.815 \text{ V} = -1.229 \text{ V}$$

so the decomposition of water to produce hydrogen and oxygen does not occur spontaneously. It can be made to occur by applying a potential that is sufficiently large, called the **decomposition potential** of water, which is 1.229 V though practical applications require a larger potential, called an overpotential. Electrolysis of water then produces hydrogen bubbles at the cathode and oxygen bubbles at the anode (see Fig. 1.2).

What happens when we attempt to run electrolysis reactions in aqueous solutions? The products that are produced depend upon the nature of the solutes, their standard reduction potentials, and their concentrations. We could imagine the following reactions occurring in a 0.10 M aqueous solution of NaCl.

Cathode:

Anode:

Let's examine each of these reactions in turn. The reduction potential for the first half-reaction is

$$\begin{aligned} E(\text{Na}^+|\text{Na}) &= E^\circ(\text{Na}^+|\text{Na}) - \frac{0.0592 \text{ V}}{1} \log \frac{1}{[\text{Na}^+]} \\ &= -2.71 - 0.06 = -2.77 \text{ V} \end{aligned}$$

which is more negative than the reduction potential for  $\text{H}_3\text{O}^+$  in pure water:  $E^\circ = -0.414 \text{ V}$ . Hydronium ions are reduced preferentially over sodium ions under these conditions. The reduction potential for the third half-reaction is

$$\begin{aligned} E(\text{Cl}_2|\text{Cl}^-) &= E^\circ(\text{Cl}_2|\text{Cl}^-) - \frac{0.0592 \text{ V}}{1} \log \frac{[\text{Cl}^-]}{P_{\text{Cl}_2}^{1/2}} \\ &= 1.36 + 0.06 = 1.42 \text{ V} \end{aligned}$$

which is more positive than the reduction potential for water under these conditions:  $E^\circ = 0.815 \text{ V}$ .  $\text{Cl}_2$  is more easily reduced than  $\text{O}_2$ , so running this half reaction in reverse at the anode is more difficult than producing  $\text{O}_2(\text{g})$ . Thus,  $\text{O}_2(\text{g})$  is generated at the anode, not  $\text{Cl}_2(\text{g})$ . Increasing the potential above 1.229 V only *increases* the rate of the electrolysis reaction. It is not possible to generate sodium and chlorine electrolytically in aqueous solutions of NaCl.

Suppose now that 0.10 M NaI is substituted for the 0.10 M NaCl solution. Sodium ions still will not be reduced; however,  $E(\text{I}_2|\text{I}^-)$  is

$$\begin{aligned} E(\text{I}_2|\text{I}^-) &= E^\circ(\text{I}_2|\text{I}^-) - \frac{0.0592 \text{ V}}{1} \log [\text{I}^-] \\ &= 0.535 + 0.059 = 0.594 \text{ V} \end{aligned}$$

The iodine reduction potential is more negative than the reduction potential of  $\text{O}_2(\text{g})$  in water at  $\text{pH} = 7$ , so the oxidation of 0.10 M  $\text{I}^-$  occurs in preference to the oxidation of water. The anode reaction is therefore

and the overall cell reaction is

The intrinsic cell voltage is

$$\Delta E_{\text{cell}} = E(\text{cathode}) - E(\text{anode}) = -0.414 - 0.594 = -1.008 \text{ V} < 0$$

$\text{H}_2(\text{g})$  and  $\text{I}_2(\text{s})$  will be generated by applying a potential greater than the decomposition potential of the solution, which is 1.008 V. The concentration of  $\text{I}^-$  begins to decrease as the electrolysis proceeds, making the potential of the  $(\text{I}_2|\text{I}^-)$  couple more positive. When the iodide ion concentration reaches about  $2 \times 10^{-5} \text{ M}$ ,  $E(\text{I}_2|\text{I}^-) = 0.815 \text{ V}$ , the external voltage required to maintain electrolysis would have to be increased to 1.229 V. At this point, water will start to be electrolyzed, and oxygen will be produced at the anode.

Our results for the electrolysis of *neutral* aqueous solutions are summarized as follows:

1. A species can be reduced only if its reduction potential is more positive than  $-0.414 \text{ V}$ .
2. A species can be oxidized only if its reduction potential is less than  $0.815 \text{ V}$ .

In solutions with pH different from 7, these results must be modified, as shown by the following example.

### EXAMPLE 17.15

An aqueous 0.10 M solution of  $\text{NiCl}_2$  is electrolyzed under 1 atm pressure. Determine the products formed at the anode and the cathode and the decomposition potential, if the pH is (a) 7.0; (b) 0.0.

#### Solution

The reduction of  $\text{Ni}^{2+}$  at the cathode has the half-cell potential

$$\begin{aligned} E(\text{Ni}^{2+}|\text{Ni}) &= E^\circ(\text{Ni}^{2+}|\text{Ni}) - \frac{0.0592 \text{ V}}{2} \log \frac{1}{[\text{Ni}^{2+}]} \\ &= -0.23 - 0.03 = -0.26 \text{ V} \end{aligned}$$

and the oxidation of the  $\text{Cl}^-$  at the anode has the *reduction* potential

$$\begin{aligned} E(\text{Cl}_2|\text{Cl}^-) &= E^\circ(\text{Cl}_2|\text{Cl}^-) - \frac{0.0592 \text{ V}}{2} \log \frac{[\text{Cl}^-]}{P_{\text{Cl}_2}^{1/2}} \\ &= 1.36 \text{ V} - (0.0592 \text{ V}) \log 0.2 = 1.40 \text{ V} \end{aligned}$$

(a) In neutral solution the cathode half-reaction is

because  $E(\text{Ni}^{2+}|\text{Ni}) = -0.26 \text{ V} > -0.414 \text{ V}$ . The anode half-reaction is

because  $E(\text{Cl}_2|\text{Cl}^-) = 1.40 \text{ V} > 0.815 \text{ V}$  (the reduction potential for this half-reaction). The cell voltage is

$$\begin{aligned} \Delta E_{\text{cell}} &= E(\text{cathode}) - E(\text{anode}) \\ &= -0.26 - 0.815 \text{ V} = -1.08 \text{ V} \end{aligned}$$

so the decomposition potential is 1.08 V.

(b) In 1.0 M acid solution (pH = 0.0), the anode half-reaction is still

The reduction potential for this reaction is now  $E_{\text{hc}} = E_{\text{hc}}^\circ = 1.229 \text{ V}$ , which is still less than 1.40 V, the reduction potential for the competing reaction involving chlorine.

The cathode half-reaction now becomes

because  $E(\text{H}_3\text{O}^+|\text{H}_2) = 0.0 \text{ V} > -0.26 \text{ V}$  for  $E(\text{Ni}^{2+}|\text{Ni})$ . We now have

$$\begin{aligned} \Delta E_{\text{cell}} &= E(\text{cathode}) - E(\text{anode}) \\ &= 0.00 - 1.229 = -1.229 \text{ V} \end{aligned}$$

so the decomposition potential of the solution is now 1.229 V, just as it is for pure water.

**Related Problems: 63, 64**

## CHAPTER SUMMARY

Electrochemical reactions are an important class of oxidation–reduction (redox) reactions that interconvert chemical and electrical energy. The free energy released in a spontaneous chemical reaction can be used to generate electricity, or electrical energy can be provided from an external source to drive chemical reactions that are not normally spontaneous. The key to this flexibility is the separation of the oxidation and reduction parts of the reaction with the electrons being transferred through an external circuit. The cell potential  $\Delta E_{\text{cell}}$  is simply related to the Gibbs free energy for an electrochemical reaction, providing a quantitative measure of the driving force for the reaction. The cell potential goes to zero for reactions at equilibrium, so the standard cell potential  $\Delta E_{\text{cell}}^{\circ}$  is a direct measure of the equilibrium constant in electrochemical reactions. Standard reduction potentials can be associated with orbital energies and provide a molecular level interpretation of electrochemical reactions and processes. Electrochemical organic synthesis, sensors, and photoelectrochemistry were discussed from this point of view. Electrochemistry is enormously important in many existing technologies such as energy conversion and storage, and large-scale chemical syntheses of commodity chemicals like chlorine. It plays an important role in alternative energy sources such as fuel cells for deployment in transportation and small dedicated power plants. It allows the storage of solar energy in lightweight batteries for electric cars and as chemical energy potentially stored in hydrogen produced by photoelectrochemical water splitting.

## CONCEPTS AND SKILLS

### Section 17.1 – Electrochemical Cells

*Sketch a typical galvanic cell, identify all of its components, specifically the anode and the cathode, write out the oxidation and reduction reactions explicitly, and use the standard shorthand notation to represent the cell (Problems 1–2).*

- There are many possible choices. The sketch in Figure 17.2 could be modified to illustrate any number of cells by substituting different metals and electrolytes in each half-cell. The galvanic cell represented by the notation  $\text{Zn}|\text{Zn}^{2+}||\text{Cu}^{2+}|\text{Cu}$  would have a Zn electrode immersed in a solution of  $\text{Zn}(\text{NO}_3)_2$  in the left-hand beaker and a Cu electrode immersed in a solution of  $\text{Cu}(\text{NO}_3)_2$  in the right-hand beaker. Cu would be the cathode and Zn would be the anode in this cell, with the reactions being

*Use Faraday's laws to calculate the quantities of substances produced or consumed at the electrodes of electrochemical cells in relation to the total charge passing through the circuit (Problems 3–10).*

- The number of moles of a substance that are oxidized or reduced in an electrochemical reaction is proportional to the number of moles of electrons passed through the cell. The magnitude of the charge per mole of electrons is  $96,485 \text{ C mol}^{-1}$  and it is called the Faraday constant,  $F$ .

### Section 17.2 – Cell Potentials and the Gibbs Free Energy

*Explain the relationship between the change in the Gibbs free energy and the electrical work done by the system for a galvanic cell (Problems 11–12).*

- The electrical work is always  $w_{\text{elec}} = \Delta G$  for a cell operated reversibly, which for a galvanic cell is a negative quantity; work is done by the system,

and it is paid for by the decrease in the Gibbs free energy of the system. The change in the Gibbs free energy under standard conditions is calculated from the standard cell potential  $\Delta G^\circ = -nF\Delta E_{\text{cell}}^\circ$ .

*Represent cell reactions as combinations of half-reactions, and calculate standard cell potentials from the standard reduction potentials of the half-reactions (Problems 13–16).*

- Identify the oxidation and reduction half-reactions, and calculate the standard cell potential from the standard reduction potentials using  $\Delta E_{\text{cell}}^\circ = E_{\text{cathode}}^\circ - E_{\text{anode}}^\circ$ .

*Find standard reduction potentials for half-reactions not listed in Appendix E by combining the tabulated half-reactions and their standard reduction potentials (Problems 23–24).*

- Write the half-reaction whose potential is not known in terms of the half-reactions whose potentials are tabulated. If the net half-reaction is calculated by adding a reduction half-reaction with corresponding reduction potential  $E_1^\circ$  to the reverse of another reduction reaction, with reduction potential  $E_2^\circ$ , then the resulting half-reaction has reduction potential  $E_3^\circ = (n_1E_1^\circ - n_2E_2^\circ)/n_3$ .

*Use reduction potential diagrams to determine strengths of oxidizing and reducing agents and stability toward disproportionation (Problems 17–26).*

- Strong oxidizing agents are those that are easily reduced, whereas strong reducing agents are those that are easily oxidized. They are listed near the top and bottom of the table in Appendix E, respectively.
- The tendency for a given species to disproportionate can be determined by a reduction potential diagram that arranges a series of species with the most oxidized form on the left and the most reduced form on the right. Disproportionation will occur when the reduction potential for the reaction that connects a species to one on its right is more positive than the reduction potential that connects it to one on its left.

### Section 17.3 – Concentration Effects and the Nernst Equation

*Apply the Nernst equation to calculate cell potentials for cells in which the reactants and products are not in their standard states, and to calculate equilibrium constants for chemical reactions from cell potentials (Problems 27–38).*

$$\Delta E_{\text{cell}} = \Delta E_{\text{cell}}^\circ - \frac{RT}{nF} \ln Q \quad \text{and} \quad \log_{10} K = \frac{nF}{RT} \Delta E_{\text{cell}}^\circ$$

*Describe the principles that underlie the use of electrochemical cells as pH meters (Problems 39–40).*

- The  $\text{Pt}|\text{H}_2|\text{H}^+$  cell potential depends upon the concentration of  $\text{H}^+(\text{aq})$  in solution. A pH meter measures the half-cell potential of a solution of unknown pH against a reference that is calibrated against the SHE, with the unknown pH being calculated using  $\text{pH} = \frac{\Delta E_{\text{cell}} - \Delta E_{\text{ref}}}{(0.0592 \text{ V})}$ .

*Calculate solubility product constants  $K_{\text{sp}}$  from cell potentials (Problems 41, 42).*

- $K_{\text{sp}}$  is calculated from cell potentials using the Nernst equation, using the same equation presented earlier for calculating equilibrium constants.

### Section 17.4 – Molecular Electrochemistry

*Discuss electrochemical processes from a molecular point of view, considering electron transfer processes between electrodes and redox couples as well as*

between redox couples, and be able to describe the salient features of the examples chosen (Problems 43–50).

- Electrochemical organic synthesis achieves great selectivity by using potential to control the thermodynamic driving forces and kinetics of electrochemical reactions.
- Enzyme-catalyzed reactions coupled to electrochemical cells provide extremely sensitive and selective sensors.
- Light absorbed by semiconductors produces electron-hole pairs that can be used to carry out oxidation–reduction reactions. Dye-sensitized  $\text{TiO}_2$  has been shown to be a promising candidate for generating hydrogen from water using sunlight.

### Section 17.5 – Batteries and Fuel Cells

Discuss the electrochemistry of a primary battery and contrast it with that of a secondary battery and a fuel cell (Problems 51–58).

- Primary batteries cannot be recharged, due to one or more irreversible steps during the discharge reaction, the formation of a gaseous product, or corrosion of one of its components. Reactions in secondary cells can be reversed by applying voltages opposite in sign and greater in magnitude than the galvanic cell potential.

### Section 17.6 – Corrosion and Corrosion Prevention

Discuss the electrochemical corrosion of metals and describe measures that may be used to minimize it (Problems 59–62).

- Electrochemical corrosion of metals refers to the oxidation of the metal and the subsequent dissolution of the ions, resulting in the disintegration of materials. Metals may be protected by painting; by passivating layers such as the native oxides that form on aluminum or the thin layer of protective chromium oxide that forms on stainless steel; or by attaching sacrificial anodes to the material that are preferentially oxidized.

### Section 17.7 – Electrometallurgy

Describe the Hall–Héroult process for the production of aluminum and the methods used to recover magnesium from seawater (Problems 63–64).

Calculate theoretical yields for redox reactions, and the current and time required to produce specified quantities of products in electrometallurgy (Problems 65–68).

- $\text{Al}_2\text{O}_3$  is dissolved in molten cryolite,  $\text{Na}_3\text{AlF}_6$ , and reduced electrolytically to produce molten aluminum. Magnesium is produced from seawater in a multistep process. The mineral dolomite is calcined to drive off  $\text{CO}_2$ , producing  $\text{CaO}\cdot\text{MgO}$ , which reacts with  $\text{Mg}^{2+}$  ions to produce magnesium hydroxide. The hydroxide reacts with  $\text{HCl}$  to produce the chloride, which is reduced electrolytically to produce the metal.
- Use Faraday's laws to relate current to metal deposited in electrorefining and electroplating operations (Problems 69–70).

### Section 17.8 – A Deeper Look . . . Electrolysis of Water and Aqueous Solutions

Predict the products liberated at the anode and cathode of an electrolysis cell with a given aqueous electrolyte composition (Problems 71–72).

- Oxidation and reduction reactions in aqueous solution are limited to a potential window that is set by the oxidation and reduction of water at  $\text{pH} = 7$ . Applied potentials more positive than 0.814 V will oxidize  $\text{OH}^-(aq)$  to  $\text{O}_2$  and potentials more negative than  $-0.414$  V will reduce  $\text{H}^+(aq)$  to  $\text{H}_2$ .

## CUMULATIVE EXERCISE

### Manganese—A Versatile Reagent and Essential Mineral

Manganese is the twelfth-most-abundant element on the Earth's surface (Fig. 17.31). Its most important ore source is pyrolusite ( $\text{MnO}_2$ ). The preparation and uses of manganese and its compounds (which range up to +7 in oxidation state) are intimately bound up with electrochemistry.

- Elemental manganese in a state of high purity can be prepared by electrolyzing aqueous solutions of  $\text{Mn}^{2+}$ . At which electrode (anode or cathode) does the Mn appear? Electrolysis is also used to make  $\text{MnO}_2$  in high purity from  $\text{Mn}^{2+}$  solutions. At which electrode does the  $\text{MnO}_2$  appear?
- The Winkler method is an analytical procedure for determining the amount of oxygen dissolved in water. In the first step,  $\text{Mn(OH)}_2(s)$  is oxidized by gaseous oxygen to  $\text{Mn(OH)}_3(s)$  in basic aqueous solution. Write the oxidation and reduction half-equations for this step, and write the balanced overall equation. Then use Appendix E to calculate the standard voltage that would be measured if this reaction were carried out in an electrochemical cell.
- Calculate the equilibrium constant at  $25^\circ\text{C}$  for the reaction in part (b).
- In the second step of the Winkler method, the  $\text{Mn(OH)}_3$  is acidified to give  $\text{Mn}^{3+}$ , and iodide ion is added. Will  $\text{Mn}^{3+}$  spontaneously oxidize  $\text{I}^-$ ? Write a balanced equation for its reaction with  $\text{I}^-$ , and use data from Appendix E to calculate its equilibrium constant. Titration of the  $\text{I}_2$  produced completes the use of the Winkler method.
- Manganese(IV) is an even stronger oxidizing agent than manganese(III). It oxidizes zinc to  $\text{Zn}^{2+}$  in the dry cell. Such a battery has a cell voltage of 1.5 V. Calculate the electrical work done by this battery in 1.00 hour if it produces a steady current of 0.70 A.
- Calculate the mass of zinc reacting in the process described in part (e).
- The reduction potential of permanganate ion (+7 oxidation state) in acidic aqueous solution is given by

whereas that of the analogous fifth-period species, pertechnetate ion, is

Which is the stronger oxidizing agent, permanganate ion or pertechnetate ion?

- A galvanic cell is made from two half-cells. In the first, a platinum electrode is immersed in a solution at pH 2.00 that is 0.100 M in both  $\text{MnO}_4^-$  and  $\text{Mn}^{2+}$ . In the second, a zinc electrode is immersed in a 0.0100 M solution of  $\text{Zn(NO}_3)_2$ . Calculate the cell voltage that will be measured.

### Answers

- Mn appears at the cathode and  $\text{MnO}_2$  at the anode.

(b)

$$\Delta E^\circ = 0.401 - (-0.40) = 0.80 \text{ V}$$

(c)  $K = 1 \times 10^{54}$

(d)  $\text{Mn}^{3+}$  will spontaneously oxidize  $\text{I}^-$ .

(e)  $3.8 \times 10^3 \text{ J}$

(f) 0.85 g Zn is oxidized.

(g) Permanganate ion

(h) 2.12 V

## PROBLEMS

Answers to problems whose numbers are red appear in Appendix G. Problems that are more challenging are indicated with asterisks.

### 17.1 Electrochemical Cells

- Diagram the following galvanic cell, indicating the direction of flow of electrons in the external circuit and the motion of ions in the salt bridge.

Write a balanced equation for the overall reaction in this cell.

- Diagram the following galvanic cell, indicating the direction of flow of electrons in the external circuit and the motion of ions in the salt bridge.

Write a balanced equation for the overall reaction in this cell.

- A quantity of electricity equal to  $6.95 \times 10^4 \text{ C}$  passes through an electrolytic cell that contains a solution of  $\text{Sn}^{4+}(\text{aq})$  ions. Compute the maximum chemical amount, in moles, of  $\text{Sn}(\text{s})$  that can be deposited at the cathode.
- A quantity of electricity equal to  $9.263 \times 10^4 \text{ C}$  passes through a galvanic cell that has an  $\text{Ni}(\text{s})$  anode. Compute the maximum chemical amount, in moles, of  $\text{Ni}^{2+}(\text{aq})$  that can be released into solution.
- A galvanic cell is constructed that has a zinc anode immersed in a  $\text{Zn}(\text{NO}_3)_2$  solution and a platinum cathode immersed in a  $\text{NaCl}$  solution equilibrated with  $\text{Cl}_2(\text{g})$  at 1 atm and  $25^\circ\text{C}$ . A salt bridge connects the two half-cells.
  - Write a balanced equation for the cell reaction.
  - A steady current of 0.800 A is observed to flow for a period of 25.0 minutes. How much charge passes through the circuit during this time? How many moles of electrons is this charge equivalent to?

- Calculate the change in mass of the zinc electrode.
  - Calculate the volume of gaseous chlorine generated or consumed as a result of the reaction.
- A galvanic cell consists of a cadmium cathode immersed in a  $\text{CdSO}_4$  solution and a zinc anode immersed in a  $\text{ZnSO}_4$  solution. A salt bridge connects the two half-cells.
    - Write a balanced equation for the cell reaction.
    - A current of 1.45 A is observed to flow for a period of 2.60 hours. How much charge passes through the circuit during this time? How many moles of electrons is this charge equivalent to?
    - Calculate the change in mass of the zinc electrode.
    - Calculate the change in mass of the cadmium electrode.
  - An acidic solution containing copper ions is electrolyzed, producing gaseous oxygen (from water) at the anode and copper at the cathode. For every 16.0 g of oxygen generated, 63.5 g of copper plates out. What is the oxidation state of the copper in the solution?
  - Michael Faraday reported that passing electricity through one solution liberated 1 mass of hydrogen at the cathode and 8 masses of oxygen at the anode. The same quantity of electricity liberated 36 masses of chlorine at the anode and 58 masses of tin at the cathode from a second solution. What were the oxidation states of hydrogen, oxygen, chlorine, and tin in these solutions?
  - Liquid potassium chloride,  $\text{KCl}(\ell)$ , is decomposed in an electrolytic cell to form potassium and chlorine. Liquid  $\text{KCl}$  consists of  $\text{K}^+$  and  $\text{Cl}^-$  ions.
    - Write balanced equations for the half-cell reactions at the anode and at the cathode, and for the overall cell reaction.
    - If a current of 2.00 A is passed through the cell for a period of 5.00 hours, calculate the mass of metal deposited and of gas liberated.

10. In the Hall-Héroult process for the electrolytic production of aluminum,  $\text{Al}^{3+}$  ions from  $\text{Al}_2\text{O}_3$  dissolved in molten cryolite ( $\text{Na}_3\text{AlF}_6$ ) are reduced to  $\text{Al}(\ell)$  while carbon (graphite) is oxidized to  $\text{CO}_2$  by reaction with oxide ions.
- Write balanced equations for the half-reactions at the anode and at the cathode, and for the overall cell reaction.
  - If a current of 50,000 A is passed through the cell for a period of 24 hours, what mass of aluminum will be recovered?

## 17.2 Cell Potentials and the Gibbs Free Energy

11. A  $\text{Ni}|\text{Ni}^{2+}||\text{Ag}^+|\text{Ag}$  galvanic cell is constructed in which the standard cell potential is 1.03 V. Calculate the free energy change at 25°C when 1.00 g of silver plates out, if all concentrations remain at their standard value of 1 M throughout the process. What is the maximum electrical work done by the cell on its surroundings during this experiment?
12. A  $\text{Zn}|\text{Zn}^{2+}||\text{Co}^{2+}|\text{Co}$  galvanic cell is constructed in which the standard cell potential is 0.48 V. Calculate the free energy change at 25°C per gram of zinc lost at the anode, if all concentrations remain at their standard value of 1 M throughout the process. What is the maximum electrical work done by the cell on its surroundings during this experiment?
13. A galvanic cell is constructed in which a  $\text{Br}_2|\text{Br}^-$  half-cell is connected to a  $\text{Co}^{2+}|\text{Co}$  half-cell.
- By referring to Appendix E, write balanced chemical equations for the half-reactions at the anode and the cathode and for the overall cell reaction.
  - Calculate the cell potential, assuming that all reactants and products are in their standard states.
14. A galvanic cell is constructed in which a  $\text{Pt}|\text{Fe}^{2+}, \text{Fe}^{3+}$  half-cell is connected to a  $\text{Cd}^{2+}|\text{Cd}$  half-cell.
- Referring to Appendix E, write balanced chemical equations for the half-reactions at the anode and the cathode and for the overall cell reaction.
  - Calculate the cell potential, assuming that all reactants and products are in their standard states.
15. In a galvanic cell, one half-cell consists of a zinc strip dipped into a 1.00 M solution of  $\text{Zn}(\text{NO}_3)_2$ . In the second half-cell, solid indium adsorbed on graphite is in contact with a 1.00 M solution of  $\text{In}(\text{NO}_3)_3$ . Indium is observed to plate out as the galvanic cell operates, and the initial cell potential is measured to be 0.425 V at 25°C.
- Write balanced equations for the half-reactions at the anode and the cathode.
  - Calculate the standard reduction potential of an  $\text{In}^{3+}|\text{In}$  half-cell. Consult Appendix E for the reduction potential of the  $\text{Zn}^{2+}|\text{Zn}$  electrode.
16. In a galvanic cell, one half-cell consists of gaseous chlorine bubbled over a platinum electrode at a pressure of 1.00 atm into a 1.00 M solution of NaCl. The second half-cell has a strip of solid gallium immersed in a 1.00 M  $\text{Ga}(\text{NO}_3)_3$  solution. The initial cell potential is measured to be 1.918 V at 25°C, and as the cell operates, the concentration of chloride ion is observed to increase.
- Write balanced equations for the half-reactions at the anode and the cathode.
  - Calculate the standard reduction potential of a  $\text{Ga}^{3+}|\text{Ga}$  half-cell. Consult Appendix E for the reduction potential of the  $\text{Cl}_2|\text{Cl}^-$  electrode.
17. Would you expect powdered solid aluminum to act as an oxidizing agent or as a reducing agent?
18. Would you expect potassium perchlorate,  $\text{KClO}_4(\text{aq})$ , in a concentrated acidic solution to act as an oxidizing agent or as a reducing agent?
19. Bromine is sometimes used in place of chlorine as a disinfectant in swimming pools. If the effectiveness of a chemical as a disinfectant depends solely on its strength as an oxidizing agent, do you expect bromine to be better or worse than chlorine as a disinfectant, at a given concentration?
20. Many bleaches, including chlorine and its oxides, oxidize dye compounds in cloth. Predict which of the following will be the strongest bleach at a given concentration and pH 0:  $\text{NaClO}_3(\text{aq})$ ,  $\text{NaClO}(\text{aq})$ ,  $\text{Cl}_2(\text{aq})$ . How does the strongest chlorine-containing bleach compare in strength with ozone,  $\text{O}_3(\text{g})$ ?
21. Suppose you have the following reagents available at pH 0, atmospheric pressure, and 1 M concentration:
- $$\text{Co}(\text{s}), \text{Ag}^+(\text{aq}), \text{Cl}^-(\text{aq}), \text{Cr}(\text{s}), \text{BrO}_3^-(\text{aq}), \text{I}_2(\text{s})$$
- Which is the strongest oxidizing agent?
  - Which is the strongest reducing agent?
  - Which reagent will reduce  $\text{Pb}^{2+}(\text{aq})$  while leaving  $\text{Cd}^{2+}(\text{aq})$  unreacted?
22. Suppose you have the following reagents available at pH 0, atmospheric pressure, and 1 M concentration:
- $$\text{Sc}(\text{s}), \text{Hg}_2^{2+}(\text{aq}), \text{Cr}_2\text{O}_7^{2-}(\text{aq}), \text{H}_2\text{O}_2(\text{aq}), \text{Sn}^{2+}(\text{aq}), \text{Ni}(\text{s})$$
- Which is the strongest oxidizing agent?
  - Which is the strongest reducing agent?
  - Which reagent will oxidize  $\text{Fe}(\text{s})$  while leaving  $\text{Cu}(\text{s})$  unreacted?
23. (a) Use the data from Appendix E to calculate the half-cell potential  $E^\circ$  for the half-reaction
- $$\text{Mn}^{3+}(\text{aq}) + 3 e^- \longrightarrow \text{Mn}(\text{s})$$
- (b) Consider the disproportionation reaction
- $$3 \text{Mn}^{2+}(\text{aq}) \rightleftharpoons \text{Mn}(\text{s}) + 2 \text{Mn}^{3+}(\text{aq})$$
- Will  $\text{Mn}^{2+}$  disproportionate in aqueous solution?

24. The following standard reduction potentials have been measured in aqueous solution at 25°C:

- (a) Calculate the half-cell potential for the half-reaction

- (b) Consider the disproportionation reaction

Will  $\text{Tl}^{2+}$  disproportionate in aqueous solution?

25. The following reduction potentials are measured at pH 0:

- (a) Will bromine disproportionate spontaneously in acidic solution?

- (b) Which is the stronger reducing agent at pH 0:  $\text{Br}_2(\ell)$  or  $\text{Br}_2^?$

26. The following reduction potentials are measured at pH 14:

- (a) Will  $\text{ClO}^{-}$  disproportionate spontaneously in basic solution?

- (b) Which is the stronger reducing agent at pH 14:  $\text{ClO}^{-}$  or  $\text{Cl}^{-}$ ?

### 17.3 Concentration Effects and the Nernst Equation

27. A galvanic cell is constructed that carries out the reaction

If the initial concentration of  $\text{Pb}^{2+}(aq)$  is 0.15 M, that of  $\text{Cr}^{2+}(aq)$  is 0.20 M, and that of  $\text{Cr}^{3+}(aq)$  is 0.0030 M, calculate the initial voltage generated by the cell at 25°C.

28. A galvanic cell is constructed that carries out the reaction

If the partial pressure of  $\text{Cl}_2(g)$  is 1.00 atm, the initial concentration of  $\text{Ag}^{+}(aq)$  is 0.25 M, and that of  $\text{Cl}^{-}(aq)$  is 0.016 M, calculate the initial voltage generated by the cell at 25°C.

29. Calculate the reduction potential for a  $\text{Pt}|\text{Cr}^{3+}, \text{Cr}^{2+}$  half-cell in which  $[\text{Cr}^{3+}]$  is 0.15 M and  $[\text{Cr}^{2+}]$  is 0.0019 M.

30. Calculate the reduction potential for an  $\text{I}_2(s)|\text{I}^{-}$  half-cell in which  $[\text{I}^{-}]$  is  $1.5 \times 10^{-6}$  M.

31. An  $\text{I}_2(s)|\text{I}^{-}$  (1.00 M) half-cell is connected to an  $\text{H}_3\text{O}^{+}|\text{H}_2$  (1 atm) half-cell in which the concentration of the hydronium ion is unknown. The measured cell potential is 0.841 V, and the  $\text{I}_2|\text{I}^{-}$  half-cell is the cathode. What is the pH in the  $\text{H}_3\text{O}^{+}|\text{H}_2$  half-cell?

32. A  $\text{Cu}^{2+}(1.00 \text{ M})|\text{Cu}$  half-cell is connected to a  $\text{Br}_2(\ell)|\text{Br}^{-}$  half-cell in which the concentration of bromide ion is unknown. The measured cell potential is 0.963 V, and the  $\text{Cu}^{2+}|\text{Cu}$  half-cell is the anode. What is the bromide ion concentration in the  $\text{Br}_2(\ell)|\text{Br}^{-}$  half-cell?

33. The following reaction occurs in an electrochemical cell:

- (a) Calculate  $\Delta E^{\circ}$  for this cell.

- (b) At pH 0, with  $[\text{Cr}_2\text{O}_7^{2-}] = 0.80 \text{ M}$ ,  $[\text{HClO}_2] = 0.15 \text{ M}$ , and  $[\text{HClO}] = 0.20 \text{ M}$ , the cell potential is found to be 0.15 V. Calculate the concentration of  $\text{Cr}^{3+}(aq)$  in the cell.

34. A galvanic cell is constructed in which the overall reaction is

- (a) Calculate  $\Delta E^{\circ}$  for this cell.

- (b) At pH 0, with  $[\text{Cr}_2\text{O}_7^{2-}] = 1.5 \text{ M}$  and  $[\text{I}^{-}] = 0.40 \text{ M}$ , the cell potential is found to equal 0.87 V. Calculate the concentration of  $\text{Cr}^{3+}(aq)$  in the cell.

35. By using the half-cell potentials in Appendix E, calculate the equilibrium constant at 25°C for the reaction in problem 33. Dichromate ion ( $\text{Cr}_2\text{O}_7^{2-}$ ) is orange, and  $\text{Cr}^{3+}$  is light green in aqueous solution. If 2.00 L of 1.00 M  $\text{HClO}_2$  solution is added to 2.00 L of 0.50 M  $\text{Cr}(\text{NO}_3)_3$  solution, what color will the resulting solution have?

36. By using the half-cell potentials in Appendix E, calculate the equilibrium constant at 25°C for the reaction

If 1.00 L of a 1.00 M  $\text{Au}(\text{NO}_3)_3$  solution is added to 1.00 L of a 1.00 M  $\text{Hg}_2(\text{NO}_3)_2$  solution, calculate the concentrations of  $\text{Hg}^{2+}$ ,  $\text{Hg}_2^{2+}$ , and  $\text{Au}^{3+}$  at equilibrium.

37. The following standard reduction potentials have been determined for the aqueous chemistry of indium:

Calculate the equilibrium constant ( $K$ ) for the disproportionation of  $\text{In}^{+}(aq)$  at 25°C.

38. Use data from Appendix E to compute the equilibrium constant for the reaction

39. A galvanic cell consists of a Pt|H<sub>3</sub>O<sup>+</sup>(1.00 M)|H<sub>2</sub>(g) cathode connected to a Pt|H<sub>3</sub>O<sup>+</sup>(aq)|H<sub>2</sub>(g) anode in which the concentration of H<sub>3</sub>O<sup>+</sup> is unknown but is kept constant by the action of a buffer consisting of a weak acid, HA(0.10 M), mixed with its conjugate base, A<sup>-</sup>(0.10 M). The measured cell potential is ΔE<sub>cell</sub> = 0.150 V at 25°C, with a hydrogen pressure of 1.00 atm at both electrodes. Calculate the pH in the buffer solution, and from it determine the K<sub>a</sub> of the weak acid.

40. In a galvanic cell, the cathode consists of a Ag<sup>+</sup>(1.00 M)|Ag half-cell. The anode is a platinum wire, with hydrogen bubbling over it at 1.00-atm pressure, which is immersed in a buffer solution containing benzoic acid and sodium benzoate. The concentration of benzoic acid (C<sub>6</sub>H<sub>5</sub>COOH) is 0.10 M, and that of benzoate ion (C<sub>6</sub>H<sub>5</sub>COO<sup>-</sup>) is 0.050 M. The overall cell reaction is then

and the measured cell potential is 1.030 V. Calculate the pH in the buffer solution and determine the K<sub>a</sub> of benzoic acid.

41. A galvanic cell is constructed in which the overall reaction is

- (a) Calculate ΔE° for this cell.  
 (b) Silver ions are added until AgBr precipitates at the cathode and [Ag<sup>+</sup>] reaches 0.060 M. The cell potential is then measured to be 1.710 V at pH = 0 and P<sub>H<sub>2</sub></sub> = 1.0 atm. Calculate [Br<sup>-</sup>] under these conditions.  
 (c) Calculate the solubility product constant K<sub>sp</sub> for AgBr.
42. A galvanic cell is constructed in which the overall reaction is
- $$\text{Pb}(s) + 2 \text{H}_3\text{O}^+(aq) \longrightarrow \text{Pb}^{2+}(aq) + \text{H}_2(g) + 2 \text{H}_2\text{O}(\ell)$$
- (a) Calculate ΔE° for this cell.  
 (b) Chloride ions are added until PbCl<sub>2</sub> precipitates at the anode and [Cl<sup>-</sup>] reaches 0.15 M. The cell potential is then measured to be 0.22 V at pH = 0 and P<sub>H<sub>2</sub></sub> = 1.0 atm. Calculate [Pb<sup>2+</sup>] under these conditions.  
 (c) Calculate the solubility product constant K<sub>sp</sub> of PbCl<sub>2</sub>.

## 17.4 Molecular Electrochemistry

43. Sketch and interpret the cyclic voltammogram you expect for the [Ru(NH<sub>3</sub>)<sub>6</sub>]<sup>3+</sup>/[Ru(NH<sub>3</sub>)<sub>6</sub>]<sup>2+</sup> redox couple measured with a Ag/AgCl reference electrode. The standard reduction potential for this system is -0.215 V measured with respect to SCE and the standard reduction potential of the Ag/AgCl reference electrode with respect to SHE is 0.2223 V (see Appendix E).

44. Ferrocene is an organometallic complex that contains iron sandwiched between two five-membered cyclopentadiene rings (C<sub>5</sub>H<sub>5</sub>). Ferrocene methanol, a derivative, is another convenient reference redox couple used in electrochemistry. Sketch and interpret the cyclic voltammogram for the ferrocene methanol couple (Fc<sup>+</sup>/Fc) measured with respect to SHE; the standard redox potential is 0.64 V.

45. What is the wavelength and color of light emitted in an ECL experiment in which the redox potential associated with the HOMO is 1.5 V and that associated with the LUMO is -0.9 V? The experiment is conducted in a non-aqueous solution.

46. Suppose that you were asked to synthesize a molecule for use in ECL that emits light at 520 nm and has a potential associated with the HOMO located at 0.5 V, for compatibility with other requirements in a particular analytical application. What is the redox potential associated with the LUMO?

47. Would n-CdS be a suitable semiconductor for direct photoelectrochemical water splitting? Why or why not? The conduction band lies at about -0.65 V vs NHE and the valence band lies at about 1.75 V vs NHE.

48. The p-GaP semiconductor has a bandgap of 2.3 eV with a conduction band redox potential located at -1.2 V vs SHE. Would this material be suitable for direct photoelectrochemical water splitting? Why or why not?

49. Strontium titanate (SrTiO<sub>3</sub>) is another wide bandgap semiconductor that has been investigated for use in dye-sensitized solar cells. Depending on morphology and pH the conduction band of SrTiO<sub>3</sub> lies around -0.2 V vs. SHE. What energies for the HOMO and LUMO of a sensitizing dye would you specify for electron injection into the conduction band of strontium titanate and for water oxidation by the radical cation formed by photoexcitation?

50. A Grätzel cell is to be designed using strontium titanate as the semiconductor and the iodide/triiodide mediator discussed in the *Connection to Energy: Solar Energy Conversion*. Where should the energy levels of the sensitizer lie for maximum solar-to-electrical conversion efficiency?

## 17.5 Batteries and Fuel Cells

51. Calculate the potential of a lead-acid cell if all reactants and products are in their standard states. What will be the voltage if six such cells are connected in a series?

52. Calculate the standard potential of the zinc-mercuric oxide cell shown in Figure 17.18. (*Hint:* The easiest way to proceed is to calculate ΔG° for the corresponding overall reaction, and then find ΔE° from it.) Take ΔG<sub>f</sub>° [Zn(OH)<sub>2</sub>(s)] = -553.5 kJ mol<sup>-1</sup>.

53. (a) What quantity of charge (in coulombs) is a fully charged 12-V lead–acid storage battery theoretically capable of furnishing if the spongy lead available for reaction at the anodes weighs 10 kg and there is excess  $\text{PbO}_2$ ?  
 (b) What is the theoretical maximum amount of work (in joules) that can be obtained from this battery?
54. (a) What quantity of charge (in coulombs) is a fully charged 1.34-V zinc–mercuric oxide watch battery theoretically capable of furnishing if the mass of  $\text{HgO}$  in the battery is 0.50 g?  
 (b) What is the theoretical maximum amount of work (in joules) that can be obtained from this battery?
55. The concentration of the electrolyte, sulfuric acid, in a lead–acid storage battery diminishes as the battery is discharged. Is a discharged battery recharged by replacing the dilute  $\text{H}_2\text{SO}_4$  with fresh, concentrated  $\text{H}_2\text{SO}_4$ ? Explain.
56. One cold winter morning the temperature is well below  $0^\circ\text{F}$ . In trying to start your car, you run the battery down completely. Several hours later, you return to replace your fouled spark plugs and find that the liquid in the battery has now frozen even though the air temperature is actually a bit higher than it was in the morning. Explain how this can happen.
57. Consider the fuel cell that accomplishes the overall reaction

If the fuel cell operates with 60% efficiency, calculate the amount of electrical work generated per gram of water produced. The gas pressures are constant at 1 atm, and the temperature is  $25^\circ\text{C}$ .

58. Consider the fuel cell that accomplishes the overall reaction

Calculate the maximum electrical work that could be obtained from the conversion of 1.00 mol of  $\text{CO}(\text{g})$  to  $\text{CO}_2(\text{g})$  in such a fuel cell operated with 100% efficiency at  $25^\circ\text{C}$  and with the pressure of each gas equal to 1 atm.

### 17.6 Corrosion and Corrosion Prevention

59. Two half-reactions proposed for the corrosion of iron in the absence of oxygen are

Calculate the standard cell potential generated by a galvanic cell running this pair of half-reactions. Is the overall reaction spontaneous under standard conditions? As the pH falls from 14, will the reaction become spontaneous?

60. In the presence of oxygen, the cathode half-reaction written in the preceding problem is replaced by

but the anode half-reaction is unchanged. Calculate the standard cell potential for *this* pair of reactions operating as a galvanic cell. Is the overall reaction spontaneous under standard conditions? As the water becomes more acidic, does the driving force for the rusting of iron increase or decrease?

61. Could sodium be used as a sacrificial anode to protect the iron hull of a ship?
62. If it is shown that titanium can be used as a sacrificial anode to protect iron, what conclusion can be drawn about the standard reduction potential of its half-reaction?

### 17.7 Electrometallurgy

63. In the Downs process, molten sodium chloride is electrolyzed to produce sodium. A valuable byproduct is chlorine. Write equations representing the processes taking place at the anode and at the cathode in the Downs process.
64. The first element to be prepared by electrolysis was potassium. In 1807, Humphry Davy, then 29 years old, passed an electric current through molten potassium hydroxide ( $\text{KOH}$ ), obtaining liquid potassium at one electrode and water and oxygen at the other. Write equations to represent the processes taking place at the anode and at the cathode.
65. A current of 55,000 A is passed through a series of 100 Hall–Héroult cells for 24 hours. Calculate the maximum theoretical mass of aluminum that can be recovered.
66. A current of 75,000 A is passed through an electrolysis cell containing molten  $\text{MgCl}_2$  for 7.0 days. Calculate the maximum theoretical mass of magnesium that can be recovered.
67. An important use for magnesium is to make titanium. In the Kroll process, magnesium reduces titanium(IV) chloride to elemental titanium in a sealed vessel at  $800^\circ\text{C}$ . Write a balanced chemical equation for this reaction. What mass of magnesium is needed, in theory, to produce 100 kg of titanium from titanium(IV) chloride?
68. Calcium is used to reduce vanadium(V) oxide to elemental vanadium in a sealed steel vessel. Vanadium is used in vanadium steel alloys for jet engines, high-quality knives, and tools. Write a balanced chemical equation for this process. What mass of calcium is needed, in theory, to produce 20.0 kg of vanadium from vanadium(V) oxide?

69. Galvanized steel consists of steel with a thin coating of zinc to reduce corrosion. The zinc can be deposited electrolytically, by making the steel object the cathode and a block of zinc the anode in an electrochemical cell containing a dissolved zinc salt. Suppose a steel garbage can is to be galvanized and requires that a total mass of 7.32 g of zinc be coated to the required thickness. How long should a current of 8.50 A be passed through the cell to achieve this?
70. In the electroplating of a silver spoon, the spoon acts as the cathode and a piece of pure silver as the anode. Both dip into a solution of silver cyanide ( $\text{AgCN}$ ). Suppose that a current of 1.5 A is passed through such a cell for 22 minutes and that the spoon has a surface area of  $16 \text{ cm}^2$ . Calculate the average thickness of the silver layer deposited on the spoon, taking the density of silver to be  $10.5 \text{ g cm}^{-3}$ .

### 17.8 A Deeper Look . . . Electrolysis of Water and Aqueous Solutions

71. An electrolytic cell consists of a pair of inert metallic electrodes in a solution buffered to  $\text{pH} = 5.0$  and containing nickel sulfate ( $\text{NiSO}_4$ ) at a concentration of 1.00 M. A current of 2.00 A is passed through the cell for 10.0 hours.
- What product is formed at the cathode?
  - What is the mass of this product?
  - If the  $\text{pH}$  is changed to  $\text{pH} = 1.0$ , what product will form at the cathode?
72. A 0.100 M neutral aqueous  $\text{CaCl}_2$  solution is electrolyzed using platinum electrodes. A current of 1.50 A passes through the solution for 50.0 hours.
- Write the half-reactions occurring at the anode and at the cathode.
  - What is the decomposition potential?
  - Calculate the mass, in grams, of the product formed at the cathode.

## ADDITIONAL PROBLEMS

73. The drain cleaner Drano consists of aluminum turnings mixed with sodium hydroxide. When it is added to water, the sodium hydroxide dissolves and releases heat. The aluminum reacts with water to generate bubbles of hydrogen and aqueous ions. Write a balanced net ionic equation for this reaction.
74. Sulfur-containing compounds in the air tarnish silver, giving black  $\text{Ag}_2\text{S}$ . A practical method of cleaning tarnished silverware is to place the tarnished item in electrical contact with a piece of zinc and dip both into water containing a small amount of salt. Write balanced half-equations to represent what takes place.
75. A current passed through inert electrodes immersed in an aqueous solution of sodium chlorate produces chlorate ion,  $\text{ClO}_3^-$  (*aq*), at the anode and gaseous hydrogen at the cathode. Given this fact, write a balanced equation for the chemical reaction if gaseous hydrogen and aqueous sodium chlorate are mixed and allowed to react spontaneously until they reach equilibrium.
76. A galvanic cell is constructed by linking a  $\text{Co}^{2+}|\text{Co}(s)$  half-cell to an  $\text{Ag}^+|\text{Ag}(s)$  half-cell through a salt bridge and then connecting the cobalt and silver electrodes through an external circuit. When the circuit is closed, the cell potential is measured to be 1.08 V, and silver is seen to plate out while cobalt dissolves.
- Write the half-reactions that occur at the anode and at the cathode and the balanced overall cell reaction.
  - The cobalt electrode is weighed after 150 minutes of operation and is found to have decreased in mass by 0.36 g. By what amount has the silver electrode increased in mass?
  - What is the average current drawn from the cell during this period?
77. The galvanic cell  $\text{Zn}(s)|\text{Zn}^{2+}(aq)||\text{Ni}^{2+}(aq)|\text{Ni}(s)$  is constructed using a completely immersed zinc electrode that weighs 32.68 g and a nickel electrode immersed in 575 mL of 1.00 M  $\text{Ni}^{2+}(aq)$  solution. A steady current of 0.0715 A is drawn from the cell as the electrons move from the zinc electrode to the nickel electrode.
- Which reactant is the limiting reactant in this cell?
  - How long does it take for the cell to be completely discharged?
  - How much mass has the nickel electrode gained when the cell is completely discharged?
  - What is the concentration of the  $\text{Ni}^{2+}(aq)$  when the cell is completely discharged?
78. A newly discovered bacterium can reduce selenate ion,  $\text{SeO}_4^{2-}$  (*aq*), to elemental selenium,  $\text{Se}(s)$ , in reservoirs. This is significant because the soluble selenate ion is potentially toxic, but elemental selenium is insoluble and harmless. Assume that water is oxidized to oxygen as the selenate ion is reduced. Compute the mass of oxygen produced if all the selenate in a 1012-L reservoir contaminated with  $100 \text{ mg L}^{-1}$  of selenate ion is reduced to selenium.
79. Thomas Edison invented an electric meter that was nothing more than a simple coulometer, a device to measure the amount of electricity passing through a circuit. In this meter, a small, fixed fraction of the total current supplied to a household was passed through an electrolytic cell, plating out zinc at the cathode. Each month the cathode could then be removed and weighed to determine the amount of electricity used. If 0.25% of a household's electricity passed through such a coulometer and the cathode increased in mass by 1.83 g in a month, how many coulombs of electricity were used during that month?

80. The chief chemist of the Brite-Metal Electroplating Co. is required to certify that the rinse solutions that are discharged from the company's tin-plating process into the municipal sewer system contain no more than 10 ppm (parts per million) by mass of  $\text{Sn}^{2+}$ . The chemist devises the following analytical procedure to determine the concentration. At regular intervals, a 100-mL (100-g) sample is withdrawn from the waste stream and acidified to  $\text{pH} = 1.0$ . A starch solution and 10 mL of 0.10 M potassium iodide are added, and a 25.0-mA current is passed through the solution between platinum electrodes. Iodine appears as a product of electrolysis at the anode when the oxidation of  $\text{Sn}^{2+}$  to  $\text{Sn}^{4+}$  is practically complete and signals its presence with the deep blue color of a complex formed with starch. What is the maximum duration of electrolysis to the appearance of the blue color that ensures that the concentration of  $\text{Sn}^{2+}$  does not exceed 10 ppm?
81. Estimate the cost of the electrical energy needed to produce  $1.5 \times 10^{10}$  kg (a year's supply for the world) of aluminum from  $\text{Al}_2\text{O}_3(\text{s})$  if electrical energy costs 10 cents per kilowatt-hour ( $1 \text{ kWh} = 3.6 \text{ MJ} = 3.6 \times 10^6 \text{ J}$ ) and if the cell potential is 5 V.
82. Titanium can be produced by electrolytic reduction from an anhydrous molten salt electrolyte that contains titanium(IV) chloride and a spectator salt that furnishes ions to make the electrolyte conduct electricity. The standard enthalpy of formation of  $\text{TiCl}_4(\ell)$  is  $-750 \text{ kJ mol}^{-1}$ , and the standard entropies of  $\text{TiCl}_4(\ell)$ ,  $\text{Ti}(\text{s})$ , and  $\text{Cl}_2(\text{g})$  are 253, 30, and  $223 \text{ J K}^{-1} \text{ mol}^{-1}$ , respectively. What minimum applied voltage will be necessary at  $100^\circ\text{C}$ ?
83. A half-cell has a graphite electrode immersed in an acidic solution ( $\text{pH} 0$ ) of  $\text{Mn}^{2+}$  (concentration 1.00 M) in contact with solid  $\text{MnO}_2$ . A second half-cell has an acidic solution ( $\text{pH} 0$ ) of  $\text{H}_2\text{O}_2$  (concentration 1.00 M) in contact with a platinum electrode past which gaseous oxygen at a pressure of 1.00 atm is bubbled. The two half-cells are connected to form a galvanic cell.
- (a) Referring to Appendix E, write balanced chemical equations for the half-reactions at the anode and the cathode and for the overall cell reaction.
- (b) Calculate the cell potential.
84. By considering these half-reactions and their standard reduction potentials,

account for the fact that platinum will dissolve in a mixture of hydrochloric acid and nitric acid (*aqua regia*) but will not dissolve in either acid alone.

85. (a) One method to reduce the concentration of unwanted  $\text{Fe}^{3+}(\text{aq})$  in a solution of  $\text{Fe}^{2+}(\text{aq})$  is to drop a piece of metallic iron into the storage container. Write the reaction that removes the  $\text{Fe}^{3+}$ , and compute its standard cell potential.
- (b) Referring to problem 23, suggest a way to remove unwanted  $\text{Mn}^{3+}(\text{aq})$  from solutions of  $\text{Mn}^{2+}(\text{aq})$ .
86. (a) Based only on the standard reduction potentials for the  $\text{Cu}^{2+}|\text{Cu}^+$  and  $\text{I}_2(\text{s})|\text{I}^-$  the half-reactions, would you expect  $\text{Cu}^{2+}(\text{aq})$  to be reduced to  $\text{Cu}^+(\text{aq})$  by  $\text{I}^-(\text{aq})$ ?
- (b) The formation of solid  $\text{CuI}$  plays a role in the interaction between  $\text{Cu}^{2+}(\text{aq})$  and  $\text{I}^-(\text{aq})$ .

Taking into account this added information, do you expect  $\text{Cu}^{2+}$  to be reduced by iodide ion?

87. In some old European churches, the stained-glass windows have so darkened from corrosion and age that hardly any light comes through. Microprobe analysis showed that tiny cracks and defects on the glass surface were enriched in insoluble Mn(III) and Mn(IV) compounds. From Appendix E, suggest a reducing agent and conditions that might successfully convert these compounds to soluble Mn(II) without simultaneously reducing Fe(III) (which gives the glass its colors) to Fe(II). Take  $\text{MnO}_2$  as representative of the insoluble Mn(III) and Mn(IV) compounds.
88. (a) Calculate the half-cell potential for the reaction
- $$\text{O}_2(\text{g}) + 4 \text{H}_3\text{O}^+(\text{aq}) + 4 e^- \longrightarrow 6 \text{H}_2\text{O}(\ell)$$
- at  $\text{pH} 7$  with the oxygen pressure at 1 atm.
- (b) Explain why aeration of solutions of  $\text{I}^-$  leads to their decomposition. Write a balanced equation for the redox reaction that occurs.
- (c) Will the same problem arise with solutions containing  $\text{Br}^-$  or  $\text{Cl}^-$ ? Explain.
- (d) Will decomposition be favored or opposed by increasing acidity?
89. An engineer needs to prepare a galvanic cell that uses the reaction

and generates an initial voltage of 1.50 V. She has 0.010 M  $\text{AgNO}_3(\text{aq})$  and 0.100 M  $\text{Zn}(\text{NO}_3)_2(\text{aq})$  solutions, as well as electrodes of metallic copper and silver, wires, containers, water, and a  $\text{KNO}_3$  salt bridge. Sketch the cell. Clearly indicate the concentrations of all solutions.

90. Consider a galvanic cell for which the anode reaction is

and the cathode reaction is

The measured cell potential is 0.640 V.

- (a) Calculate  $E^\circ$  for the  $\text{VO}^{2+}|\text{V}^{3+}$  half-reaction, using  $E^\circ(\text{Pb}^{2+}|\text{Pb})$  from Appendix E.
- (b) Calculate the equilibrium constant ( $K$ ) at  $25^\circ\text{C}$  for the reaction

91. Suppose we construct a pressure cell in which the gas pressures differ in the two half-cells. Suppose such a cell consists of a  $\text{Cl}_2(0.010 \text{ atm})|\text{Cl}^-(1 \text{ M})$  half-cell connected to a  $\text{Cl}_2(0.50 \text{ atm})|\text{Cl}^-(1 \text{ M})$  half-cell. Determine which half-cell will be the anode, write the overall equation for the reaction, and calculate the cell potential.
92. A student decides to measure the solubility of lead sulfate in water and sets up the electrochemical cell

At  $25^\circ\text{C}$  the student finds the cell potential to be  $0.546 \text{ V}$ , and from Appendix E the student finds

What does he find for the  $K_{\text{sp}}$  of  $\text{PbSO}_4$ ?

93. A wire is fastened across the terminals of the Leclanché cell in Figure 17.17. Indicate the direction of electron flow in the wire.
94. Overcharging a lead–acid storage battery can generate hydrogen. Write a balanced equation to represent the reaction taking place.
95. An ambitious chemist discovers an alloy electrode that is capable of catalytically converting ethanol reversibly to carbon dioxide at  $25^\circ\text{C}$  according to the half-reaction

Believing that this discovery is financially important, the chemist patents its composition and designs a fuel cell that may be represented as

- (a) Write the half-reaction occurring at the cathode.
- (b) Using data from Appendix D, calculate  $\Delta E^\circ$  for the cell at  $25^\circ\text{C}$ .
- (c) What is the  $E^\circ$  value for the ethanol half-cell?
96. Iron or steel is often covered by a thin layer of a second metal to prevent rusting; Tin cans consist of steel covered with tin, and galvanized iron is made by coating iron with a layer of zinc. If the protective layer is broken, however,

iron will rust more readily in a tin can than in galvanized iron. Explain this observation by comparing the half-cell potentials of iron, tin, and zinc.

97. An electrolysis cell contains a solution of  $0.10 \text{ M NiSO}_4$ . The anode and cathode are both strips of Pt foil. Another electrolysis cell contains the same solution, but the electrodes are strips of Ni foil. In each case a current of  $0.10 \text{ A}$  flows through the cell for 10 hours.
- (a) Write a balanced equation for the chemical reaction that occurs at the anode in each cell.
- (b) Calculate the mass, in grams, of the product formed at the anode in each cell. (The product may be a gas, a solid, or an ionic species in solution.)
98. A potential difference of  $2.0 \text{ V}$  is impressed across a pair of inert electrodes (e.g., platinum) that are immersed in a  $0.050 \text{ M}$  aqueous  $\text{KBr}$  solution. What are the products that form at the anode and the cathode?
99. An aqueous solution is simultaneously  $0.10 \text{ M}$  in  $\text{SnCl}_2$  and in  $\text{CoCl}_2$ .
- (a) If the solution is electrolyzed, which metal will appear first?
- (b) At what decomposition potential will that metal first appear?
- (c) As the electrolysis proceeds, the concentration of the metal being reduced will drop and the potential will change. How complete a separation of the metals using electrolysis is theoretically possible? In other words, at the point where the second metal begins to form, what fraction of the first metal is left in solution?
100. A  $55.5\text{-kg}$  slab of crude copper from a smelter has a copper content of  $98.3\%$ . Estimate the time required to purify it electrochemically if it is used as the anode in a cell that has acidic copper(II) sulfate as its electrolyte and a current of  $2.00 \times 10^3 \text{ A}$  is passed through the cell.
101. Sheet iron can be galvanized by passing a direct current through a cell containing a solution of zinc sulfate between a graphite anode and the iron sheet. Zinc plates out on the iron. The process can be made continuous if the iron sheet is a coil that unwinds as it passes through the electrolysis cell and coils up again after it emerges from a rinse bath. Calculate the cost of the electricity required to deposit a  $0.250\text{-mm-thick}$  layer of zinc on both sides of an iron sheet that is  $1.00 \text{ m}$  wide and  $100 \text{ m}$  long, if a current of  $25 \text{ A}$  at a voltage of  $3.5 \text{ V}$  is used and the energy efficiency of the process is  $90\%$ . The cost of electricity is 10 cents per kilowatt–hour ( $1 \text{ kWh} = 3.6 \text{ MJ}$ ). Consult Appendix F for data on zinc.

## CUMULATIVE PROBLEMS

102. A  $1.0 \text{ M}$  solution of  $\text{NaOH}$  is electrolyzed, generating  $\text{O}_2(g)$  at the anode. A current of  $0.15 \text{ A}$  is passed through the cell for 75 minutes. Calculate the volume of (wet) oxygen generated in this period if the temperature is held at  $25^\circ\text{C}$  and the total pressure is  $0.985 \text{ atm}$ . (*Hint:* Use the vapor pressure of water at this temperature from Table 10.3.)
103. Use standard entropies from Appendix D to predict whether the standard potential of the  $\text{Cu}|\text{Cu}^{2+}||\text{Ag}^+|\text{Ag}$  cell (diagrammed in Fig. 17.2) will increase or decrease if the temperature is raised above  $25^\circ\text{C}$ .

104. About 50,000 kJ of electrical energy is required to produce 1.0 kg of Al from its  $\text{Al}(\text{OH})_3$  ore. The major energy cost in recycling aluminum cans is the melting of the aluminum. The enthalpy of fusion of  $\text{Al}(s)$  is  $10.7 \text{ kJ mol}^{-1}$ . Compare the energy cost for making new aluminum with that for recycling.

105. (a) Use the following half-reactions and their reduction potentials to calculate the  $K_{\text{sp}}$  of  $\text{AgBr}$ :

(b) Estimate the solubility of  $\text{AgBr}$  in  $0.10 \text{ M NaBr}(aq)$ .

106. Amounts of iodine dissolved in aqueous solution,  $\text{I}_2(aq)$ , can be determined by titration with thiosulfate ion ( $\text{S}_2\text{O}_3^{2-}$ ). The thiosulfate ion is oxidized to  $\text{S}_4\text{O}_6^{2-}$  while

the iodine is reduced to iodide ion. Starch is used as an indicator because it has a strong blue color in the presence of dissolved iodine.

(a) Write a balanced equation for this reaction.

(b) If  $56.40 \text{ mL}$  of  $0.100 \text{ M S}_2\text{O}_3^{2-}$  solution is used to reach the endpoint of a titration of an unknown amount of iodine, calculate the number of moles of iodine originally present.

(c) Combine the appropriate half-cell potentials from Appendix E with thermodynamic data from Appendix D for the equilibrium

to calculate the equilibrium constant at  $25^\circ\text{C}$  for the reaction in part (a).

# Rates of Chemical and Physical Processes

J. Phys. Chem. C, 2009, 113(25), pp 10913–10920

Scanning tunneling microscope images of dibutyl sulfide adsorbed on a single crystal gold surface, measured at 7 K, 13 K, and 25 K (top row, left to right), with corresponding ball-and-stick models shown in the bottom row. The molecule occupies a single unique site at 7 K, then samples the two lowest energy, nearly equivalent sites at 13 K, and finally rotates freely at 25 K. These “molecular rotors” are being studied to understand how more complex “molecular machines” operate in biological processes and potential applications in nanotechnology are also being explored. This series of images was chosen to illustrate the role of temperature in activating molecular motions and to anticipate the central role it plays in controlling the rates of chemical reactions.

**T**hermodynamics explains *why* chemical reactions occur; minimizing the Gibbs free energy is the driving force toward chemical equilibrium. Thermodynamics provides deep insight into the nature of chemical equilibrium, but it gives no answer to the crucial question of how rapidly that equilibrium is achieved.

Chemical kinetics explains *how* reactions occur by studying their rates and mechanisms. Chemical kinetics explains how the speeds of different chemical reactions vary from explosive rapidity to glacial sluggishness and how slow reactions can be accelerated by materials called catalysts. Chemical kinetics has enormous practical importance because it provides the basis for optimizing conditions to carry out chemical reactions at reasonable speed, under proper control.

The central goal in chemical kinetics is to find the relationship between the rate of a reaction and the amount of reactants present. Once this connection is established, the influence of external conditions—principally the temperature—can be explored. Modern experiments probe how the reaction rate and product branching depend on the vibrational motions and the relative velocity between the colliding molecules.

Nuclear chemistry represents a particularly simple limiting form of kinetics in which unstable nuclei decay with a constant probability during any time interval. Its richness arises from the multiplicity of decay paths that are possible, which arise from the mass-energy relationships that determine nuclear stability.

The interactions between molecules and electromagnetic radiation form the basis of molecular spectroscopy, allowing us to determine the structure of molecules and investigate their vibrational motion and excited electronic states. The absorption of visible and ultraviolet light can result in chemical reactions that are different than those initiated thermally. The role of photo-initiated reactions in the atmosphere and in photosynthesis are discussed.

## Unit Chapters

### CHAPTER 18

Chemical Kinetics

### CHAPTER 19

Nuclear Chemistry

### CHAPTER 20

Molecular Spectroscopy and Photochemistry

## Unit Goals

- To relate the rate of a chemical reaction to the instantaneous concentration(s) of reactants by determining the rate law and the rate constant for the reaction
- To describe the influence of temperature on the reaction rate by measuring the activation energy for the reaction
- To explain the mechanism of a complex reaction by identifying the separate elementary reaction steps through which it proceeds
- To explain the role of catalysts in manipulating reaction rates
- To introduce experiments that probe energy transfer and reaction dynamics at the level of individual collisions between molecules
- To develop an elementary description of the rates of nuclear reactions, emphasizing the half-life of radioactive species
- To survey the applications and consequences of nuclear reactions in medicine, biology, energy production, and the environment
- To introduce and discuss methods and applications of molecular spectroscopy to determining molecular structure, probing the vibrational motion and excited states of molecules, and investigating the importance of reactions initiated by the absorption of light in atmospheric chemistry and in photosynthesis

© Cengage Learning/Charles D. Winters

Powdered chalk (mostly calcium carbonate  $\text{CaCO}_3$ ) reacts rapidly with dilute hydrochloric acid because it has a large total surface area. A stick of chalk has a much smaller surface area, so it reacts much more slowly.

Why do some chemical reactions proceed with lightning speed when others require days, months, or even years to produce detectable amounts of products? How do catalysts increase the rates of chemical reactions? Why do small changes in temperature often have such large effects on the cooking rate of food? How does a study of the rate of a chemical reaction inform us about the way in which molecules combine to form products? All of these questions involve studies of reaction rates, which is the subject of chemical kinetics.

Chemical kinetics is a complex subject, the details of which are not currently as well understood as in chemical thermodynamics. For many reactions the equilibrium constants are known accurately, but the rates and detailed reaction pathways remain poorly understood. This is particularly true of reactions in

which many species participate in the overall process connecting reactants to products. One good example is the reaction

We can measure the equilibrium constant for this reaction easily from the voltage of a galvanic cell, and then calculate from it the equilibrium concentrations that will result from arbitrary initial conditions. It is considerably harder to determine the exact pathway by which the reaction goes from reactants to products. This path certainly does *not* involve the simultaneous collision of five  $\text{Fe}^{2+}$  ions and one  $\text{MnO}_4^{-}$  ion with eight  $\text{H}_3\text{O}^{+}$  ions, because such a collision would be exceedingly rare. Instead, the path proceeds through a series of elementary steps involving two or at most three ions, such as

Other postulated steps take the process to its final products. Some of these steps are slow, and others fast; taken together they constitute the **reaction mechanism**.

The primary goal of chemical kinetics is to deduce the mechanism of a reaction from experimental studies of its rate. For this, we have to measure how the rate depends on the concentrations of the reacting species. This chapter lays out the methods and concepts for measuring and interpreting reaction rates and for identifying the mechanism. We then introduce modern methods to probe the dynamics of the reactions at the molecular level.

## 18.1 Rates of Chemical Reactions

The speed of a reaction depends on many factors. Concentrations of reacting species certainly play a major role in speeding up or slowing down a particular reaction (Fig. 18.1). As we see in Section 18.5, many reaction rates are extremely

**FIGURE 18.1** The rate of reaction of zinc with aqueous sulfuric acid depends on the concentration of the acid. The dilute solution reacts slowly (left), and the more concentrated solution reacts rapidly (right).

**FIGURE 18.2** Steel wool burning in oxygen.

sensitive to temperature. This means that careful control of temperature is critical for quantitative measurements in chemical kinetics. Finally, the rate often depends crucially on the physical forms of the reactants, as shown in the chapter opening photograph. An iron nail oxidizes only very slowly in dry air to iron oxide, but steel wool burns spectacularly in oxygen (Fig. 18.2). Because the quantitative study of heterogeneous reactions—those involving two or more phases, such as a solid and a gas—is difficult, we begin with homogeneous reactions, which take place entirely within the gas phase or solution. In Section 18.8 we turn briefly to some important aspects of heterogeneous reactions.

### 18.1.1 Measuring Reaction Rates

A kinetics experiment measures the rate of change of the concentration of a substance participating in a chemical reaction. How can we experimentally monitor a changing concentration? If the reaction is slow enough, we can let it run for a measured time and then abruptly “quench” (effectively stop) it by rapidly cooling the reaction mixture sufficiently. At that low temperature the composition of the reaction mixture remains constant, so we have time to analyze the mixture for some particular reactant or product. This procedure is not useful for rapid reactions, especially those involving gas mixtures, because they are difficult to cool quickly. An alternative is to probe the concentrations by the absorption of light. Chapter 20 shows that different molecules absorb at different wavelengths. If a wavelength is absorbed by only one particular reactant or product, measuring the amount of light absorbed by the reaction mixture at that wavelength determines the concentration of the absorbing species. A series of such measurements at different times reveals the rate of change of the concentration. Often, a flash of light can also be used to initiate a very fast reaction, whose rate is then tracked by measuring absorption at a particular wavelength.

The average rate of a reaction is analogous to the average speed of a car. If the average position of a car is recorded at two different times, then

$$\text{average speed} = \frac{\text{distance traveled}}{\text{time elapsed}} = \frac{\text{change in location}}{\text{change in time}}$$

In the same way, the **average reaction rate** is obtained by dividing the change in concentration of a product (or the negative of the change in concentration of a reactant) by the time interval over which that change occurs:

$$\text{average reaction rate} = \frac{\text{change in concentration of product}}{\text{change in time}}$$

If concentration is measured in  $\text{mol L}^{-1}$  and time in seconds, then the rate of a reaction has units of  $\text{mol L}^{-1} \text{s}^{-1}$ .

Consider a specific example. In the gas-phase reaction

$\text{NO}_2$  and  $\text{CO}$  are consumed as  $\text{NO}$  and  $\text{CO}_2$  are produced. If a probe can measure the  $\text{NO}$  concentration, the average rate of reaction can be estimated from the ratio of the change in  $\text{NO}$  concentration  $\Delta[\text{NO}]$  to the time interval  $\Delta t$ :

$$\text{average rate} = \frac{\Delta[\text{NO}]}{\Delta t} = \frac{[\text{NO}]_f - [\text{NO}]_i}{t_f - t_i}$$

This estimate depends on the time interval  $\Delta t$  that is selected, because the rate at which  $\text{NO}$  is produced changes with time. Average rates for this reaction can

be calculated for various time periods (see Fig. 18.3), the average rate during the first 50 s being given by

$$\text{average rate} = \frac{\Delta[\text{NO}]}{\Delta t} = \frac{(0.0160 - 0) \text{ mol L}^{-1}}{(50 - 0) \text{ s}} = 3.2 \times 10^{-4} \text{ mol L}^{-1} \text{ s}^{-1}$$

During the second 50 s, the average rate is  $1.6 \times 10^{-4} \text{ mol L}^{-1} \text{ s}^{-1}$ , and during the third 50 s it is  $9.6 \times 10^{-5} \text{ mol L}^{-1} \text{ s}^{-1}$ . Clearly, this reaction slows as it progresses, and its average rate indeed depends on the time interval chosen. Figure 18.3 shows a graphical method for determining average rates. The average rate is the slope of the straight line connecting the concentrations at the initial and final points of a time interval.

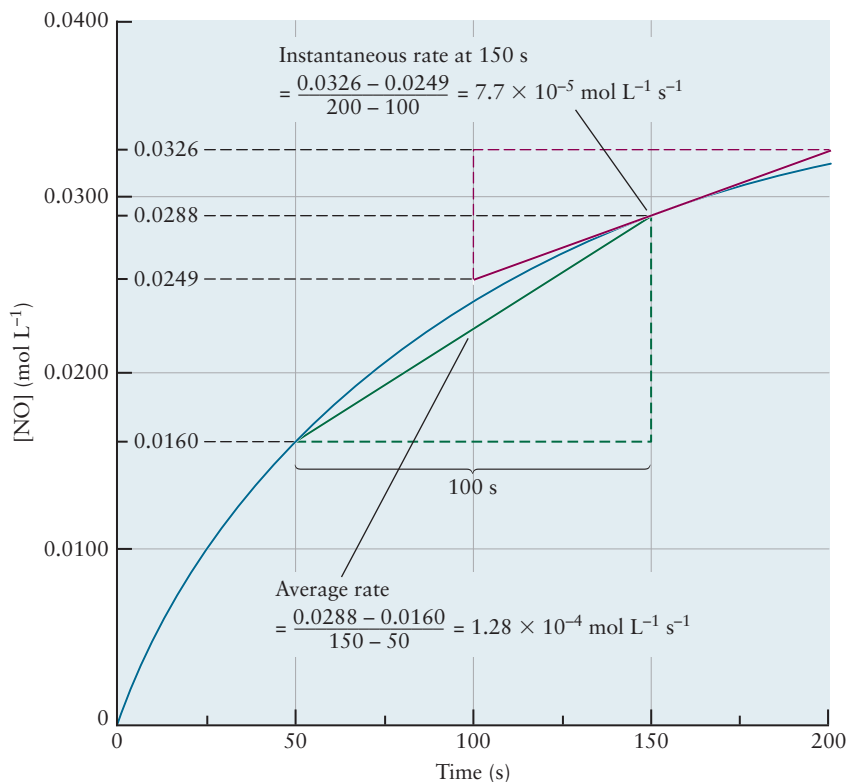

The **instantaneous rate** of a reaction is obtained by considering smaller and smaller time increments  $\Delta t$  (with correspondingly smaller values of  $\Delta[\text{NO}]$ ). As  $\Delta t$  approaches 0, the rate becomes the slope of the line tangent to the curve at time  $t$  (see Fig. 18.3). This slope is written as the derivative of  $[\text{NO}]$  with respect to time:

$$\text{instantaneous rate} = \lim_{\Delta t \rightarrow 0} \frac{[\text{NO}]_{t+\Delta t} - [\text{NO}]_t}{\Delta t} = \frac{d[\text{NO}]}{dt}$$

Throughout the rest of this book, we refer to the instantaneous rate simply as the *rate*. The instantaneous rate of a reaction at the moment that it begins (at  $t = 0$ ) is the **initial rate** of that reaction.

The rate of this sample reaction could just as well have been measured by monitoring changes in the concentration of  $\text{CO}_2$ ,  $\text{NO}_2$ , or  $\text{CO}$  instead of  $\text{NO}$ . Because every molecule of  $\text{NO}$  produced is accompanied by one molecule of  $\text{CO}_2$ , the rate of increase of  $\text{CO}_2$  concentration is the same as that of  $\text{NO}$ . The concentrations of the two reactants,  $\text{NO}_2$  and  $\text{CO}$ , *decrease* at the same rate that

**FIGURE 18.3** A graph of the concentration of  $\text{NO}$  against time in the reaction  $\text{NO}_2 + \text{CO} \longrightarrow \text{NO} + \text{CO}_2$ . The average rate during the time interval from 50 to 150 seconds is obtained by dividing the change in  $\text{NO}$  concentration by the duration of the interval (green box). Note that the average rate (green line) underestimates the true production rate over the time interval. The instantaneous rate 150 seconds after the start of the reaction is found by calculating the slope of the line tangent to the curve at that point (red box).

the concentrations of the products increase, because the coefficients in the balanced equation are also both equal to 1. This is summarized as

$$\text{rate} = -\frac{d[\text{NO}_2]}{dt} = -\frac{d[\text{CO}]}{dt} = \frac{d[\text{NO}]}{dt} = \frac{d[\text{CO}_2]}{dt}$$

Another gas-phase reaction is

This equation states that two molecules of  $\text{NO}_2$  disappear and two molecules of  $\text{NO}_2\text{F}$  appear for each molecule of  $\text{F}_2$  that reacts. Thus, the  $\text{NO}_2$  concentration changes twice as fast as the  $\text{F}_2$  concentration; the  $\text{NO}_2\text{F}$  concentration also changes twice as fast and has the opposite sign. We write the rate in this case as

$$\text{rate} = -\frac{1}{2} \frac{d[\text{NO}_2]}{dt} = -\frac{d[\text{F}_2]}{dt} = \frac{1}{2} \frac{d[\text{NO}_2\text{F}]}{dt}$$

The rate of change of concentration of each species is divided by its coefficient in the balanced chemical equation. Rates of change of reactants appear with negative signs and those of products with positive signs. For the general reaction

the rate is

$$\text{rate} = -\frac{1}{a} \frac{d[\text{A}]}{dt} = -\frac{1}{b} \frac{d[\text{B}]}{dt} = \frac{1}{c} \frac{d[\text{C}]}{dt} = \frac{1}{d} \frac{d[\text{D}]}{dt} \quad [18.1]$$

These relations hold true provided there are no transient intermediate species or, if there are intermediates, their concentrations are independent of time for most of the reaction period.

## 18.2 Rate Laws

In discussing chemical equilibrium we stressed that both forward and reverse reactions can occur; once products are formed, they can react back to give the original reactants. The net rate is the difference:

$$\text{net rate} = \text{forward rate} - \text{reverse rate}$$

Strictly speaking, measurements of concentration give the net rate rather than simply the forward rate. Near the beginning of a reaction that starts from pure reactants the concentrations of reactants are far higher than those of products, and the reverse rate can be neglected. In addition, many reactions go to “completion” ( $K \gg 1$ ). This means they have a measurable rate only in the forward direction, or else the experiment can be arranged so that the products are removed as they are formed. This section focuses on forward rates exclusively.

### 18.2.1 Order of a Reaction

The forward rate of a chemical reaction depends on the concentrations of the reactants. As an example, consider the decomposition of gaseous dinitrogen pentoxide ( $\text{N}_2\text{O}_5$ ). This compound is a white solid that is stable below  $0^\circ\text{C}$  but decomposes when vaporized:

**FIGURE 18.4** The rate of decomposition of  $\text{N}_2\text{O}_5(\text{g})$  at  $25^\circ\text{C}$  is proportional to its concentration. The slope of this line is equal to the rate constant  $k$  for the reaction.

The rate of the reaction depends on the concentration of  $\text{N}_2\text{O}_5(\text{g})$ . Figure 18.4 shows the graph of rate versus concentration to be a straight line that can be extrapolated to pass through the origin. So, the rate can be written

$$\text{rate} = k[\text{N}_2\text{O}_5]$$

This relation between the rate of a reaction and concentration is called an **empirical rate expression** or *rate law*, and the proportionality constant  $k$  is called the **rate constant** for the reaction. Like an equilibrium constant, a rate constant is independent of concentration but depends on temperature, as we describe in Section 18.5.

For many (but not all) reactions with a single reactant, the rate is proportional to the concentration of that reactant raised to a power. That is, the rate expression for

frequently has the form

$$\text{rate} = k[\text{A}]^n$$

It is important to note that the power  $n$  in the rate expression has no direct relation to the coefficient  $a$  in the balanced chemical equation. This number has to be determined experimentally for each rate law. For the decomposition of ethane at high temperatures and low pressures,

the rate expression has the form

$$\text{rate} = k[\text{C}_2\text{H}_6]^2$$

Therefore,  $n = 2$  even though the coefficient in the chemical equation is 1.

The power to which the concentration is raised is called the **order** of the reaction with respect to that reactant. Thus, the decomposition of  $\text{N}_2\text{O}_5$  is a **first-order reaction**, whereas that of  $\text{C}_2\text{H}_6$  is a **second-order reaction**. Some processes are **zeroth-order reactions** over a range of concentrations. Because  $[\text{A}]^0 = 1$ , such reactions have rates that are independent of concentration:

$$\text{rate} = k \quad (\text{for zeroth-order kinetics})$$

The order of a reaction does not have to be an integer; fractional powers are sometimes found. At  $450 \text{ K}$ , the decomposition of acetaldehyde ( $\text{CH}_3\text{CHO}$ ) is described by the rate expression

$$\text{rate} = k[\text{CH}_3\text{CHO}]^{3/2}$$

These examples demonstrate that reaction order is an experimentally determined property that cannot be predicted from the form of the chemical equation.

The following example illustrates how the order of a reaction can be deduced from experimental data.

### EXAMPLE 18.1

At elevated temperatures, HI reacts according to the chemical equation

At  $443^\circ\text{C}$ , the rate of the reaction increases with concentration of HI as follows:

[HI] (mol L <sup>-1</sup> )	0.0050	0.010	0.020
Rate (mol L <sup>-1</sup> s <sup>-1</sup> )	$7.5 \times 10^{-4}$	$3.0 \times 10^{-3}$	$1.2 \times 10^{-2}$

(Continued)

- (a) Determine the order of the reaction and write the rate expression.  
 (b) Calculate the rate constant, and give its units.  
 (c) Calculate the reaction rate for a 0.0020 M concentration of HI.

**Solution**

- (a) The rate expressions at two different concentrations  $[\text{HI}]_1$  and  $[\text{HI}]_2$  are

$$\text{rate}_1 = k([\text{HI}]_1)^n$$

$$\text{rate}_2 = k([\text{HI}]_2)^n$$

After dividing the second equation by the first, the rate constant  $k$  drops out, leaving the reaction order  $n$  as the only unknown quantity.

$$\frac{\text{rate}_2}{\text{rate}_1} = \left( \frac{[\text{HI}]_2}{[\text{HI}]_1} \right)^n$$

We can now substitute any two sets of data into this equation and solve for  $n$ . Taking the first two sets with  $[\text{HI}]_1 = 0.0050 \text{ M}$  and  $[\text{HI}]_2 = 0.010 \text{ M}$  gives

$$\frac{3.0 \times 10^{-3}}{7.5 \times 10^{-4}} = \left( \frac{0.010}{0.0050} \right)^n$$

which simplifies to

$$4 = (2)^n$$

By inspection,  $n = 2$ , so the reaction is second order in HI. When the solution of the equation is less obvious, we can take the logarithms of both sides, giving (in this case)

$$\log_{10} 4 = n \log_{10} 2$$

$$n = \frac{\log_{10} 4}{\log_{10} 2} = \frac{0.602}{0.301} = 2$$

The rate expression has the form

$$\text{rate} = k[\text{HI}]^2$$

- (b) The rate constant  $k$  is calculated by inserting any of the sets of data into the rate expression. Taking the first set gives

$$7.5 \times 10^{-4} \text{ mol L}^{-1} \text{ s}^{-1} = k(0.0050 \text{ mol L}^{-1})^2$$

Solving for  $k$  gives

$$k = 30 \text{ L mol}^{-1} \text{ s}^{-1}$$

- (c) Finally, the rate is calculated for  $[\text{HI}] = 0.0020 \text{ M}$ :

$$\begin{aligned} \text{rate} &= k[\text{HI}]^2 = (30 \text{ L mol}^{-1} \text{ s}^{-1})(0.0020 \text{ mol L}^{-1})^2 \\ &= 1.2 \times 10^{-4} \text{ mol L}^{-1} \text{ s}^{-1} \end{aligned}$$

So far, each example reaction rate has depended only on a single concentration. In reality, many rates depend on the concentrations of two or more different chemical species, and the rate expression is written in a form such as

$$\text{rate} = -\frac{1}{a} \frac{d[\text{A}]}{dt} = k[\text{A}]^m[\text{B}]^n$$

Again the exponents  $m$  and  $n$  do not derive from the coefficients in the balanced equation for the reaction; they must be determined experimentally and are usually integers or half-integers.

The exponents  $m, n, \dots$  give the order of the reaction, just as in the simpler case where only one concentration appeared in the rate expression. The preceding reaction is said to be  $m$ th order in A, meaning that a change in the concentration of A by a certain factor leads to a change in the rate by that factor raised to the  $m$ th power. The reaction is  $n$ th order in B, and the **overall reaction order** is  $m + n$ . For the reaction

the experimentally determined rate expression is

$$\text{rate} = k[\text{H}_2\text{PO}_2^-][\text{OH}^-]^2$$

so the reaction is said to be first order in  $\text{H}_2\text{PO}_2^-(aq)$  and second order in  $\text{OH}^-(aq)$ , with an overall reaction order of 3. The units of  $k$  depend on the reaction order. If all concentrations are expressed in  $\text{mol L}^{-1}$  and if  $p = m + n + \dots$  is the overall reaction order, then  $k$  has units of  $\text{mol}^{-(p-1)} \text{L}^{p-1} \text{s}^{-1}$ .

### EXAMPLE 18.2

Use the preceding rate expression to determine the effect of the following changes on the rate of decomposition of  $\text{H}_2\text{PO}_2^-(aq)$ :

- (a) Tripling the concentration of  $\text{H}_2\text{PO}_2^-(aq)$  at constant pH  
 (b) Changing the pH from 13 to 14 at a constant concentration of  $\text{H}_2\text{PO}_2^-(aq)$

- (b) A change in pH from 13 to 14 corresponds to an increase in the  $\text{OH}^-(aq)$  concentration by a factor of 10. Because the reaction is second order in  $\text{OH}^-(aq)$  (that is, this term is squared in the rate expression), this will increase the reaction rate by a factor of  $10^2$ , or 100.

#### Solution

- (a) Because the reaction is first order in  $\text{H}_2\text{PO}_2^-(aq)$ , tripling this concentration will triple the reaction rate.

**Related Problems: 5, 6**

Rate expressions that depend on more than one concentration are more difficult to obtain experimentally than those that depend just on one. One method is to find the instantaneous initial rates of reaction for several values of one of the concentrations, holding the other initial concentrations fixed from one run to the next. The experiment can then be repeated, changing one of the other concentrations. The following example illustrates this procedure.

### EXAMPLE 18.3

The reaction of  $\text{NO}(g)$  with  $\text{O}_2(g)$  gives  $\text{NO}_2(g)$ :

From the dependence of the initial rate ( $-\frac{1}{2}d[\text{NO}]/dt$ ) on the initial concentrations of NO and  $\text{O}_2$ , determine the rate expression and the value of the rate constant.

[NO] ( $\text{mol L}^{-1}$ )	[O <sub>2</sub> ] ( $\text{mol L}^{-1}$ )	Initial Rate ( $\text{mol L}^{-1} \text{s}^{-1}$ )
$1.0 \times 10^{-4}$	$1.0 \times 10^{-4}$	$2.8 \times 10^{-6}$
$1.0 \times 10^{-4}$	$3.0 \times 10^{-4}$	$8.4 \times 10^{-6}$
$2.0 \times 10^{-4}$	$3.0 \times 10^{-4}$	$3.4 \times 10^{-5}$

(Continued)

**Solution**

When  $[\text{O}_2]$  is multiplied by 3 (with  $[\text{NO}]$  constant), the rate is also multiplied by 3 (from  $2.8 \times 10^{-6}$  to  $8.4 \times 10^{-6}$ ), so the reaction is first order in  $\text{O}_2$ . When  $[\text{NO}]$  is multiplied by 2 (with  $[\text{O}_2]$  constant), the rate is multiplied by

$$\frac{3.4 \times 10^{-5}}{8.4 \times 10^{-6}} \approx 4 = 2^2$$

so the reaction is second order in  $\text{NO}$ . Thus, the form of the rate expression is

$$\text{rate} = k[\text{O}_2][\text{NO}]^2$$

To evaluate  $k$ , we insert any set of data into the equation. From the first set,

$$2.8 \times 10^{-6} \text{ mol L}^{-1} \text{ s}^{-1} = k(1.0 \times 10^{-4} \text{ mol L}^{-1})(1.0 \times 10^{-4} \text{ mol L}^{-1})^2$$

$$k = 2.8 \times 10^6 \text{ L}^2 \text{ mol}^{-2} \text{ s}^{-1}$$

**Related Problems: 7, 8**

## 18.2.2 Integrated Rate Laws

Measuring an initial rate involves determining small changes in concentration  $\Delta[A]$  that occur during a short time interval  $\Delta t$ . Sometimes it can be difficult to obtain sufficiently precise experimental data for these small changes. An alternative is to use an **integrated rate law**, which expresses the concentration of a species directly as a function of the time. For any simple rate expression, a corresponding integrated rate law can be obtained.

### First-Order Reactions

Consider again the reaction

whose rate law has been determined experimentally to be

$$\text{rate} = -\frac{d[\text{N}_2\text{O}_5]}{dt} = k[\text{N}_2\text{O}_5]$$

This is a first-order reaction. If we let  $[\text{N}_2\text{O}_5] = c$ , a function of time, we have

$$\frac{dc}{dt} = -kc$$

We seek a function whose slope at every time is proportional to the value of the function itself. This function can be found through the use of calculus. Separating the variables (with concentration  $c$  on the left and time  $t$  on the right) gives

$$\frac{1}{c} dc = -k dt$$

Integrating from an initial concentration  $c_0$  at time  $t = 0$  to a concentration  $c$  at time  $t$  (see Appendix C, Section C.5) gives

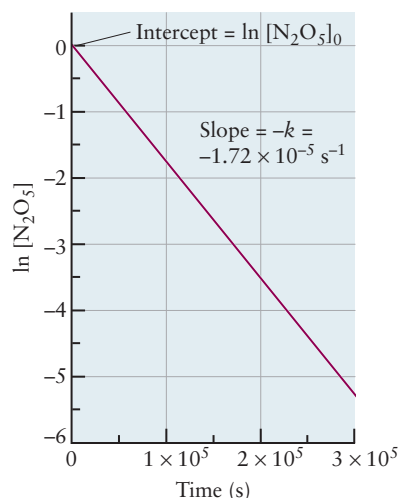

$$\int_{c_0}^c \frac{1}{c} dc = -k \int_0^t dt$$

$$\ln c - \ln c_0 = -kt$$

$$\ln(c/c_0) = -kt$$

$$c = c_0 e^{-kt}$$

[18.2]

**FIGURE 18.5** In a first-order reaction such as the decomposition of  $\text{N}_2\text{O}_5$ , a graph of the natural logarithm of the concentration against time is a straight line, whose negative slope gives the rate constant for the reaction.

**FIGURE 18.6** The same data as in Figure 18.5 are graphed in a concentration-versus-time picture. The half-life  $t_{1/2}$  is the time it takes for the concentration to be reduced to half its initial value. In two half-lives, the concentration falls to one quarter of its initial value.

The concentration falls off exponentially with time. For a first-order reaction, a plot of  $\ln c$  against  $t$  is a straight line with slope  $-k$  (Fig. 18.5).

A useful concept in discussions of first-order reactions is the **half-life**  $t_{1/2}$  which is defined as the time it takes for the original concentration  $c_0$  to be reduced to half its value,  $c_0/2$ . Setting  $c = c_0/2$  at time  $t = t_{1/2}$  in Equation 18.2 gives

$$\ln \left( \frac{c_0/2}{c_0} \right) = -\ln 2 = -kt_{1/2}$$

$$t_{1/2} = \frac{\ln 2}{k} = \frac{0.6931}{k} \quad [18.3]$$

If  $k$  has units of  $\text{s}^{-1}$ ,  $(\ln 2)/k$  is the half-life in seconds. During each half-life, the concentration of A falls to half its value (at the start of that time interval) again (Fig. 18.6).

#### EXAMPLE 18.4

- (a) What is the rate constant  $k$  for the first-order decomposition of  $\text{N}_2\text{O}_5(\text{g})$  at  $25^\circ\text{C}$  if the half-life of  $\text{N}_2\text{O}_5(\text{g})$  at that temperature is  $4.03 \times 10^4 \text{ s}$ ?
- (b) What percentage of the  $\text{N}_2\text{O}_5$  molecules will *not* have reacted after one day?

#### Solution

(a) 
$$t_{1/2} = \frac{\ln 2}{k} = 4.03 \times 10^4 \text{ s}$$

Solving for the rate constant  $k$  gives

$$k = \frac{\ln 2}{t_{1/2}} = \frac{0.6931}{4.03 \times 10^4 \text{ s}} = 1.72 \times 10^{-5} \text{ s}^{-1}$$

- (b) From the integrated rate law for a first-order reaction,

$$\frac{c}{c_0} = e^{-kt}$$

Putting in the value for  $k$  and setting  $t$  to 1 day =  $8.64 \times 10^4 \text{ s}$  gives

$$\begin{aligned} \frac{c}{c_0} &= \exp [-(1.72 \times 10^{-5} \text{ s}^{-1})(8.64 \times 10^4 \text{ s})] \\ &= e^{-1.49} = 0.226 \end{aligned}$$

Therefore, 22.6% of the molecules will not yet have reacted after one day.

**Related Problems: 11, 12**

### Second-Order Reactions

Integrated rate laws can be obtained for reactions of other orders. The observed rate of the reaction

is second order in  $[\text{NO}_2]$ :

$$\text{rate} = -\frac{1}{2} \frac{d[\text{NO}_2]}{dt} = k[\text{NO}_2]^2$$

Writing  $[\text{NO}_2] = c$  and multiplying both sides of the equation by  $-1$  gives

$$\frac{dc}{dt} = -2kc^2$$

$$\frac{1}{c^2} dc = -2k dt$$

Integrating this from the initial concentration  $c_0$  at time 0 to  $c$  at time  $t$  gives

$$\int_{c_0}^c \frac{1}{c^2} dc = -2k \int_0^t dt$$

$$-\frac{1}{c} + \frac{1}{c_0} = -2kt$$

$$\frac{1}{c} = \frac{1}{c_0} + 2kt \quad [18.4]$$

For such a second-order reaction, a plot of  $1/c$  against  $t$  is linear (Fig. 18.7). The factor 2 multiplying  $kt$  in this expression arises from the stoichiometric coefficient 2 for  $\text{NO}_2$  in the balanced equation for the specific example reaction. For other second-order reactions with different stoichiometric coefficients for the reactant (see the thermal decomposition of ethane described on page 759), we must modify the integrated rate law accordingly.

The concept of half-life has little use for second-order reactions. Setting  $[\text{NO}_2]$  equal to  $[\text{NO}_2]_0/2$  in the preceding equation and solving for  $t$  gives

$$\frac{2}{[\text{NO}_2]_0} = 2kt_{1/2} + \frac{1}{[\text{NO}_2]_0}$$

$$t_{1/2} = \frac{1}{2k[\text{NO}_2]_0}$$

**FIGURE 18.7** For a second-order reaction such as  $2 \text{NO}_2 \longrightarrow 2 \text{NO} + \text{O}_2$ , a graph of the reciprocal of the concentration against time is a straight line with slope  $2k$ .

For second-order reactions, the half-life is not a constant; it depends on the initial concentration.

### EXAMPLE 18.5

The dimerization of tetrafluoroethene ( $C_2F_4$ ) to octafluorocyclobutane ( $C_4F_8$ ) is second order in the reactant  $C_2F_4$ , and at 450 K its rate constant is  $k = 0.0448 \text{ L mol}^{-1} \text{ s}^{-1}$ . If the initial concentration of  $C_2F_4$  is  $0.100 \text{ mol L}^{-1}$ , what will its concentration be after 205 s?

#### Solution

For this second-order reaction,

$$\frac{1}{c} - \frac{1}{c_0} = 2kt$$

Solving for the concentration  $c$  after a time  $t = 205 \text{ s}$  gives

$$\frac{1}{c} = (2)(0.0448 \text{ L mol}^{-1} \text{ s}^{-1})(205 \text{ s}) + \frac{1}{0.100 \text{ mol L}^{-1}} = 28.4 \text{ L mol}^{-1}$$

$$c = 3.52 \times 10^{-2} \text{ mol L}^{-1}$$

**Related Problems:** 15, 16

Empirical rate laws are established in two ways: by measuring the dependence of initial rates on the concentrations of each reactant and by plotting the concentration as a function of time, as illustrated earlier. It is often the case that rate laws cannot be definitively established by one concentration–time plot alone and is helpful to plot the data in several ways to choose the best fit, as shown in Figure 18.8. You may use this approach in one of your undergraduate laboratories. Determining the order of a reaction in more complicated cases requires sophisticated data analysis using specialized computer codes designed for chemical kinetics.

**FIGURE 18.8** For the reaction in Example 18.5, (a) plotting the logarithm of the concentration of  $C_2F_4$  against time tests for first-order kinetics and (b) plotting the reciprocal of the concentration of  $C_2F_4$  against time tests for second-order kinetics. It is clear that the assumption of first-order kinetics does not fit the data as well; no straight line will pass through the data.

## 18.3 Reaction Mechanisms

Many reactions do not occur in a single step, but rather proceed through a sequence of steps to arrive at the products. Each step is called an **elementary reaction** and occurs through the collisions of atoms, ions, or molecules, as discussed in Section 9.7. The rate expression for an overall reaction cannot be derived from the stoichiometry of the balanced equation, and must be determined experimentally. But the rate of an *elementary* reaction is directly proportional to the product of the concentrations of the reacting species, each raised to a power equal to its coefficient in the balanced elementary equation.

### 18.3.1 Elementary Reactions

A **unimolecular reaction** is an elementary reaction that involves only a single reactant molecule. An example is the dissociation of energized  $\text{N}_2\text{O}_5$  molecules in the gas phase:

The asterisk indicates that the  $\text{N}_2\text{O}_5$  molecules have far more than average thermal energy. This step is unimolecular and has the rate expression

$$\text{rate} = k[\text{N}_2\text{O}_5^*]$$

An important class of unimolecular reactions is the decay of radioactive nuclei, considered in Chapter 19.

The most common type of elementary reaction involves the collision of two atoms, ions, or molecules and is called a **bimolecular reaction**. An example is the reaction

The frequency at which a given NO molecule collides with ozone molecules is proportional to the concentration of ozone: If there are twice as many ozone molecules per unit volume, each NO molecule will undergo twice as many collisions per unit time with ozone as it moves through space, and NO will react twice as rapidly. The rate of collisions of *all* the NO molecules in the container is proportional to the concentration of NO as well, so the rate law of a bimolecular reaction like this one has the form

$$\text{rate} = k[\text{NO}][\text{O}_3]$$

A **termolecular reaction** step involves the simultaneous collision of three molecules, which is a much less likely event. An example is the recombination of iodine atoms in the gas phase to form iodine molecules. So much energy is released in forming the I–I bond that the molecule would simply fly apart as soon as it was formed if the event were a binary collision. A third atom or molecule is necessary to take away some of the excess energy. If iodine recombination takes place in the presence of a sufficiently high concentration of an inert gas such as argon, termolecular reactions

occur in which the argon atom leaves with more kinetic energy than it had initially. The rate law for this termolecular reaction is

$$\text{rate} = k[\text{I}]^2[\text{Ar}]$$

Elementary reactions involving collisions of four or more molecules are not observed, and even termolecular collisions are rare if other pathways are possible.

Elementary reactions in liquid solvents involve encounters of solute species with one another. If the solution is ideal, the rates of these processes are proportional to the product of the concentrations of the solute species involved. Solvent molecules are always present and may affect the reaction, even though they do not appear in the rate expression because the solvent concentration cannot be varied appreciably. A reaction such as the recombination of iodine atoms occurs readily in a liquid. It appears to be second order with rate law

$$\text{rate} = k[\text{I}]^2$$

only because the third bodies involved are solvent molecules, with constant concentrations. In the same way, a reaction between a solvent molecule and a solute molecule appears to be unimolecular, and only the concentration of solute molecules enters the rate expression for that step.

### 18.3.2 Reaction Mechanisms

A **reaction mechanism** is a detailed sequence of elementary reactions, with their rates, that are combined to yield the overall reaction. It is often possible to write several reaction mechanisms, each of which is consistent with a given overall reaction. One of the goals of chemical kinetics is to use the observed rate of a reaction to choose among various conceivable reaction mechanisms.

The gas-phase reaction of nitrogen dioxide with carbon monoxide provides a good example of a reaction mechanism. The generally accepted mechanism at low temperatures has two steps, both bimolecular:

For any reaction mechanism, combining the steps must give the overall reaction. When each elementary step occurs the same number of times in the course of the reaction, the chemical equations can simply be added. (If one step occurs twice as often as the others, it must be multiplied by 2 before the elementary reactions are added.) In this case, we add the two chemical equations to give

Canceling out the  $\text{NO}_3$  and one molecule of  $\text{NO}_2$  from each side leads to

A **reaction intermediate** (here,  $\text{NO}_3$ ) is a chemical species that is formed and consumed in the reaction but does not appear in the overall balanced chemical equation. One of the major challenges in chemical kinetics is to identify intermediates, which are often so short-lived that they are difficult to detect directly. Modern experimental methods to study highly reactive intermediates are discussed in Section 18.6.4.

#### EXAMPLE 18.6

Consider the following reaction mechanism:

(Continued)

- (a) What is the molecularity of each elementary step?  
 (b) Write the overall equation for the reaction.  
 (c) Identify the reaction intermediate(s).

**Solution**

(a) The first step is unimolecular, and the other two are bimolecular. (Note the  $\text{CCl}_4$  product of the third reaction would have to undergo collisions with an inert molecule to lose some of its energy; it is assumed that those inert collision partners are in high concentrations.)

(b) Adding the three steps gives

The two species that appear in equal amounts on both sides cancel out to leave

(c) The two reaction intermediates are  $\text{Cl}$  and  $\text{CCl}_3$ .

**Related Problems: 21, 22****18.3.3 Kinetics and Chemical Equilibrium**

There is a direct connection between the rates for the elementary steps in a chemical reaction mechanism and the overall equilibrium constant  $K$ . To see this connection, consider the reaction

This reaction is believed to occur in a three-step process involving  $\text{N}_2\text{O}_2$  and  $\text{N}_2\text{O}$  as intermediates:

These elementary reactions are shown as equilibria, so the reverse reactions (from products to reactants) are included here as well;  $k_1$ ,  $k_2$ , and  $k_3$  are the rate constants for the forward elementary steps, and  $k_{-1}$ ,  $k_{-2}$ , and  $k_{-3}$  are the rate constants for the corresponding reverse reactions.

We now invoke the **principle of detailed balance**, which states that at equilibrium the rate of *each* elementary process is balanced by (equal to) the rate of its reverse process. For the preceding mechanism we conclude that

$$\begin{aligned} k_1[\text{NO}]_{\text{eq}}^2 &= k_{-1}[\text{N}_2\text{O}_2]_{\text{eq}} \\ k_2[\text{N}_2\text{O}_2]_{\text{eq}}[\text{H}_2]_{\text{eq}} &= k_{-2}[\text{N}_2\text{O}]_{\text{eq}}[\text{H}_2\text{O}]_{\text{eq}} \\ k_3[\text{N}_2\text{O}]_{\text{eq}}[\text{H}_2]_{\text{eq}} &= k_{-3}[\text{N}_2]_{\text{eq}}[\text{H}_2\text{O}]_{\text{eq}} \end{aligned}$$

The equilibrium constants<sup>1</sup>  $K_1$ ,  $K_2$ , and  $K_3$  for the elementary reactions are equal to the ratio of the forward and reverse reaction rate constants:

$$K_1 = \frac{[\text{N}_2\text{O}_2]_{\text{eq}}}{[\text{NO}]_{\text{eq}}^2} = \frac{k_1}{k_{-1}}$$

$$K_2 = \frac{[\text{N}_2\text{O}]_{\text{eq}}[\text{H}_2\text{O}]_{\text{eq}}}{[\text{N}_2\text{O}_2]_{\text{eq}}[\text{H}_2]_{\text{eq}}} = \frac{k_2}{k_{-2}}$$

$$K_3 = \frac{[\text{N}_2]_{\text{eq}}[\text{H}_2\text{O}]_{\text{eq}}}{[\text{N}_2\text{O}]_{\text{eq}}[\text{H}_2]_{\text{eq}}} = \frac{k_3}{k_{-3}}$$

The steps of the mechanism are now added together to obtain the overall reaction. Recall from Section 14.4 that when reactions are added, their equilibrium constants are multiplied. Therefore, the overall equilibrium constant  $K$  is

$$K = K_1K_2K_3 = \frac{k_1k_2k_3}{k_{-1}k_{-2}k_{-3}} = \frac{[\text{N}_2\text{O}_2]_{\text{eq}}[\text{N}_2\text{O}]_{\text{eq}}[\text{H}_2\text{O}]_{\text{eq}}[\text{N}_2]_{\text{eq}}[\text{H}_2\text{O}]_{\text{eq}}}{[\text{NO}]_{\text{eq}}^2[\text{N}_2\text{O}_2]_{\text{eq}}[\text{H}_2]_{\text{eq}}[\text{N}_2\text{O}]_{\text{eq}}[\text{H}_2]_{\text{eq}}}$$

$$= \frac{[\text{H}_2\text{O}]_{\text{eq}}^2[\text{N}_2]_{\text{eq}}}{[\text{NO}]_{\text{eq}}^2[\text{H}_2]_{\text{eq}}}$$

The concentrations of the intermediates  $\text{N}_2\text{O}_2$  and  $\text{N}_2\text{O}$  cancel out, giving the usual expression of the mass-action law.

This result can be generalized to any reaction mechanism. The product of the forward rate constants for the elementary reactions divided by the product of the reverse rate constants is always equal to the equilibrium constant of the overall reaction. If there are several possible mechanisms for a given reaction (which might involve intermediates other than  $\text{N}_2\text{O}_2$  and  $\text{N}_2\text{O}$ ), their forward and reverse rate constants will all be consistent in this way with the equilibrium constant of the overall reaction.

## 18.4 Reaction Mechanisms and Rate

In many reaction mechanisms, one step is significantly slower than all the others; this step is called the **rate-determining step**. Because an overall reaction can occur only as fast as its slowest step, that step is crucial in determining the rate of the reaction. This is analogous to the flow of automobile traffic on a highway which has a slowdown at some point. The rate at which cars can complete a trip down the full length of the highway (in cars per minute) is approximately equal to the rate at which they pass through the bottleneck.

If the rate-determining step is the first one, the analysis is particularly simple. An example is the reaction

<sup>1</sup>Thermodynamic equilibrium constants are dimensionless because they are expressed in terms of activities rather than partial pressure or concentration. The convention in chemical kinetics is to use concentrations rather than activities, even for gaseous species. Therefore, the equilibrium constants  $K_1$ ,  $K_2$ , and  $K_3$  introduced here are the empirical equilibrium constants  $K_c$  described briefly in Section 14.2. These constants are not dimensionless and must be multiplied by the concentration of the reference state,  $c_{\text{ref}} = RT/P_{\text{ref}}$ , raised to the appropriate power to be made equal to the thermodynamic equilibrium constant. Nevertheless, to maintain consistency with the conventions of chemical kinetics, such constants as  $K_1$ ,  $K_2$ , and  $K_3$  are referred to as equilibrium constants in this section and are written without the subscript  $c$ .

for which the experimental rate law is

$$\text{rate} = k_{\text{obs}}[\text{NO}_2][\text{F}_2]$$

A possible mechanism for the reaction is

The first step is slow and determines the rate,  $k_1[\text{NO}_2][\text{F}_2]$ , in agreement with the observed rate expression. The subsequent fast step does not affect the reaction rate because fluorine atoms react with  $\text{NO}_2$  almost as soon as they are produced.

Mechanisms in which the rate-determining step occurs after one or more fast steps are often signaled by a reaction order greater than 2, by a nonintegral reaction order, or by an inverse concentration dependence on one of the species taking part in the reaction. An example is the reaction

for which the experimental rate law is

$$\text{rate} = k_{\text{obs}}[\text{NO}]^2[\text{O}_2]$$

One possible mechanism would be a single-step termolecular reaction of two  $\text{NO}$  molecules with one  $\text{O}_2$  molecule. This would be consistent with the form of the rate expression, but termolecular collisions are rare, and if there is an alternative pathway it is usually followed.

One such alternative is the two-step mechanism

Because the slow step determines the overall rate, we can write

$$\text{rate} = k_2[\text{N}_2\text{O}_2][\text{O}_2]$$

(Note that the slow step produces two  $\text{NO}_2$  molecules as does the net reaction, so the overall rate is correctly expressed.) The concentration of a reactive intermediate such as  $\text{N}_2\text{O}_2$  cannot be varied at will. Because the  $\text{N}_2\text{O}_2$  reacts only slowly with  $\text{O}_2$ , the reverse reaction (to 2  $\text{NO}$ ) is possible and must be taken into account. In fact, it is reasonable to assume that all of the elementary reactions that occur *before* the rate-determining step are in equilibrium, with the forward and reverse reactions occurring at the same rate. In this case, we have

$$\frac{[\text{N}_2\text{O}_2]}{[\text{NO}]^2} = \frac{k_1}{k_{-1}} = K_1$$

$$[\text{N}_2\text{O}_2] = K_1[\text{NO}]^2$$

$$\text{rate} = k_2K_1[\text{NO}]^2[\text{O}_2]$$

This result is consistent with the observed reaction order, with  $k_2K_1 = k_{\text{obs}}$ .

### EXAMPLE 18.7

In basic aqueous solution the reaction

(Continued)

follows a rate law that is consistent with the following mechanism:

What rate law is predicted by this mechanism?

**Solution**

The rate is determined by the slowest elementary step, the second one:

$$\text{rate} = k_2[\text{I}^-][\text{HOCl}]$$

But, the HOCl is in equilibrium with OCl<sup>-</sup> and OH<sup>-</sup> due to the first step:

$$\frac{[\text{HOCl}][\text{OH}^-]}{[\text{OCl}^-]} = K_1 = \frac{k_1}{k_{-1}}$$

Solving this for [HOCl] and inserting it into the previous expression gives the prediction

$$\text{rate} = k_2 K_1 \frac{[\text{I}^-][\text{OCl}^-]}{[\text{OH}^-]}$$

which is, in fact, the experimentally observed rate law.

**Related Problems: 25, 26, 27, 28, 29, 30**

The rate law of the foregoing example depends on the inverse of the concentration of OH<sup>-</sup> ion. Such a form is often a clue that a rapid equilibrium occurs in the first steps of a reaction, preceding the rate-determining step. Fractional orders of reaction provide a similar clue, as in the reaction of H<sub>2</sub> with Br<sub>2</sub> to form HBr,

for which the initial reaction rate (before very much HBr builds up) is

$$\text{rate} = k_{\text{obs}}[\text{H}_2][\text{Br}_2]^{1/2}$$

How can such a fractional power appear? One reaction mechanism that predicts this rate law is

Here M stands for a second molecule that does not react but that supplies the energy to break up the bromine molecules. For such a mechanism the reaction rate is determined by the slow step:

$$\text{rate} = k_2[\text{Br}][\text{H}_2]$$

However, [Br] is fixed by the establishment of equilibrium in the first reaction,

$$\frac{[\text{Br}]^2}{[\text{Br}_2]} = K_1 = \frac{k_1}{k_{-1}}$$

so

$$[\text{Br}] = K_1^{1/2}[\text{Br}_2]^{1/2}$$

The rate expression predicted by this mechanism is thus

$$\text{rate} = k_2 K_1^{1/2} [\text{H}_2][\text{Br}_2]^{1/2}$$

This is in accord with the observed fractional power in the rate law. On the other hand, the simple bimolecular mechanism

predicts a rate law:

$$\text{rate} = k_1 [\text{H}_2][\text{Br}_2]$$

This disagrees with the observed rate law, so it can be ruled out as the major contributor to the measured rate.

This discussion shows that deducing a rate law from a proposed mechanism is relatively straightforward, but doing the reverse is much harder. In fact, several competing mechanisms often give rise to the same rate law, and only some independent type of measurement can distinguish between them. A proposed reaction mechanism cannot be proven to be correct if its predictions agree with an experimental rate law, but it can be proven wrong if its predictions disagree with the experimental results.

A classic example is the reaction

for which the observed rate law is

$$\text{rate} = k_{\text{obs}} [\text{H}_2][\text{I}_2]$$

(Contrast this with the rate law already given for the analogous reaction of  $\text{H}_2$  with  $\text{Br}_2$ .) This is one of the earliest and most extensively studied reactions in chemical kinetics, and until 1967 it was widely believed to occur as a one-step elementary reaction. At that time J. H. Sullivan investigated the effect of illuminating the reacting sample with light, which splits some of the  $\text{I}_2$  molecules into iodine atoms. If the mechanism we proposed for  $\text{H}_2$  and  $\text{Br}_2$  is correct here as well, the effect of the light on the reaction should be small because it leads only to a small decrease in the  $\text{I}_2$  concentration.

Instead, Sullivan observed a dramatic *increase* in the rate of reaction under illumination, which could be explained only by the participation of iodine *atoms* in the reaction mechanism. One such mechanism is

for which the rate law is

$$\text{rate} = k_2 [\text{H}_2][\text{I}]^2 = k_2 K_1 [\text{H}_2][\text{I}_2]$$

This mechanism gives the same rate law that is observed experimentally, and it is consistent with the effect of light on the reaction. The other reaction mechanism also appears to contribute significantly to the overall rate.

This example illustrates the hazards of trying to determine reaction mechanisms from rate laws: several mechanisms can fit any given empirical rate law, and it is always possible that a new piece of information suggesting a different mechanism will be found. A number of experimental methods have been developed to

investigate reaction mechanisms. Isotopic labelling has been used for nearly a century to trace the fates of individual atoms as they are converted from reactants into products. Molecular beam methods, discussed in Section 18.6, generate radical intermediates in a vacuum environment and collide them with a chosen reactant to selectively study the intermediate elementary steps in overall reaction mechanisms. Time-resolved spectroscopic methods developed over the past 40 years or so have allowed us to identify transient intermediates present in extremely low concentrations with lifetimes as short as a femtosecond ( $10^{-15}$  s). These methods provide great insight into the mechanisms of chemical reactions occurring in environments that include low-density gases (atmospheric chemistry and the chemistry of interstellar space), solutions, the solid state (including geochemistry), and the biology of life processes.

### 18.4.1 The Steady-State Approximation

In some reaction mechanisms there is no single step that is much slower than the others, so the methods discussed so far cannot predict the rate law. In such cases we use the **steady-state approximation**, which states that the concentrations of reactive intermediates remain nearly constant through most of the reaction.

To illustrate this approximation, let's examine the mechanism proposed by F. A. Lindemann for the dissociation of molecules in the gas phase. A molecule such as  $\text{N}_2\text{O}_5$  undergoes collisions with neighboring molecules  $M$ , where  $M$  can stand for another  $\text{N}_2\text{O}_5$  molecule or for an inert gas such as argon. Through such collisions the  $\text{N}_2\text{O}_5$  molecule can become excited (or activated) to a state indicated by  $\text{N}_2\text{O}_5^*$ :

The reverse process, with rate constant  $k_{-1}$ , is also indicated because the activated molecule can be deactivated by collisions with other molecules. The second step is the unimolecular decomposition of  $\text{N}_2\text{O}_5^*$ :

Subsequent reaction steps to form  $\text{O}_2$  and  $\text{NO}_2$  from  $\text{NO}_3$  occur rapidly and do not affect the measured rate:

The  $\text{N}_2\text{O}_5^*$  is a reactive intermediate; it is produced at a rate  $k_1[\text{N}_2\text{O}_5][M]$  from collisions of  $\text{N}_2\text{O}_5$  molecules with other molecules and is lost at a rate  $k_{-1}[\text{N}_2\text{O}_5^*][M]$  due to deactivation and at a rate  $k_2[\text{N}_2\text{O}_5^*]$  due to dissociation. The net rate of change of  $[\text{N}_2\text{O}_5^*]$  is then

$$\frac{d[\text{N}_2\text{O}_5^*]}{dt} = k_1[\text{N}_2\text{O}_5][M] - k_{-1}[\text{N}_2\text{O}_5^*][M] - k_2[\text{N}_2\text{O}_5^*]$$

At the beginning of the reaction,  $[\text{N}_2\text{O}_5^*] = 0$ , but this concentration builds up after a short time to a small value. The steady-state approximation consists of the assumption that after this short time the rates of production and loss of  $\text{N}_2\text{O}_5^*$  become equal, and

$$\frac{d[\text{N}_2\text{O}_5^*]}{dt} = 0$$

The steady-state concentration of  $[\text{N}_2\text{O}_5^*]$  persists practically unchanged throughout most of the course of the reaction.

Setting the net rate of change of the  $\text{N}_2\text{O}_5^*$  concentration to 0 gives

$$\frac{d[\text{N}_2\text{O}_5^*]}{dt} = 0 = k_1[\text{N}_2\text{O}_5][\text{M}] - k_{-1}[\text{N}_2\text{O}_5^*][\text{M}] - k_2[\text{N}_2\text{O}_5^*]$$

Solving for  $[\text{N}_2\text{O}_5^*]$  gives

$$\begin{aligned} [\text{N}_2\text{O}_5^*](k_2 + k_{-1}[\text{M}]) &= k_1[\text{N}_2\text{O}_5][\text{M}] \\ [\text{N}_2\text{O}_5^*] &= \frac{k_1[\text{N}_2\text{O}_5][\text{M}]}{k_2 + k_{-1}[\text{M}]} \end{aligned}$$

The rate of the overall reaction  $\text{N}_2\text{O}_5 \longrightarrow 2 \text{NO}_2 + \frac{1}{2} \text{O}_2$  is

$$\text{rate} = \frac{1}{2} \frac{d[\text{NO}_2]}{dt} = k_2[\text{N}_2\text{O}_5^*] = \frac{k_1 k_2 [\text{N}_2\text{O}_5][\text{M}]}{k_2 + k_{-1}[\text{M}]}$$

This expression has two limiting cases:

1. *Low pressure* When  $[\text{M}]$  is small enough,  $k_2 \gg k_{-1}[\text{M}]$  and we can use the approximation

$$\text{rate} = k_1[\text{N}_2\text{O}_5][\text{M}] \quad (\text{second order})$$

This same result would be found by assuming the first step to be rate-determining.

2. *High pressure* When  $[\text{M}]$  is large enough,  $k_{-1}[\text{M}] \gg k_2$  and we can use the approximation

$$\text{rate} = \left( \frac{k_1}{k_{-1}} \right) k_2 [\text{N}_2\text{O}_5] = K_1 k_1 [\text{N}_2\text{O}_5] \quad (\text{first order})$$

This same result would be found by assuming the second step to be rate-determining.

The steady-state approximation is a more general approach than those considered earlier and produces identical results under the limiting conditions defined above. The steady-state approximation is invoked in many areas of chemical kinetics, an example of which is the kinetics of enzyme-catalyzed reactions discussed in Section 18.8.

### 18.4.2 Chain Reactions

A **chain reaction** proceeds through a series of elementary steps, some of which are repeated many times. Chain reactions have three stages: (1) **initiation**, in which two or more reactive intermediates are generated; (2) **propagation**, in which products are formed but reactive intermediates are continuously regenerated; and (3) **termination**, in which two intermediates combine to give a stable product.

An example of a chain reaction is the reaction of methane with fluorine to give  $\text{CH}_3\text{F}$  and  $\text{HF}$ :

Although in principle this reaction could occur through a one-step bimolecular process, that route turns out to be too slow to contribute significantly under

normal reaction conditions. Instead, the mechanism involves a chain reaction of the following type:

In the initiation step, two reactive intermediates ( $\text{CH}_3$  and  $\text{F}$ ) are produced. During the propagation steps, these intermediates are not used up while reactants ( $\text{CH}_4$  and  $\text{F}_2$ ) are being converted to products ( $\text{CH}_3\text{F}$  and  $\text{HF}$ ). The propagation steps can be repeated again and again, until eventually two reactive intermediates come together in a termination step. As we see in Chapter 23, chain reactions are important in building up long-chain molecules called polymers.

The chain reaction just considered proceeds at a constant rate, because each propagation step both uses up and produces a reactive intermediate. (Note that the concentrations of the  $\text{CH}_4$  and  $\text{F}_2$  reactants are large compared to the concentrations of the reactive intermediates  $\text{CH}_3$  and  $\text{F}$ .) The concentrations of the reactive intermediates remain approximately constant and are determined by the rates of chain initiation and termination. Another type of chain reaction is possible in which the number of reactive intermediates increases during one or more propagation steps. This is called a **branching chain reaction**. An example is the reaction of oxygen with hydrogen. The mechanism is complex and can be initiated in various ways, leading to the formation of several reactive intermediates such as  $\text{O}$ ,  $\text{H}$ , and  $\text{OH}$ . Some propagation steps are of the type already seen for  $\text{CH}_4$  and  $\text{F}_2$ , such as

in which one reactive intermediate ( $\text{OH}$ ) is used up and one ( $\text{H}$ ) is produced. Other propagation steps are branching:

In these steps, each reactive intermediate used up causes the generation of two others. This leads to rapid growth in the number of reactive species, speeding the rate further and possibly causing an explosion. Branching chain reactions are critical in the fission of uranium (see Chapter 19).

## 18.5 Effect of Temperature on Reaction Rates

The first four sections of this chapter describe the experimental determination of rate laws and their relation to assumed mechanisms for chemical reactions. Now we have to find out what determines the actual magnitudes of rate constants (either for elementary reactions or for overall rates of multistep reactions), and how temperature affects reaction rates. To consider these matters, it is necessary to connect molecular collision rates to the rates of chemical reactions. We limit the discussion to gas-phase reactions, for which the kinetic theory of Chapter 9 is applicable.

### 18.5.1 Gas-Phase Reaction Rate Constants

In Section 9.7, we applied the kinetic theory of gases to estimate the frequency of collisions between a particular molecule and other molecules in a gas. In

**FIGURE 18.9** An Arrhenius plot of  $\ln k$  against  $1/T$  for the reaction of benzene vapor with oxygen atoms. An extrapolation to  $1/T = 0$  gives the constant  $\ln A$  from the intercept of this line.

Example 9.12, we calculated this frequency to be  $4.1 \times 10^9 \text{ s}^{-1}$  under room conditions for a typical small molecule such as oxygen. If every collision led to reaction, the reaction would be practically complete in about  $10^{-9} \text{ s}$ . Some reactions do proceed at rates almost this high. An example is the bimolecular reaction between two  $\text{CH}_3$  radicals to give ethane,  $\text{C}_2\text{H}_6$ ,

for which the observed rate constant is  $1 \times 10^{10} \text{ L mol}^{-1} \text{ s}^{-1}$ . For initial pressure of  $\text{CH}_3$  near 1 atm at  $25^\circ\text{C}$ , the concentration initially is about 0.04 M. The second-order integrated rate law from Section 18.2 predicts that the concentration would drop to 0.02 M after a period of  $10^{-9} \text{ s}$ . But, reaction rates that are much lower—by factors of  $10^{12}$  or more—are common. The naive idea that “to collide is to react” clearly must be modified if we are to understand these lower rates.

We find a clue in the observed temperature dependence of reaction rate constants. The rates of many reactions increase extremely rapidly as temperature increases; typically a  $10^\circ\text{C}$  rise in temperature may double the rate. In 1889 Svante Arrhenius suggested that rate constants vary exponentially with inverse temperature,

$$k = Ae^{-E_a/RT} \quad [18.5]$$

where  $E_a$  is a constant with dimensions of energy and  $A$  is a constant with the same dimensions as  $k$ . Taking the natural logarithm of this equation gives

$$\ln k = \ln A - \frac{E_a}{RT} \quad [18.6]$$

So a plot of  $\ln k$  against  $1/T$  should be a straight line with slope  $-E_a/R$  and intercept  $\ln A$ . Many rate constants do show just this kind of temperature dependence (Fig. 18.9).

**EXAMPLE 18.8**

The decomposition of hydroxylamine ( $\text{NH}_2\text{OH}$ ) in the presence of oxygen follows the rate law

$$-\frac{d[\text{NH}_2\text{OH}]}{dt} = k_{\text{obs}}[\text{NH}_2\text{OH}][\text{O}_2]$$

where  $k_{\text{obs}}$  is  $0.237 \times 10^{-4} \text{ L mol}^{-1} \text{ s}^{-1}$  at  $0^\circ\text{C}$  and  $2.64 \times 10^{-4} \text{ L mol}^{-1} \text{ s}^{-1}$  at  $25^\circ\text{C}$ . Calculate  $E_a$  and the factor  $A$  for this reaction.

**Solution**

Let us write the Arrhenius equation at two different temperatures  $T_1$  and  $T_2$ :

$$\ln k_1 = \ln A - \frac{E_a}{RT_1} \quad \text{and} \quad \ln k_2 = \ln A - \frac{E_a}{RT_2}$$

If the first equation is subtracted from the second, the term  $\ln A$  cancels out, leaving

$$\ln k_2 - \ln k_1 = \ln \frac{k_2}{k_1} = -\frac{E_a}{R} \left( \frac{1}{T_2} - \frac{1}{T_1} \right)$$

which can be solved for  $E_a$ . In the present case,  $T_1 = 273 \text{ K}$  and  $T_2 = 298 \text{ K}$ ; therefore,

$$\begin{aligned} \ln \frac{2.64 \times 10^{-4}}{0.237 \times 10^{-4}} &= \frac{-E_a}{8.315 \text{ J K}^{-1} \text{ mol}^{-1}} \left( \frac{1}{298 \text{ K}} - \frac{1}{273 \text{ K}} \right) \\ 2.410 &= \frac{E_a}{8.315 \text{ J K}^{-1} \text{ mol}^{-1}} (3.07 \times 10^{-4} \text{ K}^{-1}) \\ E_a &= 6.52 \times 10^4 \text{ J mol}^{-1} = 65.2 \text{ kJ mol}^{-1} \end{aligned}$$

Now that  $E_a$  is known, the constant  $A$  can be calculated by using data at either temperature. At  $273 \text{ K}$ ,

$$\begin{aligned} \ln A &= \ln k_1 + \frac{E_a}{RT} \\ &= \ln(0.237 \times 10^{-4}) + \frac{6.52 \times 10^4 \text{ J mol}^{-1}}{(8.315 \text{ J K}^{-1} \text{ mol}^{-1})(273 \text{ K})} \\ &= -10.65 + 28.73 = 18.08 \\ A &= e^{18.08} = 7.1 \times 10^7 \text{ L mol}^{-1} \text{ s}^{-1} \end{aligned}$$

We could determine  $E_a$  and  $A$  more accurately from measurements at a series of temperatures and a least-squares fit to a plot such as that in Figure 18.9.

**Related Problems: 35, 36**

Arrhenius believed that for molecules to react upon collision they must become “activated,” so the parameter  $E_a$  came to be known as the **activation energy**. His ideas were refined by later scientists. In 1915 A. Marcelin pointed out that, while molecules make many collisions, not all collisions are reactive. Only those collisions for which the collision energy (i.e., the relative translational kinetic energy,  $(1/2)\mu v_{\text{rel}}^2$ , of the colliding molecules) exceeds some critical energy result in reaction. Thus, Marcelin gave a dynamic interpretation for the activation energy inferred from reaction rates.

The strong temperature dependence of rate constants, described by the Arrhenius law, is explained by the Maxwell–Boltzmann distribution of relative

**FIGURE 18.10** The Maxwell–Boltzmann distribution of relative speeds for  $^{35}\text{Cl} + \text{CH}_4$  collisions at 300 K and 600 K. The fraction of collisions that have a relative kinetic energy greater than  $E_a$  is shown by the shaded areas. Doubling the temperature increases the fraction of collisions with the needed relative kinetic energy by a factor of 15, from 0.73% to 11%. This figure shows only translational energy; internal vibrational and rotational energy also promote reactions.

molecular speeds,  $v_{\text{rel}}$  (see Section 18.6). If  $E_a$  is roughly the critical relative collision energy required for a pair of molecules to react, only a small fraction of the collisions between molecules will have at least this much energy at moderate temperature. Figure 18.10 plots the Maxwell–Boltzmann distribution of the *relative* speeds between  $^{35}\text{Cl}$  atoms and methane molecules at two temperatures. The activation energy  $E_a$  of the  $\text{Cl} + \text{CH}_4 \rightarrow \text{HCl} + \text{CH}_3$  reaction is about  $15 \text{ kJ mol}^{-1}$ . For collisions with  $v_{\text{rel}} > (2 E_a/\mu)^{1/2} = 1.65 \times 10^3 \text{ m s}^{-1}$  the relative kinetic energy is larger than  $15 \text{ kJ mol}^{-1}$ . The fraction of collisions with large enough  $v_{\text{rel}}$  thus corresponds to the area under the Maxwell–Boltzmann distribution curve between  $v_{\text{rel}} = 1.65 \times 10^3 \text{ m s}^{-1}$  and  $\infty$ . As the temperature increases, the distribution function spreads out to include higher energies. The fraction of collisions having more than the critical energy  $E_a$  increases in agreement with the increase in rate calculated with Arrhenius’s law and measured in experiments. The reaction rate is then proportional to  $\exp(-E_a/RT)$ . So, both the strong temperature dependence and the order of magnitude of the experimental rate constants are explained by the kinetic theory of gases.

### 18.5.2 The Reaction Coordinate and the Activated Complex

Why should there be a critical collision energy for reaction to occur between two molecules, and why is this energy similar to  $E_a$ , the activation energy that you calculate from a plot of  $\ln k$  versus  $1/T$ ? To understand the first of these questions, let’s consider the physical analogy of marbles rolling on a hilly surface. As a marble rolls up a hill, its potential energy increases and its kinetic energy decreases; it slows down as it climbs the hill. If it can reach the top of the hill, it will fall down the other side, whereupon its kinetic energy will increase and its potential energy will decrease. Not every marble will make it over the hill. If its initial speed, and therefore kinetic energy, is too small, a marble will roll only part way up and then fall back down. Only those marbles with initial kinetic energy higher than some critical threshold will pass over the hill.

We can use this physical model to describe molecular collisions and reactions. As two reactant molecules, atoms, or ions approach each other along a **reaction path**, their potential energy increases as the bonds within them distort. At some maximum potential energy the collision partners become connected in an unstable entity called the **activated complex** or *transition state*. The activated complex is the cross-over stage where the smooth ascent in potential energy as the reactants come together becomes a smooth descent as the product molecules separate. As in the case of the marbles, not all pairs of colliding bodies react.

Only those pairs with sufficient relative kinetic energy can stretch bonds and rearrange atoms enough to become the transition state through which reactants become products. If the energy  $\varepsilon_B$  (the height of the potential energy hill) of the barrier to reach the transition state is too high, almost all colliding pairs of reactant molecules separate from each other without reacting. The height  $\varepsilon_B$  of the barrier is close to the measured activation energy for the reaction.

Figure 18.11 shows a graph of the potential energy versus position along the reaction path for the reaction

Two barrier energies are shown in Figure 18.11:  $\varepsilon_{B,f}$  is the barrier energy for the forward reaction, and is approximately equal to activation energy  $E_{a,f}$  for the forward reaction, and  $\varepsilon_{B,r}$  is the barrier for the reverse reaction, in which NO takes an oxygen atom from  $\text{CO}_2$  to form  $\text{NO}_2$  and CO. It is approximately equal to the activation energy  $E_{a,r}$  for the reverse reaction. The difference between the two is  $\Delta U$ , the change in internal energy of the chemical reaction:

$$\Delta U = \varepsilon_{B,f} - \varepsilon_{B,r} \approx E_{a,f} - E_{a,r}$$

Whereas  $\Delta U$  is a thermodynamic quantity that can be obtained from calorimetric measurements or calculated with the electronic structure methods described in Chapter 6,  $E_{a,f}$  and  $E_{a,r}$  must be found from the temperature dependence of the rate constants for the forward and reverse reactions. In this reaction the forward and reverse activation energies are roughly 132 and 358  $\text{kJ mol}^{-1}$ , respectively, and  $\Delta U$  from thermodynamics is  $-226 \text{ kJ mol}^{-1}$ .

The activation energy for an elementary reaction in the gas phase is always positive—although in some cases it can be quite small—because there is always some energy barrier to surmount. Rates of elementary reactions therefore increase with increasing temperature. This is not necessarily true for rates of overall reactions consisting of more than one elementary reaction. These sometimes have “negative activation energies,” which means that the overall reaction rate is slower at higher temperature. How can this be? Let’s examine a specific example: the reaction of NO with oxygen

has the observed rate law

$$\text{rate} = k_{\text{obs}}[\text{NO}]^2[\text{O}_2]$$

**FIGURE 18.11** The energy profile along the reaction coordinate for the reaction  $\text{NO}_2 + \text{CO} \longrightarrow \text{NO} + \text{CO}_2$ . This direct reaction dominates the kinetics at high temperatures (above about 500 K).

where  $k_{\text{obs}}$  decreases with increasing temperature. In Section 18.4 we accounted for this rate expression with a two-step mechanism. The first step is a rapid equilibrium (with equilibrium constant  $K_1$ ) between two NO molecules and their dimer,  $\text{N}_2\text{O}_2$ . The second step is the slow reaction (with rate constant  $k_2$ ) of  $\text{N}_2\text{O}_2$  with  $\text{O}_2$  to form products. The overall rate constant is therefore the product of  $k_2$  and  $K_1$ . Whereas  $k_2$  is the rate constant for an elementary reaction, and so increases with increasing temperature,  $K_1$  is an *equilibrium* constant and may decrease as temperature increases. Provided the reaction is sufficiently exothermic (as it is in this case),  $K_1$  will decrease so rapidly with increasing temperature that the product  $k_2K_1$  will decrease as well. This combination of effects explains the observation of “negative activation energies” in some overall chemical reactions.

## 18.6 Molecular Theories of Elementary Reactions

The kinetic theory of gases, introduced in Section 9.5, is the starting point for the development of microscopic theories of reaction rates, a field of study that is called **reaction dynamics**. We introduce you to several different theories and experimental approaches to the study of reaction dynamics in this section to provide you with insight into the nature of chemical reactions at the molecular level. These include collision theory, built upon the kinetic theory of gases; transition state theory, which is based in statistical mechanics; and the experimental technique that uses molecular beams to probe the details of reactive collisions between single pairs of molecules.

### 18.6.1 Collision Theory

Collision theory provides a method for calculating rate constants for bimolecular reactions based upon the properties of the reacting molecules that influence the probabilities of reactive encounters; these include size, relative kinetic energy, and relative orientation.

Let's begin by giving you a feel for why it is the relative kinetic energy,  $\epsilon_{\text{rel}} = \frac{1}{2} \mu v_{\text{rel}}^2$ , of two colliding molecules, calculated from their relative speed  $v_{\text{rel}}$ , that matters in a collision. Figure 18.12 plots three examples of collisions. In all of them the speed of molecule 2 (blue) is 40 miles per hour and the speed of molecule 1 (red) is 30 miles per hour, but the relative speed is very different in each. In Figure 18.12a, molecule 2 is traveling in the  $+x$  direction and molecule 1 is traveling in the  $-x$  direction, so the relative speed (the magnitude of the relative velocity vector  $\vec{v}_{\text{rel}}$  where  $\vec{v}_{\text{rel}} = \vec{v}_2 - \vec{v}_1$ ) is 70 miles per hour. If instead both molecules are traveling in the  $+x$  direction, with molecule 2 catching up from behind as shown in Figure 18.12b, the relative speed is only 10 miles per hour. This may not be a large enough relative speed for the colliding molecules to climb the energetic barrier en route to the transition state. (An analogy with cars on the highway is frightening, but makes it clear that the relative speed matters more in a collision than the speeds of the two individual objects.) Finally, Figure 18.12c depicts a situation where the two molecules are about to collide with their velocity vectors perpendicular to each other (a common configuration in crossed molecular beam experiments discussed later in this section); the calculated relative speed is 50 miles per hour (this is easy to see from the Pythagorean theorem, but you should calculate this using the definition  $\vec{v}_{\text{rel}} = \vec{v}_2 - \vec{v}_1$ , as shown in the figure caption so you get used to the direction of the vector  $\vec{v}_{\text{rel}}$  and its magnitude, the relative speed  $v_{\text{rel}}$ ). Thus, in a gaseous mixture of two types of molecules that collide with each other, and potentially react with each collision, the collisions with the higher relative

**FIGURE 18.12** Calculating the relative velocity and the relative speed for three collisions. We use  $\vec{v}_{\text{rel}} = \vec{v}_2 - \vec{v}_1$  to calculate the relative velocity  $\vec{v}_{\text{rel}}$  (see Appendix C.7 for help with vectors), and  $v_{\text{rel}} = \sqrt{(v_{\text{rel},x})^2 + (v_{\text{rel},y})^2}$ , by the Pythagorean theorem, to calculate the relative speed. You may determine  $\vec{v}_{\text{rel}}$  by graphically subtracting  $\vec{v}_1$  from  $\vec{v}_2$ .

speeds that are more likely to result in a reaction where bonds break and other bonds form. This is the reason why in Figure 18.10 we plotted the Maxwell-Boltzmann distribution of *relative* speeds between the colliding Cl atoms and CH<sub>4</sub> molecules. The Maxwell-Boltzmann distribution of relative speeds, in a bulk mixture of the two gases at temperature  $T$ , is

$$f(v_{\text{rel}}) = 4\pi \left( \frac{\mu}{2\pi k_{\text{B}}T} \right)^{\frac{3}{2}} v_{\text{rel}}^2 \exp(-\mu v_{\text{rel}}^2 / 2k_{\text{B}}T) \quad [18.7]$$

This looks very similar to the Maxwell-Boltzmann speed distribution in Equation 9.19 for an individual molecule, but the mass  $m$  of the molecule is replaced in Equation 18.7 by the reduced mass  $\mu$  of the colliding molecules, where  $\mu = m_1 m_2 / (m_1 + m_2)$  and the speed  $v$  is now the relative speed  $v_{\text{rel}}$ . Because of this similarity, the average relative speed  $\overline{v_{\text{rel}}}$  is given by Equation 9.20, but with  $m$  replaced by the reduced mass  $\mu$  of the colliding molecules.

### EXAMPLE 18.9

A <sup>35</sup>Cl atom with velocity  $\vec{v}_1 = (v_{1,x}, v_{1,y}) = (300 \text{ m s}^{-1}, -400 \text{ m s}^{-1})$  collides with a methane molecule with velocity  $\vec{v}_2 = (v_{2,x}, v_{2,y}) = (-500 \text{ m s}^{-1}, 300 \text{ m s}^{-1})$ .

- What is the speed of the Cl atom and the speed of the CH<sub>4</sub> molecule?
- What is the relative speed of the two colliding molecules?
- What is the relative kinetic energy in this collision?
- Would this relative kinetic energy alone be enough to surmount the barrier to the reaction  $\text{Cl} + \text{CH}_4 \rightarrow \text{HCl} + \text{CH}_3$  if that barrier were  $15 \text{ kJ mol}^{-1}$ ? (Assume that the collision is not a glancing one, so that all of the relative kinetic energy could be converted to potential energy.)

#### Solution

- The speed of the Cl atom =  $\sqrt{300^2 + (-400)^2} = 500 \text{ m s}^{-1}$  and the speed of the methane molecule =  $\sqrt{(-500)^2 + 300^2} = 583 \text{ m s}^{-1}$ .
- The relative speed is the magnitude of the relative velocity vector.  $\vec{v}_{\text{rel}} = \vec{v}_2 - \vec{v}_1 = (-500, 300) - (300, -400) = (-800, 700)$  in units of  $\text{m s}^{-1}$ . This gives a relative speed of  $v_{\text{rel}} = \sqrt{(-800)^2 + 700^2} = 1063 \text{ m s}^{-1}$ .

(Continued)

(c) The relative kinetic energy is

$$\begin{aligned}\epsilon_{\text{rel}} &= \frac{1}{2} \mu v_{\text{rel}}^2 \\ &= \frac{1}{2} \left( \frac{(35)(16)}{51} \text{ g mol}^{-1} \right) \left( \frac{\text{kg}}{1000 \text{ g}} \right) (1063 \text{ m s}^{-1})^2 \\ &= \frac{1}{2} (0.011 \text{ kg mol}^{-1}) (1063 \text{ m s}^{-1})^2 \\ &= 6203 \text{ J mol}^{-1} = 6.2 \text{ kJ mol}^{-1}\end{aligned}$$

(d) No, this does not provide enough energy to surmount the barrier, even in the best case of it not being a glancing collision.

**Related Problems: 43, 44**

Now let's consider a very simple type of reaction, one in which there is no barrier, so all collisions have enough relative kinetic energy to surmount the barrier to the reaction. (For example, the reaction between two radicals is often nearly barrier-less.) One would conclude that if the two molecules collide, they react, so the reaction rate should be equal to the collision rate that we discussed in Section 9.7 and is depicted again in Figure 18.13. Specifically, the number of collisions per second per  $\text{m}^3$  of volume between molecules of type 1 (say Cl atoms) and molecules of type 2 (say  $\text{CH}_4$  molecules) is:

$$\frac{\text{collisions of type 1 molecules with type 2}}{\text{m}^3 \text{ s}} = \pi d^2 \bar{v}_{\text{rel}} \frac{N_1}{V} \frac{N_2}{V} \quad [18.8]$$

where  $d$  is the sum of the radii of the two colliding molecules, or the average of their diameters, as shown in Figure 18.13. The expression looks very similar to the expression for the rate of the  $\text{A} + \text{B} \rightarrow \text{C} + \text{D}$  bimolecular elementary reaction

$$\text{rate (in mol L}^{-1} \text{ s}^{-1}) = \frac{d[\text{C}]}{dt} = k[\text{A}][\text{B}] \quad [18.9]$$

with the time  $t$  in seconds, except the concentrations in Equation 18.8 are expressed in molecules per  $\text{m}^3$  and the concentrations in Equation 18.9 are expressed in moles per liter. The rate calculated in Equation 18.8 is called the *gas kinetic collision rate*. If a reaction proceeds with that fast rate, one concludes that the barrier to the reaction is small and that there are no other restrictions, such as the relative orientation of the two colliding molecules, that would prevent a collision from resulting in a reaction. Thus, to within-unit conversions, we can immediately deduce the rate constant for a reaction with no barrier that

**FIGURE 18.13** Molecule A (red) sweeps out a cylinder of volume  $\pi d^2 \bar{v}_{\text{rel}}$  per second, where  $d = \frac{(d_1 + d_2)}{2}$ . It will collide with all of the B molecules (blue) whose centers lie within the cylinder.

evidences a rate consistent with the gas kinetic collision rate. It is, comparing Equations 18.8 and 18.9,  $k = \pi d^2 \overline{v_{\text{rel}}}$ . Figure 18.13 shows that the effective cross-sectional area that the two colliding molecules present to each other is  $\pi d^2$ . The symbol  $\sigma_c$  is used for this hard-sphere **collision cross section**, so  $\sigma_c = \pi d^2$ . Thus, for a reaction without a barrier, the hard sphere collision rate constant  $k = \sigma_c \overline{v_{\text{rel}}}$ .

### EXAMPLE 18.10

The measured rate constant for the reaction of  $^{35}\text{Cl}$  atoms with methane at 300 K is  $1.0 \times 10^{-13} \text{ cm}^3 \text{ s}^{-1}$ .

- (a) If the concentration of  $^{35}\text{Cl}$  atoms were  $3 \times 10^5 \text{ cm}^{-3}$  (think of this as molecules per  $\text{cm}^3$ , but don't carry the molecules with your units) and the concentration of methane were  $9 \times 10^5 \text{ cm}^{-3}$ , calculate the rate of the reaction in  $\text{mol L}^{-1} \text{ s}^{-1}$ .
- (b) Compare your result with the gas kinetic collision rate of  $^{35}\text{Cl}$  atoms with methane at this temperature, taking the hard sphere diameter of a methane molecule to be the Lennard-Jones parameter  $\sigma = 3.82 \text{ \AA}$  in Table 9.4, and approximating the hard sphere radius of a Cl atom by its van der Waals radius of 175 pm. (This is larger, as expected, than the atomic radius for Cl in Appendix F, as the latter is calculated by halving the equilibrium bond length  $R_e$  for two covalently bound Cl atoms.)
- (c) Calculate the gas kinetic rate constant in  $\text{L mol}^{-1} \text{ s}^{-1}$  and compare it to the measured rate constant. Discuss the difference.

#### Solution

(a)  $\text{rate} = k[\text{Cl}][\text{CH}_4]$

$$\begin{aligned} &= (1 \times 10^{-13} \text{ cm}^3 \text{ s}^{-1}) \left( \frac{\text{L}}{1000 \text{ cm}^3} \right) \left( \frac{6.022 \times 10^{23}}{\text{mol}} \right) [\text{Cl}][\text{CH}_4] \\ &= (6.022 \times 10^7 \text{ L mol}^{-1} \text{ s}^{-1}) [\text{Cl}][\text{CH}_4] \\ &= (6.022 \times 10^7 \text{ L mol}^{-1} \text{ s}^{-1}) \left( \frac{3 \times 10^8 \text{ L}^{-1}}{6.022 \times 10^{23} \text{ mol}^{-1}} \right) \left( \frac{9 \times 10^8 \text{ L}^{-1}}{6.022 \times 10^{23} \text{ mol}^{-1}} \right) \\ &= 4.5 \times 10^{-23} \text{ mol L}^{-1} \text{ s}^{-1} \end{aligned}$$

- (b) To calculate the gas kinetic collision rate, first calculate the average relative speed between a Cl atom and a  $\text{CH}_4$  molecule at 300 K.

$$\begin{aligned} \overline{v_{\text{rel}}} &= \sqrt{\frac{8k_{\text{B}}T}{\pi\mu}} \\ &= \sqrt{\frac{8(1.38 \times 10^{-23} \text{ J K}^{-1})(300 \text{ K})}{\pi(0.011 \text{ kg mol}^{-1}) \left( \frac{\text{mol}}{6.022 \times 10^{23}} \right)}} \\ &= 759.7 \text{ m s}^{-1} \end{aligned}$$

Using Equation 18.8, the number of collisions per second per  $\text{m}^3$  between Cl and methane is

$$\begin{aligned} \frac{\text{collisions of Cl with CH}_4}{\text{m}^3 \text{ s}} &= \pi(3.66 \times 10^{-10} \text{ m}^3)^2 (759.7 \text{ m s}^{-1}) \\ &\quad (3 \times 10^{11} \text{ m}^{-3})(9 \times 10^{11} \text{ m}^{-3}) \\ &= 8.63 \times 10^7 \text{ m}^{-3} \text{ s}^{-1} \end{aligned}$$

(Continued)

This gives a gas kinetic collision rate, in units of  $\text{mol L}^{-1} \text{s}^{-1}$  equal to

$$(8.63 \times 10^7 \text{ m}^{-3} \text{ s}^{-1}) \left( \frac{\text{m}^3}{1000 \text{ L}} \right) \left( \frac{\text{mol}}{6.022 \times 10^{23}} \right) = 1.43 \times 10^{-19} \text{ mol L}^{-1} \text{ s}^{-1}$$

- (c) The gas kinetic collision rate is roughly a factor of 3000 larger than the measured rate of reaction. There must be a barrier to this reaction. We further show in the following derivation that if the collision is a glancing one, the relative kinetic energy must be *much larger than* the barrier height to convert enough of the relative kinetic energy to potential energy on impact.

So how do we get an expression for the rate constant when there is a barrier to the reaction? We can make a simple model similar to that above, but incorporate one important new feature—that if a collision is a glancing one not all of the relative kinetic energy can be converted to potential energy when the reactant molecules collide. If you imagine one of the collisions depicted in Figure 18.13 where the red molecule barely collides with one of the blue molecules near the edge of the collision volume, such a collision will not be able to convert much of the relative kinetic energy to potential energy on impact. We consider this carefully in the next few pages. Depending on the level of your introductory chemistry class, your instructor may suggest you skip to the paragraph immediately after Equation 18.12 and study the concept of an impact parameter for a collision presented in Figure 18.14. Thus, you can easily understand the quantitative expressions in Equations 18.13-18.18, then skip again to the final result in Equation 18.19 and the applications presented after that. Key steps in the derivation include:

1. Defining an energy-dependent **reactive cross section**  $\sigma_r(\epsilon_{\text{rel}})$  to account for the fact that only those collisions that meet a specific energy criterion will lead to reaction. Reactive cross sections are generally smaller than hard sphere collision cross sections because not every collision is effective for reaction.
2. Asserting that there is an energy threshold that determines whether a particular collision leads to reaction or not; those collisions with relative energies above this threshold are reactive and those with relative energies below this threshold are not. We find the threshold energy and determine the functional dependence of  $\sigma_r(\epsilon_{\text{rel}})$  on  $\epsilon_{\text{rel}}$  by analyzing the portion of the relative kinetic energy from the component of  $\vec{v}_{\text{rel}}$  along the line of centers when the colliding molecules, modeled as hard spheres, impact each other.

**FIGURE 18.14** Molecule A is moving towards molecule B with relative velocity vector  $\vec{v}_{\text{rel}}$  shown. The distance between the parallel lines is called the impact parameter  $b$ . (Note: In the diagram, the molecular mass of reactant A is assumed to be half of the molecular mass of reactant B.)

3. Recognizing that there is a distribution of relative kinetic energies given by the Maxwell–Boltzmann distribution  $f(\varepsilon_{\text{rel}})$  and integrating the energy-dependent reaction probability over all possible relative kinetic energies weighted by that distribution.

We begin with the bimolecular rate equation introduced above and indicate our intention to integrate over the energy-dependent factors as follows. Showing that the rate is a function of  $\varepsilon_{\text{rel}}$  gives

$$\begin{aligned} \text{rate}(\varepsilon_{\text{rel}}) &= k_r \left( \frac{N_1}{V} \right) \left( \frac{N_2}{V} \right) = \sigma_r(\varepsilon_{\text{rel}}) v_{\text{rel}} \left( \frac{N_1}{V} \right) \left( \frac{N_2}{V} \right) \\ &= \sigma_r(\varepsilon_{\text{rel}}) \left( \frac{2\varepsilon_{\text{rel}}}{\mu} \right)^{1/2} \left( \frac{N_1}{V} \right) \left( \frac{N_2}{V} \right) \end{aligned} \quad [18.10]$$

$$\text{total rate} = \left( \int_0^{\infty} \sigma_r(\varepsilon_{\text{rel}}) \left( \frac{2\varepsilon_{\text{rel}}}{\mu} \right)^{1/2} f(\varepsilon_{\text{rel}}) d\varepsilon_{\text{rel}} \right) \left( \frac{N_1}{V} \right) \left( \frac{N_2}{V} \right)$$

from which we see that the rate constant is given by

$$k_r = \int_0^{\infty} \sigma_r(\varepsilon_{\text{rel}}) \left( \frac{2\varepsilon_{\text{rel}}}{\mu} \right)^{1/2} f(\varepsilon_{\text{rel}}) d\varepsilon_{\text{rel}} \quad [18.11]$$

The next step is to relate  $f(\varepsilon_{\text{rel}})d\varepsilon_{\text{rel}}$  to  $f(v_{\text{rel}})dv_{\text{rel}}$  where  $f(v_{\text{rel}})$  is the Maxwell–Boltzmann distribution of relative speeds of the two colliding reactant molecules given in Equation 18.7. We make the following substitutions into Equation 18.7

$$\varepsilon_{\text{rel}} = \frac{1}{2} \mu v_{\text{rel}}^2, \quad v_{\text{rel}}^2 = \left( \frac{2\varepsilon_{\text{rel}}}{\mu} \right), \quad dv_{\text{rel}} = d\varepsilon_{\text{rel}} / (2\mu\varepsilon_{\text{rel}})^{1/2}$$

which allows us to relate  $f(v_{\text{rel}})dv_{\text{rel}}$ , and  $f(\varepsilon_{\text{rel}})d\varepsilon_{\text{rel}}$  as follows.

$$\begin{aligned} f(v_{\text{rel}})dv_{\text{rel}} &= 4\pi \left( \frac{\mu}{2\pi k_B T} \right)^{3/2} \frac{2\varepsilon_{\text{rel}}}{\mu} \exp(-\varepsilon_{\text{rel}}/k_B T) \frac{d\varepsilon_{\text{rel}}}{(2\mu\varepsilon_{\text{rel}})^{1/2}} \\ &= 2\pi \left( \frac{1}{\pi k_B T} \right)^{3/2} \varepsilon_{\text{rel}}^{1/2} \exp(-\varepsilon_{\text{rel}}/k_B T) d\varepsilon_{\text{rel}} = f(\varepsilon_{\text{rel}})d\varepsilon_{\text{rel}} \end{aligned}$$

Substituting this result into the integral in Equation 18.11 gives

$$\begin{aligned} k_r &= 2\pi \left( \frac{1}{\pi k_B T} \right)^{3/2} \int_0^{\infty} \sigma_r(\varepsilon_{\text{rel}}) \left( \frac{2\varepsilon_{\text{rel}}}{\mu} \right)^{1/2} \varepsilon_{\text{rel}}^{1/2} \exp(-\varepsilon_{\text{rel}}/k_B T) d\varepsilon_{\text{rel}} \\ &= \left( \frac{8}{\pi\mu k_B T} \right)^{1/2} \left( \frac{1}{k_B T} \right) \int_0^{\infty} \varepsilon_{\text{rel}} \sigma_r(\varepsilon_{\text{rel}}) \exp(-\varepsilon_{\text{rel}}/k_B T) d\varepsilon_{\text{rel}} \end{aligned} \quad [18.12]$$

We develop a model to determine the functional dependence of  $\sigma_r$  on  $\varepsilon_{\text{rel}}$  by asserting that only the component of the relative velocity directed along the line of centers  $v_{\parallel}$  is effective in activating a reaction. Figure 18.14 shows the molecules A and B represented as hard spheres separated by the distance  $d$  when they collide. The velocity of molecule A,  $\vec{v}_2$ , relative to the velocity of molecule B,  $\vec{v}_1$ , is the vector  $\vec{v}_{\text{rel}}$ . We draw a line parallel to  $\vec{v}_{\text{rel}}$  that goes through the center of B; the distance  $b$  between the two parallel lines is called the **impact parameter**. We find the component of the velocity directed along the line of centers,  $v_{\parallel}$ , using the geometric construction illustrated in Figure 18.14.  $v_{\parallel} = v_{\text{rel}} \cos \theta$ . The angle  $\theta$  is calculated using the particular collision's impact parameter  $b$  and the distance  $d$ , where  $\sin \theta = b/d$ .

Thus, the total relative kinetic energy  $\varepsilon_{\text{rel}}$  may be written as the sum of two parts:

$$\varepsilon_{\text{rel}} = (1/2)\mu v_{\text{rel}}^2 = (1/2)\mu v_{\parallel}^2 + (1/2)\mu v_{\perp}^2 \quad [18.13]$$

We are modeling the colliding molecules as hard spheres, so when they collide at a distance  $d$  between them  $v_{\parallel}$  must go to zero; the kinetic energy from this component of the velocity,  $(1/2)\mu v_{\parallel}^2$ , is converted to potential energy to surmount the barrier to the chemical reaction. Thus a collision with impact parameter  $b = 0$  can convert all of the relative kinetic energy to potential energy on impact, while a collision with a larger impact parameter  $b$  (a glancing collision) converts a smaller fraction of the relative kinetic energy to potential energy on impact. Using Equation 18.13 and letting  $(1/2)\mu v_{\parallel}^2$  be converted to potential energy on impact,  $V_{\text{max}}(d)$ , gives

$$(1/2)\mu v_{\text{rel}}^2 = V_{\text{max}}(d) + (1/2)\mu v_{\perp}^2 \quad [18.14]$$

Substituting  $v_{\perp} = v_{\text{rel}} \sin \theta = v_{\text{rel}}(b/d)$ , then solving for the maximum potential energy on impact gives

$$V_{\text{max}}(d) = (1/2)\mu v_{\text{rel}}^2(1 - (b/d)^2) = \varepsilon_{\text{rel}}(1 - (b/d)^2) \quad (\text{for } 0 \leq b \leq d) \quad [18.15]$$

The fraction of the relative kinetic energy that is useful to surmount the barrier to the reaction thus decreases as  $b$  increases (and when  $b > d$  there is no collision at all). For each  $\varepsilon_{\text{rel}}$  then, we need to find the critical impact parameter  $b_o$  where the potential energy on impact,  $V_{\text{max}}(d)$ , is just large enough to surmount the barrier to the chemical reaction  $\varepsilon_B$ . Using Equation 18.14 with  $V_{\text{max}}(d) = \varepsilon_B$  and  $b = b_o$  gives

$$\varepsilon_B = \varepsilon_{\text{rel}}(1 - (b_o/d)^2) \quad (\text{for } 0 \leq b_o \leq d) \quad [18.16]$$

and solving for the critical impact parameter  $b_o$  gives

$$b_o = d(1 - (\varepsilon_B/\varepsilon_{\text{rel}}))^{1/2} \quad (\text{for } 0 \leq b_o \leq d) \quad [18.17]$$

Since any collision with  $b < b_o$  results in reaction, the reaction cross section  $\sigma_r$  at a given  $\varepsilon_{\text{rel}}$  is  $\pi b_o^2$ , and it is smaller than the collision cross section  $\pi d^2$  because a collision with an impact parameter greater than  $b_o$  will not convert enough relative kinetic energy on impact to potential energy. This explains why the rate for a reaction with a barrier is less than the gas kinetic rate, as we saw in Example 18.10. Note that the reaction cross section is now dependent on the relative kinetic energy, only equaling  $\pi d^2$  at large relative kinetic energy. Figure 18.15 shows this graphically. We thus have a rate constant  $k(\varepsilon_{\text{rel}}) = \sigma_r v_{\text{rel}}$  for the reaction that depends on  $\varepsilon_{\text{rel}}$  because both  $v_{\text{rel}}$  and the reaction cross section depend on  $\varepsilon_{\text{rel}}$ . Using Equation 18.15 the reaction cross section is

$$\sigma_r = \pi b_o^2 = \pi d^2(1 - (\varepsilon_B/\varepsilon_{\text{rel}})) \quad (\text{for } 0 \leq b_o \leq d) \quad [18.18]$$

**FIGURE 18.15** Dependence of the reactive cross section  $\sigma_r(\varepsilon_{\text{rel}})$  on the relative translational energy  $\varepsilon_{\text{rel}}$ .

We are now in a position to derive an expression for the rate constant by substituting Equation 18.18 into the integral in Equation 18.12 and integrating to get (with the lower limit set to  $\varepsilon_B$  as  $\varepsilon_{\text{rel}}$  must be  $\geq \varepsilon_B$  for reaction to occur)

$$\begin{aligned} \int_0^{\infty} \varepsilon_{\text{rel}} \sigma_r(\varepsilon_{\text{rel}}) \exp(-\varepsilon_{\text{rel}}/k_B T) d\varepsilon_{\text{rel}} &= \sigma_c \int_{\varepsilon_B}^{\infty} \varepsilon_{\text{rel}} \left(1 - \frac{\varepsilon_B}{\varepsilon_{\text{rel}}}\right) \exp(-\varepsilon_{\text{rel}}/k_B T) d\varepsilon_{\text{rel}} \\ &= (k_B T)^2 \sigma_c \exp(-\varepsilon_B/k_B T) \end{aligned}$$

with  $\sigma_c = \pi d^2$ . We arrive at our final goal by substituting this result into Equation 18.12, giving

$$\begin{aligned} k_r &= \left(\frac{8}{\pi\mu k_B T}\right)^{1/2} \left(\frac{1}{k_B T}\right) (k_B T)^2 \sigma_c \exp(-\varepsilon_B/k_B T) \\ &= \sigma_c \left(\frac{8k_B T}{\pi\mu}\right)^{1/2} \exp(-\varepsilon_B/k_B T) \end{aligned} \quad [18.19]$$

which expresses the temperature-dependent rate constant in terms of molecular parameters. The rate constant depends upon the rate of collisions (which depends upon both the collision cross section and the relative speed), and the probability that a particular collision has sufficient energy directed along the line of centers to cause reaction. Comparing this expression with the empirical Arrhenius equation provides a physical rationale for the form of the Arrhenius equation and an interpretation for each of its factors.  $\varepsilon_B$  is a threshold energy, below which no reaction occurs and the derivation showed that for glancing collisions the relative kinetic energy must be larger than  $\varepsilon_B$ . As temperature increases, the relative energy of the colliding molecules increases, more collisions overcome the energy threshold, and the reaction rate increases. Finally, since the activation energy  $E_a/k_B = -d \ln k_r/d(1/T)$ , if we treat the factors in front of the exponential as roughly constant with temperature we would conclude that the barrier height  $\varepsilon_B$  equals  $E_a$ . Then you would identify the Arrhenius pre-exponential factor  $A$  with the first two factors in Equation 18.19, suggesting that  $A$  can be interpreted as a collision rate. It also shows that a more realistic form of the Arrhenius equation should have a temperature-dependent pre-exponential factor that reflects the  $\sqrt{T}$  dependence of molecular speeds on temperature. This rather weak temperature dependence is generally overwhelmed by the much stronger temperature dependence of the exponential factor, but it is observed experimentally and must be accounted for in accurate kinetic studies.

How well does this simple theory agree with experiment? We obtain experimental activation energies and pre-exponential factors by fitting gas-phase elementary reaction rate data to the Arrhenius form. The value of  $A$  can be compared with theory, once we estimate the molecular diameter to determine the hard sphere cross section. For the elementary reaction

the measured rate constant is 0.16 times the calculated rate constant. This result indicates that not all collisions lead to reaction, even if the molecules have sufficient relative kinetic energy. What other effect have we overlooked? The relative orientations of the colliding molecules should certainly play a role in determining whether a particular collision results in a reaction. It seems obvious from the models shown in Figure 18.16 that the most favorable orientation is the one in which the chlorine ends of the two NOCl molecules collide head on. We improve on the predictions of collision theory by multiplying by a **steric factor**  $P$  (0.16 for this reaction) to account for the fact that only a fraction of the collisions occur with the proper orientation to lead to reaction. The steric factor

**FIGURE 18.16** The steric effect on the probability of a reaction. The two NOCl molecules must approach each other in such a way that the two chlorine atoms are close together, if the encounter is to produce  $\text{Cl}_2(\text{g})$  and  $\text{NO}(\text{g})$ .

**TABLE 18.1**

Steric Factors for Gas-Phase Reactions

Reaction	Steric Factor $P$
$2 \text{NOCl} \rightarrow 2 \text{NO} + \text{Cl}_2$	0.16
$2 \text{NO}_2 \rightarrow 2 \text{NO} + \text{O}_2$	$5.0 \times 10^{-2}$
$2 \text{ClO} \rightarrow \text{Cl}_2 + \text{O}_2$	$2.5 \times 10^{-3}$
$\text{H}_2 + \text{C}_2\text{H}_4 \rightarrow \text{C}_2\text{H}_6$	$1.7 \times 10^{-6}$
$\text{K} + \text{Br}_2 \rightarrow \text{KBr} + \text{Br}$	4.8

is an empirical correction that has to be identified by comparing results of the simple theory with experimental data. It can be predicted in more advanced theories, but only for especially simple reactions.

Steric factors for a number of bimolecular reactions are given in Table 18.1; they are simply the ratios of the measured rate constants to those predicted using the hard-sphere collision rates for each reaction. These data show some interesting features.  $P$  generally decreases down the series as the molecules become progressively more complex. There are a larger number of possible relative orientations for more complex molecules, which means that a smaller fraction of those relative orientations will be optimal. The unusually large cross section for the reaction  $\text{K} + \text{Br}_2 \rightarrow \text{KBr} + \text{Br}$  is quite interesting; it appears that the molecules react *before* they collide, because the cross section is *larger* than the hard-sphere cross section. This result is explained by the harpoon mechanism mentioned in Section 3.8. The highly electronegative Br atoms in  $\text{Br}_2$  pull an electron away from K, which has a very low ionization energy. The strong Coulomb attraction between the ions pulls them together to initiate the reaction. The electron is the harpoon, being fired from the potassium atom to draw in the bromine molecule.

## 18.6.2 Transition State Theory

The goal of transition state theory (also called activated complex theory) is to provide an approach to the calculation of rate constants from molecular properties that is more sophisticated than collision theory but not intractable. A full discussion of the theory is beyond the scope of this textbook, but an outline of the general approach used and the thermodynamic viewpoint developed provides additional insight into the molecular details of chemical reaction dynamics. Interpreting thermodynamic driving forces in terms of molecular structure and motion has greatly enhanced our understanding of the rates and mechanisms of chemical reactions of interest in chemistry and biology. We illustrate this point of view in our discussion of the mechanisms of enzyme catalysis in Section 18.8.

Transition state theory postulates the existence of an **activated complex**, as shown in Figure 18.11, for example, which is the configuration of atoms at the highest point on the potential energy function that describes the passage from reactants to products. The terms *transition state* and *activated complex* are often used interchangeably but we find it helpful to refer to the geometric configuration of the atoms as the activated complex and the location of that configuration on a potential energy diagram as the transition state. The activated complex is assumed to exist as if it were in equilibrium with the reactants and the theory focuses on calculating the rate at which the activated complex passes through the transition state to form products. The equilibrium constant is calculated using the methods of statistical thermodynamics in which all of the motions of the

molecules are considered separately and explicitly, particularly the rotational and vibrational motions. Motion though the transition state is imagined to proceed along one set of displacements associated with a particular molecular vibration. The simplest situation to imagine is the reaction  $A + BC \rightarrow \text{products}$ , in which the relevant mode of the activated complex is one in which the  $A-B$  and  $B-C$  bonds vibrate out of phase with respect to one another (an antisymmetric stretch, see Section 20.4). We imagine the frequency of that mode decreasing as the reaction proceeds with the vibrational energy stored in the  $B-C$  bond being transformed into the translational kinetic energy of the separated  $AB + C$  products. Reaction rates predicted using transition state theory are often expressed by the Eyring formula:

$$k_r = \kappa \frac{k_B T}{h} K^\ddagger$$

in which  $\kappa$  (the transmission coefficient) measures the probability that the system will proceed through the transition state and  $k_B T/h$  is the rate at which the activated complex dissociates to form products.  $k_B T/h$  is of the order  $5 \times 10^{12} \text{ s}^{-1}$  at 300 K, which is a useful number to remember when estimating reaction rates using transition state theory.

The thermodynamic formulation of transition state theory is more useful than the method just described because it is very difficult to calculate equilibrium constants involving activated complexes. We substitute  $\exp(-\Delta G^\ddagger/RT)$  for  $K^\ddagger$  in the preceding expression to get

$$\begin{aligned} k_r &= \kappa \frac{k_B T}{h} \exp(-\Delta G^\ddagger/RT) \\ &= \kappa \frac{k_B T}{h} \exp(\Delta S^\ddagger/R) \exp(-\Delta H^\ddagger/RT) \end{aligned}$$

which we compare to the Arrhenius equation

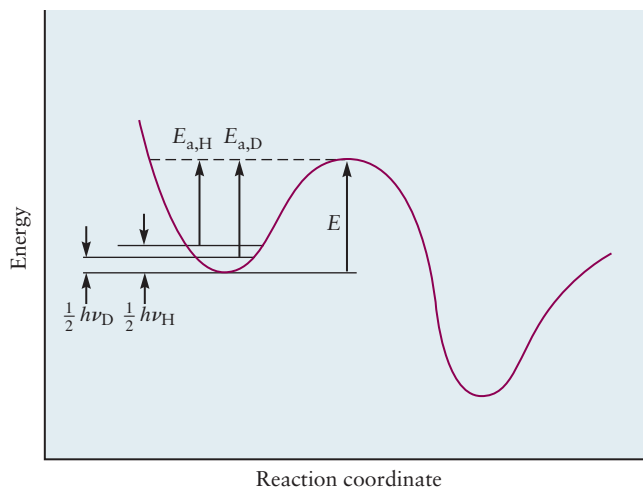

$$k_r = A \exp(-E_a/RT)$$

Transition state theory provides some additional insight into the factors that govern activation. The Arrhenius activation energy  $E_a$  may now be expressed as  $\Delta H^\ddagger$ , an activation enthalpy, and the product of  $\exp(\Delta S^\ddagger/R)$  and  $\kappa(k_B T/h)$  may be associated with the pre-exponential factor  $A$ . Although it is possible in principle, and sometimes in practice, to calculate enthalpies and entropies of activation, the real utility of this approach is that it provides us with a conceptual framework from which to analyze the driving forces for particular chemical reactions from a molecular point of view. This approach is extremely useful in helping to understand patterns of reactivity in complex systems like enzymes, for example, and it has been adopted widely for that purpose, as we illustrate briefly in the *Connection to Biology* at the end of this chapter.

### 18.6.3 Isotope Effects in Chemical Kinetics

Isotopes are widely used as tracers in kinetics to help determine reaction mechanisms, as discussed in Section 18.4. Isotopic substitution of the lighter elements in molecules also leads to rather dramatic effects on the rates of chemical reactions that have important ramifications in a number of fields of science. Some plants, for example, preferentially utilize  $^{12}\text{CO}_2$  in photosynthesis, and the ratio of the various carbon isotopes measured in materials derived from plants can be used to identify their sources. The ratio of  $^{12}\text{CO}_2$  to the heavier isotopes in atmospheric  $\text{CO}_2$  identifies fossil fuels as the source of the recent increases in the concentrations of this greenhouse gas. Kinetic isotope effects have a purely quantum mechanical origin. They arise because the zero-point energy of the

**FIGURE 18.17** Energy profiles along a C—H bond reaction coordinate showing the origin of the primary kinetic isotope effect. The zero-point vibrational energy of the C—D bond is less than the zero-point vibrational energy of the C—H bond, which leads to an increase in the activation energy  $E_a$  for reactions that involve breaking C—D bonds.

heavier isotopes is less than the zero-point energy of the lighter isotopes, producing an increase in activation energies and a decrease in reaction rates.

The physical origin of kinetic isotope effects is most easily understood by examining a potential energy diagram like that shown in Figure 18.17. The largest effects observed occur for the high-frequency stretching motions of X—H bonds, where X is typically one of the main group elements important in organic chemistry, like carbon, nitrogen, and oxygen. We have drawn this diagram in a slightly different way than those in earlier figures to emphasize the fact that both the reactants and the products have potential energy diagrams, like those introduced in Chapter 3, that describe their bond lengths, dissociation energies, and vibrational frequencies (see Section 20.3). Kinetic isotope effects are considered *primary* when the isotope involved is one of the atoms in a bond and *secondary* when it is in an adjacent bond; the former are generally much larger than the latter, which are nevertheless useful in mechanistic studies. We typically calculate the *maximum* primary kinetic isotope effect by assuming that the zero-point energy of the relevant vibration in the activated complex is identical for both isotopes and it is only the difference in the zero-point energies in the reactants that matters. Let's use the C—H stretching vibration as an example and calculate the kinetic isotope effect that results from deuterium substitution using the Arrhenius equation. We label the rate constants and activation energies associated with the C—H bond and the C—D bond as  $k_H(T)$ ,  $E_{a,H}$  and  $k_D(T)$ ,  $E_{a,D}$ , respectively, identifying the energy difference between the minimum of the potential energy well for the reactants and the maximum in the potential energy curve for the activated complex simply as  $E$ . The activation energies are then given by  $E_{a,H} = E - \frac{1}{2} h\nu_{CH}$  and  $E_{a,D} = E - \frac{1}{2} h\nu_{CD}$ . Substituting these values into the Arrhenius equation and taking the ratios of the rate constants gives

$$\begin{aligned} \frac{k_H(T)}{k_D(T)} &= \frac{A \exp(-E_{a,H}/RT)}{A \exp(-E_{a,D}/RT)} = \frac{\exp[(-E + \frac{1}{2} h\nu_{CH})/RT]}{\exp[(-E + \frac{1}{2} h\nu_{CD})/RT]} \\ &= \exp[\frac{1}{2} (h\nu_{CH} - h\nu_{CD})/RT] \end{aligned}$$

We can calculate the reduction in rate expected when deuterium is substituted for hydrogen in a C—H bond using vibrational frequencies measured by infrared spectroscopy (see Section 20.3) and converting them into vibrational energies using  $E = hv$ . Typical energies for C—H stretching vibrations are about  $36 \text{ kJ mol}^{-1}$  and those for C—D vibrations are about  $25 \text{ kJ mol}^{-1}$ , respectively, giving a ratio  $k(D)/k(H) = 0.12$  at 300 K. The rate decreases by a factor of 8.

Measuring the effect of deuterium substitution on the rates of organic reactions provides insight into reaction mechanisms. Experimental kinetic isotope

effects in the range 5 to 10 near room temperature or above strongly imply C—H bond breaking at the labeled carbon atom. Secondary kinetic isotope effects involving C—H bond breaking are smaller, but measurable (around 1.5) and point to the role of the increased reduced mass of a functional group adjacent to the carbon atom undergoing reaction.

### 18.6.4 Molecular Beams

The kinetics experiments described thus far are all carried out by varying the macroscopic properties of the system, such as reactant concentrations and temperature. This approach necessarily averages over the details of individual reactive encounters that depend on particular molecular details such as the distribution of energy among the various modes of the reactants (see Section 12.8) and their relative orientations when they collide with one another. Studying reactions in crossed molecular beams provides a powerful alternative that allows us to investigate the details of chemical reactions at the molecular level. A crossed molecular beam apparatus comprises an ultrahigh vacuum chamber, collimated sources of molecules with well-defined kinetic energies, internal energies, and orientations in space that intersect and react, and one or more detectors that identify the reaction products and characterize their energy distributions as a function of position in three dimensions (see Fig. 18.18).

This apparatus allows the reactant molecules to be prepared in highly selective states. A velocity selector located between the beam source and the collision region (see Fig. 9.17) introduces only those molecules whose velocities fall within a small range. This method allows for much greater control over relative energies than can be achieved simply by controlling the temperature in a macroscopic kinetics experiment. Electric and magnetic fields or laser radiation can be applied to select reactants according to how rapidly they rotate and vibrate. The velocity of products can be measured, their angular distribution relative to the directions of the initial beams can be determined, and their vibration and rotation energies can be determined. All this information allows a much more detailed examination of the way in which molecules collide and react. For example, if the activated complex rotates many times before it finally breaks up into products, the angular distribution of products should be uniform as shown in Figure 18.19a. But if it breaks up before it has a chance to rotate, the angular distribution of products should be very nonuniform and should depend on the directions of the original beams as shown in Figure 18.19b. This type of measurement gives information on the lifetime of an activated complex.

**FIGURE 18.18** Diagram of a crossed molecular beam experiment. The reaction being studied is  $K + HBr \rightarrow KBr + H$ . The curved arrows on the right side of the figure represent rotation of the detector in the vertical and horizontal planes.

**FIGURE 18.19** Angular distributions in the center-of-mass reference frame of the products of the  $O(^1D) + CH_4$  reaction in a crossed molecular beams experiment. (a) The long lifetime of the complex en route to  $H + CH_2OH$  gives the complex time to rotate before breaking up into products. (b) The  $CH_3 + OH$  product channel proceeds through a short-lived activated complex. (Adapted from Xueming Yang, "Multiple channel dynamics in the  $O(^1D)$  reaction with alkanes" *Phys. Chem. Chem. Phys.*, 2006, 8, 205–215, Figures 6 and 9.)

Molecular beams are limited to reactions that are carried out in a vacuum, where well-defined beams of reactant molecules can be prepared. This limits their application to gas-phase reactions and to reactions of gaseous molecules with solid surfaces. Molecular beam methods cannot be used to study kinetics in liquid solvents, though they can be used to study reactions at the liquid-gas interface. The detailed information they provide for gas-gas and gas-surface reactions allows precise testing of models and theories for the dynamics of these classes of reactions.

### EXAMPLE 18.11

In a crossed molecular beams experiment on the  $F_2 + C_2H_4$  reaction, the fluorine molecular beam crossed the ethene molecular beam at right angles, similar to the experiment shown in Figure 18.18. Using velocity selectors, the  $F_2$  reactant molecules selected had a speed of  $700 \text{ m s}^{-1}$  in the  $+x$  direction and the ethene molecules selected had a speed of  $1713 \text{ m s}^{-1}$  in the  $+y$  direction. What is the relative kinetic energy of such a collision? Using a hard sphere model, what is the largest impact parameter that has a chance to result in the reactants surmounting the  $23 \text{ kJ mol}^{-1}$  potential energy barrier and going on to products? Assume the hard sphere radius of  $F_2 = 1.8 \text{ \AA}$  and of  $C_2H_4 = 2.3 \text{ \AA}$ .

#### Solution

You may choose either reactant as #1; here we choose the  $F_2$  molecule.  $\vec{v}_{\text{rel}} = \vec{v}_2 - \vec{v}_1 = (0, 1713) - (700, 0) = (-700, 1713)$  and the magnitude of the relative velocity is  $1851 \text{ m s}^{-1}$ . The relative kinetic energy is

$$\epsilon_{\text{rel}} = \frac{1}{2} \mu v_{\text{rel}}^2 = \frac{1}{2} \left( 16.12 \frac{\text{g}}{\text{mol}} \right) \left( \frac{1 \text{ kg}}{1000 \text{ g}} \right) (1851 \text{ m s}^{-1})^2 = 27.6 \text{ kJ mol}^{-1}.$$

$$\text{Using Equation 18.17 } b_o = 4.1 \text{ \AA} \left( 1 - \frac{23 \text{ kJ mol}^{-1}}{27.6 \text{ kJ mol}^{-1}} \right)^{\frac{1}{2}} = 1.7 \text{ \AA}.$$

## 18.7 Reactions in Solution

Reactions in solution are much more complicated to describe than their gas-phase counterparts because the transport mechanism in solutions is much different. Molecules in the gas phase travel in straight lines between collisions, whereas solute molecules in solution are continually being bounced around by collisions with solvent molecules that lead to transport by diffusion. Collisions between reactants in solution occur much less frequently than for those in the

gas phase, but the reactants may be bound together by a “cage” of solvent molecules for sufficiently long periods that they can acquire enough energy through collisions with the solvent to react. We can use the steady-state approximation to help understand the process.

Consider the two-step sequence

We invoke the steady-state approximation to calculate the concentration of the intermediate AB, from which we can calculate the rate of the overall reaction as follows.

$$\begin{aligned} \text{rate} &= k_2[AB] \\ \frac{d[AB]}{dt} &= k_1[A][B] - k_{-1}[AB] - k_2[AB] = 0 \\ [AB] &= \frac{k_1[A][B]}{k_{-1} + k_2} \\ \text{rate} &= k_2[AB] = \frac{k_1 k_2 [A][B]}{k_{-1} + k_2} \end{aligned}$$

Let's investigate the limits  $k_2 \gg k_{-1}$  and  $k_2 < k_{-1}$ , respectively. The overall rate in the former case is given by

$$\text{rate} = k_1[A][B]$$

and if  $k_1$  is limited by the rate at which the reactants encounter one another by diffusion, we call this a **diffusion-controlled reaction**, with a rate constant conventionally called  $k_d$ . If instead the rate constant for the second step is slower than that of the first step and equilibrium is established in the first step, then the rate expression becomes

$$\text{rate} = k_2 K_1 [A][B]$$

where  $K_1$  is the equilibrium constant for the first reaction in the series. A slow second step implies a large activation energy, so reactions of this type are often called *activation-energy controlled*.

A simple model for diffusion-controlled reactions was constructed by M. V. Smoluchowski in 1916, shortly after Einstein presented his model of Brownian motion. The idea is that molecules diffuse toward one another with mean-square displacements given by the formula

$$\overline{(\Delta r)^2} = 6Dt$$

where  $D$  is the diffusion constant in units  $\text{m}^2 \text{s}^{-1}$ . Typical values for diffusion constants of small molecules in solution are of the order of  $10^{-9} \text{m}^2 \text{s}^{-1}$ , which means that a small molecule will travel about  $10 \mu\text{m}$  in a second, in contrast to molecular speeds in gases that are the order of a few hundred meters per second near room temperature. The molecule does not travel far because its motion is that depicted in Figure 9.25; it keeps changing direction as it becomes trapped in local solvent cages and then escapes to nearby cages, but in ever-changing directions. Smoluchowski's model assumes that a number of B molecules, for example, are diffusing toward a stationary molecule A and solves the radial diffusion equation to find the rate at which B molecules arrive at A. Reaction is assumed to occur when the molecules (represented as hard spheres of radii  $r_A$

and  $r_B$ ) collide, being separated by a distance  $R^* = (r_A + r_B)$ . There is no reason to prefer B over A for the species that is diffusing, so an effective diffusion constant  $D = D_A + D_B$  is used instead. The final result is

$$k_d = 4\pi R^* D N_A$$

where  $N_A$  is Avogadro's number, not the number density of A molecules. Bimolecular rate constants have units  $\text{L mol}^{-1} \text{s}^{-1}$ , from which we can extract a typical value for  $R^*$  by substituting  $10^{-9} \text{ m}^2 \text{ s}^{-1}$  for a typical diffusion constant in liquids into the above expression and the measured diffusion controlled rate constant. Diffusion sets an upper limit for the rates of many solution-phase reactions, including enzyme-catalyzed reactions (see Section 18.8). Enzymes with the greatest catalytic efficiencies cannot convert substrates into products any faster than they encounter them. Enzymes whose rates are diffusion-limited are said to have reached “catalytic perfection.”

## 18.8 Catalysis

A **catalyst** is a substance that takes part in a chemical reaction and speeds up the rate but undergoes no permanent chemical change itself. Catalysts therefore do not appear in the overall balanced chemical equation. But their presence very much affects the rate law, modifying and speeding existing pathways or, more commonly, providing completely new pathways by which a reaction can occur (Fig. 18.20). Catalysts have significant effects on reaction rates even when they are present in very small amounts. Industrial chemistry devotes great effort to finding catalysts to accelerate particular desired reactions without increasing the generation of undesired products.

Catalysts increase reaction rates by providing alternate pathways for reactions to occur, pathways that lower the activation energy  $E_a$ , as shown in Figure 18.21. Catalysts lower the activation energies for both the forward *and* the reverse reaction by the same amount, however, which means that they increase the rate of approach to equilibrium as shown in Figure 14.8, for example. Catalysts do not change the thermodynamics of chemical reactions because Gibbs free energies, and therefore equilibrium constants, are state functions and changes in the values of state functions are independent of the path. Reactions that are not allowed thermodynamically will not proceed even under the influence of a catalyst. Catalysts are vitally important in the chemistry of life

**FIGURE 18.20** (a) The decomposition of hydrogen peroxide,  $\text{H}_2\text{O}_2$ , to water and oxygen is catalyzed by adding a very small amount of transition metal oxide. (b) The water evolves as steam because of the heat given off in the reaction.

© Cengage Learning/Charles D. Winters

**FIGURE 18.21** The most important way in which catalysts speed reactions is by reducing the activation energy. Both the uncatalyzed (red) and catalyzed (blue) reaction coordinates are shown. Here we roughly associate the empirical activation energy with the energy barrier (a risky thing to do, especially in solution).

processes as well as in industrial chemistry. Virtually all biochemical reactions are catalyzed by enzymes, and catalysts are used in virtually all industrial reactions. Products are often removed as they are formed in industrial processes so that equilibrium is never reached and very high conversion efficiencies are realized. An **inhibitor**, in contrast, slows down the rate of a chemical reaction, often by increasing an activation energy or by physically blocking a reactive site. Inhibitors are important in industrial chemistry because they reduce the rates of undesirable side reactions, allowing the desired products to form in greater yield. They are also important in biology, where they influence the rates of enzyme-catalyzed reactions by blocking the active sites of enzymes.

Catalysis are classified into two types: homogeneous and heterogeneous. In **homogeneous catalysis** the catalyst is present in the same phase as the reactants, as when a gas-phase catalyst speeds up a gas-phase reaction, or a species dissolved in solution speeds up a reaction in solution. Chlorofluorocarbons and oxides of nitrogen are homogeneous catalysts responsible for the destruction of ozone in the stratosphere. These reactions are examined in more detail in Section 20.6. A second example is the catalysis of the oxidation–reduction reaction

by silver ions in solution. The direct reaction of  $\text{Tl}^+$  with a single  $\text{Ce}^{4+}$  ion to give  $\text{Tl}^{2+}$  as an intermediate is slow. The reaction can be speeded up by adding  $\text{Ag}^+$  ions, which take part in a reaction mechanism of the form

The  $\text{Ag}^+$  ions are not permanently transformed by this reaction because those used up in the first step are regenerated in the second; they play the role of catalyst in significantly speeding the rate of the overall reaction.

In **heterogeneous catalysis** the catalyst is present as a phase distinct from the reaction mixture. The most important case is the catalytic action of certain solid surfaces on gas-phase and solution-phase reactions. A critical step in the production of sulfuric acid relies on a solid oxide of vanadium ( $\text{V}_2\text{O}_5$ ) as catalyst. Many other solid catalysts are used in industrial processes. One of the best studied is the addition of hydrogen to ethylene to form ethane:

**FIGURE 18.22** Platinum catalyzes the reaction  $\text{H}_2 + \text{C}_2\text{H}_4$  by providing a surface that promotes the dissociation of  $\text{H}_2$  to H atoms, which can then add to the  $\text{C}_2\text{H}_4$  stepwise to give ethane,  $\text{C}_2\text{H}_6$ .

The process occurs extremely slowly in the gas phase but is catalyzed by a platinum surface (Fig. 18.22).

Another example is the solid catalyst used to reduce the emission of pollutants such as unburned hydrocarbons, carbon monoxide, and nitrogen oxides in the exhaust streams of automobile engines (Fig. 18.23). A **catalytic converter** is designed to simultaneously *oxidize* hydrocarbons and CO through the reactions

and *reduce* nitrogen oxides through the reactions

Clearly, the best catalyst for the reduction reactions may not be the best for the oxidation reactions, so two catalysts are combined. The noble metals, although expensive, are particularly useful. Typically, platinum and rhodium are deposited on a fine honeycomb mesh of alumina ( $\text{Al}_2\text{O}_3$ ) to give a large surface area that increases the contact time of the exhaust gas with the catalysts. The platinum serves primarily as an oxidation catalyst and the rhodium as a reduction catalyst. Catalytic converters can be poisoned with certain metals that block their active

**FIGURE 18.23** (a) The arrangement of a catalytic converter used to reduce automobile pollution. (b) Cutaway views of several catalytic converters showing different structures for organizing metal catalysts, platinum, palladium, and rhodium on different substrates and supports. A steel-alloy heating element raises the temperature to  $400^\circ\text{C}$  in seconds, activating the catalysts and reducing the pollution emitted in the first minutes after the car is started.

sites and reduce their effectiveness. Because lead is one of the most serious such poisons, automobiles with catalytic converters must use unleaded fuel.

### 18.8.1 Enzyme Catalysis

The vast majority of chemical reactions in living organisms are catalyzed by **enzymes**, proteins that have evolved to enhance reaction rates by many orders of magnitude with exquisite selectivity. Classes of enzyme-catalyzed reactions include oxidation–reduction, hydrolysis, isomerization, and the transfer of functional groups, for example. The reactants (**substrates**) may be either small organic molecules or specific regions of much larger molecules such as proteins and nucleic acids. The oxidation of glucose to carbon dioxide and water in the series of metabolic reactions called glycolysis is an excellent example; glucose, a sugar, is perfectly stable on the shelf but is rapidly metabolized in cells to provide energy. As another example, consider the hydrolysis of urea by the enzyme urease, as represented by the following reaction.

The ratio of the rate constants for the catalyzed and uncatalyzed reactions is called the catalytic power, which for urease is an astonishing factor of  $10^{14}$ . In the subsections that follow we introduce you to the general characteristics of enzymes, present a discussion of the kinetics of enzyme-catalyzed reactions, and introduce you to some mechanisms of enzyme-catalyzed reactions.

### 18.8.2 Enzyme Kinetics

Enzymes are proteins (polypeptides with molar masses of the order  $10^4 \text{ g mol}^{-1}$ ) that selectively bind substrates in a small region called the active site, as shown in Figure 18.24. A particular enzyme is selective with respect both to substrate and to the reaction it catalyzes. Each individual step in a multistep metabolic pathway, for example, must produce actual yields of products in excess of 90% of the theoretical yield to avoid accumulation of undesirable side products.

Enzymes are identified using both common and systematic names, as in other areas of chemistry. Many common names were derived by adding the suffix *-ase* to the name of the substrate: urease catalyzes the hydrolysis of urea, and phosphatases catalyze the hydrolysis of phosphate ester bonds ( $\text{RO}-\text{PO}_3\text{R}'$ ), for example. Other common names provide no clue whatsoever as to the nature of the substrate or the reaction. Catalase enhances the rate of hydrogen peroxide decomposition, and proteases are a class of enzymes that hydrolyze peptide bonds ( $\text{RO}-\text{NHR}'$ ). The International Commission on Enzymes established a systematic classification of enzymes that divides them into six classes, based upon the general nature of the reactions they catalyze, and several subclasses within each class. The major classes and the reactions they catalyze include (1) *oxidoreductases*—redox reactions; (2) *transferases*—functional group transfer reactions, for example, methyl group transfer; (3) *hydrolases*—hydrolysis reactions; (4) *lyases*—addition to carbon–carbon double bonds; (5) *isomerases*—isomerization reactions; and (6) *ligases*—bond-forming reactions. Many enzymes require **cofactors** to carry out their catalytic functions. These are often metal ions, such as  $\text{Fe}^{2+}/\text{Fe}^{3+}$  in the cytochromes, which catalyze electron-transfer reactions, or they may be small organic molecules called **coenzymes**, examples of which include vitamins.

Enzymes work by finding alternate pathways with lower activation energies, as represented by the graph in Figure 18.21. It is customary in enzyme kinetics to refer to the activation energy as a free energy of activation, symbolized as  $\Delta G^\ddagger$ , and to identify the driving forces for enzyme-catalyzed reactions in terms

**FIGURE 18.24** A sketch of an enzyme showing the active site where the enzyme binds the substrate.

of the enthalpies and entropies of activation,  $\Delta H^\ddagger$  and  $\Delta S^\ddagger$ , as discussed in Section 18.6.

The kinetics of enzyme-catalyzed reactions are generally treated using the steady-state approximation in a form that has become known as Michaelis–Menten kinetics. The overall reaction is summarized by the following mechanism

in which E represents the free enzyme, S is the substrate, ES represents the complex formed when the substrate binds to the active site, and P is the final product. The rate constants  $k_1$  and  $k_{-1}$  are the forward and reverse rate constants of the first step, in which an equilibrium may be established, and  $k_2$  is the rate constant of the second step, which is assumed to be irreversible. We find the initial rate (before any back reaction between P and E might occur) by invoking the steady-state approximation to find the concentration of the enzyme–substrate complex, [ES], as discussed in Section 18.4. The concentration of [ES] reaches a steady state when the rate of formation equals the rate of decay.

$$\frac{d[\text{ES}]}{dt} = 0 = k_1[\text{E}][\text{S}] - k_{-1}[\text{ES}] - k_2[\text{ES}]$$

We could solve this equation to find [ES] in terms of [E], but it is not straightforward to measure the concentration of the free enzyme directly, so an alternative approach has been developed. The total concentration  $[\text{E}_\text{T}]$  of enzyme present is the sum of the concentrations of the free enzyme [E] and the enzyme–substrate complex [ES], a quantity that is readily accessible experimentally. Setting  $[\text{E}_\text{T}] = [\text{E}] + [\text{ES}]$  allows us to make the substitution  $[\text{E}] = [\text{E}_\text{T}] - [\text{ES}]$  in the preceding steady-state equation to get

$$\frac{d[\text{ES}]}{dt} = 0 = k_1[\text{E}_\text{T}][\text{S}] - k_1[\text{ES}][\text{S}] - k_{-1}[\text{ES}] - k_2[\text{ES}]$$

and solve for [ES] to give

$$[\text{ES}] = \frac{k_1[\text{E}_\text{T}][\text{S}]}{(k_{-1} + k_2) + k_1[\text{S}]}$$

We define the *Michaelis constant*  $K_\text{m}$  (in units of *molarity*) as

$$K_\text{m} = \frac{k_{-1} + k_2}{k_1}$$

which allows us to express the steady-state concentration of [ES] as

$$[\text{ES}] = \frac{[\text{E}_\text{T}][\text{S}]}{K_\text{m} + [\text{S}]}$$

The rate of formation of product is then given by

$$\frac{d[\text{P}]}{dt} = k_2[\text{ES}] = \frac{k_2[\text{E}_\text{T}][\text{S}]}{K_\text{m} + [\text{S}]} \quad [18.20]$$

which is called the **Michaelis–Menten equation**. Figure 18.25 shows a plot of the overall rate as a function of substrate concentration [S].

The rate is linear (first order) at low substrate concentrations but rolls over to become independent of [S] at higher concentrations, saturating at a maximum rate  $V_\text{max}$ . The physical origin of this saturation behavior is easy to understand.

**FIGURE 18.25** Michaelis–Menten plot of the dependence of the rate of an enzyme-catalyzed reaction on the concentration of the substrate, showing saturation behavior.

The first step in the overall reaction is first order in E, first order in S, and second order overall. The rate increases with increasing [S], for a fixed concentration of enzyme, until all of the available active sites have bound substrate, after which point no further increase in rate with increasing [S] occurs. We can calculate  $V_{\max}$  from Equation 18.20 by taking the limit in which  $[S] \gg K_m$  and setting  $K_m = 0$  in the denominator to get  $V_{\max} = k_2[E_T]$ . The Michaelis–Menten equation is often written in the following alternative form to emphasize the central role of  $V_{\max}$  in enzyme kinetics.

$$\frac{d[P]}{dt} = k_2[ES] = \frac{V_{\max}[S]}{K_m + [S]}$$

Rearranging this equation into the form

$$K_m = [S] \left[ \left( \frac{V_{\max}}{dP/dt} \right) - 1 \right]$$

allows us to find  $K_m$  experimentally.  $K_m = [S]$  when  $dP/dt = V_{\max}/2$ , so we simply measure the substrate concentration for which the rate is exactly half the maximum rate, as indicated on the graph in Figure 18.25. This procedure is only approximate, however, because it may be very difficult to arrange conditions that permit the accurate determination of  $V_{\max}$ .

The **turnover number**  $k_{\text{cat}}$  is an important measure of catalytic activity for enzyme-catalyzed reactions. It is defined as the number of substrate molecules converted into product per enzyme molecule per second (turnover numbers are defined in analogous ways for other kinds of catalysts as well) and is easily calculated by measuring the maximum rate for a known enzyme concentration. The maximum rate for a given total enzyme concentration is obtained from the alternative form of the Michaelis–Menten equation by making  $[S] \gg K_m$  and recognizing that  $[ES] = [E_T]$  at saturation, from which we get

$$k_{\text{cat}} \equiv k_2 = \frac{V_{\max}}{E_T}$$

Turnover numbers for different enzymes vary over an enormously wide range; each catalase molecule can decompose 40 million molecules of hydrogen peroxide per second, whereas the turnover number of chymotrypsin (see the *Connection to Biology* in Chapter 7) is about 100 and that of lysozyme is about 0.5.

Enzymes rarely operate near saturation under physiological conditions, so it is interesting to consider another measure of catalytic efficiency for low substrate concentrations. Recall from Section 18.4 that reactions for which  $k_2 \gg k_{-1}[M]$  show second-order kinetics; that is, the first step is rate-limiting. In the present

**FIGURE 18.26** A graph of the linear form of the Michaelis–Menten equation that shows how the parameters  $K_m$  and  $V_{\max}$  are determined.

case we can begin with the alternative form of the Michaelis–Menten equation, substitute  $V_{\max} = k_{\text{cat}}[E_T]$  and set  $[S] = K_m$  to get

$$\frac{d[\text{P}]}{dt} = \left( \frac{k_{\text{cat}}}{K_m} \right) [\text{E}][\text{S}]$$

where  $[\text{E}]$  is the concentration of the free enzyme. The maximum rate for this first step is the rate at which  $\text{E}$  and  $\text{S}$  encounter one another; diffusion-limited rate constants are typically about  $10^9 \text{ L mol}^{-1} \text{ s}^{-1}$  for small substrates (such as  $\text{H}_2\text{O}_2$ ), and about an order of magnitude smaller for high molecular weight substrates, such as proteins and nucleic acids (see Section 18.6). Comparing experimental ( $k_{\text{cat}}/K_m$ ) ratios to the diffusion-limited rate constants provides an important measure of the catalytic efficiency of enzymes. Finally, a linear version of the Michaelis–Menten equation makes it convenient to obtain both  $V_{\max}$  and  $K_m$  graphically. We rewrite the equation in the following form

$$\frac{1}{d[\text{P}]/dt} = \left( \frac{K_m}{V_{\max}} \right) \left( \frac{1}{[\text{S}]} \right) + \frac{1}{V_{\max}}$$

and plot the inverse of the rate versus  $1/[\text{S}]$ , as shown in Figure 18.26. The slope is  $K_m/V_{\max}$  and the  $y$ -intercept is  $1/V_{\max}$ , allowing us to extract the values of both constants from one plot.

The kinetics of enzyme-catalyzed reactions are temperature-dependent, like most chemical reactions, but the rates begin to fall off gradually with temperature above  $50\text{--}60^\circ\text{C}$  or so, as shown in Figure 18.27. The rates increase with temperature, typically doubling every  $10^\circ\text{C}$  like many other reactions, but eventually beginning to decline as the three-dimensional structures of proteins, which are essential for their catalytic function, unfold and degrade.

**FIGURE 18.27** Plot of the activity of an enzyme versus temperature. The increase in rate at low temperatures is described by the Arrhenius equation whereas the falloff in rate at higher temperatures is due to loss of structure necessary for function.

## CONNECTION TO BIOLOGY

## Mechanisms of Enzyme-Catalyzed Reactions

The high degree of specificity observed for enzyme-catalyzed reactions was first attributed to a “lock-and-key” mechanism, in which binding of substrates (the key) was effected through molecular recognition by the active site of enzymes (the lock), as suggested by Figure C18.1.

Enzymes are considerably more flexible than suggested by the lock-and-key model, however, and the realization that enzyme–substrate interactions were more dynamic than suggested by that model led to the development of the **induced fit** hypothesis, in which the binding of substrate by active sites is a cooperative endeavor. The conformation of the enzyme and the substrate change dynamically during binding, catalysis, and product release to destabilize the ES and EP (enzyme–product) complexes and stabilize the transition state (or create a new one). The specificity of this process is illustrated schematically in Figure C18.2 for the

FIGURE C18.1 Lock and key mechanism.

enzyme hexokinase showing (a) the active site before binding substrate and (b) binding of glucose accompanied by global structural changes that brings the two domains together and closes off the active site. The inset shows the relative sizes of glucose, glycerol and water.

enzyme hexokinase, which adds a phosphate group to six-carbon sugars but not to smaller molecules, even those of similar size and shape like glycerol ( $C_3H_5(OH)_3$ ) shown in the inset. The protein consists of two subunits (domains) with a cleft in between, in which the residues of the active site reside. Binding of glucose causes a conformational change in the protein that brings the two domains into closer contact, thus creating the active site. This induced-fit mechanism explains how enzymes have evolved to confer such great selectivity; catalysis depends upon the properties of both the enzyme and the substrate, a very restrictive set of requirements.

Plotting the free-energy system as a function of reaction coordinate helps us understand how enzymes catalyze reactions from the point of view of chemical thermodynamics. Molecular models (see later) help us visualize the mechanisms by which they operate. Figure C18.3 shows a plot of the Gibbs free energy for the uncatalyzed reaction (a) as well as for the enzyme-catalyzed reaction (b). The activated complex for the uncatalyzed reaction is represented by the symbol  $X^\ddagger$ , and the enzyme transition-state complex in the enzyme-catalyzed reaction is represented by the symbol  $EX^\ddagger$ . The energy of the  $EX^\ddagger$  complex is certainly lower than the energy of the  $X^\ddagger$  complex for the uncatalyzed reaction, which suggests a mechanism for accelerating the rate by lowering the activation energy barrier. Notice, however, that there is a shallow well that corresponds to the binding energy of the ES complex. Enzymes only catalyze reactions when they destabilize (lower the energy of) the transition state complex more than they stabilize the ES complex. Let's see how this comes about by separately analyzing the enthalpic and entropic contributions to the Gibbs free energy associated with binding of substrate.

Attractive intermolecular interactions (see Section 10.2) ensure that the binding of substrate is exothermic, which favors spontaneity. Strong binding of substrate,

however, is undesirable, for it would create a permanent ES complex, making an enzyme unavailable for catalysis. The key to efficient catalytic activity is the fine tuning of the ES stabilization energy that allows for selective molecular recognition and binding without rendering the enzyme inactive. Two effects counteract the strong driving force provided by enthalpy. First, there is a loss of entropy that accompanies the formation of the ES complex from E and S, particularly due to the reduction in entropy of small molecule substrates as they effectively leave solution. Second, the ES complex is destabilized to some extent by strain, distortion, and loss of solvent. Figure C18.3 shows how the combination of transition state stabilization and ES complex destabilization leads to a reduction in the activation energy.

What are the mechanisms by which enzymes actually work to catalyze reactions? Structures of the active sites of enzymes, with and without bound substrates, have

been investigated in great detail by X-ray crystallography in the solid state and by a number of spectroscopic techniques, such as NMR (see Section 20.4), in solution. These studies, supported by molecular dynamics simulations, have led to the conclusion that the “preorganization” of the active site prepares it for its catalytic role in which it directs the substrate to adopt the conformation most favorable for effecting the reaction of interest. We have already shown, in the *Connection to Biology* in Chapter 7, how the three amino acid residues that comprise the active site of the enzyme chymotrypsin are organized in space to optimally carry out the hydrolysis of peptide bonds. Protein motion is essential to catalysis: to configure the active site to recognize and bind substrates in optimal conformations, to locate catalytic groups near where they are needed, facilitate bond breaking and bond formation, and, finally, to assist in the conversion to products and their release.

**FIGURE C18.3** (a) Free energy profile for the uncatalyzed conversion of substrate to product. (b) Energy profile for the enzyme-catalyzed reaction that shows the preferential stabilization of the enzyme transition-state complex with respect to the enzyme substrate complex.

## CHAPTER SUMMARY

Chemical kinetics is the study of the rates of chemical reactions and the factors that control those rates. The rates of chemical reactions depend on the concentrations of all of the reactants and products as well as the temperature. The concentration dependence of reaction rates is given by empirical rate laws in which the rate depends on the concentration of each reactant raised to some power that is not, in general, related to the stoichiometric coefficients in the balanced equation for the reaction. Rate laws may be determined by measuring the initial rate of a reaction as a function of initial concentration or by inspecting the concentration-time profile over the course of the reaction. Concentrations decrease exponentially with time for first-order reactions and the half-life is a characteristic time scale for the reaction. Most chemical reactions occur as a series of elementary reactions, which constitute the reaction mechanism. The steady-state approximation provides a simple framework to analyze the kinetics of multistep reactions. This approximation, which is widely used in many areas of chemistry and biochemistry, shows how a reaction may display either first- or second-order kinetics, depending on the

concentration of inert collision partners. It also accounts for the rate-limiting step, which determines the overall rate of the reaction. Spectroscopic detection or chemical trapping of reaction intermediates is a powerful way to establish a reaction mechanism. The rates of elementary reactions increase with increasing temperature. As temperatures rise, more molecules have enough energy to overcome the potential energy barrier to the reaction and proceed to form products. Microscopic theories have been developed that provide molecular-level understanding of the factors that govern the rates of chemical reactions. These theories are based on the collision theory, which asserts that the rates are proportional to the rates of collisions times the probability of particular collisions leading to reaction. The probabilities are expressed in terms of the reactive cross section, which is interpreted as the effective size two colliding molecules present to each other that ensures reaction upon every collision. Catalysts increase the rates of chemical reactions without being either consumed or produced. Synthetic catalysts are widely used in industrial processes, and natural catalysts called enzymes catalyze and regulate the rates of virtually all biological processes. Catalysts work by lowering the activation barrier for chemical reactions.

## CONCEPTS AND SKILLS

### Section 18.1 – Rates of Chemical Reactions

*Describe experimental methods for measuring average and instantaneous rates (Problems 1–2).*

- The rates of chemical reactions are measured by determining the concentrations of reactants and products as a function of time. Concentrations may be measured by a variety of chemical or instrumental methods. The average rate is the change in concentration measured over a period of time divided by the time. The instantaneous rate is the slope of a line that is tangent to the concentration-time plot at the time of interest.

### Section 18.2 – Rate Laws

*Deduce rate laws and reaction orders from experimental measurements of the dependence of reaction rates on concentrations (Problems 5–8).*

- Rate laws and reaction orders are deduced from the concentration dependence of the reaction rate as follows. The reaction is run under two conditions with the concentration of only one reactant being changed; if the rate doubles when the concentration of that reactant doubles, then the reaction is first order with respect to that reactant; if it quadruples, then it is second order. The process is repeated, changing the concentrations of each of the reactants in a pair of experiments while keeping all of the other concentrations and the other conditions the same. The rate constant is determined from any single experiment, once the dependence on concentrations has been determined, by dividing the rate by the product of the concentrations raised to their respective orders.

*Use the integrated rate laws for first- and second-order reactions to calculate the concentrations remaining after a certain elapsed time (Problems 9–18).*

- Concentrations at a given elapsed time are calculated by solving the rate equations, inserting the initial conditions and the rate constant as known values.
  - First-order reactions  $c = c_0 e^{-kt}$
  - Second-order reactions  $\frac{1}{c} = \frac{1}{c_0} + 2kt$

### 18.3 – Reaction Mechanisms

*Describe the relationship between the equilibrium constant for an elementary reaction and the corresponding forward and reverse rate constants (Problems 23–24).*

- The equilibrium constant is the ratio of rate constants for the forward and reverse reactions  $K_{\text{eq}} = k_f/k_r$  as required by the principle of detailed balance for elementary processes.

#### 18.4 – Reaction Mechanisms and Rate

*Deduce the rate law from a mechanism characterized by a single rate-determining step (Problems 25–30).*

- The rate law for a mechanism characterized by a single rate-limiting step is given by the rate law for that elementary process, which is determined by inspection.

*Use the steady-state approximation to deduce rate laws when no single rate-determining step exists (Problems 31–34).*

- The rate law for the dissociation of a molecule in the Lindemann mechanism is  $\text{rate} = \frac{k_1 k_2 [A][M]}{k_2 + k_{-1}[M]}$  with limiting forms:  $\text{rate} = k_1 [A][M]$  at low pressure and  $\text{rate} = (k_1/k_{-1})k_2 [A]$  at high pressure.
- Rate laws for other reactions may be deduced using the approximation that the concentration of each reactive intermediate is roughly constant in time.

#### 18.5 – Effect of Temperature on Reaction Rates

*Calculate Arrhenius factors and activation energies from measurements of the temperature dependence of rate constants (Problems 35–40).*

- Arrhenius factors are calculated by plotting  $\ln k$  versus  $1/T$ , the slope of which is  $-E_a/R$ .

*Discuss the connection between activation energy and the energy distribution of molecules, and relate the forward and reverse activation energies to each other through thermodynamics (Problems 41–42).*

- The activation energy is roughly equal to the barrier energy, which is the minimum amount of energy necessary to initiate a chemical reaction. The fraction of collisions having a relative kinetic energy that is greater than or equal to the barrier is determined by the area under the curve of the Maxwell–Boltzmann energy distribution of relative speeds, shown in Fig. 18.10 (and given later in Eq. 18.7), between  $E_a$  and infinity. The fraction of collisions with energy greater than  $E_a$  increases with increasing temperature. The difference between the barrier heights for the forward and reverse reactions is the 0 K enthalpy change of the reaction.

#### 18.6 – Molecular Theories of Elementary Reactions

*Outline the quantitative calculation of rate constants, using the collision theory of gases (Problems 45–46).*

- Collision theory calculates the rates of collisions between molecules using the kinetic theory of gases, and estimates the rates of reactive collisions by asserting that reactions occur only when the relative kinetic energy of the colliding molecules along the line of centers on impact exceeds a minimum energy  $\epsilon_B$ .

#### 18.7 – Reactions in Solution

*Identify reactions as diffusion-controlled or activation-energy controlled (Problems 47–48).*

- Diffusion-controlled reactions are second-order reactions with rate-limiting steps determined by an effective diffusion constant that is the sum of the diffusion constants of the reactants. Activation-energy controlled reactions are ones for which the rate of diffusion for reactants A and B to encounter each other is much faster than the rate at which the AB complex forms products.

## 18.8 – Catalysis

Describe several types of catalysts and their effects on chemical reactions.

- Catalysts increase the rates of chemical reactions by lowering the activation barrier, typically by providing alternate paths.
- Homogeneous catalysts are present in the same phase as the reaction being catalyzed, whereas heterogeneous catalysts are present in a different phase.
- Enzymes are biological catalysts that bind substrates with exquisite selectivity, position reactants at optimal locations, and stabilize transition states, all of which leads to lower activation barriers than those in the uncatalyzed reaction.

Relate the rate of an enzyme-catalyzed reaction to the concentrations of substrate and enzyme in the reaction mixture (Problems 49–50).

- Enzyme-catalyzed reactions often follow the Michaelis–Menten equation, which shows saturation of the rate at high substrate concentrations.

$$\frac{d[P]}{dt} = k_2[ES] = \frac{k_2[E_T][S]}{K_m + [S]} \quad [18.20]$$

## CUMULATIVE EXERCISE

### Sulfite and Sulfate Kinetics in Atmospheric Chemistry

Sulfur dioxide dissolves in water droplets (fog, clouds, and rain) in the atmosphere (Fig. 18.28) and reacts according to the equation

$\text{HSO}_3^-(aq)$  (hydrogen sulfite ion) is then slowly oxidized by oxygen that is also dissolved in the droplets:

Although the second reaction has been studied for many years, only recently was it shown to proceed by the steps

The reactive intermediate,  $\text{S}_2\text{O}_7^{2-}(aq)$ , which had not been detected in earlier studies of this reaction, is well known in other reactions. It is the *disulfate* ion.

In an experiment at 25°C, a solution was mixed with the realistic initial concentrations of 0.270 M  $\text{HSO}_3^-(aq)$  and 0.0135 M  $\text{O}_2(aq)$ . The initial pH was 3.90. The following table tells what happened in the solution, beginning at the moment of mixing.

Time (s)	$[\text{HSO}_3^-]$ (M)	$[\text{O}_2]$ (M)	$[\text{S}_2\text{O}_7^{2-}]$ (M)	$[\text{HSO}_4^-] + [\text{SO}_4^{2-}]$ (M)
0.000	0.270	0.0135	0.000	0.000
0.010	0.243	0.000	$13.5 \times 10^{-3}$	0.000
10.0	0.243	0.000	$11.8 \times 10^{-3}$	$3.40 \times 10^{-3}$
45.0	0.243	0.000	$7.42 \times 10^{-3}$	$12.2 \times 10^{-3}$
90.0	0.243	0.000	$4.08 \times 10^{-3}$	$18.8 \times 10^{-3}$
150.0	0.243	0.000	$1.84 \times 10^{-3}$	$23.3 \times 10^{-3}$
450.0	0.243	0.000	$0.034 \times 10^{-3}$	$26.9 \times 10^{-3}$
600.0	0.243	0.000	$0.005 \times 10^{-3}$	$27.0 \times 10^{-3}$

**FIGURE 18.28** Air pollution is damaging the white marble of one of the world's most famous monuments, the Taj Mahal. Particulate matter and acid rain both contribute to the problem.

- Determine the average rate of increase of the total of the concentrations of the sulfate plus hydrogen sulfate ions during the first 10 s of the experiment.
- Determine the average rate of disappearance of hydrogen sulfite ion during the first 0.010 s of the experiment.
- Explain why the hydrogen sulfite ion stops disappearing after 0.010 s.
- Plot the concentration of disulfate ion versus time, and use the curve to graphically estimate the instantaneous rate of disappearance of disulfate ion 90.0 s after the reaction starts.
- Determine the order with respect to the disulfate ion of the second step of the conversion, and the rate constant of that step.
- Determine the half-life of the second step of the conversion process.
- At 15°C the rate constant of the second step of the conversion is only 62% of its value at 25°C. Compute the activation energy of the second step.
- The first step of the conversion occurs much faster when  $1.0 \times 10^{-6}$  M  $\text{Fe}^{2+}(\text{aq})$  ion is added (but the rate of the second step is unaffected). What role does  $\text{Fe}^{2+}$  play?
- Write a balanced equation for the overall reaction that gives sulfuric acid from  $\text{SO}_2$  dissolved in water droplets in the air.

### Answers

- $3.40 \times 10^{-4} \text{ mol L}^{-1} \text{ s}^{-1}$
- $2.7 \text{ mol L}^{-1} \text{ s}^{-1}$
- All of the oxygen is consumed, so the first step of the process is over.
- $5.43 \times 10^{-5} \text{ mol L}^{-1} \text{ s}^{-1}$
- First order;  $k = 0.0133 \text{ s}^{-1}$
- 52 s
- 34 kJ mol<sup>-1</sup>
- $\text{Fe}^{2+}$  acts as a catalyst.
- $2 \text{ SO}_2(\text{aq}) + \text{O}_2(\text{aq}) + 6 \text{ H}_2\text{O}(\ell) \longrightarrow \text{SO}_4^{2-}(\text{aq}) + 4 \text{ H}_3\text{O}^+(\text{aq})$

## PROBLEMS

Answers to problems whose numbers are red appear in Appendix G. Problems that are more challenging are indicated with asterisks.

### 18.1 Rates of Chemical Reactions

- Use Figure 18.3 to estimate graphically the instantaneous rate of production of NO at  $t = 200$  s.
- Use Figure 18.3 to estimate graphically the instantaneous rate of production of NO at  $t = 100$  s.
- Give three related expressions for the rate of the reaction

assuming that the concentrations of any intermediates are constant and that the volume of the reaction vessel does not change.

- Give four related expressions for the rate of the reaction

assuming that the concentrations of any intermediates are constant and that the volume of the reaction vessel does not change.

### 18.2 Rate Laws

- Nitrogen oxide reacts with hydrogen at elevated temperatures according to the following chemical equation:

It is observed that, when the concentration of  $\text{H}_2$  is cut in half, the rate of the reaction is also cut in half. When the concentration of NO is multiplied by 10, the rate of the reaction increases by a factor of 100.

- Write the rate expression for this reaction, and give the units of the rate constant  $k$ .
- If  $[\text{NO}]$  were multiplied by 3 and  $[\text{H}_2]$  by 2, what change in the rate would be observed?

6. In the presence of vanadium oxide,  $\text{SO}_2(\text{g})$  reacts with an excess of oxygen to give  $\text{SO}_3(\text{g})$ :

This reaction is an important step in the manufacture of sulfuric acid. It is observed that tripling the  $\text{SO}_2$  concentration increases the rate by a factor of 3, but tripling the  $\text{SO}_3$  concentration decreases the rate by a factor of  $1.7 \approx \sqrt{3}$ . The rate is insensitive to the  $\text{O}_2$  concentration as long as an excess of oxygen is present.

- (a) Write the rate expression for this reaction, and give the units of the rate constant  $k$ .
- (b) If  $[\text{SO}_2]$  is multiplied by 2 and  $[\text{SO}_3]$  by 4 but all other conditions are unchanged, what change in the rate will be observed?
7. In a study of the reaction of pyridine ( $\text{C}_5\text{H}_5\text{N}$ ) with methyl iodide ( $\text{CH}_3\text{I}$ ) in a benzene solution, the following set of initial reaction rates was measured at  $25^\circ\text{C}$  for different initial concentrations of the two reactants:

$[\text{C}_5\text{H}_5\text{N}]$ (mol L <sup>-1</sup> )	$[\text{CH}_3\text{I}]$ (mol L <sup>-1</sup> )	Rate (mol L <sup>-1</sup> s <sup>-1</sup> )
$1.00 \times 10^{-4}$	$1.00 \times 10^{-4}$	$7.5 \times 10^{-7}$
$2.00 \times 10^{-4}$	$2.00 \times 10^{-4}$	$3.0 \times 10^{-6}$
$2.00 \times 10^{-4}$	$4.00 \times 10^{-4}$	$6.0 \times 10^{-6}$

- (a) Write the rate expression for this reaction.
- (b) Calculate the rate constant  $k$  and give its units.
- (c) Predict the initial reaction rate for a solution in which  $[\text{C}_5\text{H}_5\text{N}]$  is  $5.0 \times 10^{-5}$  M and  $[\text{CH}_3\text{I}]$  is  $2.0 \times 10^{-5}$  M.
8. The rate for the oxidation of iron(II) by cerium(IV)

is measured at several different initial concentrations of the two reactants:

$[\text{Ce}^{4+}]$ (mol L <sup>-1</sup> )	$[\text{Fe}^{2+}]$ (mol L <sup>-1</sup> )	Rate (mol L <sup>-1</sup> s <sup>-1</sup> )
$1.1 \times 10^{-5}$	$1.8 \times 10^{-5}$	$2.0 \times 10^{-7}$
$1.1 \times 10^{-5}$	$2.8 \times 10^{-5}$	$3.1 \times 10^{-7}$
$3.4 \times 10^{-5}$	$2.8 \times 10^{-5}$	$9.5 \times 10^{-7}$

- (a) Write the rate expression for this reaction.
- (b) Calculate the rate constant  $k$  and give its units.
- (c) Predict the initial reaction rate for a solution in which  $[\text{Ce}^{4+}]$  is  $2.6 \times 10^{-5}$  M and  $[\text{Fe}^{2+}]$  is  $1.3 \times 10^{-5}$  M.
9. The reaction  $\text{SO}_2\text{Cl}_2(\text{g}) \longrightarrow \text{SO}_2(\text{g}) + \text{Cl}_2(\text{g})$  is first order, with a rate constant of  $2.2 \times 10^{-5} \text{ s}^{-1}$  at  $320^\circ\text{C}$ . The partial pressure of  $\text{SO}_2\text{Cl}_2(\text{g})$  in a sealed vessel at  $320^\circ\text{C}$  is 1.0 atm. How long will it take for the partial pressure of  $\text{SO}_2\text{Cl}_2(\text{g})$  to fall to 0.50 atm?
10. The reaction  $\text{FCIO}_2(\text{g}) \longrightarrow \text{FCIO}(\text{g}) + \text{O}(\text{g})$  is first order with a rate constant of  $6.76 \times 10^{-4} \text{ s}^{-1}$  at  $322^\circ\text{C}$ .
- (a) Calculate the half-life of the reaction at  $322^\circ\text{C}$ .
- (b) If the initial partial pressure of  $\text{FCIO}_2$  in a container at  $322^\circ\text{C}$  is 0.040 atm, how long will it take to fall to 0.010 atm?

11. The decomposition of benzene diazonium chloride

follows first-order kinetics with a rate constant of  $4.3 \times 10^{-5} \text{ s}^{-1}$  at  $20^\circ\text{C}$ . If the initial partial pressure of  $\text{C}_6\text{H}_5\text{N}_2\text{Cl}$  is 0.0088 atm, calculate its partial pressure after 10.0 hours.

12. At 600 K, the rate constant for the first-order decomposition of nitroethane

is  $1.9 \times 10^{-4} \text{ s}^{-1}$ . A sample of  $\text{CH}_3\text{CH}_2\text{NO}_2$  is heated to 600 K, at which point its initial partial pressure is measured to be 0.078 atm. Calculate its partial pressure after 3.0 hours.

13. Chloroethane decomposes at elevated temperatures according to the reaction

This reaction obeys first-order kinetics. After 340 s at 800 K, a measurement shows that the concentration of  $\text{C}_2\text{H}_5\text{Cl}$  has decreased from 0.0098 mol L<sup>-1</sup> to 0.0016 mol L<sup>-1</sup>. Calculate the rate constant  $k$  at 800 K.

14. The isomerization reaction

obeys the first-order rate law

$$\text{rate} = -k[\text{CH}_3\text{NC}]$$

in the presence of an excess of argon. Measurements at 500 K reveal that in 520 s the concentration of  $\text{CH}_3\text{NC}$  decreases to 71% of its original value. Calculate the rate constant  $k$  of the reaction at 500 K.

15. At  $25^\circ\text{C}$  in  $\text{CCl}_4$  solvent, the reaction

is second order in the concentration of the iodine atoms. The rate constant  $k$  has been measured as  $8.2 \times 10^9 \text{ L mol}^{-1} \text{ s}^{-1}$ . Suppose the initial concentration of I atoms is  $1.00 \times 10^{-4}$  M. Calculate their concentration after  $2.0 \times 10^{-6}$  s.

16.  $\text{HO}_2$  is a highly reactive chemical species that plays a role in atmospheric chemistry. The rate of the gas-phase reaction

is second order in  $[\text{HO}_2]$ , with a rate constant at  $25^\circ\text{C}$  of  $1.4 \times 10^9 \text{ L mol}^{-1} \text{ s}^{-1}$ . Suppose some  $\text{HO}_2$  with an initial concentration of  $2.0 \times 10^{-8}$  M could be confined at  $25^\circ\text{C}$ . Calculate the concentration that would remain after 1.0 s, assuming no other reactions take place.

17. The rate for the reaction

is first order in both  $\text{OH}^-$  and  $\text{NH}_4^+$  concentrations, and the rate constant  $k$  at  $20^\circ\text{C}$  is  $3.4 \times 10^{10} \text{ L mol}^{-1} \text{ s}^{-1}$ . Suppose 1.00 L of a 0.0010 M NaOH solution is rapidly mixed with the same volume of 0.0010 M  $\text{NH}_4\text{Cl}$  solution. Calculate the time (in seconds) required for the  $\text{OH}^-$  concentration to decrease to a value of  $1.0 \times 10^{-5}$  M.

18. The rate for the reaction

is first order in both  $\text{OH}^-$  and  $\text{HCN}$  concentrations, and the rate constant  $k$  at  $25^\circ\text{C}$  is  $3.7 \times 10^9 \text{ L mol}^{-1} \text{ s}^{-1}$ . Suppose 0.500 L of a 0.0020 M  $\text{NaOH}$  solution is rapidly mixed with the same volume of a 0.0020 M  $\text{HCN}$  solution. Calculate the time (in seconds) required for the  $\text{OH}^-$  concentration to decrease to a value of  $1.0 \times 10^{-4} \text{ M}$ .

### 18.3 Reaction Mechanisms

19. Identify each of the following elementary reactions as unimolecular, bimolecular, or termolecular, and write the rate expression.

20. Identify each of the following elementary reactions as unimolecular, bimolecular, or termolecular, and write the rate expression.

21. Consider the following reaction mechanism:

- (a) What is the molecularity of each elementary step?  
 (b) Write the overall equation for the reaction.  
 (c) Identify the reaction intermediate(s).

22. Consider the following reaction mechanism:

- (a) What is the molecularity of each elementary step?  
 (b) Write the overall equation for the reaction.  
 (c) Identify the reaction intermediate(s).

23. The rate constant of the elementary reaction

is  $1.3 \times 10^{10} \text{ L mol}^{-1} \text{ s}^{-1}$  at  $25^\circ\text{C}$ , and its equilibrium constant is  $5.0 \times 10^{10}$  at this temperature. Calculate the rate constant at  $25^\circ\text{C}$  of the elementary reaction

24. The compound
- $\text{IrH}_3(\text{CO})(\text{P}(\text{C}_6\text{H}_5)_3)_2$
- exists in two forms: the meridional (“mer”) and facial (“fac”). At
- $25^\circ\text{C}$
- in a nonaqueous solvent, the reaction mer
- $\longrightarrow$
- fac has a rate constant of
- $2.33 \text{ s}^{-1}$
- , and the reaction fac
- $\longrightarrow$
- mer has a rate constant of
- $2.10 \text{ s}^{-1}$
- . What is the equilibrium constant of the mer-to-fac reaction at
- $25^\circ\text{C}$
- ?

### 18.4 Reaction Mechanisms and Rate

25. Write the overall reaction and rate laws that correspond to the following reaction mechanisms. Be sure to eliminate intermediates from the answers.

26. Write the overall reaction and the rate laws that correspond to the following reaction mechanisms. Be sure to eliminate intermediates from the answers.

- 27.
- $\text{HCl}$
- reacts with propene (
- $\text{CH}_3\text{CHCH}_2$
- ) in the gas phase according to the overall reaction

The experimental rate expression is

$$\text{rate} = k[\text{HCl}]^3[\text{CH}_3\text{CHCH}_2]$$

Which, if any, of the following mechanisms are consistent with the observed rate expression?

28. Chlorine reacts with hydrogen sulfide in aqueous solution

in a second-order reaction that follows the rate expression

$$\text{rate} = k[\text{Cl}_2][\text{H}_2\text{S}]$$

Which, if any, of the following mechanisms are consistent with the observed rate expression?

- (a)  $\text{Cl}_2 + \text{H}_2\text{S} \longrightarrow \text{H}^+ + \text{Cl}^- + \text{Cl}^+ + \text{HS}^-$  (slow)  
 $\text{Cl}^+ + \text{HS}^- \longrightarrow \text{H}^+ + \text{Cl}^- + \text{S}$  (fast)
- (b)  $\text{H}_2\text{S} \rightleftharpoons \text{HS}^- + \text{H}^+$  (fast equilibrium)  
 $\text{HS}^- + \text{Cl}_2 \longrightarrow 2 \text{Cl}^- + \text{S} + \text{H}^+$  (slow)
- (c)  $\text{H}_2\text{S} \rightleftharpoons \text{HS}^- + \text{H}^+$  (fast equilibrium)  
 $\text{H}^+ + \text{Cl}_2 \rightleftharpoons \text{H}^+ + \text{Cl}^- + \text{Cl}^+$  (fast equilibrium)  
 $\text{Cl}^+ + \text{HS}^- \longrightarrow \text{H}^+ + \text{Cl}^- + \text{S}$  (slow)
29. Nitryl chloride is a reactive gas with a normal boiling point of  $-16^\circ\text{C}$ . Its decomposition to nitrogen dioxide and chlorine is described by the equation

The rate expression for this reaction has the form

$$\text{rate} = k[\text{NO}_2\text{Cl}]$$

Which, if any, of the following mechanisms are consistent with the observed rate expression?

- (a)  $\text{NO}_2\text{Cl} \longrightarrow \text{NO}_2 + \text{Cl}$  (slow)  
 $\text{Cl} + \text{NO}_2\text{Cl} \longrightarrow \text{NO}_2 + \text{Cl}_2$  (fast)
- (b)  $2 \text{NO}_2\text{Cl} \rightleftharpoons \text{N}_2\text{O}_4 + \text{Cl}_2$  (fast equilibrium)  
 $\text{N}_2\text{O}_4 \longrightarrow 2 \text{NO}_2$  (slow)
- (c)  $2 \text{NO}_2\text{Cl} \rightleftharpoons \text{ClO}_2 + \text{N}_2\text{O} + \text{ClO}$  (fast equilibrium)  
 $\text{N}_2\text{O} + \text{ClO}_2 \rightleftharpoons \text{NO}_2 + \text{NOCl}$  (fast equilibrium)  
 $\text{NOCl} + \text{ClO} \longrightarrow \text{NO}_2 + \text{Cl}_2$  (slow)
30. Ozone in the upper atmosphere is decomposed by nitrogen oxide through the reaction

The experimental rate expression for this reaction is

$$\text{rate} = k[\text{O}_3][\text{NO}]$$

Which, if any, of the following mechanisms are consistent with the observed rate expression?

- (a)  $\text{O}_3 + \text{NO} \longrightarrow \text{O} + \text{NO}_3$  (slow)  
 $\text{O} + \text{O}_3 \longrightarrow 2 \text{O}_2$  (fast)  
 $\text{NO}_3 + \text{NO} \longrightarrow 2 \text{NO}_2$  (fast)
- (b)  $\text{O}_3 + \text{NO} \longrightarrow \text{O}_2 + \text{NO}_2$  (slow)
- (c)  $\text{NO} + \text{NO} \rightleftharpoons \text{N}_2\text{O}_2$  (fast equilibrium)  
 $\text{N}_2\text{O}_2 + \text{O}_3 \longrightarrow \text{NO}_2 + 2 \text{O}_2$  (slow)
31. Consider the mechanism of problem 25(a). Suppose *no* assumptions are made about the relative rates of the steps. By making a steady-state approximation for the concentration of the intermediate (C), express the rate of production of the product (F) in terms of the concentrations of A, B, D, and E. In what limit does this reduce to the result of problem 25(a)?
32. Consider the mechanism of problem 25(b). Suppose *no* assumptions are made about the relative rates of the steps. By making a steady-state approximation for the concentrations of the intermediates (C and E), express the rate of production of the product (F) in terms of the concentrations of A, B, and D. In what limit does this reduce to the result of problem 25(b)?

33. The mechanism for the decomposition of  $\text{NO}_2\text{Cl}$  is

By making a steady-state approximation for  $[\text{Cl}]$ , express the rate of appearance of  $\text{Cl}_2$  in terms of the concentrations of  $\text{NO}_2\text{Cl}$  and  $\text{NO}_2$ .

34. A key step in the formation of sulfuric acid from dissolved  $\text{SO}_2$  in acid precipitation is the oxidation of hydrogen sulfite ion by hydrogen peroxide:

The mechanism involves peroxymonosulfurous acid,  $\text{SO}_2\text{OOH}^-$ :

By making a steady-state approximation for the reactive intermediate concentration,  $[\text{SO}_2\text{OOH}^-(aq)]$ , express the rate of formation of  $\text{HSO}_4^-(aq)$  in terms of the concentrations of  $\text{HSO}_3^-(aq)$ ,  $\text{H}_2\text{O}_2(aq)$ , and  $\text{H}_3\text{O}^+(aq)$ .

## 18.5 Effect of Temperature on Reaction Rates

35. The rate of the elementary reaction

has been studied as a function of temperature between 5000 and 18,000 K. The following data were obtained for the rate constant  $k$ :

Temperature (K)	$k$ ( $\text{L mol}^{-1} \text{s}^{-1}$ )
5,000	$5.49 \times 10^6$
10,000	$9.86 \times 10^8$
15,000	$5.09 \times 10^9$
18,000	$8.60 \times 10^9$

- (a) Calculate the activation energy of this reaction.  
 (b) Calculate the factor  $A$  in the Arrhenius equation for the temperature dependence of the rate constant.
36. The gas-phase reaction

is the exchange of isotopes of hydrogen of atomic mass 1 (H) and 2 (D, deuterium). The following data were obtained for the rate constant  $k$  of this reaction:

Temperature (K)	$k$ ( $\text{L mol}^{-1} \text{s}^{-1}$ )
299	$1.56 \times 10^4$
327	$3.77 \times 10^4$
346	$7.6 \times 10^4$
440	$10^6$
549	$1.07 \times 10^6$
745	$8.7 \times 10^7$

- (a) Calculate the activation energy of this reaction.  
 (b) Calculate the factor  $A$  in the Arrhenius equation for the temperature dependence of the rate constant.

## 37. The rate constant of the elementary reaction

is  $k = 1.94 \times 10^{-4} \text{ L mol}^{-1} \text{ s}^{-1}$  at  $30.0^\circ\text{C}$ , and the reaction has an activation energy of  $161 \text{ kJ mol}^{-1}$ .

- (a) Compute the rate constant of the reaction at a temperature of  $40.0^\circ\text{C}$ .  
 (b) After equal concentrations of  $\text{BH}_4^-(aq)$  and  $\text{NH}_4^+(aq)$  are mixed at  $30.0^\circ\text{C}$ ,  $1.00 \times 10^4 \text{ s}$  is required for half of them to be consumed. How long will it take to consume half of the reactants if an identical experiment is performed at  $40.0^\circ\text{C}$ ?

38. Dinitrogen tetraoxide ( $\text{N}_2\text{O}_4$ ) decomposes spontaneously at room temperature in the gas phase:

The rate law governing the disappearance of  $\text{N}_2\text{O}_4$  with time is

$$-\frac{d[\text{N}_2\text{O}_4]}{dt} = k[\text{N}_2\text{O}_4]$$

At  $30^\circ\text{C}$ ,  $k = 5.1 \times 10^6 \text{ s}^{-1}$  and the activation energy for the reaction is  $54.0 \text{ kJ mol}^{-1}$ .

- (a) Calculate the time (in seconds) required for the partial pressure of  $\text{N}_2\text{O}_4(g)$  to decrease from  $0.10 \text{ atm}$  to  $0.010 \text{ atm}$  at  $30^\circ\text{C}$ .  
 (b) Repeat the calculation of part (a) at  $300^\circ\text{C}$ .

39. The activation energy for the isomerization reaction of  $\text{CH}_3\text{NC}$  in Problem 14 is  $161 \text{ kJ mol}^{-1}$ , and the reaction rate constant at  $600 \text{ K}$  is  $0.41 \text{ s}^{-1}$ .

- (a) Calculate the Arrhenius factor  $A$  for this reaction.  
 (b) Calculate the rate constant for this reaction at  $1000 \text{ K}$ .

## 40. Cyclopropane isomerizes to propylene according to a first-order reaction:

The activation energy is  $E_a = 272 \text{ kJ mol}^{-1}$ . At  $500^\circ\text{C}$ , the reaction rate constant is  $6.1 \times 10^{-4} \text{ s}^{-1}$ .

- (a) Calculate the Arrhenius factor  $A$  for this reaction.  
 (b) Calculate the rate constant for this reaction at  $25^\circ\text{C}$ .

## 41. The activation energy of the gas-phase reaction

is  $3.5 \text{ kJ mol}^{-1}$ , and the change in the internal energy in the reaction is  $\Delta U = -66.8 \text{ kJ mol}^{-1}$ . Calculate the activation energy of the reaction

42. The compound  $\text{HOCl}$  is known, but the related compound  $\text{HClO}$ , with a different order for the atoms in the molecule, is not known. Calculations suggest that the activation energy for the conversion  $\text{HOCl} \longrightarrow \text{HClO}$  is  $311 \text{ kJ mol}^{-1}$  and that for the conversion  $\text{HClO} \longrightarrow \text{HOCl}$  is  $31 \text{ kJ mol}^{-1}$ . Estimate  $\Delta U$  for the reaction  $\text{HOCl} \longrightarrow \text{HClO}$ .

## 18.6 Molecular Theories of Elementary Reactions

43. The reaction of  $\text{OH}$  with hydrocarbons initiates the formation of atmospheric aerosols, and is an important

elementary step in combustion. The rate constants for the reaction of  $\text{OH}$  with ethane measured between  $822$  and  $1367 \text{ K}$  are well fit to an Arrhenius expression with  $k = (1.1 \times 10^{-10} \text{ cm}^3 \text{ s}^{-1})\exp(-2537 \text{ K}/T)$ . In contrast, the rate constant for the reaction of  $\text{OH}$  with ethene is nearly constant with temperature at  $k = 6 \times 10^{-12} \text{ cm}^3 \text{ s}^{-1}$ . What can you conclude about the probable barrier heights for each reaction? For the  $\text{OH} + \text{ethane}$  reaction, would an  $\text{OH}$  radical with a speed equal to twice the average speed of  $\text{OH}$  at  $1000 \text{ K}$  have a chance of having a reactive collision with a ethane molecule that also had a speed equal to twice the average speed in the Maxwell-Boltzmann distribution for ethane molecules? Explain.

44. Calculate the maximum potential energy on impact that the collision described in problem 43 could achieve if the  $\text{OH}$  molecule were instead catching up to the ethane molecule from behind.

## 45. Use collision theory to estimate the preexponential factor in the rate constant for the elementary reaction

at  $25^\circ\text{C}$ . Take the average diameter of an  $\text{NOCl}$  molecule to be  $3.0 \times 10^{-10} \text{ m}$  and use the steric factor  $P$  from Table 18.1.

## 46. Use collision theory to estimate the preexponential factor in the rate constant for the elementary reaction

at  $500 \text{ K}$ . Take the average diameter of an  $\text{NO}_2$  molecule to be  $2.6 \times 10^{-10} \text{ m}$  and use the steric factor  $P$  from Table 18.1.

## 18.7 Reactions in Solution

47. The rate constant for the reaction  $\text{CH}_3\text{Br} + \text{Cl}^- \longrightarrow \text{CH}_3\text{Cl} + \text{Br}^-$  in acetone is  $5.9 \times 10^{-3} \text{ L mol}^{-1} \text{ s}^{-1}$ . Is this reaction diffusion-controlled or limited by a large activation energy?48. The rate constant for the reaction  $\text{H}^+ + \text{HS}^- \longrightarrow \text{H}_2\text{S}$  in aqueous solution is  $7.5 \times 10^{10} \text{ L mol}^{-1} \text{ s}^{-1}$ . Is this reaction diffusion-controlled or limited by a large activation energy?

## 18.8 Catalysis

49. Certain bacteria use the enzyme penicillinase to decompose penicillin and render it inactive. The Michaelis-Menten constants for this enzyme and substrate are  $K_m = 5 \times 10^{-5} \text{ mol L}^{-1}$  and  $k_2 = 2 \times 10^3 \text{ s}^{-1}$ .

- (a) What is the maximum rate of decomposition of penicillin if the enzyme concentration is  $6 \times 10^{-7} \text{ M}$ ?  
 (b) At what substrate concentration will the rate of decomposition be half that calculated in part (a)?

50. The conversion of dissolved carbon dioxide in blood to  $\text{HCO}_3^-$  and  $\text{H}_3\text{O}^+$  is catalyzed by the enzyme carbonic anhydrase. The Michaelis-Menten constants for this enzyme and substrate are  $K_m = 8 \times 10^{-5} \text{ mol L}^{-1}$  and  $k_2 = 6 \times 10^5 \text{ s}^{-1}$ .

- (a) What is the maximum rate of reaction of carbon dioxide if the enzyme concentration is  $5 \times 10^{-6} \text{ M}$ ?  
 (b) At what  $\text{CO}_2$  concentration will the rate of decomposition be 30% of that calculated in part (a)?

## ADDITIONAL PROBLEMS

51. Hemoglobin molecules in blood bind oxygen and carry it to cells, where it takes part in metabolism. The binding of oxygen

is first order in hemoglobin and first order in dissolved oxygen, with a rate constant of  $4 \times 10^7 \text{ L mol}^{-1} \text{ s}^{-1}$ . Calculate the initial rate at which oxygen will be bound to hemoglobin if the concentration of hemoglobin is  $2 \times 10^{-9} \text{ M}$  and that of oxygen is  $5 \times 10^{-5} \text{ M}$ .

- \*52. Suppose 1.00 L of  $9.95 \times 10^{-3} \text{ M S}_2\text{O}_3^{2-}$  is mixed with 1.00 L of  $2.52 \times 10^{-3} \text{ M H}_2\text{O}_2$  at a pH of 7.0 and a temperature of 25°C. These species react by two competing pathways, represented by the balanced equations

At the instant of mixing, the thiosulfate ion ( $\text{S}_2\text{O}_3^{2-}$ ) is observed to be disappearing at the rate of  $7.9 \times 10^{-7} \text{ mol L}^{-1} \text{ s}^{-1}$ . At the same moment, the  $\text{H}_2\text{O}_2$  is disappearing at the rate of  $8.8 \times 10^{-7} \text{ mol L}^{-1} \text{ s}^{-1}$ .

- (a) Compute the percentage of the  $\text{S}_2\text{O}_3^{2-}$  that is, at that moment, reacting according to the first equation.  
 (b) It is observed that the hydronium ion concentration drops. Use the data and answer from part (a) to compute how many milliliters per minute of 0.100 M  $\text{H}_3\text{O}^+$  must be added to keep the pH equal to 7.0.
53.  $8.23 \times 10^{-3} \text{ mol}$  of  $\text{InCl}(s)$  is placed in 1.00 L of 0.010 M  $\text{HCl}(aq)$  at 75°C. The  $\text{InCl}(s)$  dissolves quite quickly, and then the following reaction occurs:

As this disproportionation proceeds, the solution is analyzed at intervals to determine the concentration of  $\text{In}^+(aq)$  that remains.

Time (s)	$[\text{In}^+]$ (mol L <sup>-1</sup> )
0	$8.23 \times 10^{-3}$
240	$6.41 \times 10^{-3}$
480	$5.00 \times 10^{-3}$
720	$3.89 \times 10^{-3}$
1000	$3.03 \times 10^{-3}$
1200	$3.03 \times 10^{-3}$
10,000	$3.03 \times 10^{-3}$

- (a) Plot  $\ln [\text{In}^+]$  versus time, and determine the apparent rate constant for this first-order reaction.  
 (b) Determine the half-life of this reaction.  
 (c) Determine the equilibrium constant  $K$  for the reaction under the experimental conditions.
- \*54. A compound called di-*t*-butyl peroxide [abbreviation DTBP, formula  $(\text{CH}_3)_3\text{COOC}(\text{CH}_3)_3$ ] decomposes to give acetone [ $(\text{CH}_3)_2\text{CO}$ ] and ethane ( $\text{C}_2\text{H}_6$ ):
- $$(\text{CH}_3)_3\text{COOC}(\text{CH}_3)_3(g) \longrightarrow 2 (\text{CH}_3)_2\text{CO}(g) + \text{C}_2\text{H}_6(g)$$

The total pressure of the reaction mixture changes with time, as shown by the following data at 147.2°C:

Time (min)	$P_{\text{tot}}$ (atm)	Time (min)	$P_{\text{tot}}$ (atm)
0	0.2362	26	0.3322
2	0.2466	30	0.3449
6	0.2613	34	0.3570
10	0.2770	38	0.3687
14	0.2911	40	0.3749
18	0.3051	42	0.3801
20	0.3122	46	0.3909
22	0.3188		

- (a) Calculate the partial pressure of DTBP at each time from these data. Assume that at time 0, DTBP is the only gas present.  
 (b) Are the data better described by a first-order or a second-order rate expression with respect to DTBP concentration?
55. The reaction of  $\text{OH}^-$  with HCN in aqueous solution at 25°C has a forward rate constant  $k_f$  of  $3.7 \times 10^9 \text{ L mol}^{-1} \text{ s}^{-1}$ . Using this information and the measured acid ionization constant of HCN (see Table 15.2), calculate the rate constant  $k_r$  in the first-order rate law rate =  $k_r[\text{CN}^-]$  for the transfer of hydrogen ions to  $\text{CN}^-$  from surrounding water molecules:

56. Carbon dioxide reacts with ammonia to give ammonium carbamate, a solid. The reverse reaction also occurs:

The forward reaction is first order in  $\text{CO}_2(g)$  and second order in  $\text{NH}_3(g)$ . Its rate constant is  $0.238 \text{ atm}^{-2} \text{ s}^{-1}$  at 0.0°C (expressed in terms of partial pressures rather than concentrations). The reaction in the reverse direction is zero order, and its rate constant, at the same temperature, is  $1.60 \times 10^{-7} \text{ atm s}^{-1}$ . Experimental studies show that, at all stages in the progress of this reaction, the net rate is equal to the forward rate minus the reverse rate. Compute the equilibrium constant of this reaction at 0.0°C.

57. For the reactions

the rate laws are

$$-\frac{d[\text{I}]}{dt} = k_{\text{I}}[\text{I}]^2[\text{M}]$$

$$-\frac{d[\text{Br}]}{dt} = k_{\text{Br}}[\text{Br}]^2[\text{M}]$$

The ratio  $k_{\text{I}}/k_{\text{Br}}$  at 500°C is 3.0 when M is an Ar molecule. Initially,  $[\text{I}]_0 = 2[\text{Br}]_0$ , while  $[\text{M}]$  is the same for both reactions and is much greater than  $[\text{I}]_0$ . Calculate the ratio of

the time required for [I] to decrease to half its initial value to the same time for [Br] at 500°C.

58. In some reactions there is a competition between kinetic control and thermodynamic control over product yields. Suppose compound A can undergo two elementary reactions to stable products:

For simplicity we assume first-order kinetics for both forward and reverse reactions. We take the numerical values  $k_1 = 1 \times 10^8 \text{ s}^{-1}$ ,  $k_{-1} = 1 \times 10^2 \text{ s}^{-1}$ ,  $k_2 = 1 \times 10^9 \text{ s}^{-1}$ , and  $k_{-2} = 1 \times 10^4 \text{ s}^{-1}$ .

- (a) Calculate the equilibrium constant for the equilibrium

From this value, give the ratio of the concentration of B to that of C at equilibrium. This is an example of thermodynamic control.

- (b) In the case of kinetic control, the products are isolated (or undergo additional reaction) before the back reactions can take place. Suppose the back reactions in the preceding example ( $k_{-1}$  and  $k_{-2}$ ) can be ignored. Calculate the concentration ratio of B to C reached in this case.

59. Compare and contrast the mechanisms for the two gas-phase reactions

60. In Section 18.4 the steady-state approximation was used to derive a rate expression for the decomposition of  $\text{N}_2\text{O}_5(\text{g})$ :

$$\text{rate} = \frac{k_1 k_2 [\text{M}][\text{N}_2\text{O}_5]}{k_2 + k_{-1}[\text{M}]} = k_{\text{eff}}[\text{N}_2\text{O}_5]$$

At 300 K, with an excess of nitrogen present, the following values of  $k_{\text{eff}}$  as a function of total pressure were found:

$P$ (atm)	$k_{\text{eff}}$ ( $\text{s}^{-1}$ )	$P$ (atm)	$k_{\text{eff}}$ ( $\text{s}^{-1}$ )
9.21	0.265	0.625	0.116
5.13	0.247	0.579	0.108
3.16	0.248	0.526	0.104
3.03	0.223	0.439	0.092
		0.395	0.086

Use the data to estimate the value of  $k_{\text{eff}}$  at very high total pressure and the value of  $k_1$  in  $\text{L mol}^{-1} \text{ s}^{-1}$ .

61. The decomposition of ozone by light can be described by the mechanism

with the overall reaction being

The rate constant  $k_1$  depends on the light intensity and the type of light source used. By making a steady-state approximation for the concentration of oxygen atoms, express the rate of formation of  $\text{O}_2$  in terms of the  $\text{O}_2$ ,  $\text{O}_3$ , and M concentrations and the elementary rate constants. Show that only the ratio  $k_3/k_2$ , and not the individual values of  $k_2$  and  $k_3$ , affects the rate.

- \*62. In Section 18.4 we considered the following mechanism for the reaction of  $\text{Br}_2$  with  $\text{H}_2$ :

Although this is adequate for calculating the *initial* rate of reaction, before product HBr builds up, there is an additional process that can participate as the reaction continues:

- (a) Write an expression for the rate of change of [H].  
 (b) Write an expression for the rate of change of [Br].  
 (c) As hydrogen and bromine atoms are both short-lived species, we can make the steady-state approximation and set the rates from parts (a) and (b) to 0. Express the steady-state concentrations [H] and [Br] in terms of concentrations of  $\text{H}_2$ ,  $\text{Br}_2$ , HBr, and M. [*Hint*: Try adding the rate for part (a) to that for part (b).]  
 (d) Express the rate of production of HBr in terms of concentrations of  $\text{H}_2$ ,  $\text{Br}_2$ , HBr, and M.
63. The following observations have been made about a certain reacting system: (i) When A, B, and C are mixed at about equal concentrations in neutral solution, two different products are formed, D and E, with the amount of D about 10 times as great as the amount of E. (ii) If everything is done as in (i) except that a trace of acid is added to the reaction mixture, the same products are formed, except that now the amount of D produced is much smaller than (about 1% of) the amount of E. The acid is not consumed in the reaction. The following mechanism has been proposed to account for some of these observations and others about the order of the reactions:
- (1)  $\text{A} + \text{B} \xrightleftharpoons[k_{-1}]{k_2} \text{F}$  (rapid equilibrium)  
 (2)  $\text{C} + \text{F} \xrightarrow{k_2} \text{D}$  (negligible reverse rate)  
 (3)  $\text{C} + \text{F} \xrightarrow{k_3} \text{E}$  (negligible reverse rate)
- (a) Explain what this proposed scheme of reactions implies about the dependence (if any) of the rate of formation of D on the concentrations of A, of B, and of C. What about the dependence (if any) of the rate of formation of E on these same concentrations?

- (b) What can you say about the relative magnitudes of  $k_2$  and  $k_3$ ?  
 (c) What explanation can you give for observation (ii) in view of your answer to (b)?

64. Iron(II) ion is oxidized by chlorine in aqueous solution, the overall equation being

It is found experimentally that the rate of the overall reaction is decreased when either the iron(III) ion or the chloride-ion concentration is increased. Which of the following possible mechanisms is consistent with the experimental observations?

- (a) (1)  $\text{Fe}^{2+} + \text{Cl}_2 \xrightleftharpoons[k_{-1}]{k_1} \text{Fe}^{3+} + \text{Cl}^- + \text{Cl}$  (rapid equilibrium)  
 (2)  $\text{Fe}^{2+} + \text{Cl} \xrightarrow{k_2} \text{Fe}^{3+} + \text{Cl}^-$  (negligible reverse rate)
- (b) (3)  $\text{Fe}^{2+} + \text{Cl}_2 \xrightleftharpoons[k_{-3}]{k_3} \text{Fe(IV)} + 2 \text{Cl}^-$  (rapid equilibrium)  
 (4)  $\text{Fe(IV)} + \text{Fe}^{2+} \xrightarrow{k_4} 2 \text{Fe}^{3+}$  (negligible reverse rate)

where Fe(IV) is Fe in the (+IV) oxidation state.

65. Manfred Eigen, a German physical chemist working during the 1970s and 1980s, earned a Nobel Prize for developing the “temperature-jump” method for studying kinetics of very rapid reactions in solution, such as proton transfer. Eigen and his co-workers found that the specific rate of proton transfer from a water molecule to an ammonia molecule in a dilute aqueous solution is  $k = 2 \times 10^5 \text{ s}^{-1}$ . The equilibrium constant  $K_b$  for the reaction of ammonia with water is  $1.8 \times 10^{-5}$ . What, if anything, can be deduced from this information about the rate of transfer of a proton from  $\text{NH}_4^+$  to a hydroxide ion? Write equations for any reactions you mention, making it clear to which reaction(s) any quoted constant(s) apply.
66. Consider the reaction

with all reactants and products gaseous (for simplicity) and an equilibrium constant  $K$ . (a) Assume that the elementary steps in the reaction are those indicated by the stoichiometric equation (in each direction), with specific rate constants for the forward reaction and the reverse reaction, respectively,  $k_f$  and  $k_r$ . Derive the relation between  $k_f$ ,  $k_r$ , and  $K$ . Comment on the general validity of the assumptions made about the relation of elementary steps and the stoichiometric equation and also on the general validity of  $K$ . (b) Assume that the reaction as written is exothermic. Explain what this implies about the change of  $K$  with temperature. Explain also what it implies about the relation of the activation energies of the forward and reverse reactions and how this relation is consistent with your statement about the variation of  $K$  with temperature.

67. The gas-phase decomposition of acetaldehyde can be represented by the overall chemical equation

It is thought to occur through the sequence of reactions

Show that this reaction mechanism corresponds to a chain reaction, and identify the initiation, propagation, and termination steps.

68. Lanthanum(III) phosphate crystallizes as a hemihydrate,  $\text{LaPO}_4 \cdot \frac{1}{2} \text{H}_2\text{O}$ . When it is heated, it loses water to give anhydrous lanthanum(III) phosphate:

This reaction is first order in the chemical amount of  $\text{LaPO}_4 \cdot \frac{1}{2} \text{H}_2\text{O}$ . The rate constant varies with temperature as follows:

Temperature (°C)	$k$ (s <sup>-1</sup> )
205	$2.3 \times 10^{-4}$
219	$3.69 \times 10^{-4}$
246	$7.75 \times 10^{-4}$
260	$12.3 \times 10^{-4}$

Compute the activation energy of this reaction.

69. The water in a pressure cooker boils at a temperature greater than 100°C because it is under pressure. At this higher temperature, the chemical reactions associated with the cooking of food take place at a greater rate.
- (a) Some food cooks fully in 5 min in a pressure cooker at 112°C and in 10 minutes in an open pot at 100°C. Calculate the average activation energy for the reactions associated with the cooking of this food.
- (b) How long will the same food take to cook in an open pot of boiling water in Denver, where the average atmospheric pressure is 0.818 atm and the boiling point of water is 94.4°C?
70. (a) A certain first-order reaction has an activation energy of 53 kJ mol<sup>-1</sup>. It is run twice, first at 298 K and then at 308 K (10°C higher). All other conditions are identical. Show that, in the second run, the reaction occurs at double its rate in the first run.
- (b) The same reaction is run twice more at 398 K and 408 K. Show that the reaction goes 1.5 times as fast at 408 K as it does at 398 K.

- \*71. The gas-phase reaction between hydrogen and iodine

proceeds with a forward rate constant at 1000 K of  $k_f = 240 \text{ L mol}^{-1} \text{ s}^{-1}$  and an activation energy of  $165 \text{ kJ mol}^{-1}$ . By using this information and data from Appendix D, calculate the activation energy for the reverse reaction and the value of  $k_r$  at 1000 K. Assume that  $\Delta H$  and  $\Delta S$  for the reaction are independent of temperature between 298 and 1000 K.

72. The following reaction mechanism has been proposed for a chemical reaction:

- (a) Write a balanced equation for the overall reaction.  
 (b) Write the rate expression that corresponds to the preceding mechanism. Express the rate in terms of concentrations of reactants only ( $\text{A}_2$ , B, CD).  
 (c) Suppose that the first two steps in the preceding mechanism are endothermic and the third one is exothermic. Will an increase in temperature increase the

reaction rate constant, decrease it, or cause no change? Explain.

73. How would you describe the role of the  $\text{CF}_2\text{Cl}_2$  in the reaction mechanism of Problem 21?  
 74. In Section 18.8 we wrote a mechanism in which silver ions catalyze the reaction of  $\text{Tl}^+$  with  $\text{Ce}^{4+}$ . Determine the rate law for this mechanism by making a steady-state approximation for the concentration of the reactive intermediate  $\text{Ag}^{2+}$ .  
 75. The rates of enzyme catalysis can be lowered by the presence of inhibitor molecules I, which bind to the active site of the enzyme. This adds the following additional step to the reaction mechanism considered in Section 18.7:

Determine the effect of the presence of inhibitor at total concentration  $[\text{I}]_0 = [\text{I}] + [\text{EI}]$  on the rate expression for formation of products derived at the end of this chapter.

76. The enzyme lysozyme kills certain bacteria by attacking a sugar called *N*-acetylglucosamine (NAG) in their cell walls. At an enzyme concentration of  $2 \times 10^{-6} \text{ M}$ , the maximum rate for substrate (NAG) reaction, found at high substrate concentration, is  $1 \times 10^{-6} \text{ mol L}^{-1} \text{ s}^{-1}$ . The rate is reduced by a factor of 2 when the substrate concentration is reduced to  $6 \times 10^{-6} \text{ M}$ . Determine the Michaelis–Menten constants  $K_m$  and  $k_2$  for lysozyme.

## CUMULATIVE PROBLEMS

77. The rate of the gas-phase reaction

is given by

$$\text{rate} = -\frac{d[\text{I}_2]}{dt} = k[\text{H}_2][\text{I}_2]$$

with  $k = 0.0242 \text{ L mol}^{-1} \text{ s}^{-1}$  at  $400^\circ\text{C}$ . If the initial concentration of  $\text{H}_2$  is  $0.081 \text{ mol L}^{-1}$  and that of  $\text{I}_2$  is  $0.036 \text{ mol L}^{-1}$ , calculate the initial rate at which heat is absorbed or emitted during the reaction. Assume that the enthalpy change at  $400^\circ\text{C}$  is the same as that at  $25^\circ\text{C}$ .

78. The rate of the reaction

is given by

$$\text{rate} = k[\text{ClO}_2]^2[\text{OH}^-]$$

with  $k = 230 \text{ L}^2 \text{ mol}^{-2} \text{ s}^{-1}$  at  $25^\circ\text{C}$ . A solution is prepared that has initial concentrations  $[\text{ClO}_2] = 0.020 \text{ M}$ ,  $[\text{HCN}] = 0.095 \text{ M}$ , and  $[\text{CN}^-] = 0.17 \text{ M}$ . Calculate the initial rate of the reaction.

79. A gas mixture was prepared at 500 K with total pressure 3.26 atm and a mole fraction of 0.00057 of NO and 0.00026 of  $\text{O}_3$ . The elementary reaction

has a second-order rate constant of  $7.6 \times 10^7 \text{ L mol}^{-1} \text{ s}^{-1}$  at this temperature. Calculate the initial rate of the reaction under these conditions.

80. The activation energy for the reaction

is  $E_a = 111 \text{ kJ mol}^{-1}$ . Calculate the root-mean-square velocity of an  $\text{NO}_2$  molecule at 400 K and compare it to the velocity of an  $\text{NO}_2$  molecule with kinetic energy  $E_a/N_A$ .

Tim Wright/Encyclopedia/Corbis

A spent fuel rod assembly being lowered in a cooling pond for long-term storage. The blue glow is Cerenkov radiation, light emitted by high-energy beta particles slowing to the speed of light in water.

In the preceding chapters, we discuss chemical reactions essentially as rearrangements of atoms from one set of “bonding partners” to another set. We turn now to a different kind of reaction in which the elemental identity of the atomic nucleus changes in the course of the reaction. This is a fascinating subject that arose early in the 20th century from experimental studies of the physical structure of the atom (see Section 1.4).

A fundamentally different new feature distinguishes this field from the material in earlier chapters. The separate laws of conservation of matter and conservation of energy must be generalized. Nuclear reactions occur at energies sufficiently high that energy and matter are interconverted. This is the origin of the enormous amounts of energy that can be released during nuclear reactions. Mass and energy are related through Einstein’s relation  $E = mc^2$ , and their *sum* is conserved during nuclear reactions.

## 19.1 Mass–Energy Relationships in Nuclei

Recall from Section 1.4 that almost all the mass of an atom is concentrated in a very small volume in the nucleus. The small size of the nucleus (which occupies less than one *trillionth* of the space in the atom) and the strong forces between the protons and neutrons that make it up largely isolate its behavior from the outside world of electrons and other nuclei. This greatly simplifies our analysis of nuclear chemistry, allowing us to examine single nuclei without concern for the atoms, ions, or molecules in which they may be found.

A nucleus (or **nuclide**) is built from two kinds of **nucleons**—protons and neutrons. A nucleus is characterized by its number of protons  $Z$  (also called the atomic number) and its mass number,  $A$ . The mass number  $A$  of a nucleus is the sum of the number of protons  $Z$  and the number of neutrons  $N$ ; so  $A = Z + N$  is an integer closest to the relative atomic mass of the nucleus. A nuclide or an elementary particle such as an electron is designated with the symbol  ${}^A_ZX$ , where  $X$  is the chemical symbol for the particle. The chemical symbol of an element is determined by the number of protons in the nucleus, each isotope having a different number of neutrons. The letter  $Z$  in the symbol determines the charge,  $+Ze$ , on a nuclide, where it equals the number of protons, and on particles such as electrons and positrons (described later), which are assigned  $Z = -1$  and  $+1$ , respectively, to reflect their charge only. (See Table 19.1.)

The absolute masses of nuclides and of elementary particles such as the proton, neutron, and electron are far too small to express in kilograms or grams without the constant use of 10 raised to some large negative exponent. A unit of mass that is better sized for measuring on the submicroscopic scale is needed. An **atomic mass unit** (abbreviated u) is defined as exactly  $\frac{1}{12}$  the mass of a single atom of  ${}^{12}\text{C}$ . Because 1 mol of  ${}^{12}\text{C}$  atoms weighs exactly 12 g, one atom weighs  $12/N_A$  grams, and

$$\begin{aligned} 1 \text{ u} &= \frac{1}{12} \left( \frac{12 \text{ g mol}^{-1}}{6.0221420 \times 10^{23} \text{ mol}^{-1}} \right) \\ &= 1.6605387 \times 10^{-24} \text{ g} = 1.6605387 \times 10^{-27} \text{ kg} \end{aligned}$$

The conversion factor between atomic mass units and grams is numerically equal to the inverse of Avogadro's number  $N_A$ , and the mass of a single atom in atomic mass units is numerically equal to the mass of one mole of atoms in grams. Thus, one atom of  ${}^1\text{H}$  has a mass of 1.007825 u because 1 mol of  ${}^1\text{H}$  has a mass of 1.007825 g. The *dalton* is a mass unit that is equivalent to the atomic mass unit and is used frequently in biochemistry.

Table 19.1 lists the masses of elementary particles and selected neutral atoms, obtained from mass spectrometry (see Fig. C1.1). Note that each atomic mass includes the contribution from the surrounding  $Z$  electrons as well as that from the nucleus.

### 19.1.1 The Einstein Mass–Energy Relationship

Some nuclides are stable and can exist indefinitely, but others are unstable (radioactive) and decay spontaneously to form other nuclides in processes to be considered in Section 19.2. Figure 19.1 shows the distribution of the number of neutrons  $N (= A - Z)$  against atomic number  $Z$  (protons in the nucleus) for the known nuclides of the elements. For the light elements,  $N/Z \approx 1$  for stable nuclides, meaning nearly equal numbers of protons and neutrons are found in the nucleus. For the heavier elements,  $N/Z > 1$  and there are progressively more neutrons than protons in the nucleus. One of the goals of nuclear chemistry is

TABLE 19.1

## Masses of Selected Elementary Particles and Atoms

Elementary Particle	Symbol	Mass (u)	Mass (kg)
Electron	${}_{-1}^0e^{-}$	0.000548579911	$9.1093819 \times 10^{-31}$
Positron	${}_{+1}^0e^{+}$	0.000548579911	$9.1093819 \times 10^{-31}$
Proton	${}_{+1}^1p^{+}$	1.0072764669	$1.6726216 \times 10^{-27}$
Neutron	${}_{0}^1n$	1.0086649158	$1.6749272 \times 10^{-27}$

  

Atom	Mass (u)	Atom	Mass (u)
${}_{1}^1\text{H}$	1.007825032	${}_{11}^{23}\text{Na}$	22.9897697
${}_{1}^2\text{H}$	2.014101778	${}_{12}^{24}\text{Mg}$	23.9850419
${}_{1}^3\text{H}$	3.016049268	${}_{14}^{30}\text{Si}$	29.97377022
${}_{2}^3\text{He}$	3.016029310	${}_{15}^{30}\text{P}$	29.9783138
${}_{2}^4\text{He}$	4.002603250	${}_{16}^{32}\text{S}$	31.9720707
${}_{3}^7\text{Li}$	7.0160040	${}_{17}^{35}\text{Cl}$	34.96885271
${}_{4}^7\text{Be}$	7.01692983	${}_{20}^{40}\text{Ca}$	39.9625912
${}_{4}^8\text{Be}$	8.00530509	${}_{22}^{49}\text{Ti}$	48.947871
${}_{4}^9\text{Be}$	9.0121821	${}_{35}^{81}\text{Br}$	80.916291

${}_{11}^{23}\text{Na}$	22.9897697		

Values are taken from National Institute of Standards and Technology Special Publication 961, Jan. 2001

to understand the differing stabilities of the isotopes. Nuclear mass provides the key to this understanding.

Note from Table 19.1 that the neutron has a slightly greater mass than the proton. The neutron is stable inside a nucleus, but in free space it is unstable, decaying into a proton and an electron with a half-life of about 10 minutes:

Here  ${}_{0}^1n$  and  ${}_{+1}^1p^{+}$  represent the neutron and the proton, respectively. We have written this as a **balanced nuclear equation**. To check such an equation for balance, first verify that the total mass numbers (the superscripts) are equal on the two sides. Then verify that the nuclear charges are balanced by checking the sum of the subscripts. The third product is an antineutrino (see Section 19.2.1).

Mass is not conserved in the reaction just written. By subtracting the mass of the reactant from the masses of the products (using Table 19.1; the antineutrino's mass is negligible), the change in mass is calculated to be

$$\Delta m = -1.3947 \times 10^{-30} \text{ kg} = -8.398690 \times 10^{-4} \text{ u}$$

**FIGURE 19.1** A plot of  $N$  versus  $Z$  for nuclides with the stable nuclides represented by blue dots and the known radioactive nuclides represented by red dots. The stable nuclides lie along a “line of stability” with slope  $N/Z = 1$  (shown) for the lighter elements, increasing to 1.5 for the heavier elements. Arrows show the directions of decay of unstable nuclides via alpha emission, beta emission, positron emission, or electron capture.

What has happened to the “lost” mass? It has been converted to energy—specifically, kinetic energy carried off by the electron and proton. According to Einstein’s special theory of relativity, a change in mass always accompanies a change in energy:

$$E = mc^2$$

or, better,

$$\Delta E = c^2 \Delta m \quad [19.1]$$

where  $c$  is the speed of light in a vacuum and  $\Delta m$  is the change in mass (mass of products minus mass of reactants). To express  $\Delta E$  in joules,  $c$  must have units of meters per second, and  $\Delta m$ , units of kilograms. In the decay of one neutron, for example,

$$\Delta E = c^2 \Delta m = (2.9979 \times 10^8 \text{ m s}^{-1})^2 (-1.3947 \times 10^{-30} \text{ kg}) = -1.2535 \times 10^{-13} \text{ J}$$

In ordinary chemical reactions, the change in mass is negligibly small. In the combustion of 1 mol of carbon to  $\text{CO}_2$ , the energy change is about 400 kJ, corresponding to a change in mass of only  $4 \times 10^{-9}$  g.

Changes in energy in nuclear reactions are nearly always expressed in more convenient energy units than the joule—namely, the **electron volt** (eV) and the **megaelectron volt** (MeV). The electron volt is defined as the energy given to an electron when it is accelerated through a potential difference of exactly 1 V:

$$1 \text{ eV} = 1.60217646 \times 10^{-19} \text{ C} \times 1 \text{ V} = 1.60217646 \times 10^{-19} \text{ J}$$

The megaelectron volt is 1 million times larger:

$$1 \text{ MeV} = 1.60217646 \times 10^{-13} \text{ J}$$

A change in mass of  $1 \text{ u} = 1.6605387 \times 10^{-27} \text{ kg}$  corresponds to

$$\begin{aligned} \Delta E = c^2 \Delta m &= (2.9979246 \times 10^8 \text{ m s}^{-1})^2 (1.6605387 \times 10^{-27} \text{ kg}) \\ &= 1.4924178 \times 10^{-10} \text{ J} \end{aligned}$$

Converting to MeV,

$$\frac{1.4924178 \times 10^{-10} \text{ J}}{1.60217646 \times 10^{-13} \text{ J MeV}^{-1}} = 931.494 \text{ MeV}$$

We say that the **energy equivalent** of  $1 \text{ u}$  is  $931.494 \text{ MeV}$ . In the decay of a neutron,

$$\Delta E = (-8.39869 \times 10^{-4} \text{ u})(931.494 \text{ MeV u}^{-1}) = -0.782 \text{ MeV}$$

### 19.1.2 Binding Energies of Nuclei

The **binding energy**  $E_B$  of a nucleus is defined as the negative of the energy change  $\Delta E$  that would occur if that nucleus were formed from its component protons and neutrons. For the  ${}^4_2\text{He}$  nucleus, for example,

Binding energies of nuclei are calculated with Einstein's relationship and accurate data from a mass spectrometer. Most measurements determine the mass of the atom with most or all of its electrons, not the mass of the bare nucleus (recall that it is the  ${}^{12}\text{C}$  *atom*, not the  ${}^{12}\text{C}$  nucleus, that is defined to have atomic mass 12). Therefore, we take the nuclear binding energy  $E_B$  of the helium nucleus to be the negative of the energy change  $\Delta E$  for the formation of an *atom* of helium from hydrogen *atoms* and neutrons.

The correction for the differences in binding energies of electrons (which of course are present both in the hydrogen atoms and in the atom being formed) is a very small one that need not concern us here.

#### EXAMPLE 19.1

Calculate the binding energy of  ${}^4_2\text{He}$  from the data in Table 19.1, and express it both in joules and in megaelectron volts (MeV).

#### Solution

The mass change is

$$\begin{aligned} \Delta m &= m[{}^4_2\text{He}] - 2m[{}^1_1\text{H}] - 2m[{}^1_0\text{n}] \\ &= 4.00260325 \text{ u} - 2(1.00782503 \text{ u}) - 2(1.00866492 \text{ u}) = -0.03037665 \text{ u} \end{aligned}$$

(Continued)

Einstein's relation then gives

$$\begin{aligned}\Delta E &= (-0.03037665 \text{ u})(1.6605387 \times 10^{-27} \text{ kg u}^{-1})(2.9979246 \times 10^8 \text{ m s}^{-1})^2 \\ &= -4.533465 \times 10^{-12} \text{ J} \\ E_{\text{B}} &= 4.533465 \times 10^{-12} \text{ J}\end{aligned}$$

If 1 mol of  ${}^4_2\text{He}$  atoms were formed in this way, the energy change would be greater by a factor of Avogadro's number  $N_{\text{A}}$ , giving  $\Delta E = -2.73 \times 10^{12} \text{ J mol}^{-1}$ . This is an enormous quantity, seven orders of magnitude greater than typical energy changes in chemical reactions.

(Note that we have used the mass of the neutron given in Table 19.1 rather than in the Physical Constants, updated in 2010, given in the back of this text. The atomic masses in Table 19.1 are determined by mass differences, so one should use the masses of the elementary particles consistent with those in nuclear chemistry calculations. We also use the conversion factor  $1 \text{ u} = 1.6605387 \times 10^{-27} \text{ kg}$  given at the start of Section 19.1, although the last digit was revised to a 9 in 2010.)

The energy change, in MeV, accompanying the formation of a  ${}^4_2\text{He}$  atom is

$$\Delta E = (-0.03037665 \text{ u})(931.494 \text{ MeV u}^{-1}) = -28.2957 \text{ MeV}$$

**Related Problems: 3, 4**

There are four nucleons in the  ${}^4_2\text{He}$  nucleus, so the binding energy *per nucleon* is

$$\frac{E_{\text{B}}}{4} = \frac{28.2957 \text{ MeV}}{4} = 7.07392 \text{ MeV}$$

The binding energy per nucleon is a direct measure of the stability of the nucleus. It varies with atomic number among the stable elements, increasing to a maximum of about 8.8 MeV for iron and nickel, as Figure 19.2 illustrates.

## 19.2 Nuclear Decay Processes

Why are some nuclei **radioactive**, decaying spontaneously, when others are stable? Thermodynamics gives the criterion  $\Delta G < 0$  for a process to be spontaneous at constant  $T$  and  $P$ . The energy change  $\Delta E$  in a nuclear decay process is so great that the free energy change is essentially equal to it, and the thermodynamic criterion for spontaneous nuclear reaction consequently simplifies to

$$\Delta E < 0 \quad \text{or} \quad \Delta m < 0$$

The equivalence of these criteria follows from Einstein's mass–energy relationship. Spontaneous transformations of one nucleus into others can occur only if the combined mass of products is less than the mass of the original nuclide.

Before we address the details of nuclear decay, it is necessary to mention **antiparticles**. Each subatomic particle is thought to have an antiparticle of the same mass but opposite charge. Thus, the antiparticle of an electron is a **positron** ( $e^+$ ), and the antiparticle of a proton is a negatively charged particle called an **antiproton**. Antiparticles have only transient existences because matter and antimatter annihilate one another when they come together, emitting radiation carrying an equivalent amount of energy. In the case of an electron and a positron, two oppositely directed **gamma rays** ( $\gamma$ -rays; high-energy photons), called the **annihilation radiation**, are emitted. Another important particle–antiparticle pair is the neutrino (symbol  $\nu$ ) and antineutrino ( $\bar{\nu}$ ), both of which are uncharged and almost massless. (They differ only in parity, a quantum-mechanical symmetry

**FIGURE 19.2** The variation of the binding energy per nucleon with mass number. A total of 2212 nuclides are shown, of which fewer than 270 are stable. The greatest nuclear stability is seen in the vicinity of  $^{56}\text{Fe}$ . Note that  $^4\text{He}$  (red circle) is unusually stable for its mass number.

upon reflection.) Neutrinos interact so weakly with matter that elaborate detectors are required to record the extremely rare events induced by them in selected nuclides.

### 19.2.1 Beta Decay by Electron Emission ( $\beta^-$ decay)

If an unstable nuclide contains fewer protons than do stable isotopes of the same mass number, it is called “proton deficient.” Such a nucleus can decay by transforming one of its neutrons into a proton and emitting a high-energy electron  ${}_{-1}^0e^-$ , also called a **beta particle**, and an antineutrino ( $\bar{\nu}$ ). The superscript 0 indicates a mass number of 0 because an electron contains neither protons nor neutrons and has a much smaller mass than a nucleus. The subscript  $-1$  indicates the negative charge on the particle. It is not a true “atomic number,” but writing the symbol in this way is helpful in balancing nuclear equations. The nuclide that results has the same mass number  $A$ , but its atomic number  $Z_{\text{da}}$  is one larger than the parent nucleus’s ( $Z_{\text{da}} = Z_{\text{pa}} + 1$ ) because a neutron has been transformed into a proton. Examples of **electron emission** from unstable nuclei are

The criterion  $\Delta m < 0$  for spontaneous  $\beta^-$  decay requires that

$$m[{}^{A}_{Z_{\text{pa}}}\text{X}_{\text{pa}}] > m[{}^{A}_{Z_{\text{pa}}+1}\text{X}_{\text{da}}] + m[{}_{-1}^0e^-]$$

(Parent nucleus)    (Daughter nucleus)

because the mass of the antineutrino ( $\bar{\nu}$ ) is almost zero, and where the daughter nucleus  ${}_{Z_{\text{da}}+1}^AX_{\text{da}}$  has a different chemical symbol because the number of protons has increased by 1. This inequality refers to the masses of the parent and daughter nuclei and the emitted electron. It must be reformulated in terms of neutral atom masses because the mass spectrometer yields masses of atoms rather than nuclei. To do this, add the mass of  $Z_{\text{pa}}$  electrons to both sides, giving a total of  $Z_{\text{pa}} + 1$  electrons on the right side (because the emitted  ${}_{-1}^0e^{-}$  is also counted). The inequality becomes

$$m[{}_{Z_{\text{pa}}}^AX_{\text{pa}}] > m[{}_{Z_{\text{pa}}+1}^AX_{\text{da}}]$$

(Parent atom)                  (Daughter atom)

A direct comparison of atomic masses (Table 19.1) lets us determine whether electron emission can take place.

The condition that energy be released follows from the Einstein mass–energy relation:

$$\Delta E = c^2 \{ m[{}_{Z_{\text{pa}}+1}^AX_{\text{da}}] - m[{}_{Z_{\text{pa}}}^AX_{\text{pa}}] \} < 0$$

where the masses in this expression are the masses of the atoms given in Table 19.1, not the masses of the nuclei. The liberated energy is carried off as kinetic energy by the beta particle (electron) and the antineutrino, because the nucleus produced is heavy enough that its recoil energy is small and can be neglected. The kinetic energy of the electron can fall anywhere in a continuous range from 0 up to  $-\Delta E$  (Fig. 19.3), with the antineutrino carrying off the balance of the energy.

**FIGURE 19.3** Emitted beta particles have a distribution of kinetic energies up to a cutoff value of  $E_{\text{max}}$ .

### EXAMPLE 19.2

Calculate the maximum kinetic energy of the electron in the decay

#### Solution

Table 19.1 gives the masses of the relevant atoms. From them we calculate

$$\Delta m = m[{}_{7}^{14}\text{N}] - m[{}_{6}^{14}\text{C}] = 14.0030740 \text{ u} - 14.0032420 \text{ u} = -0.0001680 \text{ u}$$

$$\Delta E = (-1.68 \times 10^{-4} \text{ u})(931.5 \text{ MeV u}^{-1}) = -0.156 \text{ MeV}$$

The  $\Delta E$  of the nuclear reaction is negative, so some of the energy released to the surroundings may be carried off by the electron. The maximum kinetic energy of the electron is 0.156 MeV.

**Related Problem: 8**

## 19.2.2 Positron Emission ( $\beta^{+}$ decay)

When a nucleus has too many protons for stability relative to the number of neutrons it contains, it may decay by emitting a positron. In this event a proton is converted to a neutron, and a high-energy positron (symbolized  ${}_{1}^{0}\text{e}^{+}$ ) and a neutrino ( $\nu$ ) are emitted. As in electron emission, the mass number of the nuclide remains the same, but now the atomic number of the daughter nucleus  $Z_{\text{da}}$  is 1 less than the parent nucleus's ( $Z_{\text{da}} = Z_{\text{pa}} - 1$ ). Examples of **positron emission** are

The positron has the same mass as an electron but has a positive charge. The mass criterion  $\Delta m < 0$  is different from that for electron emission. For the bare nuclei the criterion is

$$m[{}_{Z_{\text{pa}}}^A X_{\text{pa}}] > m[{}_{Z_{\text{pa}}-1}^A X_{\text{da}}] + m[{}_1^0 e^+]$$

(Parent nucleus)      (Daughter nucleus)

Adding the mass of  $Z_{\text{pa}}$  electrons to both sides gives the mass of the neutral atom  ${}_{Z_{\text{pa}}}^A X_{\text{pa}}$  on the left,<sup>1</sup> but only  $Z_{\text{pa}} - 1$  electrons are needed on the right side to form a neutral atom  ${}_{Z_{\text{pa}}-1}^A X_{\text{da}}$ . This leaves additional electron and positron masses on the right. These masses are the same, so the criterion for spontaneous positron emission is

$$m[{}_{Z_{\text{pa}}}^A X_{\text{pa}}] > m[{}_{Z_{\text{pa}}-1}^A X_{\text{da}}] + 2m[{}_1^0 e^+]$$

(Parent atom)      (Daughter atom)

The energy change in positron emission is

$$\Delta E = c^2 \{ m[{}_{Z_{\text{pa}}-1}^A X_{\text{da}}] + 2m[{}_1^0 e^+] - m[{}_{Z_{\text{pa}}}^A X_{\text{pa}}] \} < 0$$

where the first and last masses in this expression are each neutral atom's mass from Table 19.1. The kinetic energy ( $-\Delta E$ ) is distributed between the positron and the neutrino.

### EXAMPLE 19.3

Calculate the maximum kinetic energy of the positron emitted in the decay

#### Solution

The change in mass is

$$\begin{aligned} \Delta m &= m[{}_{5}^{11}\text{B}] + 2m[{}_1^0 e^+] - m[{}_{6}^{11}\text{C}] \\ &= 11.0093055 \text{ u} + 2(0.00054858 \text{ u}) - 11.011433 \text{ u} \\ &= -0.00130 \text{ u} \end{aligned}$$

The energy change is then

$$\Delta E = (-0.00130 \text{ u})(931.5 \text{ MeV u}^{-1}) = -0.960 \text{ MeV}$$

The maximum kinetic energy of the positron is +0.960 MeV.

#### Related Problem: 7

## 19.2.3 Electron Capture

If  $m[{}_{Z_{\text{pa}}}^A X_{\text{pa}}]$  exceeds  $m[{}_{Z_{\text{pa}}-1}^A X_{\text{da}}]$  (both referring to neutral atoms) but by less than  $1.0972 \times 10^{-3} \text{ u}$  (equivalent to  $2m[{}_1^0 e^+]$ ), positron emission cannot occur. An alternative process that is allowed is **electron capture**, in which an electron outside the nucleus of the parent atom is captured by the nucleus and a proton is converted to a neutron. As in positron emission, the mass number is unchanged and the atomic number decreases by 1. In this case, however, the only particle emitted is a neutrino. An example is

<sup>1</sup>Of course this statement is not true, as when  $Z$  electrons are bound to a nucleus, the total mass of the atom is not the mass of the bare nucleus added to the mass of  $Z$  free electrons. There are mass changes associated with this reaction, just as there are with all others. The *difference* between atomic masses, however, is very close to accurate in this calculation because it is only in error by the binding energy of one electron.

The mass criterion for electron capture is simply that

$$m[{}_{Z_{\text{pa}}}^A X_{\text{pa}}] > m[{}_{Z_{\text{pa}}-1}^A X_{\text{da}}]$$

(Parent atom)                      (Daughter atom)

so the energy change is

$$\Delta E = c^2 \{m[{}_{Z_{\text{pa}}-1}^A X_{\text{da}}] - m[{}_{Z_{\text{pa}}}^A X_{\text{pa}}]\} < 0$$

where the masses in this expression are the masses of the atoms given in Table 19.1, not the masses of the nuclei. Electron capture is common for heavier neutron-deficient nuclei, for which the mass change with atomic number is too small for positron emission to be possible. In the preceding example,

$$\Delta m = m[{}_{91}^{231}\text{Pa}] - m[{}_{92}^{231}\text{U}] = 231.035879 \text{ u} - 231.036289 \text{ u} = -0.00041 \text{ u}$$

Because  $\Delta m < 0$ , this process can and does occur by electron capture, but because 0.00041 u is less than  $2m[{}_{1}^0 e^+]$ , the analogous process could not occur through positron emission.

### 19.2.4 Alpha Decay

The three forms of decay discussed so far all lead to changes in the atomic number  $Z$  but not in the mass number  $A$ . Another process, **alpha decay**, involves the emission of an alpha particle ( ${}_{2}^4\text{He}^{2+}$  ion) and a decrease in mass number  $A$  by 4 (the atomic number  $Z$  and the neutron number  $N$  each decrease by 2). An example is

Such alpha decay occurs chiefly for elements in the unstable region beyond bismuth ( $Z = 83$ ) in the periodic table.

The criterion for alpha decay is once again  $\Delta m < 0$ . In the preceding example,

$$\begin{aligned} \Delta m &= m[{}_{90}^{234}\text{Th}] + m[{}_{2}^4\text{He}] - m[{}_{92}^{238}\text{U}] \\ &\quad \text{(Atom)} \quad \quad \quad \text{(Atom)} \quad \quad \quad \text{(Atom)} \\ &= 234.043595 \text{ u} + 4.002603 \text{ u} - 238.050783 \text{ u} = -0.004585 \text{ u} < 0 \\ \Delta E &= (-0.004585 \text{ u})(931.5 \text{ MeV u}^{-1}) = -4.27 \text{ MeV} \end{aligned}$$

Most of the energy is carried away by the lighter helium atom, with a small fraction appearing as recoil energy of the heavy thorium atom. The energy released into recoil kinetic energy,  $1/2 \mu v_{\text{rel}}^2$ , a maximum of 4.27 MeV, is partitioned between the two products, with the kinetic energy of the He nucleus being partitioned 234/238 of the relative kinetic energy and the kinetic energy of the Th nucleus being partitioned 4/238 of the relative kinetic energy.

### 19.2.5 Other Modes of Decay

The arrows in Figure 19.1 show the directions of the types of decay discussed so far. Nuclei whose values of  $N/Z$  are too great move toward the line of stability by electron emission, whereas those whose values are too small undergo positron emission or electron capture. Nuclei that are simply too massive can move to lower values of both  $N$  and  $Z$  by alpha emission. The range of stable nuclides is limited by the interplay of attractive nuclear forces and repulsive Coulomb forces between protons in the nucleus. Scientists believe that it is unlikely that additional stable elements will be found, although long-lived radioactive nuclides may well exist at still higher  $Z$ .

When nuclei are very proton-deficient or very neutron-deficient, an excess particle may “boil off,” that is, be ejected directly from the nucleus. These decay modes are called **neutron emission** and **proton emission**, respectively, and move nuclides down or to the left in Figure 19.1. Finally, certain unstable nuclei undergo spontaneous **fission**, in which they split into two nuclei of roughly equal size. Nuclear fission will be discussed in more detail in Section 19.5.

### 19.2.6 Detecting and Measuring Radioactivity

Many methods have been developed to detect, identify, and quantitatively measure the products of nuclear reactions. Some are quite simple, but others require complex electronic instrumentation. Perhaps the simplest radiation detector is the *photographic emulsion*, first used by Henri Becquerel, the discoverer of radioactivity. In 1896 Becquerel reported his observation that potassium uranyl sulfate ( $\text{K}_2\text{UO}_2(\text{SO}_4)_2 \cdot 2\text{H}_2\text{O}$ ) could expose a photographic plate even in the dark. Such detectors are still used today in the form of film badges (radiation dosimeters) that are worn to monitor exposure to penetrating radiation. The degree of darkening of the film is proportional to the quantity of radiation received.

Working in Rutherford’s laboratory, Hans Geiger and Ernest Marsden used a screen coated with zinc sulfide to detect the arrival of alpha particles by the pinpoint scintillations of light they produce. That simple device has been developed into the modern **scintillation counter**. Instead of a ZnS screen, the modern scintillation counter uses a crystal, such as sodium iodide, in which a small fraction of the  $\text{Na}^+$  ions have been replaced by thallium ( $\text{Tl}^+$ ) ions. The crystal emits a pulse of light when it absorbs a beta particle or a gamma ray, and a photo-multiplier tube converts the light pulses to electrons and multiplies that electronic pulse proportional to the light pulse intensity.

The **Geiger-Müller counter** (Fig. 19.4) consists of a cylindrical tube, usually of glass, coated internally with metal to provide a negative electrode and with a wire down the center for a positive electrode. The tube is filled to a total pressure of about 0.1 atm with a mixture of a noble gas and a quench gas, an organic vapor or a halogen, e.g., 90% argon and 10% ethyl alcohol vapor, and a potential difference of about 1000 V is applied across the electrodes. When a high-energy electron (beta particle) enters the tube, it produces positive ions and electrons. The light electrons are quickly accelerated toward the positively charged wire. As they advance, they encounter and ionize other neutral atoms. An avalanche of electrons builds up, and a large electron current flows into the central wire. This causes a drop in the potential difference, which is recorded, and the multiplicative electron discharge is quenched by the alcohol molecules. In this way single beta particles produce electrical pulses that can be amplified

**FIGURE 19.4** In a Geiger-Müller tube, radiation ionizes gas in the tube, freeing electrons that are accelerated to the anode wire in a cascade. Their arrival creates an electrical pulse, which is detected by a ratemeter. The ratemeter displays the accumulated pulses as the number of ionization events per minute.

and counted. Portable Geiger-Müller counters are widely used in uranium prospecting and to measure radiation in workplaces. Various tube sizes are used to detect different levels of radiation, and modifications must be made to detect  $\gamma$  rays more efficiently. **Proportional counters** are similar to Geiger-Müller counters but with the ability to measure energies like scintillation counters. They are filled with inert gases (typically He or Ar) along with a small partial pressure of a polyatomic molecule like  $\text{CH}_4$  that improves the instrument response time. The magnitude of each current pulse in these counters is proportional to the energy of the incident particles, hence the name. Proportional counters can be modified to detect neutrons by using  $^{10}\text{BF}_3$  as the fill gas, which efficiently captures neutrons to form an unstable nucleus that decays by emitting  $\alpha$  particles, which are readily detected. Finally, many modern detectors are solid-state semiconductor devices in which the ionizing radiation creates a number of electron-hole pairs in a semiconductor junction (see Section 22.7) producing a current pulse that is proportional to the intensity of the incident radiation.

### 19.3 Kinetics of Radioactive Decay

The decay of any given unstable nucleus is a random event and is independent of the number of surrounding nuclei that have decayed. When the number of nuclei is large, we can be confident that during any given period a definite fraction of the original number of nuclei will have undergone a transformation into another nuclear species. In other words, the rate of decay of a collection of nuclei is proportional to the number of nuclei present, showing that nuclear decay follows a first-order rate equation of the type discussed in Chapter 18. All the results developed in that chapter apply to the present situation; for example, the integrated rate law has the form

$$N = N_i e^{-kt}$$

where  $N_i$  is the number of nuclei originally present at  $t = 0$ . The decay constant  $k$  (or a Greek lambda,  $\lambda$ , as used by nuclear scientists) is related to a half-life  $t_{1/2}$  through

$$t_{1/2} = \frac{\ln 2}{k} = \frac{0.6931}{k}$$

just as in the first-order gas-phase chemical kinetics of Section 18.2. The half-life is the time required for the nuclei in a sample to decay to one-half their initial number, and it can range from less than  $10^{-21}$  s to more than  $10^{25}$  years for unstable nuclei. Table 19.2 lists the half-lives and decay modes of some unstable nuclides.

There is one important practical difference between chemical kinetics and nuclear kinetics. In chemical kinetics the concentration of a reactant or product is monitored over time, and the rate of a reaction is then found from the rate of change of that concentration. In nuclear kinetics the rate of occurrence of decay events,  $-dN/dt$ , is measured directly with a Geiger counter or other radiation detector. This decay rate—the average disintegration rate in numbers of nuclei per unit time—is called the **activity A**.

$$A = -\frac{dN}{dt} = kN \quad [19.2]$$

TABLE 19.2

## Decay Characteristics of Some Radioactive Nuclei

Nuclide	$t_{1/2}$	Decay Mode <sup>†</sup>	Daughter
${}^3_1\text{H}$ (tritium)	12.26 years	$e^-$	${}^3_2\text{He}$
${}^8_4\text{Be}$	$\sim 1 \times 10^{-16}$ s	$\alpha$	${}^4_2\text{He}$
${}^{14}_6\text{C}$	5730 years	$e^-$	${}^{14}_7\text{N}$
${}^{22}_{11}\text{Na}$	2.601 years	$e^+$	${}^{22}_{10}\text{Ne}$
${}^{24}_{11}\text{Na}$	15.02 hours	$e^-$	${}^{24}_{12}\text{Mg}$
${}^{32}_{15}\text{P}$	14.28 days	$e^-$	${}^{32}_{16}\text{S}$
${}^{35}_{16}\text{S}$	87.2 days	$e^-$	${}^{35}_{17}\text{Cl}$
${}^{36}_{17}\text{Cl}$	$3.01 \times 10^5$ years	$e^-$	${}^{36}_{18}\text{Ar}$
${}^{40}_{19}\text{K}$	$1.28 \times 10^9$ years	$\left\{ \begin{array}{l} e^- (89.3\%) \\ \text{E.C. (10.7\%)} \end{array} \right.$	$\left\{ \begin{array}{l} {}^{40}_{20}\text{Ca} \\ {}^{40}_{18}\text{Ar} \end{array} \right.$
${}^{59}_{26}\text{Fe}$	44.6 days	$e^-$	${}^{59}_{27}\text{Co}$
${}^{60}_{27}\text{Co}$	5.27 years	$e^-$	${}^{60}_{28}\text{Ni}$
${}^{90}_{38}\text{Sr}$	29 years	$e^-$	${}^{90}_{39}\text{Y}$
${}^{109}_{48}\text{Cd}$	453 days	E.C.	${}^{109}_{47}\text{Ag}$
${}^{125}_{53}\text{I}$	59.7 days	E.C.	${}^{125}_{52}\text{Te}$
${}^{131}_{53}\text{I}$	8.041 days	$e^-$	${}^{131}_{54}\text{Xe}$
${}^{127}_{54}\text{Xe}$	36.41 days	E.C.	${}^{127}_{53}\text{I}$
${}^{137}_{57}\text{La}$	$\sim 6 \times 10^4$ years	E.C.	${}^{137}_{56}\text{Ba}$
${}^{222}_{86}\text{Rn}$	3.824 days	$\alpha$	${}^{218}_{84}\text{Po}$
${}^{226}_{88}\text{Ra}$	1600 years	$\alpha$	${}^{222}_{86}\text{Rn}$
${}^{232}_{90}\text{Th}$	$1.40 \times 10^{10}$ years	$\alpha$	${}^{228}_{88}\text{Ra}$
${}^{235}_{92}\text{U}$	$7.04 \times 10^8$ years	$\alpha$	${}^{231}_{90}\text{Th}$
${}^{238}_{92}\text{U}$	$4.468 \times 10^9$ years	$\alpha$	${}^{234}_{90}\text{Th}$
${}^{239}_{93}\text{Np}$	2.350 days	$e^-$	${}^{239}_{94}\text{Pu}$
${}^{239}_{94}\text{Pu}$	$2.411 \times 10^4$ years	$\alpha$	${}^{235}_{92}\text{U}$

<sup>†</sup>E.C. stands for electron capture;  $e^+$  for positron emission;  $e^-$  for electron emission;  $\alpha$  for alpha emission.

**FIGURE 19.5** A graph of the logarithm of the activity of a radioactive nuclide against time is a straight line with slope  $-k = -(\ln 2)/t_{1/2}$ . The decay rate constant  $k$  can also be measured as the ratio of the activity to the number of atoms of the radioisotope present at time  $t$  if the latter is known.

Because the activity is proportional to the number of nuclei  $N$ , it also decays exponentially with time:

$$A = A_i e^{-kt} \quad [19.3]$$

A plot of  $\ln A$  against time  $t$  is linear with slope  $-k = -(\ln 2)/t_{1/2}$ , as Figure 19.5 shows. The activity  $A$  is reduced to half its initial value in a time  $t_{1/2}$ . Once  $A$  and  $k$  are known, the number of nuclei  $N$  at that time can be calculated from

$$N = \frac{A}{k} = \frac{At_{1/2}}{\ln 2} = \frac{At_{1/2}}{0.6931}$$

The S.I. unit of activity is the *becquerel* (Bq), defined as 1 radioactive disintegration per second. An older and much larger unit of activity is the *curie* (abbreviated Ci), which is defined as  $3.7 \times 10^{10}$  disintegrations per second. The activity of 1 g of radium is 1 Ci.

**EXAMPLE 19.4**

Tritium ( $^3\text{H}$ ) decays by beta emission to  $^3\text{He}$  with a half-life of 12.26 years. A sample of a tritiated compound has an initial activity of 0.833 Bq. Calculate the number  $N_i$  of tritium nuclei in the sample initially, the decay constant  $k$ , and the activity after 2.50 years.

**Solution**

Convert the half-life to seconds:

$$t_{1/2} = (12.26 \text{ yr})(60 \times 60 \times 24 \times 365.25 \text{ s yr}^{-1}) = 3.869 \times 10^8 \text{ s}$$

The number of nuclei originally present was

$$N_i = \frac{A_i t_{1/2}}{\ln 2} = \frac{(0.833 \text{ s}^{-1})(3.869 \times 10^8 \text{ s})}{0.6931} = 4.65 \times 10^8 \text{ } ^3\text{H nuclei}$$

The decay constant  $k$  is calculated directly from the half-life:

$$k = \frac{\ln 2}{t_{1/2}} = \frac{0.6931}{3.869 \times 10^8 \text{ s}} = 1.791 \times 10^{-9} \text{ s}^{-1}$$

To find the activity after 2.50 years, convert this time to seconds ( $7.889 \times 10^7 \text{ s}$ ) and use

$$A = A_i e^{-kt} = (0.833 \text{ Bq}) \exp[-(1.791 \times 10^{-9} \text{ s}^{-1})(7.889 \times 10^7 \text{ s})] = 0.723 \text{ Bq}$$

**Related Problems: 21, 22**

**19.3.1 Radioactive Dating**

The decay of radioactive nuclides with known half-lives enables geochemists to measure the ages of rocks from their isotopic compositions. Suppose that a uranium-bearing mineral was deposited some 2 billion ( $2.00 \times 10^9$ ) years ago and has remained geologically unaltered to the present time. The  $^{238}\text{U}$  in the mineral decays with a half-life of  $4.468 \times 10^9$  years to form a series of shorter-lived intermediates, ending in the stable lead isotope  $^{206}\text{Pb}$  (Fig. 19.6). The fraction of uranium remaining after  $2.00 \times 10^9$  years should be

$$\frac{N}{N_i} = e^{-kt} = e^{-0.6931 t/t_{1/2}} = \exp\left(\frac{-0.6931 \times 2.00 \times 10^9 \text{ yr}}{4.468 \times 10^9 \text{ yr}}\right) = 0.733$$

and the number of  $^{206}\text{Pb}$  atoms should be approximately

$$(1 - 0.733) N_i = 0.267 N_i(^{238}\text{U})$$

The ratio of abundances

$$\frac{N(^{206}\text{Pb})}{N(^{238}\text{U})} = \frac{0.267}{0.733} = 0.364$$

therefore is determined by the time elapsed since the deposit was originally formed—in this case,  $2.00 \times 10^9$  years. Of course, to calculate the age of the mineral, we work backward from the measured  $N(^{206}\text{Pb})/N(^{238}\text{U})$  ratio.

To use the method, it is necessary to be certain that the stable nuclide generated ( $^{206}\text{Pb}$  in this case) arises only from the parent species ( $^{238}\text{U}$  here) and that neither lead nor uranium has left or entered the rock over the course of geologic time. If possible, it is desirable to measure the ratios of several different isotopically paired species in the same rock sample. For example,  $^{87}\text{Rb}$  decays to  $^{87}\text{Sr}$

**FIGURE 19.6** The radioactive nuclide  $^{238}\text{U}$  decays via a series of alpha and beta emissions to the stable nuclide  $^{206}\text{Pb}$ .

with a half-life of  $4.9 \times 10^{10}$  years, and one mode of  $^{40}\text{K}$  decay (with a half-life of  $1.28 \times 10^9$  years) is to  $^{40}\text{Ar}$ . Each pair should ideally yield the same age. Detailed analysis of a large number of samples suggests that the oldest surface rocks on earth are about 3.8 billion years old. An estimate of 4.5 billion years for the age of the earth and solar system comes from indirect evidence involving an isotopic analysis of meteorites, which are believed to have formed at the same time.

A somewhat different type of dating uses measurements of  $^{14}\text{C}$  decay, which covers the range of human history and prehistory back to about 60,000 years ago. This unstable species (with a half-life of 5730 years) is produced continuously in the atmosphere. Cosmic rays of very high energy cause nuclear reactions that produce neutrons. These can collide with  $^{14}_7\text{N}$  nuclei to produce  $^{14}_6\text{C}$  by the reaction

The resulting  $^{14}\text{C}$  enters the carbon reservoir on the Earth's surface, mixing with stable  $^{12}\text{C}$  as dissolved  $\text{H}^{14}\text{CO}_3^-$  in the oceans, as  $^{14}\text{CO}_2$  in the atmosphere, and in the tissues of plants and animals. This mixing, which is believed to have occurred at a fairly constant rate over the past 50,000 years, means that the  $^{14}\text{C}$  in a living organism has a specific activity of close to 15.3 disintegrations per

minute per gram of total carbon—that is,  $0.255 \text{ Bq g}^{-1}$ . When a plant or animal dies (for example, when a tree is cut down), the exchange of carbon with the surroundings stops and the amount of  $^{14}\text{C}$  in the sample falls exponentially with time. By measuring the  $^{14}\text{C}$  activity remaining in an archaeological sample, we can estimate its age. This  $^{14}\text{C}$  dating method, developed by the American chemist W. F. Libby, has been calibrated against other dating techniques (such as counting the annual rings of bristlecone pines or examining the written records that may accompany a carbon-containing artifact) and has been found to be quite reliable over the time span for which it can be checked. This indicates an approximately constant rate of production of  $^{14}\text{C}$  near the earth's surface over thousands of years. Burning fossil fuels has decreased the isotopic abundance of  $^{14}\text{CO}_2$  in the atmosphere because plants (the source of fossil fuels) preferentially use  $^{12}\text{CO}_2$  in photosynthesis. The changing isotopic composition of atmospheric  $\text{CO}_2$  will cause difficulty in applying  $^{14}\text{C}$  dating in the future.

### EXAMPLE 19.5

A wooden implement has a specific activity of  $^{14}\text{C}$  of  $0.195 \text{ Bq g}^{-1}$ . Estimate the age of the implement.

#### Solution

The decay constant for  $^{14}\text{C}$  is

$$k = \frac{0.6931}{5730 \text{ yr}} = 1.21 \times 10^{-4} \text{ yr}^{-1}$$

The initial specific activity was  $0.255 \text{ Bq g}^{-1}$ , and the measured activity now (after  $t$  years) is  $0.195 \text{ Bq g}^{-1}$ , so

$$\begin{aligned} A &= A_0 e^{-kt} \\ 0.195 \text{ Bq g}^{-1} &= 0.255 \text{ Bq g}^{-1} e^{-(1.21 \times 10^{-4})t} \\ \ln\left(\frac{0.195}{0.255}\right) &= -(1.21 \times 10^{-4} \text{ yr}^{-1})t \\ t &= 2200 \text{ yr} \end{aligned}$$

The implement comes from a tree cut down approximately 2200 years ago.

**Related Problems:** 25, 26

## 19.4 Radiation in Biology and Medicine

Radiation has both harmful and beneficial effects for living organisms. All forms of radiation cause damage in direct proportion to the amount of energy they deposit in cells and tissues. The damage takes the form of chemical changes in cellular molecules, which alter their functions and lead either to uncontrolled multiplication and growth of cells or to their death. Alpha particles lose their kinetic energy over very short distances in matter (typically 10 cm in air or 0.05 cm in water or tissues), producing intense ionization in their wakes until they accept electrons and are neutralized to harmless helium atoms. Radium, for example, is an alpha emitter that substitutes for calcium in bone tissue and destroys its capacity to produce both red and white blood cells. Beta particles, gamma rays, and x-rays have greater penetrating power than alpha particles and so present a radiation hazard even when their source is well outside an organism.

The amount of damage produced in tissue by any of these kinds of radiation is proportional to the number of particles or photons and to their energy. A given activity of tritium causes less damage than the same activity of  $^{14}\text{C}$ , because the beta particles from tritium have a maximum kinetic energy of 0.0179 MeV, whereas those from  $^{14}\text{C}$  have an energy of 0.156 MeV. What is important is the amount of ionization produced or the quantity of energy deposited by radiation. For this purpose, several units are used. The *rad* (radiation absorbed dose) is defined as the amount of radiation that deposits  $10^{-2}$  J of energy per kilogram of tissue. The damage produced in human tissue depends on still other factors, such as the nature of the tissue, the kind of radiation, the total radiation dose, and the dose rate. To take all these into account, the *rem* (roentgen equivalent in man) has been defined to measure the effective dosages of radiation received by humans. A physical dose of 1 rad of beta or gamma radiation translates into a human dose of 1 rem. Alpha radiation is more toxic; a physical dose of 1 rad of alpha radiation equals about 10 rems. The SI unit for absorbed radiation, analogous to the rad, is the gray (Gy);  $1 \text{ Gy} = 1 \text{ joule per kg of material}$ . So,  $1 \text{ Gy} = 100 \text{ rad}$ . The SI unit for effective dosage of radiation is the sievert (Sv). The sievert is defined in the same way as the rem, except the delivered dose is expressed in Gy instead of rad; consequently,  $1 \text{ Sv} = 100 \text{ rem}$ .

Exposure to radiation is unavoidable. The average person in the United States receives about 100 millirems (mrem) or 1 millisievert (mSv) annually from natural sources that include cosmic radiation and radioactive nuclides such as  $^{40}\text{K}$  and  $^{222}\text{Rn}$ . Another 50 to 100 mrem or 0.5 to 1.0 mSv (variable) comes from human activities (including dental and medical x-ray examinations and airplane flights, which increase exposure to cosmic rays higher in the atmosphere). Permissible exposure levels are difficult to establish because there is no general agreement about the appropriate dose–response model for radiation damage among scientists and policy makers. The U.S. Environmental Protection Agency (EPA) uses a linear dose–response model, which asserts that damage is proportional to exposure, down to levels where control groups show no effect. It is well known, however, that there are biological repair mechanisms that protect organisms from damage at low exposures, and it might be more reasonable to establish a higher “no observable adverse effect level” or NOAEL. At the time of this writing the EPA appears to continue to embrace the more conservative linear dose–response model. The problem is made even more complex by the necessity to distinguish between tissue damage in an exposed individual and genetic damage, which may not become apparent for several generations. The adverse effects of single exposures are much easier to quantify. A single dose less than 0.25 Sv will likely cause no effect, a 1-Sv dose will cause severe illness, and a 5-Sv dose is fatal, unless the exposed individual received prompt medical treatment. (The treatment of exposed workers following the Chernobyl nuclear accident in 1986 demonstrated that immediate treatment is effective.)

#### EXAMPLE 19.6

The beta decay of  $^{40}\text{K}$  that is a natural part of the body makes all human beings slightly radioactive. An adult weighing 70.0 kg contains about 170 g of potassium. The relative natural abundance of  $^{40}\text{K}$  is 0.0118%, its half-life is  $1.28 \times 10^9$  years, and its beta particles have an average kinetic energy of 0.55 MeV.

- Calculate the total activity of  $^{40}\text{K}$  in this person.
- Determine (in Gy per year) the annual radiation absorbed dose arising from this internal  $^{40}\text{K}$ .

(Continued)

**Solution**

(a) First calculate the decay constant of  $^{40}\text{K}$  in  $\text{s}^{-1}$ :

$$k = \frac{0.693}{t_{1/2}} = \frac{0.693}{(1.28 \times 10^9 \text{ yr})(365 \times 24 \times 60 \times 60 \text{ s yr}^{-1})}$$

$$= 1.72 \times 10^{-17} \text{ s}^{-1}$$

$$\text{number of } ^{40}\text{K atoms} = \frac{170 \text{ g}}{40.0 \text{ g mol}^{-1}} (1.18 \times 10^{-4}) (6.02 \times 10^{23} \text{ mol}^{-1})$$

$$= 3.02 \times 10^{20}$$

$$A = -\frac{dN}{dt} = kN = (1.72 \times 10^{-17} \text{ s}^{-1})(3.02 \times 10^{20}) = 5.19 \times 10^3 \text{ s}^{-1}$$

(b) Each disintegration of  $^{40}\text{K}$  emits an average of 0.55 MeV of energy, and we assume that all of this energy is deposited within the body. From part (a),  $5.19 \times 10^3$  disintegrations occur per second, and we know how many seconds are in a year. The total energy deposited per year is then

$$5.19 \times 10^3 \text{ s}^{-1} \times (60 \times 60 \times 24 \times 365 \text{ s yr}^{-1}) \times 0.55 \text{ MeV} =$$

$$9.0 \times 10^{10} \text{ MeV yr}^{-1}$$

Next, because a Gy is 1 J per kilogram of tissue, we express this answer in joules per year:

$$(9.0 \times 10^{10} \text{ MeV yr}^{-1})(1.602 \times 10^{-13} \text{ J MeV}^{-1}) = 0.0144 \text{ J yr}^{-1}$$

Each kilogram of body tissue receives 1/70.0 of this amount of energy per year, because the person weighs 70.0 kg. The dose is thus  $21 \times 10^{-5} \text{ J kg}^{-1} \text{ yr}^{-1}$ , which is equivalent to  $0.21 \text{ Gy yr}^{-1}$  or  $21 \text{ mrad yr}^{-1}$ . This is about a fifth of the annual background dosage received by a person.

**Related Problems: 35, 36**

Although radiation can do great harm, it confers great benefits in medical applications. The diagnostic importance of X-ray imaging hardly needs mention. Computerized axial tomography (CAT) provides high-resolution three-dimensional images of bones, soft tissues, and tumors; it has become an indispensable tool in modern medicine. Ionizing radiation of all types (X-rays, gamma rays, and particles) are used both externally and internally to treat cancers. The beta-emitting  $^{131}\text{I}$  nuclide finds use in the treatment of cancer of the thyroid because iodine is taken up preferentially by the thyroid gland. Precise control of X-ray and particle beam cross-section shapes, coupled with precise alignment of the beams using CAT scans enable radiation oncologists to irradiate tumors selectively, eliminating damage to adjacent tissues as close as 1 mm to the perimeter of the beams.

Positron emission tomography (PET) is an important diagnostic technique using radiation (see *Connection to Medicine*). The vast majority of PET scans are used in oncology. Patients are injected with  $^{18}\text{F}$ -labelled glucose that is taken up preferentially by tumors because cancer cells metabolize glucose at greater rates than normal cells. Not only do PET scans provide images that may be more detailed than those provided by MRI or CT scans, they also monitor the metabolic activity of tumors, allowing oncologists to assess whether they are malignant or benign and to follow their response to treatment.

## CONNECTION TO MEDICINE

## Isotopes and Nuclear Medicine

## Radiotracers

The discovery of artificial radioactivity in 1934, and the invention of the cyclotron (a particle accelerator) shortly thereafter, made it possible to study the mechanisms of chemical reactions at a level of detail not previously possible. Molecules were labeled in specific positions with radioisotopes (**radiotracers**) that were incorporated using standard synthetic methods, and the disposition of the tracers among the various products was determined by measuring their activity. The method was quickly adopted to study the mechanisms of biochemical and biological processes because it is extremely sensitive, and also because radioactive isotopes of the biologically important elements were easily prepared using cyclotrons. Early studies focused on phosphorus and iodine metabolism using  $^{32}\text{P}$  and  $^{131}\text{I}$ , respectively. Considerable insight into the mechanism of photosynthesis was provided by pioneering studies that used  $^{18}\text{O}$  (a heavy stable isotope of oxygen)–labeled water to show that it was the source of the  $\text{O}_2$  produced and not  $\text{CO}_2$ .  $^{14}\text{CO}_2$  was also used to trace the location of carbon in the various carbohydrate products produced and establish the photosynthetic pathways involved.

Several dozen radioisotopes are now produced routinely for a variety of applications in medical diagnostics and radiation therapy. Neutron-deficient isotopes are generally made in medical cyclotrons, whereas proton-deficient isotopes are generally made in nuclear reactors.  $^{99\text{m}}\text{Tc}$ , an isomer of  $^{99}\text{Tc}$ , a  $\gamma$  emitter, is the most widely used radioisotope because its 6-hour half-life is particularly convenient; it is long enough so that it can be transported from the source to the imaging center, but short enough that it emits  $\gamma$ -rays at a sufficiently high rate to ensure high resolution. Compounds containing  $^{99\text{m}}\text{Tc}$  have been specifically designed to incorporate the tracer into tissues and structures of interest in order to image organs, bones, and tumors, as well as to monitor blood flow through the circulatory system, in particular the heart, brain, and lungs. Other radioisotopes are used to monitor thyroid function, and to image tumors and measure their metabolic activity. Positron emission tomography (PET), using  $^{18}\text{F}$ , has become one of the most powerful of the radiotracer-based imaging techniques in recent years, with about 90% of PET scans being used to image tumors.

## Positron Emission Tomography

Positron emission tomography detects both members of a pair of 0.511 MeV photons called *annihilation radiation* that are emitted when positrons and electrons

**FIGURE C19.1** Schematic of the electron–positron annihilation process.

annihilate one another in a collision, the location of the radiotracer being determined by working backward from the positions of the photons measured by a large cylindrical detector. The reaction is written as follows, and a schematic of the electron–positron annihilation process is shown in Figure C19.1.

The most important radioisotopes used for PET imaging include  $^{11}\text{C}$ ,  $^{13}\text{N}$ ,  $^{15}\text{O}$ , and  $^{18}\text{F}$ , with half-lives of approximately 20, 10, 2, and 110 minutes respectively. They are synthesized by bombarding a target with high-energy (few MeV) particles in a cyclotron or a linear accelerator, as shown by the following nuclear reactions.

The schematic of a cyclotron (Fig. C19.2) identifies its key features. Ions are injected into the center of the cyclotron, which is an evacuated chamber that contains a pair of D-shaped electrodes (dees) separated by a gap and a magnet that establishes a constant field perpendicular to the plane of the dees. A very high frequency-alternating voltage is applied to the dees, which causes the ions to accelerate each time they cross the gap. The magnetic field forces the ions to follow circular orbits of increasing radii with increasing kinetic energy, resulting in a spiral trajectory. They are eventually extracted and bombard the target as shown.

The radioisotopes must be incorporated into molecules very quickly after they are made; rapid organic

**FIGURE C19.2** Schematic of a cyclotron.

synthetic methods developed at Brookhaven National Laboratories were key to the widespread implementation of PET technology. The synthesis of 2-deoxy-2- $(^{18}\text{F})$ fluoro-D-glucose, (FDG), in particular, was significant because it enabled the relatively long-lived  $^{18}\text{F}$  isotope to be incorporated into a sugar that is metabolized by all cells.  $^{18}\text{F}$ FDG is the dominant isotope used in cancer studies because it is preferentially taken up in cancer cells due to their high metabolic rates. One of the earliest applications of PET used  $^{11}\text{C}$  to label drugs and investigate their mechanisms of action by imaging the brain.  $^{15}\text{O}_2$  and  $^{15}\text{OH}_2$  are used to measure blood flow in the heart and brain, as is  $^{13}\text{NH}_3$ , and the early pioneering studies of the interactions of drugs that cross the blood-brain barrier were conducted using drugs labeled with  $^{11}\text{C}$ .

The combination of positron emission tomography with computerized tomography (CT) or magnetic resonance imaging (MRI) allows clinicians to acquire

**FIGURE C19.3** A PET/CT scanner.

functional (metabolic) and structural (anatomical) images sequentially, enabling them to locate tumors with very high precision. Figure C19.3 shows a PET/CT scanner in which the patient is transferred between the instruments on a gurney that preserves the patient's general alignment. Extremely small gold seeds (less than 1 mm) that are clearly visible in the CT images are implanted at several locations in patients to serve as accurate reference markers for position.

The recent development of 4D PET/CT takes the process one step further, allowing radiation oncologists to image patients in real time and monitor the movement of tumors as patients breathe. The method is so sophisticated that radiation from a pulsed linear accelerator can be delivered to the tumor at a particular time in the breathing cycle, minimizing irradiation of normal tissue and the radiation damage that it causes. The PET/CT scans in Figure C19.4 illustrate the power of the method. The tumor is clearly visible in Figure C19.4a. Figure C19.4b shows that it has largely been destroyed after a course of radiation. The field of nuclear medicine continues to evolve to provide us with diagnostic and therapeutic tools of unprecedented power and scope.

**FIGURE C19.4** Scans from a 4D PET/CT scanner. (a) A tumor is visualized (orange and yellow areas). (b) Tumor area shown after treatment with radiation.

Less direct benefits come from other applications. An example is the study of the mechanism of photosynthesis, in which carbon dioxide and water are combined to form glucose in the green leaves of plants.

Radioactive tracers have been invaluable in establishing the mechanisms of organic and biochemical reactions.  $^{14}\text{C}$ , for example, can be introduced into starting re-agents using standard synthetic methods and its position in the products is used to distinguish among several possible mechanisms. Radioactive tracers are also widely used in medical diagnosis. The radioimmunoassay technique, invented by Nobel laureate Rosalyn Yalow, determines the levels of drugs and hormones in body fluids. Antigens (the drug or hormone of interest) are labeled with a radioactive tracer and bound to a known amount of antibody. Samples of blood containing unknown amounts of the antigen are added to the complex, and the unlabeled antigen displaces the labeled antigen, whose concentrations are determined by measuring its activity in solution after rinsing.

## 19.5 Nuclear Fission

By the 1920s, physicists and chemists were using particle accelerators to bombard samples with high-energy particles to *induce* nuclear reactions. The English physicist James Chadwick (yet another illustrious Rutherford student) identified the neutron in 1932, a dozen years after Rutherford predicted its existence, as a product of the reaction between alpha particles from a radioactive source and  $^9\text{Be}$ :

Shortly after Chadwick's discovery, a group of physicists in Rome, led by Enrico Fermi, began to study the interaction of neutrons with the nuclei of various elements. The experiments produced a number of radioactive species, and it was evident that the absorption of a neutron increased the  $N:Z$  ratio in target nuclei above the stability line (see Fig. 19.1). One of the targets used was uranium, the heaviest naturally occurring element. Several radioactive products resulted, none of which had chemical properties characteristic of the elements between  $Z = 86$  (radon) and  $Z = 92$  (uranium). It appeared to the Italian scientists in 1934 that several new transuranic elements ( $Z > 92$ ) had been synthesized, and an active period of investigation followed.

In 1938 in Berlin, Otto Hahn and Fritz Strassmann sought to characterize the supposed transuranic elements. To their bewilderment, they found instead that barium ( $Z = 56$ ) appeared among the products of the bombardment of uranium by neutrons. Hahn informed his former colleague Lise Meitner, and she conjectured that the products of the bombardment of uranium by neutrons were not transuranic elements but fragments of uranium atoms resulting from a process she termed **fission**. The implication of this phenomenon—the possible release of enormous amounts of energy—was immediately evident. When the outbreak of World War II appeared imminent in the summer of 1939, Albert Einstein signed a letter drafted by the top nuclear scientists to President Franklin Roosevelt to inform him of the possible military uses of fission and of his concern that Germany might develop a nuclear explosive. As a result, in 1942 President Roosevelt authorized the Manhattan District Project, an intense, coordinated effort by a large number of physicists, chemists, and engineers to make a fission bomb of unprecedented destructive power.

The operation of the first atomic bomb hinged on the fission of uranium in a chain reaction induced by absorption of neutrons. The two most abundant isotopes of uranium are  $^{235}\text{U}$  and  $^{238}\text{U}$ , whose natural relative abundances are

0.720% and 99.275%, respectively. Both undergo fission upon absorbing a neutron, the latter only with “fast” neutrons and the former with both “fast” and “slow” neutrons. In the early days of neutron research, it was not known that the absorption of neutrons by nuclei depends strongly upon neutron velocity. By accident, Fermi and his colleagues discovered that experiments conducted on a wooden table led to a much higher yield of radioactive products than those performed on a marble-topped table. Fermi then repeated the irradiation experiments with a block of paraffin wax interposed between the radium–beryllium neutron source and the target sample, with the startling result that the induced level of radioactivity was greatly enhanced. Within hours Fermi had found the explanation: The high-energy neutrons emitted from the radium–beryllium source were reduced to thermal energy by collision with the low-mass nuclei of the paraffin molecules. Because of their lower energies, their probability of reaction with  $^{235}\text{U}$  was greater and a higher yield was achieved. Hydrogen nuclei and the nuclei of other light elements such as  $^{12}\text{C}$  (in graphite) are very effective in reducing the energies of high-velocity neutrons and are called **moderators**.

The fission of  $^{235}\text{U}$  follows many different patterns, and some 40 elements have been identified among the fission products. In a typical fission event two particular nuclides are produced together with two or three secondary neutrons; collectively, they carry away about 170 MeV of kinetic energy. Usually, the daughter nuclei have different  $Z$  and  $A$  numbers, so the fission process is asymmetric. Three of the many pathways are

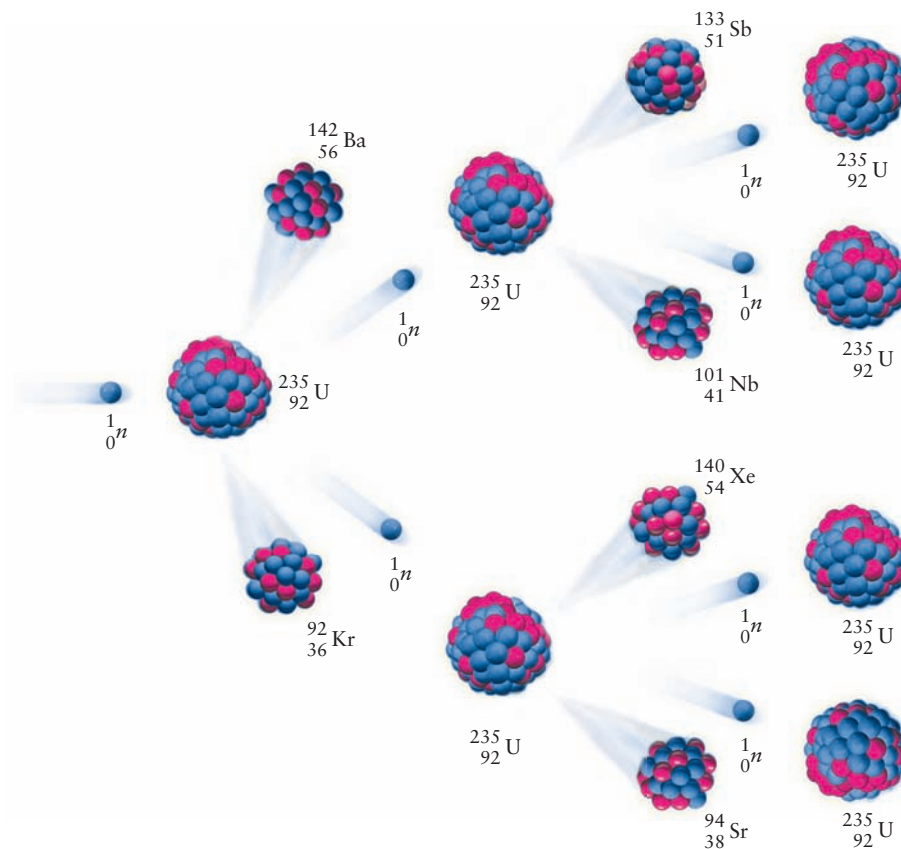

Figure 19.7 shows the distribution of the nuclides produced. On average, more than one neutron is emitted per neutron absorbed in the fission process, which

**FIGURE 19.7** The distribution of nuclides produced in the fission of  $^{235}\text{U}$  after capturing a neutron has two peaks. Nuclei having mass numbers in the vicinity of  $A = 95$  and  $A = 139$  are formed with the highest yield; those with  $A \approx 117$  are produced with lower probability.

**FIGURE 19.8** The number of free or ejected neutrons increases exponentially in a chain reaction. Not all of the emitted neutrons are shown.

leads to a branching chain reaction (see Section 18.4) with the number of neutrons growing exponentially with time (Fig. 19.8). Permitted to proceed unchecked, this reaction would quickly lead to the release of enormous quantities of energy. Neutrons can be lost by various processes, so it is not obvious that a self-propagating reaction will occur. On December 2, 1942, Fermi and his associates demonstrated that a self-sustaining neutron chain reaction occurred in a uranium “pile” with a graphite moderator. They limited its power output to  $\frac{1}{2} \text{ J s}^{-1}$  by inserting cadmium control rods to absorb neutrons, thereby balancing the rates of neutron generation and loss.

Fermi’s work made two developments possible: (1) the exploitation of nuclear fission for the controlled generation of energy in nuclear reactors and (2) the production of  ${}^{239}\text{Pu}$ , a slow- and fast-neutron fissionable isotope of plutonium, as an alternative to  ${}^{235}\text{U}$  for the construction of atomic bombs. For the sudden release of energy required in an explosive, it was necessary to obtain  ${}^{235}\text{U}$  or  ${}^{239}\text{Pu}$  in a state free of neutron-absorbing impurities. Both alternatives were pursued simultaneously. The first required enriching  ${}^{235}\text{U}$  from its relative abundance of 0.72% in natural uranium. This was accomplished through gaseous diffusion (see Section 9.7). For the second alternative,  ${}^{239}\text{Pu}$  was recovered from the partially spent uranium fuel of large nuclear reactors by means of redox reactions, precipitation, and solvent extraction.

Although Fermi and his associates were the first scientists to demonstrate a self-sustaining nuclear chain reaction, a natural uranium fission reactor “went critical” about 1.8 billion years ago in a place now called Oklo, in the Gabon Republic of equatorial Africa. In 1972 French scientists discovered that the  ${}^{235}\text{U}$  content of ore from a site in the open-pit mine at Oklo was only 0.7171%; the normal content of ore from other areas of the mine was 0.7207%. Although this deviation was not large, it was significant, and an investigation revealed that other elements were also present in the ore, in the exact proportions expected

**FIGURE 19.9** A nuclear power plant. The large structure on the left is a cooling tower; the containment building is the smaller building on the right with the domed top.

© Picture Press/Alamy

after nuclear fission. This discovery established that a self-sustaining nuclear reaction had occurred at Oklo. The geological age of the ore body was found to be about  $1.8 \times 10^9$  years, and the original  $^{235}\text{U}$  concentration is calculated to have been about 3%. From the size of the active ore mass and the depletion of  $^{235}\text{U}$ , it is estimated that the reactor generated about 15,000 megawatt-years ( $5 \times 10^{17}$  J) of energy over about 100,000 years.

### 19.5.1 Nuclear Power Reactors

Most **nuclear power reactors** in the United States (Fig. 19.9) use pellets of  $\text{UO}_2$  (Fig. 19.10) that have been sintered to form hard ceramics, which are then inserted into tubes made from a special steel alloy and bundled to form a fuel rod assembly. The uranium is primarily  $^{238}\text{U}$ , but the amount of  $^{235}\text{U}$  is enriched above natural abundance to a level of about 3%. The moderator used to slow the neutrons (to increase the efficiency of the fission) is ordinary water in most cases, so these reactors are called “light-water” reactors. The controlled release of energy by nuclear fission in power reactors demands a delicate balance between neutron generation and neutron loss. As mentioned earlier, this is accomplished by means of steel control rods containing  $^{113}\text{Cd}$  or  $^{10}\text{B}$ , isotopes that have a very large neutron-capture probability, and which effectively control the neutron flux. These rods are automatically inserted into or withdrawn from the fissioning system in response to a change in the neutron flux. As the nuclear reaction proceeds, the moderator (water) is heated and transfers its heat to a steam generator. The high-pressure steam then drives turbines that generate electricity (Fig. 19.11). The nonnuclear part of a nuclear power plant is essentially identical to that of a conventional fossil-fuel-fired power plant, the difference being the source of energy to heat the water.

The power reactors discussed so far rely on the fission of  $^{235}\text{U}$ , an isotope in limited supply. An alternative is to convert the much more abundant  $^{238}\text{U}$  to fissionable plutonium ( $^{239}\text{Pu}$ ) by neutron bombardment:

Fissionable  $^{233}\text{U}$  can also be made from thorium:

Science Source

**FIGURE 19.10**  $\text{UO}_2$  pellets and fuel rods.

**FIGURE 19.11** A schematic diagram of a pressurized-water nuclear power reactor.

In a *breeder reactor*, in addition to heat being generated by fission, neutrons are absorbed in a blanket of uranium or thorium. This causes the preceding reactions to occur and generates additional fuel for the reactor to use. An advanced technology for breeder reactors uses liquid sodium instead of water as the coolant, allowing the use of faster neutrons than in water-cooled reactors. The faster neutrons cause more complete consumption of radioactive fuels, increasing efficiency and greatly reducing radioactive waste.

The risks associated with the operation of nuclear reactors are small but not negligible, as demonstrated by the failure of the Three Mile Island reactor in the United States in 1979, the disaster at Chernobyl in the former Soviet Union in 1987, and the tsunami that led to the meltdown of the Fukushima Daiichi nuclear power plant in Japan in 2011. If a reactor has to be shut down quickly, there is danger of a meltdown, in which the heat from the continuing fission processes melts the uranium fuel. Coolant must be circulated until heat from the decay of short-lived isotopes has been dissipated. The Three Mile Island accident resulted in a partial meltdown because some water coolant pumps were inoperative and others were shut down too soon, causing damage to the core and a slight release of radioactivity into the environment. The Chernobyl disaster was caused by a failure of the water-cooling system and a meltdown. The rapid and uncontrolled nuclear reaction that took place set the graphite moderator on fire and caused the reactor building to rupture, spreading radioactive nuclides with an activity estimated at  $2 \times 10^{20}$  Bq into the atmosphere. A major part of the problem was that the reactor at Chernobyl, unlike those in the United States, was not in a massive containment building. The Fukushima nuclear disaster occurred on March 11, 2011. Three of the nuclear power plant's six reactors suffered a meltdown of the reactor core. This incident occurred as a result of destruction caused by an earthquake-generated tsunami. The incident resulted in a large amount of radioactive water being released into the ocean and surrounding environment.

The safe disposal of the radioactive wastes from nuclear reactors is an important and controversial matter. A variety of proposals have been made,

including the burial of radioactive waste in deep mines on either a recoverable or a permanent basis, burial at sea, and launching the waste into outer space. The first alternative is the only one that appears credible. The essential requirement is that the disposal site(s) be stable with respect to possible earthquakes or invasion by underground water. Spent nuclear fuel can be encased in blocks of borosilicate glass, packed in metal containers, and buried in stable rock formations. For a nuclide such as  $^{239}\text{Pu}$ , whose half-life is 24,000 years, a storage site that is stable over 240,000 years is needed before the activity drops to 0.1% of its original value. The Berkeley physicist Richard Muller has suggested that we compare the level of radioactivity of the waste to that which has already been mined and accept some probability greater than zero that there will be a leak. His calculations suggest that a facility that would provide a 99% level of confidence that there would be no leak would reduce the time needed to store the material to 300 years, by comparing the radioactivity resulting from such a leak not to zero but to the natural background levels found in the surrounding terrain.

## 19.6 Nuclear Fusion and Nucleosynthesis

**Nuclear fusion** is the union of two light nuclides to form a heavier nuclide with the release of energy. Fusion processes are often called *thermonuclear reactions* because they require that the colliding particles possess very high kinetic energies, corresponding to temperatures of millions of degrees, before they are initiated. They are the processes that occur in the sun and other stars. In 1939 the German physicists Hans Bethe (and, independently, Carl von Weizsäcker) proposed that in normal stars (main sequence) the following reactions take place:

In the first reaction, two high-velocity protons fuse to form a deuteron, with the emission of a positron and a neutrino that carry away (as kinetic energy) the additional 0.415 MeV of energy released. In the second reaction, a high-energy deuteron combines with a high-velocity proton to form a helium nucleus of mass 3 and a gamma ray. The third reaction completes the cycle with the formation of a normal helium nucleus ( ${}^4_2\text{He}$ ) and the regeneration of two protons. Each of these reactions is exothermic, but up to 1.25 MeV is required to overcome the repulsive barrier between the positively charged nuclei. The overall result of the cycle is to convert hydrogen nuclei to helium nuclei, and the process is called **hydrogen burning**.

As such a star ages and accumulates helium, it begins to contract under the influence of its immense gravity. As it contracts, its helium core heats up; when it reaches a temperature of about  $10^8$  K, a stage of **helium burning** begins. The first reaction that occurs is

This reaction is written as an equilibrium because the  ${}^8\text{Be}$  with a half-life of only  $6.7 \times 10^{-17}$  s quickly reverts to helium nuclei. Even with this short half-life, the  ${}^8\text{Be}$  nuclei are believed to occasionally react with alpha particles to form stable  ${}^{12}\text{C}$ :

The overall effect of the helium-burning phase of a star's life is to convert three helium nuclei to a carbon nucleus, just as helium was formed from four hydrogen nuclei in the hydrogen-burning phase. The density of the core of a star that is burning helium is on the order of  $10^5 \text{ g cm}^{-3}$ .

This process of **nucleosynthesis** continues beyond the formation of  $^{12}\text{C}$  to produce  $^{13}\text{N}$ ,  $^{13}\text{C}$ ,  $^{14}\text{N}$ ,  $^{15}\text{O}$ ,  $^{15}\text{N}$ , and  $^{16}\text{O}$ . The stars in this stage, classified as red giants, are near the end of their lives and expand as the temperature of the core rises. Similar cycles occur until the temperature of a star core is about  $4 \times 10^9 \text{ K}$ , its density is about  $3 \times 10^6 \text{ g cm}^{-3}$ , and the nuclei are  $^{56}\text{Fe}$ ,  $^{59}\text{Co}$ , and  $^{60}\text{Ni}$ . These are the nuclei that have the maximum binding energy per nucleon (see Fig. 19.2). It is thought that the synthesis of still heavier nuclei occurs in the immense explosions of supernovae.

Heavy elements can also be produced in particle accelerators, which accelerate ions to high speeds, causing collisions that generate the new elements. Technetium, for example, is not found in nature but was first produced in 1937 when high-energy deuterons were directed at a molybdenum target:

The first **transuranic element** was produced in 1940. Neptunium ( $Z = 93$ ) results from the capture of a neutron by  $^{238}\text{U}$ , followed by beta decay. Subsequent work by the American chemist Glenn Seaborg and others led to the production of plutonium ( $Z = 94$ ) and heavier elements. In recent years, nuclides with  $Z$  as high as 118 have been made, but only in tiny quantities. These nuclides have very short half-lives.

Controlled nuclear fusion is an attractive alternative to nuclear fission that could produce virtually unlimited quantities of energy from readily available sources of fuel with no adverse environmental impact. Two major efforts are underway to harness the power of the fusion of deuterium with tritium to form helium in a controlled way. There is virtually a limitless supply of deuterium that can be extracted from seawater, and tritium can be produced as a byproduct of the fusion reaction as discussed below. The reaction

produces 17.6 MeV *per event*, which corresponds to about 340,000,000 kJ  $\text{g}^{-1}$  of fuel burned. To put this into perspective, a conventional power plant produces about 1 GW ( $10^9 \text{ W}$ ) of power, consuming about 2.5 million tons of coal per year. The same amount of energy produced by nuclear fusion would consume less than 10 kg of the hydrogen isotopes, so it is little wonder that nuclear fusion research and development is being so vigorously pursued.

Initiating controlled fusion is difficult because the two nuclei must come together with sufficient energy to overcome the repulsive Coulomb potential energy barrier, which is about 1 MeV for these hydrogen isotopes. This potential barrier can be thought of as an activation energy for the reaction; temperatures of the order of 100 million K are required for it to proceed at an acceptable rate (see Section 18.5). Two very different approaches have been developed over many years in attempts to achieve these extraordinarily high temperatures; they are called magnetic confinement and inertial confinement, respectively. Magnetic confinement fusion uses magnetic fields as “walls” to contain very high temperature plasmas (ionized gases) because there are no material walls that could survive under these conditions. The fuel is heated, in part, by the absorption of electromagnetic radiation in the same way that microwave ovens heat our food. Inertial confinement fusion, on the other hand, uses short bursts of very high-power laser radiation to compress and heat the fuel to very high temperatures and densities. The main difference between the two approaches is that

magnetic confinement heats the fuel at somewhat lower pressures but for longer times, whereas inertial confinement both heats and compresses the fuel almost instantaneously.

There are currently two large-scale efforts underway to demonstrate that controlled nuclear fusion can generate more energy than that required for initiation, one focused on magnetic confinement and the other on inertial confinement. ITER (originally the International Thermonuclear Fusion Reactor but now said to be derived from the Latin word for “journey” for political reasons) is an international collaboration that is constructing a large facility in the south of France with the specific goal of producing 10 times as much energy as that required for initiation. The ITER tokamak is built around a donut-shaped vacuum chamber that contains a plasma (a gas of ionized particles, see Sec. 1.4). A large number of superconducting magnets generate a magnetic field some 200,000 times stronger than that of the earth, which confines the plasma to the interior of the vacuum chamber and prevents it from heating the walls. Figure 19.12 shows a schematic of the ITER tokamak. The design calls for an operating temperature of 150 million K and power output of 500 MW. The ITER tokamak has also been designed to produce tritium from the reaction of neutrons with lithium in the “blanket” that covers the interior surfaces of the vacuum vessel, the balanced reaction being

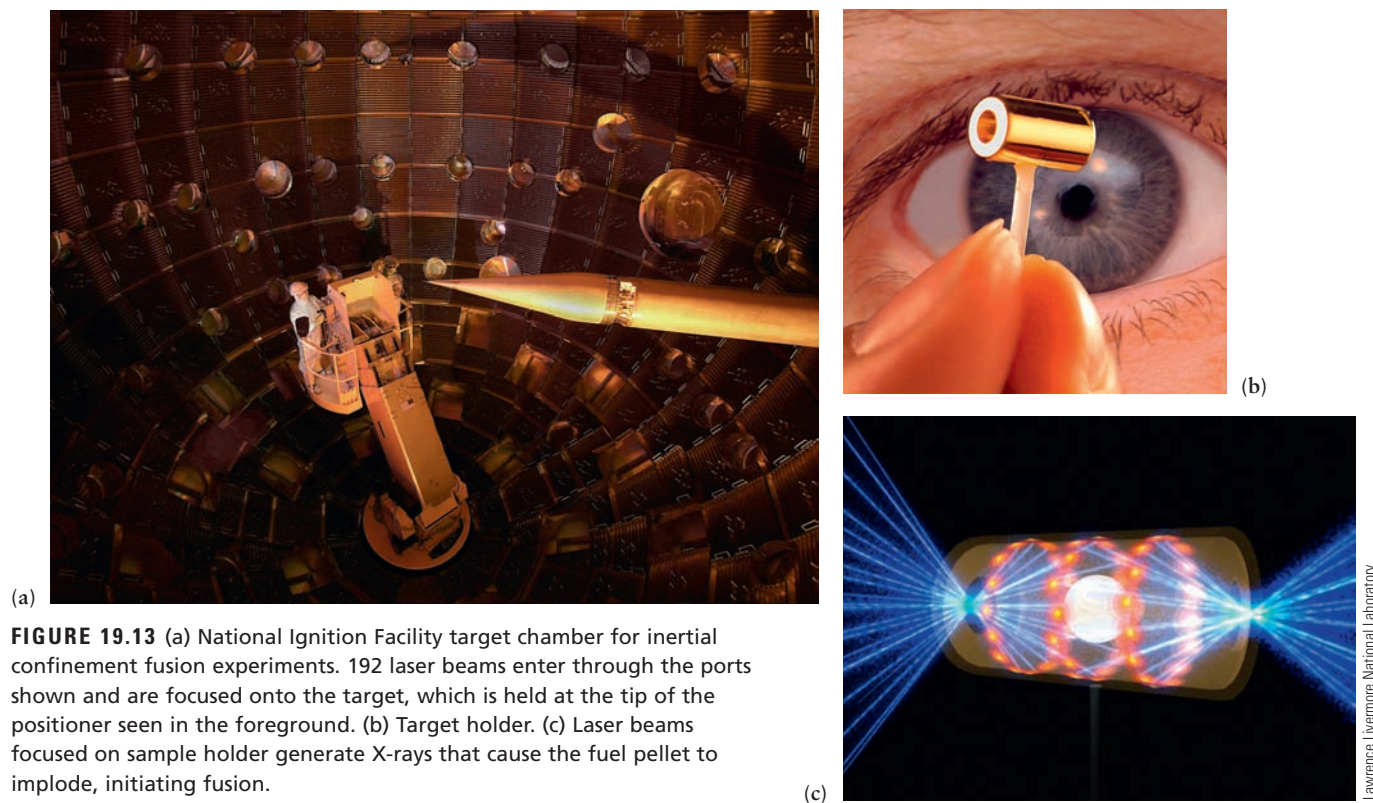

A demonstration power plant (DEMO) is intended to follow, based upon the anticipated success of the ITER experiment. The goal of that project is to demonstrate continuous fusion that produces sustained power in the 2 to 4 GW range, which is comparable to the largest existing conventional power plants.

The National Ignition Facility (NIF) is a project of the United States Department of Energy designed to demonstrate net energy production by inertial confinement fusion. The world’s largest laser, with the greatest amount of energy per pulse, has been constructed and tested. A total of 192 amplified laser beams are focused onto a tiny, hollow beryllium sphere, about the size of a peppercorn, which contains a fraction of a milligram of the target mixture of deuterium and tritium in the form of a frozen solid held at 18 K (see Fig. 19.13).

**FIGURE 19.12** Cutaway of the ITER tokamak, showing the torus-shaped vacuum vessel (yellow) that is about 60 ft in diameter along with the external magnets. The entire machine will weigh some 23,000 tons.

**FIGURE 19.13** (a) National Ignition Facility target chamber for inertial confinement fusion experiments. 192 laser beams enter through the ports shown and are focused onto the target, which is held at the tip of the positioner seen in the foreground. (b) Target holder. (c) Laser beams focused on sample holder generate X-rays that cause the fuel pellet to implode, initiating fusion.

The laser beam generates more power than the entire U.S. electrical grid during its short pulse. The extremely high power compresses the fuel and heats it to the 100 million K required to initiate the fusion reaction. The system passed a critical milestone in February 2014 when researchers for the first time initiated a controlled nuclear fusion event that produced more energy than was used to initiate the reaction. There are significant challenges that must be met before inertial confinement fusion becomes an important practical source of energy. The initial goal of the NIF is to produce 20 MJ of energy per pulse with the laser system currently capable of generating only about two pulses per day. Scaling this approach to provide power at levels that approach those provided by conventional power plants will require lasers capable of delivering perhaps 10 pulses per second that, in turn, would consume about 850,000 fuel pellets per day, which is a daunting challenge indeed.

## CHAPTER SUMMARY

The identities of the elements are not preserved in nuclear reactions—elements decay into lighter daughter elements in fission reactions and heavier elements are synthesized from lighter elements in fusion reactions. Mass changes in nuclear reactions are relatively small, but the accompanying energy changes are enormous; they are related by Einstein's famous formula  $E = mc^2$ . The isotopes of the lighter elements ( $Z < 20$  or so) are stable when the ratio of the number of neutrons to the number of protons ( $N/Z$ ) is approximately equal to 1. For these low  $Z$  elements, isotopes with  $N/Z < 1$  will decay via positron emission or electron capture to decrease the number of protons in the nucleus, whereas those with  $N/Z > 1$  will decay via electron emission to increase the number of protons in the nucleus. A fourth decay channel, alpha particle emission, becomes important for heavier nuclei. Radioactive decay follows first order kinetics, and

the half-life  $t_{1/2}$  is a convenient measure of the timescale of the reaction. Half-lives range from  $10^{-16}$  s to  $10^{20}$  years, which is an incredibly wide range of timescales. The half-life of  $^{238}\text{U}$  has been used to calibrate geological timescales, and  $^{14}\text{C}$  dating is a well-established method for dating human artifacts in anthropology. X-rays, gamma rays, electrons, positrons, and alpha particles are all used in medical diagnostics and therapy with increasing efficacy and fewer side effects. Nuclear fusion, which led to the formation of the heavier elements from hydrogen in the process called nucleosynthesis, continues to hold promise as a source of clean power for the future.

## CONCEPTS AND SKILLS

### Section 19.1 – Mass–Energy Relationships in Nuclei

*Identify and characterize patterns of nuclear stability and the nuclear decay processes.*

- Stable nuclei are those for which  $N/Z = 1$  for  $Z < 20$  and  $N/Z \approx 1.5$  for  $Z > 40$ .
- Alpha decay is the spontaneous emission of  $\alpha$  particles ( $^4_2\text{He}$  nuclei) from heavy nuclei ( $Z > 83$ ); the parent nucleus loses two protons and two neutrons.

*Describe mass energy relationships in nuclear reactions (Problems 1–6).*

- Einstein's relation  $E = mc^2$  establishes the relationship between mass and energy in nuclear reactions; the conversion of very small quantities of mass produces tremendous quantities of energy. Spontaneous nuclear reactions are those for which  $\Delta m < 0$ .

### Section 19.2 – Nuclear Decay Processes

*Summarize the characteristics of the three kinds of ionizing radiation identified by Rutherford.*

- $\alpha$  particles are  $^4_2\text{He}$  nuclei that are the least penetrating form of ionizing radiation,  $\beta$  rays are electrons that penetrate a few millimeters into matter, and  $\gamma$  rays are very high energy electromagnetic radiation that penetrate deeply.
- Electron emission and positron emission (called  $\beta^-$  and  $\beta^+$  decay, respectively) and electron capture (EC) are processes that convert protons into neutrons (and vice versa) to bring the  $N/Z$  ratio closer to the line of stability.

*Describe the various kinds of radiation detectors.*

- Photographic film darkens when exposed to radiation, the degree of darkening being proportional to the dose. Geiger-Müller counters are gas-filled tubes across which a large voltage is applied. Radiation ionizes gas molecules, and the high-energy primary electrons produced are converted into a large number of low-energy secondary electrons. Geiger-Müller counters record the resulting large current pulses. Proportional counters are gas-filled tubes, the gases being ionized by radiation. Proportional counters measure the activity by counting the number of pulses per second, and they measure the energy of the emitted particles or rays by measuring the pulse height current or number of electrons per pulse.

*Write balanced nuclear equations for electron emission (one form of beta decay), positron emission, electron capture, and alpha decay, and calculate the maximum kinetic energies of the particles emitted (Problems 7–18).*

- Charge, mass number, and atomic number are conserved in a balanced nuclear reaction.

### Section 19.3 – Kinetics of Radioactive Decay

Solve problems involving the half-life or decay constant of a radioactive sample and its activity (Problems 19–24).

- Nuclear decay follows first-order kinetics characterized by a half-life  $t_{1/2} = \ln 2/k = 0.693/k$  where  $k$  is the first-order rate constant.

Apply the kinetics of nuclear decay to the dating of rocks or artifacts (Problems 25–30).

- The ages of rocks are determined by comparing the ratio of the numbers of daughter to parent nuclei. Radiocarbon dating using  $^{14}\text{C}$  assumes that living things have  $^{14}\text{C}/^{12}\text{C}$  ratios that are in equilibrium with the atmosphere that persists until death, after which time the  $^{14}\text{C}$  decays with its characteristic 5730-year half-life.

### Section 19.4 – Radiation in Biology and Medicine

Discuss the interactions of radiation with various kinds of matter and the measurement of radiation dosage (Problems 31–36).

- The radiation dose is the energy deposited per kg of tissue; it is measured in rads or grays (SI unit). The relative biological damage is given by the dose multiplied by a factor that takes into account the damage caused by different kinds of radiation. Alpha particles and high-energy neutrons cause about 20 times as much damage as  $\beta$  or  $\gamma$  rays.

### Section 19.5 – Nuclear Fission

Describe the processes of nuclear fission and calculate the amounts of energy released when it occurs (Problems 37–41).

- Nuclear fission is the spontaneous splitting of a nucleus into two smaller fragments, whereas nuclear fusion is the synthesis of a heavier nucleus from a pair of lighter nuclei.
- Nuclear chain reactions occur when more than one neutron is produced per fission event, allowing self-propagating reactions to occur.

Explain the benefits and risks associated with nuclear power.

- Nuclear power has the potential to provide essentially unlimited energy without contributing to global climate change. The major risks include high-level waste disposal and the possibility of diverting nuclear fuel to make nuclear weapons.

### Section 19.6 – Nuclear Fusion and Nucleosynthesis

Explain the potential benefits of nuclear fusion.

- Fusion of hydrogen isotopes in normal stars produces He, which reacts further to produce most of the heavier elements in a sequence of fusion reactions called nucleosynthesis.

**FIGURE 19.14** Radon most commonly enters houses through the foundation or basement walls.

## CUMULATIVE EXERCISE

### Radon in the Environment

Radioactive  $^{222}\text{Rn}$  and  $^{220}\text{Rn}$  form constantly from the decay of uranium and thorium in rocks and soil and, being gaseous, seep out of the ground. The radon isotopes decay fairly quickly, but their products, which are also radioactive, are then in the air and attach themselves to dust particles. Thus, airborne radioactivity can accumulate to worrisome levels in poorly ventilated basements (Fig. 19.14) in ground that is rich in uranium and thorium.

- (a) Describe the composition of an atom of  $^{222}\text{Rn}$  and compare it with that of an atom of  $^{220}\text{Rn}$ .

- (b) Although  $^{222}\text{Rn}$  is a decay product of  $^{238}\text{U}$ ,  $^{220}\text{Rn}$  comes from  $^{232}\text{Th}$ . How many alpha particles are emitted in the formation of these radon isotopes from their uranium or thorium starting points? (*Hint:* Alpha decay changes the mass number  $A$ , but other decay processes do not.)
- (c) Can alpha decay alone explain the formation of these radon isotopes from  $^{238}\text{U}$  and  $^{232}\text{Th}$ ? If not, state what other types of decay must occur.
- (d) Can  $^{222}_{86}\text{Rn}$  and  $^{220}_{86}\text{Rn}$  decay by alpha particle emission? Write balanced nuclear equations for these two decay processes, and calculate the changes in mass that would result. The masses of  $^{222}\text{Rn}$  and  $^{220}\text{Rn}$  atoms are 222.01757 and 220.01140 u, respectively; those of  $^{218}\text{Po}$  and  $^{216}\text{Po}$  are 218.0089 and 216.00192 u, respectively.
- (e) Calculate the energy change in the alpha decay of one  $^{220}\text{Rn}$  nucleus, in megaelectron volts and in joules.
- (f) The half-life of  $^{222}\text{Rn}$  is 3.82 days. Calculate the initial activity of  $2.00 \times 10^{-8}$  g of  $^{222}\text{Rn}$ , in disintegrations per second.
- (g) What will be the activity of the  $^{222}\text{Rn}$  from part (f) after 14 days?
- (h) The half-life of  $^{220}\text{Rn}$  is 54 s. Are the health risks of exposure to a given amount of radon for a given short length of time greater or smaller for  $^{220}\text{Rn}$  than for  $^{222}\text{Rn}$ ?

### Answers

- (a) An atom of  $^{222}\text{Rn}$  has 86 electrons outside the nucleus. Inside the nucleus are 86 protons and  $222 - 86 = 136$  neutrons. An atom of  $^{220}\text{Rn}$  has the same number of electrons and protons, but only 134 neutrons in its nucleus.
- (b) Four alpha particles are produced to make  $^{222}\text{Rn}$  from  $^{238}\text{U}$ ; three are produced to make  $^{220}\text{Rn}$  from  $^{232}\text{Th}$ .
- (c) If  $^{238}_{92}\text{U}$  were to lose four alpha particles,  $^{222}_{84}\text{Po}$  would result instead of  $^{222}_{84}\text{Rn}$ . Two  $^0_{-1}e^-$  beta particles must be ejected from the nucleus along the way to raise the atomic number to  $Z = 86$ . The same is true of the production of  $^{220}\text{Rn}$  from  $^{232}\text{Th}$ .
- (d)  $^{222}_{86}\text{Rn} \longrightarrow ^{218}_{84}\text{Po} + ^4_2\text{He}; \Delta m = -0.00617 \text{ u} < 0$ ; allowed  
 $^{220}_{86}\text{Rn} \longrightarrow ^{216}_{84}\text{Po} + ^4_2\text{He}; \Delta m = -0.0069 \text{ u} < 0$ ; allowed
- (e)  $\Delta E = -6.4 \text{ MeV} = -1.03 \times 10^{-12} \text{ J}$
- (f)  $A = 1.14 \times 10^8 \text{ s}^{-1}$
- (g)  $A = 9.0 \times 10^6 \text{ s}^{-1}$
- (h) Greater

## PROBLEMS

Answers to problems whose numbers are red appear in Appendix G. Problems that are more challenging are indicated with asterisks.

### 19.1 Mass–Energy Relationships in Nuclei

- Complete and balance the following equations for nuclear reactions that are thought to take place in stars:
  - $2\ ^{12}_6\text{C} \longrightarrow ? +\ ^1_0n$
  - $? +\ ^1_1\text{H} \longrightarrow\ ^{12}_6\text{C} +\ ^4_2\text{He}$
  - $2\ ^3_2\text{He} \longrightarrow ? + 2\ ^1_1\text{H}$
- Complete and balance the following equations for nuclear reactions that are used in particle accelerators to make elements beyond uranium:
  - $^4_2\text{He} +\ ^{253}_{99}\text{Es} \longrightarrow ? + 2\ ^1_0n$
  - $^{249}_{98}\text{Cf} + ? \longrightarrow\ ^{257}_{103}\text{Lr} + 2\ ^1_0n$
  - $^{238}_{92}\text{U} +\ ^{12}_6\text{C} \longrightarrow\ ^{244}_{98}\text{Cf} + ?$
- Calculate the total binding energy, in both kJ per mole and MeV per atom, and the binding energy per nucleon of the following nuclides, using the data from Table 19.1.
  - $^{40}_{20}\text{Ca}$
  - $^{87}_{37}\text{Rb}$
  - $^{238}_{92}\text{U}$
- Calculate the total binding energy, in both kilojoules per mole and MeV per atom, and the binding energy per nucleon of the following nuclides, using the data from Table 19.1.
  - $^{10}_4\text{Be}$
  - $^{35}_{17}\text{Cl}$
  - $^{49}_{22}\text{Ti}$
- Use the data from Table 19.1 to predict which is more stable: four protons, four neutrons, and four electrons organized as two  $^4\text{He}$  atoms or as one  $^8\text{Be}$  atom. What is the mass difference?
- Use the data from Table 19.1 to predict which is more stable: 16 protons, 16 neutrons, and 16 electrons organized as two  $^{16}\text{O}$  atoms or as one  $^{32}\text{S}$  atom. What is the mass difference?

### 19.2 Nuclear Decay Processes

- The nuclide  $^8_5\text{B}$  decays by positron emission to  $^8_4\text{Be}$ . What is the energy released (in MeV)?
- The nuclide  $^{10}_4\text{Be}$  undergoes spontaneous radioactive decay to  $^{10}_5\text{B}$  with emission of a beta particle. Calculate the maximum kinetic energy of the emitted beta particle.
- Write balanced equations that represent the following nuclear reactions.
  - Electron emission by  $^{39}_{17}\text{Cl}$
  - Positron emission by  $^{22}_{11}\text{Na}$
  - Alpha emission by  $^{224}_{88}\text{Ra}$
  - Electron capture by  $^{82}_{38}\text{Sr}$
- Write balanced equations that represent the following nuclear reactions.
  - Alpha emission by  $^{155}_{70}\text{Yb}$
  - Positron emission by  $^{26}_{14}\text{Si}$
  - Electron capture by  $^{65}_{30}\text{Zn}$
  - Electron emission by  $^{100}_{41}\text{Nb}$
- The stable isotopes of neon are  $^{20}\text{Ne}$ ,  $^{21}\text{Ne}$ , and  $^{22}\text{Ne}$ . Predict the nuclides formed when  $^{19}\text{Ne}$  and  $^{23}\text{Ne}$  decay.
- The two stable isotopes of carbon are  $^{12}\text{C}$  and  $^{13}\text{C}$ . Predict the nuclides formed when  $^{11}\text{C}$  and  $^{14}\text{C}$  decay. Is alpha emission by  $^{14}\text{C}$  possible?
- The free neutron is an unstable particle that decays into a proton. What other particle or particles is formed in neutron decay, and what is the maximum kinetic energy (in MeV) that it can possess?
- The radionuclide  $^{210}_{84}\text{Po}$  decays by alpha emission to a daughter nuclide. The atomic mass of  $^{210}_{84}\text{Po}$  is 209.9829 u, and that of its daughter is 205.9745 u.
  - Identify the daughter, and write the nuclear equation for the radioactive decay process.
  - Calculate the total energy released per disintegration (in MeV).
  - Calculate the kinetic energy of the emitted alpha particle.
- The natural abundance of  $^{30}\text{Si}$  is 3.1%. Upon irradiation with neutrons, this isotope is converted to  $^{31}\text{Si}$ , which decays to the stable isotope  $^{31}\text{P}$ . This provides a way of introducing trace amounts of phosphorus into silicon in a much more uniform fashion than is possible by ordinary mixing of silicon and phosphorus and gives semiconductor devices the capability of handling much higher levels of power. Write balanced nuclear equations for the two steps in the preparation of  $^{31}\text{P}$  from  $^{30}\text{Si}$ .
- The most convenient way to prepare the element polonium is to expose bismuth (which is 100%  $^{209}\text{Bi}$ ) to neutrons. Write balanced nuclear equations for the two steps in the preparation of polonium.
- One convenient source of neutrons is the reaction of an alpha particle from an emitter such as polonium ( $^{210}\text{Po}$ ) with an atom of beryllium ( $^9\text{Be}$ ). Write nuclear equations for the reactions that occur.
- Three atoms of element 111 (roentgenium) were produced in 1994 by bombarding  $^{209}\text{Bi}$  with  $^{64}\text{Ni}$ .
  - Write a balanced equation for this nuclear reaction. What other species is produced?
  - Write a balanced equation for the alpha decay process of this nuclide of roentgenium.

## 19.3 Kinetics of Radioactive Decay

19. How many radioactive disintegrations occur per minute in a 0.0010-g sample of  $^{209}\text{Po}$  that has been freshly separated from its decay products? The half-life of  $^{209}\text{Po}$  is 103 years.
20. How many alpha particles are emitted per minute by a 0.0010-g sample of  $^{238}\text{U}$  that has been freshly separated from its decay products? Assume that each decay emits one alpha particle. The half-life of  $^{238}\text{U}$  is  $4.47 \times 10^9$  years.
21. The nuclide  $^{19}\text{O}$ , prepared by neutron irradiation of  $^{19}\text{F}$ , has a half-life of 29 s.
- (a) How many  $^{19}\text{O}$  atoms are in a freshly prepared sample if its decay rate is  $2.5 \times 10^4 \text{ s}^{-1}$ ?
- (b) After 2.00 min, how many  $^{19}\text{O}$  atoms remain?
22. The nuclide  $^{35}\text{S}$  decays by beta emission with a half-life of 87.1 days.
- (a) How many grams of  $^{35}\text{S}$  are in a sample that has a decay rate from that nuclide of  $3.70 \times 10^2 \text{ s}^{-1}$ ?
- (b) After 365 days, how many grams of  $^{35}\text{S}$  remain?
23. Astatine is the rarest naturally occurring element, with  $^{219}\text{At}$  appearing as the product of a very minor side branch in the decay of  $^{235}\text{U}$  (itself not a very abundant isotope). It is estimated that the mass of all the naturally occurring  $^{219}\text{At}$  in the upper kilometer of the earth's surface has a steady-state value of only 44 mg. Calculate the total activity (in disintegrations per second) caused by all the naturally occurring astatine in this part of the earth. The half-life of  $^{219}\text{At}$  is 54 s, and its atomic mass is 219.01 u.
24. Technetium has not been found in nature. It can be obtained readily as a product of uranium fission in nuclear power plants, however, and is now produced in quantities of many kilograms per year. One medical use relies on the tendency of  $^{99\text{m}}\text{Tc}$  (an excited nuclear state of  $^{99}\text{Tc}$ ) to concentrate in abnormal heart tissue. Calculate the total activity (in disintegrations per second) caused by the decay of 1.0  $\mu\text{g}$  of  $^{99\text{m}}\text{Tc}$ , which has a half-life of 6.0 hours.
25. The specific activity of  $^{14}\text{C}$  in the biosphere is  $0.255 \text{ Bq g}^{-1}$ . What is the age of a piece of papyrus from an Egyptian tomb if its beta counting rate is  $0.153 \text{ Bq g}^{-1}$ ? The half-life of  $^{14}\text{C}$  is 5730 years.
26. The specific activity of a wood article found in the Lascaux Caves in France is  $0.0375 \text{ Bq g}^{-1}$  due to  $^{14}\text{C}$ . Calculate the age of the article.
27. Over geological time, an atom of  $^{238}\text{U}$  decays to a stable  $^{206}\text{Pb}$  atom in a series of eight alpha emissions, each of which leads to the formation of one helium atom. A geochemist analyzes a rock and finds that it contains  $9.0 \times 10^{-5} \text{ cm}^3$  of helium (at  $0^\circ\text{C}$  and atmospheric pressure) per gram and  $2.0 \times 10^{-7} \text{ g}$  of  $^{238}\text{U}$  per gram. Estimate the age of the mineral, assuming that all of the He is retained, and given that  $t_{1/2}$  of  $^{238}\text{U}$  is  $4.47 \times 10^9$  years.
28. The isotope  $^{232}\text{Th}$  decays to  $^{208}\text{Pb}$  by the emission of six alpha particles, with a half-life of  $1.39 \times 10^{10}$  years. Analysis of 1.00 kg of ocean sediment shows it to contain 7.4 mg of  $^{232}\text{Th}$  and  $4.9 \times 10^{-3} \text{ cm}^3$  of gaseous helium at  $0^\circ\text{C}$  and atmospheric pressure. Estimate the age of the sediment, assuming no loss or gain of thorium or helium from the sediment since its formation and assuming that the helium arose entirely from the decay of thorium.
29. The half-lives of  $^{235}\text{U}$  and  $^{238}\text{U}$  are  $7.04 \times 10^8$  years and  $4.47 \times 10^9$  years, respectively, and the present abundance ratio is  $^{238}\text{U}/^{235}\text{U} = 137.7$ . It is thought that their abundance ratio was 1 at some time *before* our earth and solar system were formed about  $4.5 \times 10^9$  years ago. Estimate how long ago the supernova occurred that supposedly produced all the uranium isotopes in equal abundance, including the two longest lived isotopes,  $^{238}\text{U}$  and  $^{235}\text{U}$ .
30. Using the result of problem 29 and the accepted age of the earth,  $4.5 \times 10^9$  yr, calculate the  $^{238}\text{U}/^{235}\text{U}$  ratio at the time the earth was formed.

## 19.4 Radiation in Biology and Medicine

31. Write balanced equations for the decays of  $^{11}\text{C}$  and  $^{15}\text{O}$ , both of which are used in positron emission tomography to scan the uptake of glucose in the body.
32. Write balanced equations for the decays of  $^{13}\text{N}$  and  $^{18}\text{F}$ , two other radioisotopes that are used in positron emission tomography. What is the ultimate fate of the positrons?
33. The positrons emitted by  $^{11}\text{C}$  have a maximum kinetic energy of 0.99 MeV, and those emitted by  $^{15}\text{O}$  have a maximum kinetic energy of 1.72 MeV. Calculate the ratio of the number of millisieverts of radiation exposure caused by ingesting a given fixed chemical amount (equal numbers of atoms) of each of these radioisotopes.
34. Compare the relative health risks of contact with a given amount of  $^{226}\text{Ra}$ , which has a half-life of 1622 years and emits 4.78-MeV alpha particles, with contact with the same chemical amount of  $^{14}\text{C}$ , which has a half-life of 5730 years and emits beta particles with energies of up to 0.155 MeV.
35. The nuclide  $^{131}\text{I}$  undergoes beta decay with a half-life of 8.041 days. Large quantities of this nuclide were released into the environment in the Chernobyl accident. A victim of radiation poisoning has absorbed  $5.0 \times 10^{-6} \text{ g}$  ( $5.0 \mu\text{g}$ ) of  $^{131}\text{I}$ .
- (a) Compute the activity, in becquerels, of the  $^{131}\text{I}$  in this person, taking the atomic mass of the nuclide to equal  $131 \text{ g mol}^{-1}$ .

- (b) Compute the radiation absorbed dose, in milligrays, caused by this nuclide during the first *second* after its ingestion. Assume that beta particles emitted by  $^{131}\text{I}$  have an average kinetic energy of 0.40 MeV, that all of this energy is deposited within the victim's body, and that the victim weighs 60 kg.
- (c) Is this dose likely to be lethal? Remember that the activity of the  $^{131}\text{I}$  diminishes as it decays.
36. The nuclide  $^{239}\text{Pu}$  undergoes alpha decay with a half-life of  $2.411 \times 10^4$  years. An atomic energy worker breathes in  $5.0 \times 10^{-6}$  g ( $5.0 \mu\text{g}$ ) of  $^{239}\text{Pu}$ , which lodges permanently in a lung.
- (a) Compute the activity, in becquerels, of the  $^{239}\text{Pu}$  ingested, taking the atomic mass of the nuclide to be  $239 \text{ g mol}^{-1}$ .
- (b) Determine the radiation absorbed dose, in milligrays, during the first *year* after its ingestion. Assume that alpha particles emitted by  $^{239}\text{Pu}$  have an average kinetic energy of 5.24 MeV, that all of this energy is deposited within the worker's body, and that the worker weighs 60 kg.
- (c) Is this dose likely to be lethal?
- ### 19.5 Nuclear Fission
37. Strontium-90 is one of the most hazardous products of atomic weapons testing because of its long half-life ( $t_{1/2} = 28.1$  years) and its tendency to accumulate in bone.
- (a) Write nuclear equations for the decay of  $^{90}\text{Sr}$  via the successive emission of two electrons (beta particles).
- (b) The atomic mass of  $^{90}\text{Sr}$  is 89.9073 u and that of  $^{90}\text{Zr}$  is 89.9043 u. Calculate the energy released per  $^{90}\text{Sr}$  atom, in MeV, in decaying to  $^{90}\text{Zr}$ .
- (c) What will be the initial activity of 1.00 g of  $^{90}\text{Sr}$  released into the environment, in disintegrations per second?
- (d) What activity will the material from part (c) show after 100 years?
38. Plutonium-239 is the fissionable isotope produced in breeder reactors; it is also produced in ordinary nuclear plants and in weapons tests. It is an extremely poisonous substance with a half-life of 24,100 years.
- (a) Write an equation for the decay of  $^{239}\text{Pu}$  via alpha emission.
- (b) The atomic mass of  $^{239}\text{Pu}$  is 239.05216 u and that of  $^{235}\text{U}$  is 235.04393 u. Calculate the energy released per  $^{239}\text{Pu}$  atom, in MeV, in decaying via alpha emission.
- (c) What will be the initial activity, in disintegrations per second, of 1.00 g of  $^{239}\text{Pu}$  buried in a disposal site for radioactive wastes?
- (d) What activity will the material from part (c) show after 100,000 years?
39. The three naturally occurring isotopes of uranium are  $^{234}\text{U}$  (half-life  $2.5 \times 10^5$  years),  $^{235}\text{U}$  (half-life  $7.0 \times 10^8$  years), and  $^{238}\text{U}$  (half-life  $4.5 \times 10^9$  years). As time passes, will the average atomic mass of the uranium in a sample taken from nature increase, decrease, or remain constant?
40. Natural lithium consists of 7.42%  $^6\text{Li}$  and 92.58%  $^7\text{Li}$ . Much of the tritium ( $^3_1\text{H}$ ) used in experiments with fusion reactions is made by the capture of neutrons by  $^6\text{Li}$  atoms.
- (a) Write a balanced nuclear equation for the process. What is the other particle produced?
- (b) After  $^6\text{Li}$  is removed from natural lithium, the remainder is sold for other uses. Is the molar mass of the leftover lithium greater or smaller than that of natural lithium?
41. Calculate the amount of energy released, in kilojoules per gram of uranium, in the fission reaction
- $$^{235}_{92}\text{U} + {}^1_0\text{n} \longrightarrow {}^{94}_{36}\text{Kr} + {}^{130}_{56}\text{Ba} + 3 {}^1_0\text{n}$$
- Use the atomic masses in Table 19.1. The atomic mass of  $^{94}\text{Kr}$  is 93.919 u and that of  $^{139}\text{Ba}$  is 138.909 u.
- ### 19.6 Nuclear Fusion and Nucleosynthesis
42. Calculate the amount of energy released, in kilojoules per gram of deuterium ( $^2\text{H}$ ), for the fusion reaction
- $$^2_1\text{H} + ^2_1\text{H} \longrightarrow ^4_2\text{He}$$
- Use the atomic masses in Table 19.1. Compare your answer with that from the preceding problem.

## ADDITIONAL PROBLEMS

43. When an electron and a positron meet, they are replaced by two gamma rays, called the "annihilation radiation." Calculate the energies of these radiations, assuming that the kinetic energies of the incoming particles are 0.
44. The nuclide  $^{231}_{92}\text{U}$  converts spontaneously to  $^{231}_{91}\text{Pa}$ .
- (a) Write two balanced nuclear equations for this conversion, one if it proceeds by electron capture and the other if it proceeds by positron emission.
- (b) Using the nuclidic masses in Table 19.1, calculate the change in mass for each process. Explain why electron capture can occur spontaneously in this case but positron emission cannot.

45. The radioactive nuclide  ${}^{64}_{29}\text{Cu}$  decays by beta emission to  ${}^{64}_{30}\text{Zn}$  or by positron emission to  ${}^{64}_{28}\text{Ni}$ . The maximum kinetic energy of the beta particles is 0.58 MeV, and that of the positrons is 0.65 MeV. The mass of the neutral  ${}^{64}_{29}\text{Cu}$  atom is 63.92976 u.
- Calculate the mass, in atomic mass units, of the neutral  ${}^{64}_{30}\text{Zn}$  atom.
  - Calculate the mass, in atomic mass units, of the neutral  ${}^{64}_{28}\text{Ni}$  atom.
46. A puzzling observation that led to the discovery of isotopes was the fact that lead obtained from uranium-containing ores had an atomic mass lower by two full atomic mass units than lead obtained from thorium-containing ores. Explain this result, using the fact that decay of radioactive uranium and thorium to stable lead occurs via alpha and electron emission.
47. By 1913, the elements radium, actinium, thorium, and uranium had all been discovered, but element 91, between thorium and uranium in the periodic table, was not yet known. The approach used by Meitner and Hahn was to look for the parent that decays to form actinium. Alpha and beta emission are the most important decay pathways among the heavy radioactive elements. What elements would decay to actinium by each of these two pathways? If radium salts show no sign of actinium, what does this suggest about the parent of actinium? What is the origin of the name of element 91, discovered by Meitner and Hahn in 1918?
48. Working in Rutherford's laboratory in 1932, Cockcroft and Walton bombarded a lithium target with 700-keV protons and found that the following reaction occurred:

Each of the alpha particles was found to have a kinetic energy of 8.5 MeV. This research provided the first experimental test of Einstein's  $\Delta E = c^2\Delta m$  relationship. Discuss. Using the atomic masses from Table 19.1, calculate the value of  $c$  needed to account for this result.

- Calculate the binding energy per nucleon in  ${}^{30}_{15}\text{P}$ .
  - The radioactive decay of the  ${}^{30}_{15}\text{P}$  occurs through positron emission. Calculate the maximum kinetic energy carried off by the positron.
  - The half-life for this decay is 150 s. Calculate the rate constant  $k$  and the fraction remaining after 450 s.
50. Selenium-82 undergoes *double* beta decay:

This low-probability process occurs with a half-life of  $3.5 \times 10^{27}$  s, one of the longest half-lives ever measured. Estimate the activity in an 82.0-g (1.00 mol) sample of this isotope. How many  ${}^{82}\text{Se}$  nuclei decay in a day?

51. Gallium citrate, which contains the radioactive nuclide  ${}^{67}\text{Ga}$ , is used in medicine as a tumor-seeking agent. Gallium-67 decays with a half-life of 77.9 hours. How much time is required for it to decay to 5.0% of its initial activity?
52. The nuclide  ${}^{241}\text{Am}$  is used in smoke detectors. As it decays (with a half-life of 458 years), the emitted alpha particles ionize the air. When combustion products enter the detector, the number of ions changes and with it the conductivity of the air, setting off an alarm. If the activity of  ${}^{241}\text{Am}$  in the detector is  $3 \times 10^4$  Bq, calculate the mass of  ${}^{241}\text{Am}$  present.
53. The half-life of  ${}^{14}\text{C}$  is  $t_{1/2} = 5730$  years, and 1.00 g of modern wood charcoal has an activity of 0.255 Bq.
- Calculate the number of  ${}^{14}\text{C}$  atoms per gram of carbon in modern wood charcoal.
  - Calculate the fraction of carbon atoms in the biosphere that are  ${}^{14}\text{C}$ .
54. Carbon-14 is produced in the upper atmosphere by the reaction

where the neutrons come from nuclear processes induced by cosmic rays. It is estimated that the steady-state  ${}^{14}\text{C}$  activity in the biosphere is  $1.1 \times 10^{19}$  Bq.

- Estimate the total mass of carbon in the biosphere, using the data in problem 53.
  - The earth's crust has an average carbon content of 250 parts per million by mass, and the total crustal mass is  $2.9 \times 10^{25}$  g. Estimate the fraction of the carbon in the earth's crust that is part of the biosphere. Speculate on the whereabouts of the rest of the carbon in the earth's crust.
55. Analysis of a rock sample shows that it contains 0.42 mg of  ${}^{40}\text{Ar}$  for every 1.00 mg of  ${}^{40}\text{K}$ . Assuming that all the argon resulted from decay of the potassium and that neither element has left or entered the rock since its formation, estimate the age of the rock. (*Hint:* Use data from Table 19.2.) Note that not all the  ${}^{40}\text{K}$  decays to  ${}^{40}\text{Ar}$ .
- \*56. Cobalt-60 and iodine-131 are used in treatments for some types of cancer. Cobalt-60 decays with a half-life of 5.27 years, emitting beta particles with a maximum energy of 0.32 MeV. Iodine-131 decays with a half-life of 8.04 days, emitting beta particles with a maximum energy of 0.60 MeV.
- Suppose a fixed small number of moles of each of these isotopes were to be ingested and remain in the body indefinitely. What is the *ratio* of the number of millisieverts of total lifetime radiation exposure that would be caused by the two radioisotopes?
  - Now suppose that the contact with each of these isotopes is for a fixed short period, such as 1 hour. What is the ratio of millisieverts of radiation exposure for the two in this case?

57. Boron is used in control rods in nuclear power reactors because it is a good neutron absorber. When the isotope  $^{10}\text{B}$  captures a neutron, an alpha particle (helium nucleus) is emitted. What other atom is formed? Write a balanced equation.
- \*58. The average energy released in the fission of a  $^{235}\text{U}$  nucleus is about 200 MeV. Suppose the conversion of this energy to electrical energy is 40% efficient. What mass of  $^{235}\text{U}$  is converted to its fission products in a year's operation of a 1000-megawatt nuclear power station? Recall that 1 W is  $1 \text{ J s}^{-1}$ .
59. The energy released by a bomb is sometimes expressed in tons of TNT (trinitrotoluene). When one ton of TNT explodes,  $4 \times 10^9 \text{ J}$  of energy is released. The fission of 1 mol of uranium releases approximately  $2 \times 10^{13} \text{ J}$  of energy. Calculate the energy released by the fission of 1.2 kg of uranium in a small atomic bomb. Express your answer in tons of TNT.
60. The solar system abundances of the elements Li, Be, and B are four to seven orders of magnitude lower than those of the elements that immediately follow them: C, N, and O. Explain.
- \*61. The sun's distance from earth is approximately  $1.50 \times 10^8 \text{ km}$ , and the earth's radius is 6371 km. The earth receives radiant energy from hydrogen burning in the sun at a rate of  $0.135 \text{ J s}^{-1} \text{ cm}^{-2}$ . Using the data of Table 19.1, calculate the mass of hydrogen converted per second in the sun.

## CUMULATIVE PROBLEMS

62. In 1951 wood from two sequoia trees was dated by the  $^{14}\text{C}$  method. In one tree, clean borings located between the growth rings associated with the years A.D. 1057 and 1087 (that is, wood known to have grown  $880 \pm 15$  year prior to the date of measurement) had a  $^{14}\text{C}$  activity about 0.892 of that of wood growing in 1951. A sample from a second tree had an activity about 0.838 of that of new wood, and its age was established as  $1377 \pm 4$  year by tree-ring counting.
- What ages does carbon dating associate with the wood samples?
  - What values of  $t_{1/2}$  can be deduced if the tree-ring dates given are used as the starting point?
  - Discuss assumptions underlying the calculations in (a) and (b), and indicate in what direction failures of these assumptions might affect the calculations.
63. A typical electrical generating plant has a capacity of 500 megawatt (MW;  $1 \text{ MW} = 10^6 \text{ J s}^{-1}$ ) and an overall efficiency of about 25%. (a) The combustion of 1 kg of bituminous coal releases about  $3.2 \times 10^4 \text{ kJ}$  and leaves an ash residue of 100 g. What weight of coal must be used to operate a 500-MW generating plant for 1 year, and what weight of ash must be disposed of? (b) Enriched fuel for nuclear reactors contains about 4%  $^{235}\text{U}$ , fission of which gives  $1.9 \times 10^{10} \text{ kJ}$  per mole  $^{235}\text{U}$ . What weight of  $^{235}\text{U}$  is needed to operate a 500-MW power plant, assumed to have 25% efficiency, for 1 year, and what weight of fuel must be reprocessed to remove radioactive wastes? (c) The radiation from the sun striking the earth's surface on a sunny day corresponds to a power of  $1.5 \text{ kW m}^{-2}$ . How large must the collection surface be for a 500-MW solar-generating plant? (Assume that there are 6 hours of bright sun each day and that storage facilities continue to produce power at other times. The efficiency for solar-power generation would be about 25%.)
64. Examine the ratio of atomic mass to atomic number for the elements with *even* atomic number through calcium. This ratio is approximately the ratio of the average mass number to the atomic number.
- Which two elements stand out as different in this set of ten?
  - What would be the "expected" atomic mass of argon, based on the correlation considered here?
  - Show how the anomaly in the ordering of natural atomic masses of argon and potassium can be accounted for by the formation of "extra"  $^{40}\text{Ar}$  via decay of  $^{40}\text{K}$  atoms.
65. Hydrazine,  $\text{N}_2\text{H}_4(\ell)$ , reacts with oxygen in a rocket engine to form nitrogen and water vapor:
- $$\text{N}_2\text{H}_4(\ell) + \text{O}_2(\text{g}) \longrightarrow \text{N}_2(\text{g}) + 2 \text{H}_2\text{O}(\text{g})$$
- Calculate  $\Delta H^\circ$  for this highly exothermic reaction at  $25^\circ\text{C}$ , using data from Appendix D.
  - Calculate  $\Delta U^\circ$  of this reaction at  $25^\circ\text{C}$ .
  - Calculate the total change in mass, in grams, during the reaction of 1.00 mol of hydrazine.
66. The long-lived isotope of radium,  $^{226}\text{Ra}$ , decays by alpha particle emission to its daughter radon,  $^{222}\text{Rn}$ , with a half-life of 1622 years. The energy of the alpha particle is 4.79 MeV. Suppose 1.00 g of  $^{226}\text{Ra}$ , freed of all its radioactive progeny, were placed in a calorimeter that contained 10.0 g of water, initially at  $25^\circ\text{C}$ . Neglecting the heat capacity of the calorimeter and heat loss to the surroundings, calculate the temperature the water would reach after 1.00 hour. Take the specific heat of water to be  $4.18 \text{ J K}^{-1} \text{ g}^{-1}$ .

67. The radioactive nuclide  ${}^{232}_{90}\text{Th}$  has a half-life of  $1.39 \times 10^{10}$  years. It decays by a series of consecutive steps, the first two of which involve  ${}^{228}_{88}\text{Ra}$  (half-life 6.7 years) and  ${}^{228}_{89}\text{Ac}$  (half-life 6.13 hours).
- (a) Write balanced equations for the first two steps in the decay of  ${}^{232}\text{Th}$ , indicating all decay products. Calculate the total kinetic energy carried off by the decay products.
- (b) After a short initial time, the rate of formation of  ${}^{228}\text{Ra}$  becomes equal to its rate of decay. Express the number of  ${}^{228}\text{Ra}$  nuclei in terms of the number of  ${}^{232}\text{Th}$  nuclei, using the steady-state approximation from Section 18.4.
68. Zirconium is used in the fuel rods of most nuclear power plants. The following half-cell reduction potential applies to aqueous acidic solution:
- $$\text{ZrO}_2(s) + 4 \text{H}_3\text{O}^+(aq) + 4e^- \longrightarrow \text{Zr}(s) + 6 \text{H}_2\text{O}^+(\ell)$$
- $$E^\circ = -1.43 \text{ V}$$
- (a) Predict whether zirconium can reduce water to hydrogen. Write a balanced equation for the overall reaction.
- (b) Calculate  $\Delta E^\circ$  and  $K$  for the reaction in part (a).
- (c) Can your answer to part (b) explain the release of hydrogen in the Three Mile Island accident and the much greater release of hydrogen (which subsequently exploded) at Chernobyl?

Fluorescence microscope image of the mouse cerebral cortex. Three different dyes were used to selectively image structural proteins called neurofilaments, a small protein called GFAP that is a component of intermediate filaments, and cellular nuclei.

Spectroscopy, broadly defined, refers to the field of science that is devoted to understanding the interactions between electromagnetic radiation and matter, and exploiting that understanding to develop and apply new experimental techniques to probe the structures and dynamics of material systems. The line spectra of atoms and the blackbody radiation spectrum played central roles in the development of quantum mechanics, and spectroscopic measurements have either stimulated or confirmed many of the key developments in theoretical physics of the 20th century. Molecular spectroscopy enables us to determine the three-dimensional structures of molecules, to detect and identify single molecules, and to measure the rates and mechanisms of physical processes and chemical reactions on the femtosecond ( $10^{-15}$  s) timescale. Spectroscopic imaging techniques have given us unprecedented insight into biological structure and function, and the development of medical imaging techniques over the past 40 years has revolutionized the practice of medicine. Our goal for this chapter is to introduce you to the basic concepts and methods of molecular spectroscopy and photochemistry to give you an appreciation for how they have contributed to our understanding of the nature of the chemical bond and to the

development of the bonding theories discussed in Chapter 6. We also provide an introduction to the analytical applications of these methods that you will encounter in more advanced chemistry courses. Finally, we introduce you to molecular photophysics and photochemistry and illustrate the importance of these processes with examples drawn from atmospheric photochemistry and photosynthesis.

## 20.1 Introduction to Molecular Spectroscopy

Molecular spectroscopy experiments measure the intensity of radiation absorbed, emitted, or scattered by molecules as a function of frequency. Examples of atomic absorption and emission spectra are shown and discussed in Section 4.2. Peaks or bands (broad peaks) appear in molecular absorption and emission spectra at frequencies that satisfy the resonance condition,  $|\Delta E| = h\nu$ , where  $\Delta E$  is the energy difference between two levels and  $\nu$  is the frequency of the radiation.  $\Delta E = E_f - E_i$  is positive if the molecule absorbs the radiation (a photon) and negative if the molecule emits radiation, so we have noted the absolute value of  $\Delta E$  by  $|\Delta E|$ . Transitions between molecular energy levels can also be caused by **Raman scattering**, a form of inelastic light scattering. Photons can undergo *inelastic* collisions with molecules; energy conservation requires that  $\Delta E = h\nu_i - h\nu_s$ , where  $\nu_i$  and  $\nu_s$  are the frequencies of the incident and scattered radiation, respectively.

### 20.1.1 Molecular Energy Levels and Diatomic Potential Energy Curves

The Born-Oppenheimer approximation allows us to calculate the electronic wave functions for molecules as a function of the positions of the nuclei, and to generate a potential energy function for each electronic state, which governs the nuclear motion for that electronic state (see Section 6.1). Figure 20.1a shows the potential energy function for the lowest energy (ground) electronic state of HCl as well as that of one of its excited electronic states. As you learned in Chapter 3, the minimum occurs at the equilibrium internuclear separation for each state, which for the ground electronic state is  $R_e$ , the equilibrium bond length. You can see that the excited state of HCl plotted in Figure 20.1a has a larger equilibrium bond length than that in the ground electronic state, a smaller **force constant**  $k$  (fitting the potential energy near the minimum in each electronic state to  $V(R) = \frac{1}{2}k(R - R_e)^2$ ), and a smaller dissociation energy. A few vibrational levels of each electronic state are shown; the black arrow shown in Figure 20.1a represents a transition between the ground vibrational level in the ground electronic state to an excited vibrational level in the excited electronic state. Such transitions, which result in a change in the electronic configuration of a molecule, occur as a result of the absorption of ultraviolet and, for molecules other than HCl, visible radiation. They are discussed in more detail in Section 20.5. Figure 20.1b shows the ro-vibrational energy levels of a diatomic molecule, labeled by two quantum numbers  $\nu$  and  $J$ . Figure 20.1b allows you to see that the typical energy changes involved in promoting a molecule from one rotational state to another without a change in vibrational quantum number (this is called a “pure rotational transition”) are much smaller energy changes than those for transitions that simultaneously change the rotational and vibrational state, which is represented by the longer arrow. Rotational and vibrational transitions are discussed in detail in Section 20.3.

**FIGURE 20.1** (a) Absorption from the ground electronic state of HCl to an excited electronic state. The vibrational energy levels in each are shown by a blue line. (a, Adapted from Peter Atkins, Julio De Paula, and Ronald Friedman, *Quanta, Matter and Change*, W. H. Freeman and Company, New York, p. 300.) (b) Vibrational and rotational energy levels in the ground state (double primed) and the excited electronic state (single primed). The rotational level energy differences are shown exaggerated for clarity. The small unlabeled black arrow shows a pure rotational transition from the  $J = 2$  quantum state to the  $J = 3$  quantum state; the actual energy difference (in units of  $hc$ ) is  $62 \text{ cm}^{-1}$ . The longer black arrow labeled  $3031 \text{ cm}^{-1}$  shows an infrared absorption from  $(v, J) = (0, 1)$  to  $(1, 2)$  in the ground electronic state; this transition changes both the vibrational and the rotational quantum number.  $E_{\text{el}}$  is measured from the minimum of the ground state curve to the minimum of the excited state (red arrow).

We showed in Section 12.5 that molecular motions may be separated classically into translations, rotations, and vibrations (see Fig. 12.13 in particular). The couplings between these motions are sufficiently small that we may approximate the total energy as the sum of these independent contributions.

$$E_{\text{tot}} = E_{\text{trans}} + E_{\text{rot}} + E_{\text{vib}} + E_{\text{el}} \quad [20.1]$$

Absorption or emission of light in the microwave region of the optical spectrum can cause the rotational state of a molecule to change; for diatomics the rotational state is labeled by two quantum numbers  $J$  and  $M_J$ . If a molecule absorbs light in the infrared region of the spectrum the photon provides enough energy to change the vibrational quantum state at the same time. Figure 20.1b shows the energies of different vibrational states of HCl in blue lines, labeled by the quantum number  $v$ . (In Section 12.8 we introduced the vibrational energy levels of a diatomic molecule but used  $n$  as the quantum number. The label  $v$  is the more common one used in molecular spectroscopy, so will be used consistently in this chapter.) A photon does not carry enough linear momentum to substantially change the velocity of the center of mass of a molecule, so  $E_{\text{trans}}$  may be considered a constant when a photon is absorbed. You can see in Figure 20.1b that the change in electronic energy  $E_{\text{el}}$  when you promote the molecule to an excited electronic state can be quite large; this is because in an electronic transition typically an electron in the molecule is promoted from a lower energy molecular orbital to a higher energy molecular orbital.

### 20.1.2 The Fate of Excited Electronic States

When a photon promotes a molecule to an excited electronic state, several processes can contribute to the spectroscopic experiment. The fate of an electronically excited molecule depends on whether the excited electronic state can support bound vibrational quantum states or not. The excited state of HCl depicted in Figure 20.1 can support bound vibrational quantum states, but a lower energy excited electronic state of HCl is like the repulsive  $1\sigma_u^*$  state of

$H_2^+$  depicted in Figure 6.6; it will quickly dissociate (typically in less than a picosecond). If the excited electronic state can support bound vibrational quantum states, like the excited *singlet* state shown in Figure 20.2, then the electronically excited molecule can spontaneously emit a photon, returning to one of the ro-vibrational levels in the ground electronic state. (A molecule in a singlet state has half of its electrons with  $m_s = +1/2$  and the other half with  $m_s = -1/2$ .) Detecting these emitted photons in a spectroscopic experiment can measure the energies of the quantized states of the molecule both in the excited electronic state and in the ground electronic state, as we will see in Section 20.2. Figure 20.2 assumes that the molecules are in solution, so while in the excited electronic state the molecules may collisionally relax (by transferring vibrational energy to solvent molecules) to the lowest vibrational state of the excited singlet state. This process is depicted by the wavy black arrow in Figure 20.2; it does not involve emission of a photon, so the process is called a *nonradiative* process. The electronically excited molecules, now in the lowest vibrational quantum state of the excited singlet state, might then spontaneously emit a photon shown by the green downwards arrow in Figure 20.2 to transition from the excited singlet state to the ground electronic state. The process is called **fluorescence** and typically occurs within about  $10^{-9}$  s. (Now you know how a fluorescent light fixture works!) The final quantum state of the molecule after emitting a photon may be one of many different ro-vibrational quantum states in the ground electronic state. Figure 20.2 also depicts a process called **phosphorescence**; it occurs on much longer time scales than fluorescence, so the yield of photons from this process is typically small if it competes with fluorescence.

To understand electronic transitions in molecules, consider exciting an electron from the highest energy occupied molecule orbital of ethene, a  $\pi$  orbital, to the lowest unoccupied orbital, a  $\pi^*$  orbital. The constituent atoms are all from the first and second row of the periodic table; for such molecules the electron is unlikely to change its spin when it is promoted to the  $\pi^*$  orbital. Thus, the excited state reached when the molecule absorbs a photon, called a singlet state, has the electronic configuration,  $(\pi)^1(\pi^*)^1$  (we have omitted the occupied  $\sigma_{C-H}$  and  $\sigma_{C-C}$  bonding molecular orbitals here) with one electron spin up ( $m_s = 1/2$ )

**FIGURE 20.2** Absorption, emission, and nonradiative relaxation processes.

**FIGURE 20.3** The ground electronic state of ethene has two electrons in the highest occupied molecular orbital, one spin up and one spin down, so the projection of the total spin on the z-axis is zero,

$$M_S = \sum_{i=1}^N m_{s,i} = 0. \text{ The quantum}$$

number  $S$  for this multielectron molecule is 0, so there is only one ( $S, M_S$ ) spin state that characterizes the ground electronic state of ethene. The ground electronic state thus is called a singlet state. If one promotes one of the electrons to a  $\pi^*$  orbital without changing its spin, then you reach the lowest excited singlet state of ethene. If you allow an electron to change its spin, then you can reach the lowest excited triplet state of ethene. This state is characterized by three possible values of  $M_S$ :  $M_S = -1$  (both electrons spin down),  $M_S = 0$ , one electron spin up and one electron spin down, and  $M_S = +1$  (both electrons spin up, as shown in the figure). Thus, this excited state is called a triplet state, as there are three distinct spin states represented by the three values of  $M_S$ .

and the other electron spin-down ( $m_s = -1/2$ ), just as they had when they occupied the same orbital, as depicted in Figure 20.3. From the excited singlet state, a process called intersystem crossing can occur; intersystem crossing changes the spin state of the molecule to a triplet state. Figure 20.3 shows one of three possible spin configurations for a triplet state; one electron has flipped its spin so now the electron in the  $\pi$  orbital has a parallel spin to the electron in the  $\pi^*$  orbital. Intersystem crossing is a nonradiative process; it occurs without the absorption or emission of a photon (so the molecule initially has the same total energy). The triplet electronic state of the ethene molecule shown by the blue curve in Figure 20.2 has a slightly lower electronic energy than the corresponding singlet state as shown in Figure 20.2. Collisions of the solvent molecules with the triplet excited state molecule can transfer energy out of the vibrational motion, so again Figure 20.2 shows a slightly downward tilting red arrow to depict this. Finally, the excited triplet state molecules may emit a photon to transition back to one of the vibrational levels of the ground electronic state, as shown by the red arrow pointing straight downward in Figure 20.2. The light emitted during this transition, called phosphorescence, is not emitted as promptly as fluorescence (roughly, because it requires the unlikely event of a spin flip), so phosphorescence can appear microseconds or even a full second after the molecule is initially excited to an excited electronic state unless a competing process depletes the excited state molecules. This is so long that collisions with the solvent can relax the excited triplet state molecule to the high vibrational energy levels in the ground electronic state via a nonradiative process that competes with phosphorescence, so the yield of photons from phosphorescence can be orders of magnitude smaller than the yield of photons from fluorescence.

### 20.1.3 Overview of Spectroscopic Methods

In the sections that follow we discuss how we measure the following properties of molecules using the various spectroscopic techniques described:

1. Bond lengths and bond angles, from microwave, infrared, and Raman spectroscopy
2. Bond force constants and effective reduced masses from vibrational spectroscopy
3. Identification of functional groups and their relative locations in molecules, from vibrational spectroscopy, electronic spectroscopy, and nuclear magnetic resonance spectroscopy

Spectroscopic techniques have historically been classified in terms of the relevant frequencies of the electromagnetic radiation involved. Table 20.1 shows a number of important spectroscopic techniques, the relevant region of the electromagnetic spectrum, the nature of the energy levels involved, and the kinds of information obtained about the properties of molecules. We list frequencies, wavelengths, and energies in several sets of units that are used in practice, for convenience. Radiofrequency and microwave spectra are generally reported as a function of frequency (Hz), infrared and visible spectra in terms of frequency or wavelength, and ultraviolet and X-ray spectra in terms of wavelength, or energy in eV, for example.

Energies and frequencies are often reported in units of *wave numbers* (typically  $\text{cm}^{-1}$ ) where  $\tilde{\nu} = (1/\lambda)$  and  $\lambda$  is measured in cm. This is a convenient unit that is proportional to energy because  $E = h\nu = hc/\lambda = (hc)(1/\lambda)$ . Microwave spectra, for example, are presented either as a function of frequency (GHz) or energy ( $\text{cm}^{-1}$ ), infrared and Raman spectra most often use wave numbers, and ultraviolet and visible spectra are presented as functions of wavelength (nm) or energy (eV).

TABLE 20.1

## Spectroscopic Methods

Spectral Region	Frequency	Wavelength	Transition Energies	Excitations	Information Obtained
Radio waves	$10^7$ – $10^9$ Hz	30–0.3 m	$0.0033$ – $0.033$ $\text{cm}^{-1}$	Nuclear spin	Bonding environment, molecular structure
Microwave, far infrared	$10^9$ – $10^{12}$ Hz	0.3 m– $300$ $\mu\text{m}$	$0.033$ – $33$ $\text{cm}^{-1}$	Rotational	Bond lengths and bond angles
Near infrared	$10^{12}$ – $10^{14}$ Hz	$300$ $\mu\text{m}$ – $3$ $\mu\text{m}$	$33$ – $3300$ $\text{cm}^{-1}$	Vibrational	Bond force constants and effective reduced mass
Visible, ultraviolet	$10^{14}$ – $10^{17}$ Hz	$3000$ nm– $3$ nm	$3300$ – $330,000$ $\text{cm}^{-1}$	Valence electrons	Electronic energy levels and molecular environment
X-ray	$10^{17}$ – $10^{19}$ Hz	$3$ nm– $0.3$ Å	$413$ – $41,300$ eV	Core electrons	Ionization energies and atomic environment

## 20.2 Experimental Methods in Molecular Spectroscopy

Let's consider two simple experiments in optical molecular spectroscopy. The first measures the absorption of light, tuned to different wavelengths (and, correspondingly, energies), by a sample of molecules; the resulting data is called an optical absorption spectrum. The second experiment uses photons of a specific energy to promote molecules to an excited electronic state and then detects either all the photons emitted from the excited molecules or resolves the emitted photons by their energies. An example of the second is laser-induced fluorescence.

### 20.2.1 Traditional Optical Absorption Spectroscopy

Figure 20.4 shows how one might measure an optical absorption spectrum. Figure 20.4a shows an idealized experiment in which the incoming light beam is attenuated when its wavelength is such that the molecules of interest may absorb the light and undergo a transition from a lower energy quantum state to a higher energy quantum state. Thus, the ideal sample cell contains only the molecules of interest and none of the incoming light beam is scattered from the sample cell windows. Typically the incoming light is first filtered through a monochromator that contains a diffraction grating, so all the photons impinging on the sample have close to the same wavelength. (A diffraction grating consists of a series of closely spaced metal lines fabricated on a glass substrate that diffract light of different wavelengths into different directions, so you can change the wavelength of the light that passes out of the exit slit on the monochromator by tilting its diffraction grating; the principle is similar to that for electron diffraction depicted in Figure 4.32). This beam of light with intensity  $I_0$  is directed at the sample of molecules. (The intensity might be measured in photons per cross sectional area of the beam per second passing the entrance to the sample cell, photons  $\text{cm}^{-2} \text{s}^{-1}$ , or in  $\text{J cm}^{-2} \text{s}^{-1}$  if you multiply by the photon energy.) If the wavelength of the light is such that the molecules of interest in the sample cell absorb some of the incoming photons, the light that exits the sample cell, the transmitted light, has a lower intensity,  $I_t$ . The higher the concentration  $N/V$  of light-absorbing molecules, the weaker the intensity of the transmitted beam. The beam of light travels a distance  $\ell$  through the sample, so if  $\ell$  is longer the intensity  $I_t$  of the transmitted beam is decreased. Finally, each molecule has a wavelength dependent absorption cross section  $\sigma$  that the

**FIGURE 20.4** (a) Ideal absorption experiment; only the molecules of interest in the sample cell absorb the incoming light, and no light is scattered. (b) Schematic of double-beam spectrophotometer. The beam splitter directs the second beam through a reference cell that is identical to the sample cell but contains only the solvent, not the solute molecules of interest; the sample cell contains both solvent and the solute molecules of interest.

experiment is designed to determine. The larger the absorption cross-section, the more the light will be attenuated. All these factors are accounted for in the *Beer-Lambert law*.

$$\frac{I_t}{I_0} = e^{-\frac{N}{V}\sigma\ell} \quad [20.2]$$

(If the sample is a mixture or if the concentration of the sample is unknown, this law is simply written as  $I_t = I_0 \exp[-\alpha\ell]$  and  $\alpha$  is called the absorption coefficient of the sample.)

The Beer-Lambert law expresses the fact that a constant fraction of the light is absorbed per unit path length and that fraction is independent of the intensity of the incident radiation. We can also think of absorption, or Raman scattering (introduced in Section 20.1), in terms of collisions between photons and molecules, using the same ideas developed for the collision theory of gases in Section 9.5, where  $\sigma$  is the cross-section for the process of interest. The intensity of the radiation that is absorbed or scattered is then given by  $I_{a,s} = I_0 - I_t = I_0 [1 - \exp[-(N/V)\sigma\ell]]$ . Expressing absorption, emission, and scattering intensities in terms of cross sections allows us to compare the results of these different kinds of experiments from a common point of view.

### EXAMPLE 20.1

Benzene has several absorption bands in the ultraviolet region of the electromagnetic spectrum, the weakest of which appears at 260 nm with an absorption cross section of  $2.15 \times 10^{-18} \text{ cm}^2 \text{ molecule}^{-1}$ . Calculate the fraction of the incident radiation absorbed by a sample of benzene confined in a cell with a 1 cm path length at 0.001 atm and 300 K.

(Continued)

**Solution**

Use the Beer–Lambert law in the form  $I_t/I_0 = \exp[-(N/V)\sigma\ell]$  and calculate  $N/V$  using the ideal gas law. Substituting the number density, cross section, and path length into the Beer–Lambert law gives

$$\begin{aligned} I_t/I_0 &= \exp[-(2.45 \times 10^{16} \text{ molecules cm}^{-3})(2.15 \times 10^{-18} \text{ cm}^2 \text{ molecules}^{-1})(1 \text{ cm})] \\ &= 0.95 \end{aligned}$$

Only about 5% of the incident radiation is absorbed under these conditions.

**Related Problems: 1, 2, 3, 4, 5, 6**

Chemists often need to measure the absorption spectrum of a solute in solution. In this case one often uses a different form of the Beer–Lambert law, called **Beer’s law**, in which concentrations are expressed in molarity, not as number densities, and the expression uses common (base 10) logarithms instead of natural (base  $e$ ) logarithms. The integrated form of Beer’s law is

$$I_t = I_0 10^{-\varepsilon c \ell}$$

by analogy to the Beer–Lambert law, but it is usually expressed in its logarithmic form as

$$A = \log\left(\frac{I_0}{I_t}\right) = \varepsilon c \ell \quad [20.3]$$

where  $A$  is the **absorbance** (sometimes called the optical density),  $c$  is the concentration in  $\text{mol L}^{-1}$ ,  $\varepsilon$  is the **molar absorption coefficient** (molar extinction coefficient in some older textbooks) expressed in units  $\text{M}^{-1} \text{cm}^{-1}$ , and  $\ell$  is the path length in cm, as before. Chemists chose these units for convenience because they generally measure concentrations in  $\text{mol L}^{-1}$  and because 1 cm is the path length through the sample cell in a typical commercial spectrophotometer. The ratio of intensities of the incident light,  $I_0$ , and the transmitted light,  $I_t$ , is measured experimentally and the results are reported either as the absorbance  $A$  or transmittance  $T$  of the sample, which are defined and related as follows

$$A = \log\left(\frac{I_0}{I_t}\right) = -\log\left(\frac{I_t}{I_0}\right) = -\log T$$

The transmittance is often converted to percent transmission by multiplying  $T$  by 100, as shown in Figure 20.10 in Section 20.3, for example. Ultraviolet and visible absorption spectra generally graph absorbance as a function of wavelength or wave number, whereas infrared and microwave spectra generally graph percent transmission as a function of wave number.

A molar absorption coefficient  $\varepsilon$  can be related to the corresponding absorption cross section  $\sigma$  by comparing the integrated form of Beer’s law to the Beer–Lambert law.

$$I_t/I_0 = 10^{-\varepsilon c \ell} = e^{-(N/V)\sigma\ell}$$

Taking natural logarithms and rearranging gives

$$(\ln 10)(-\varepsilon c \ell) = -(N/V)\sigma\ell$$

which can be solved, with the substitution that  $N = nN_A$  (where  $N_A$  is Avogadro’s number) to get

$$\varepsilon = (nN_A/V)\sigma/2.303c = N_A\sigma/(2.303)(10^3) = 2.6 \times 10^{20} \sigma$$

where the factor of  $10^3$  arises because the cross section  $\sigma$  and the path length  $\ell$  have units of  $\text{cm}^2$  (per molecule) and cm, respectively, giving  $nN_A/V$  in units of  $\text{molecules cm}^{-3}$  while the molarity  $c$  is expressed in  $\text{mol L}^{-1}$ .

Thus far we have discussed the idealized experiment depicted in Figure 20.4a. In real absorption measurements, however, the solvent may also absorb some of the incident light. A dual-beam spectrophotometer, shown in Figure 20.4b, is commonly used to measure an  $I_t/I_0$  ratio that reflects only the absorption of light by the solute molecules of interest.<sup>1</sup> The beam splitter directs half of the incident light through the sample cell and the other half of the incident light through a reference cell filled with solvent alone.

The dual beam spectrometer shown in Figure 20.4b is used primarily for absorption experiments in the ultraviolet and visible regions of the spectrum. Modern instruments often use spectrographs, analogous to those illustrated in Figure 4.15 with a charge-coupled device (CCD) detector, like that in your cell phone or digital camera, replacing the photographic film. This kind of detection scheme is much faster than scanning because the intensity at all wavelengths of interest is measured simultaneously. *Fourier transform* (FT) methods have largely replaced incident frequency scanning methods in infrared (FTIR) and nuclear magnetic resonance (FT-NMR) spectroscopy, but a detailed description of those methods is not presented in this text.

### 20.2.2 Laser-Induced Fluorescence

A direct absorption experiment such as that described above becomes very difficult if the molecule you are interested in has a very small concentration (perhaps it is a transient radical intermediate in a kinetics experiment), or if it has a small absorption cross section. Spectroscopy was revolutionized by the discovery of *light amplification by the process of stimulated emission of radiation*; the devices that use this process to generate high intensity beams of light are called *lasers*. A modern dye laser includes a diffraction grating in the optical cavity, so the laser light consists of photons with a narrow energy distribution (typically  $< 1 \text{ cm}^{-1}$ ), or bandwidth, centered at a chosen wavelength. This center wavelength may be tuned over a wide range by tilting the diffraction grating. The narrow-bandwidth laser light is used to promote the molecules in the sample to an excited electronic state, but instead of measuring the direct absorption of the light as the laser beam is passed through a sample, a *laser-induced fluorescence* (LIF) experiment detects the small yield of photons spontaneously emitted from the excited-state molecules. A typical detector might be a photomultiplier tube, which outputs a pulse of electrons when the emitted photons strike the photocathode inside. A schematic of the LIF experiment is shown in Figure 20.5. (A similar schematic is applicable to a Raman scattering experiment.) Samples are illuminated by laser light, photons with a narrow energy distribution (or other source of nearly monochromatic radiation). When the energy of the laser photons is tuned to an energy  $h\nu_{\text{laser}} = E_f - E_i$ , the energy needed to promote a molecule in the sample from its initial quantum state with energy  $E_i$  to a final quantum state with energy  $E_f$ , the molecules can absorb the laser light. The emitted radiation, produced as the excited molecules undergo a spontaneous

**FIGURE 20.5** Schematic of an emission or scattering experiment. (Adapted from Peter Atkins, Julio de Paula and Ronald Friedman, *Quanta, Matter and Change*, W. H. Freeman and Company, New York, 2009, p. 339.)

<sup>1</sup>A simple derivation reveals why Figure 20.4b shows  $I_0$  not as the intensity of the incident light, but as the intensity of the light transmitted through the reference cell. To analyze this experiment, use  $N_{\text{sol}}/V$  for the number of solvent molecules per unit volume and  $\sigma_{\text{sol}}$  for the wavelength dependent absorption cross section of the solvent molecules. If in Figure 20.4b you designate the intensity of the light incident on both cells by  $I_{\text{in}}$ , then by the Beer-Lambert law the light *transmitted* through the reference cell would have intensity  $I_0 = I_{\text{in}} \exp[-(\sigma_{\text{sol}}(N_{\text{sol}}/V)\ell)]$  while the light transmitted through the sample cell would have intensity  $I_t = I_{\text{in}} \exp[-(\sigma_{\text{sol}}(N_{\text{sol}}/V) + \sigma(N/V))\ell]$ . Expressing the second equation as a product of two exponentials  $I_t = I_{\text{in}} \exp[-(\sigma_{\text{sol}}(N_{\text{sol}}/V)\ell)] \exp[-\sigma(N/V)\ell]$  and substituting in the first expression for  $I_0$  gives the familiar expression  $I_t = I_0 \exp[-\sigma(N/V)\ell]$ . Thus in the dual-beam spectrophotometer the ideal experiment is realized by taking the ratio,  $I_t/I_0 = \exp[-\sigma(N/V)\ell]$  of intensities of the two *transmitted* beams; this ratio accurately reproduces the ratio  $I_t/I_0$  of the transmitted beam to the incident beam in the idealized absorption experiment in Figure 20.4a.

transition back to a lower energy quantum state, is collected by a lens along a path at right angles to the incident beam. The intensity of the emitted photons is measured as a function of the wavelength of the incident radiation. Thus, when you detect emitted radiation you know you have tuned the wavelength of the incident laser beam to an energy  $h\nu_{\text{laser}} = hc(1/\lambda_{\text{laser}})$  such that  $h\nu_{\text{laser}} + E_i = E_f$ , where  $E_i$  is the energy of the quantum state reached upon absorption of the photon. The key advantage is that the experiment is nearly background free; no emitted light is detected unless the molecule absorbs the laser light, and you are measuring the appearance of emitted photons rather than the tiny reduction of the intensity of the laser beam. In a laser-induced fluorescence experiment one can also measure the wavelengths of the emitted photons. As long as the excited state molecule emits a photon before undergoing collisions with other molecules in the sample, a simple conservation of energy expression allows you to derive the energies of the ro-vibrational levels in the ground electronic state from such a measurement.

Figure 20.6 shows the electronic absorption spectra of anthracene and the resulting fluorescence and phosphorescence spectra. For each absorption or emission transition shown, the vibrational quantum number in a C–C stretching

**FIGURE 20.6** Absorption and fluorescence spectra of anthracene showing approximate mirror image symmetry between the shapes of the envelopes in the two spectra. (Adapted from Nicholas J. Turro, V. Ramamurthy, and J. C. Scaiano, *Principles of Modern Photochemistry*, University Science Books, Sausalito, 2009, p. 206.)

mode in the higher energy singlet ( $S_1$ ) or triplet ( $T_1$ ) electronic states is labeled by  $\nu'$  while the vibrational quantum number of the same mode in the lower energy electronic state  $S_0$  is labeled with the vibrational quantum number  $\nu''$ . In a LIF experiment on anthracene, if you tuned your laser to produce photons with an energy that could promote  $\nu'' = 0$  molecules in the ground electronic state to the lowest vibrational state in the  $S_1$  excited state (the transition labeled (0,0) in the figure, the molecules can fluoresce, producing emitted photons with slightly smaller energies than the laser photons used to excite the anthracene. This is because the final state of the anthracene molecules in  $S_0$ , after emitting a photon, may have  $\nu'' = 0, 1, 2, 3$  or  $4$  in a C—C stretching mode. The energies of these emitted photons are shown by the downward arrows in Figure 20.6 labeled  $(\nu'', \nu') = (0,0), (1,0), (2,0), (3,0)$  and  $(4,0)$ . You can see that the  $(4,0)$  transition leaves the anthracene molecule in a final state in  $S_0$  with four quanta in the C—C stretching vibrational mode.

### EXAMPLE 20.2

While the spectra in Figure 20.6 were taken in solution, anthracene molecules can be cooled and isolated from collisions with other gases by using a molecular beam (see Section 18.6). The photon energy needed for the (0,0) transition is then measured to be  $27,695 \text{ cm}^{-1}$ . What is the wavelength (measured in vacuum) and the photon energy (in joules per photon) of the laser light that would be needed to excite anthracene from the  $\nu'' = 0$  level of the ground electronic state,  $S_0$ , to the  $\nu' = 0$  level of the  $S_1$  excited electronic state? If you then separate the visible photons emitted from molecules in this  $S_1 \nu' = 0$  quantum state using a diffraction grating, what is the energy of the emitted photon when the final state of anthracene, after emitting the photon, in  $S_0$  is  $\nu'' = 2$ ? The vibrational frequency of the C-C stretching mode in the ground electronic state is  $1408 \text{ cm}^{-1}$ . (The final vibrational eigenstates in the emission spectrum of anthracene are more complicated than a simple progression in this stretching

vibration; we follow an early simpler interpretation of the spectrum.)

#### Solution

The laser photon energy needed to excite the (0,0) transition is  $27,695 \text{ cm}^{-1}$  and the wave number  $\tilde{\nu} = (1/\lambda)$ , so the wavelength  $\lambda$  of the photon is  $1/(27,695 \text{ cm}^{-1}) = 3.61076 \times 10^{-5} \text{ cm} = 361.076 \text{ nm}$ . Multiply  $27,695 \text{ cm}^{-1}$  by  $hc$  (with  $c$  in  $\text{cm s}^{-1}$ ) to get the laser photon energy in joules. The result is  $5.5014 \times 10^{-19} \text{ J}$ .

The emitted photon has a smaller energy. If the molecule emitted a  $27,695 \text{ cm}^{-1}$  photon the final vibrational state in  $S_0$  would be  $\nu'' = 0$ , so if the final state is instead  $\nu'' = 2$  then the emitted photon energy is smaller,  $27,695 \text{ cm}^{-1} - 2(1408 \text{ cm}^{-1}) = 24,879 \text{ cm}^{-1}$ .

**Related Problems: 7, 8**

## 20.2.3 Thermal Occupation of Molecular Energy Levels

For a sample of molecules to absorb or emit photons of a particular energy and thus undergo a transition from an initial quantum state to a final quantum state, you must of course have molecules in the initial quantum state. If your sample is at thermal equilibrium, the fraction of the total number of molecules at a particular energy level  $i$  with energy  $E_i$  is given by the **Boltzmann energy distribution**

$$N_i/N = C g_i \exp(-E_i/k_B T)$$

where  $N_i$  is the number of molecules with energy  $E_i$ ,  $N$  is the total number of molecules in the system,  $g_i$  is the number of distinct quantum states with energy  $E_i$  ( $g_i$  is called the *degeneracy* of the energy level),  $k_B$  is Boltzmann's constant ( $1.38 \times 10^{-23} \text{ J K}^{-1}$ ), and  $C$  is a normalization factor. If energies per mole are used,  $k_B$  is replaced by the gas constant  $R$ . The exponential falloff means that at thermal equilibrium few molecules have energies that are large compared with  $k_B T$ .

If you wish to calculate the *ratio* of the number of molecules with energy  $E_i$  to the number of molecules with energy  $E_j$ , the proportionality constant in the

prior equation Equation 20.4 cancels from the numerator and denominator to give

$$\frac{N_i}{N_j} = \frac{g_i e^{-E_i/k_B T}}{g_j e^{-E_j/k_B T}} = \frac{g_i}{g_j} e^{-\frac{E_i - E_j}{k_B T}} \quad [20.4]$$

In Section 12.8 we introduced the Boltzmann distribution and its application to vibrational energy levels of diatomic molecules. When the vibrational energy level spacing is large, like for HCl shown in Figure 20.1, most of the HCl molecules in a sample at 300 K are in the lowest vibrational energy level,  $v'' = 0$ , in the ground electronic state. In contrast, in a thermal population at 300 K of Br<sub>2</sub> molecules there is substantial fraction of molecules in  $v'' = 1$  because the vibrational energy level spacing in Br<sub>2</sub> is 323 cm<sup>-1</sup>, much smaller than that for HCl. Example 12.12 showed that for Br<sub>2</sub>  $N_{v''=1}/N_{v''=0} = 0.212$ , so although there are fewer Br<sub>2</sub> molecules in  $v'' = 1$  than in  $v'' = 0$ , the population in  $v'' = 1$  is only a factor of 5 smaller than that in  $v'' = 0$ . It is important to note that the ratios of degeneracies can make the population in a higher energy level larger than the population in a lower energy level. A single quantum state at a high energy will have fewer molecules populating it than a single quantum state at a lower energy, but if there are, for example, three quantum states with the same energy  $E_i$  (so  $g_i = 3$ ) and only one quantum state with the energy  $E_j$  (so  $g_j = 1$ ) then the population with energy  $E_i$  can be larger even when  $E_i$  is the higher of the two energies. This is because you are summing the population in all three quantum states at energy  $E_i$ . This is illustrated in Example 20.3 below.

### EXAMPLE 20.3

Calculate the ratio of the populations in the first two rotational energy levels of carbon monoxide, the lowest  $J = 0$  energy level and the higher  $J = 1$  energy level, at 300 K if the energy difference between the levels is 3.8 cm<sup>-1</sup> and the degeneracies  $g_J$  of the two levels are  $g_0 = 1$  and  $g_1 = 3$ , respectively. (You will see in Section 20.3 that there are  $2J + 1$  rotational quantum states at each energy level  $E_J$ .)

#### Solution

Substituting the values provided into the Equation 20.4 and expressing  $k_B$  in wave numbers ( $k_B = 0.695 \text{ cm}^{-1} \text{ K}^{-1}$ ) gives

$$\begin{aligned} \frac{N_{J=1}}{N_{J=0}} &= \frac{g_{J=1}}{g_{J=0}} e^{-\frac{E_{J=1} - E_{J=0}}{k_B T}} \\ &= \frac{3}{1} e^{-\frac{3.8 \text{ cm}^{-1} - 0 \text{ cm}^{-1}}{(0.695 \text{ cm}^{-1} \text{ K}^{-1})(300 \text{ K})}} \\ &= 2.95 \end{aligned}$$

The rotational level spacings are so much smaller than  $k_B T$ , and the degeneracy of the upper level a factor of 3 greater than that of the lower level, that there are more molecules in the  $J = 1$  level than in the  $J = 0$  level.

**Related Problems: 9, 10**

## 20.3 Rotational and Vibrational Spectroscopy

We introduced you to the properties of the chemical bond and to the shapes of molecules in Chapter 3, and showed how molecular orbital theory explained the trends in bond order, bond lengths, bond dissociation energies, and bond force constants observed for homonuclear diatomic molecules and ions (see Fig. 6.20). Where did these data come from? How do we measure bond lengths and

force constants and how can we use these data to estimate bond dissociation energies? We begin this section with a discussion of the spectroscopy of diatomic molecules to show how the properties of individual bonds are measured and then proceed to discuss the spectroscopy of polyatomic molecules from which we learn much about their three-dimensional structures.

### 20.3.1 Diatomic Molecules

The Born-Oppenheimer approximation, introduced in Section 6.1, allows us to find the electronic wave functions for diatomic molecules with the nuclei at fixed positions. The variation in the electronic energy as a function of internuclear separation generates the potential energy function that governs nuclear motion. We can write the Schrödinger equation to solve for the nuclear wave functions and energy levels if we know the form of this potential energy function. The nuclear Schrödinger equation can be solved exactly for several model potential energy functions to get wave functions and energy levels associated with rotational and vibrational motion. These include: 1) The rigid rotor model, in which the bond length is fixed and the potential energy term is constant, used to interpret rotational spectroscopy experiments; 2) The harmonic oscillator model, which represents the chemical bond as a spring with a potential given by Hooke's law, used to interpret vibrational spectroscopy experiments; and 3) The Morse potential, which is used to interpret the vibrational spectra of molecules in which the potential energy function is not harmonic, as well as to provide a method for estimating bond dissociation energies from these spectra. These methods are used for polyatomic molecules as well but we discuss them in detail only for diatomic molecules to illustrate their important general characteristics.

#### Rotational Spectroscopy

We treat the rotations of diatomic molecules using the quantum mechanical linear rigid rotor model, in which the bond length is fixed and the molecule rotates about an axis that is perpendicular to the internuclear axis and passes through its center of mass, as illustrated in Figure 20.7. The rotational motion is described by a single moment of inertia, which is defined as

$$I = \mu R_e^2$$

where  $R_e$  is the equilibrium bond length and  $\mu = m_1 m_2 / (m_1 + m_2)$  is the reduced mass.

**FIGURE 20.7** A diatomic molecule rotates about its center of mass, which for a diatomic molecule is closer to the atom with the larger mass

$$r_1 = \left( \frac{m_2}{m_1 + m_2} \right) R_e \text{ and } r_2 = \left( \frac{m_1}{m_1 + m_2} \right) R_e$$

The wave functions for the rigid rotor are identical to the angular parts of the hydrogen atom wave functions, except of course now the  $\theta$  and  $\phi$  angles represent the orientation of the internuclear axis of the diatomic. The rotational angular momentum is quantized in the same way. The square of the angular momentum and its projection along the laboratory  $z$ -axis can only take on the following values:

*Square of angular momentum:*

$$J(J + 1)(h/2\pi)^2 \quad J = 0, 1, 2, 3, \dots \quad [20.5a]$$

*Projection of angular momentum on  $z$ -axis:*

$$M_J(h/2\pi) \quad M_J = -J, -J + 1, \dots, 0, \dots, J - 1, J \quad [20.5b]$$

Equation 20.5b shows that the degeneracy of each level is given by  $g_J = 2J + 1$ . Interestingly, the  $J = 0$  state has a spherically symmetric angular distribution similar to the  $s$ -orbitals of one electron atoms in Chapter 5, so you are just as likely to find the internuclear axis pointing along the  $x$ -axis,  $y$ -axis,  $z$ -axis or any  $\theta, \phi$  angle in between. Thus molecules in  $J = 0$  pack like spheres, perhaps the most famous example being *para*-H<sub>2</sub> with paired nuclear spins (see Section 20.4).

The energy levels for the linear rigid rotor are given by

$$E_J = \frac{h^2}{8\pi^2 I} J(J + 1) = hB J(J + 1) \quad J = 0, 1, 2, \dots \quad [20.6a]$$

or

$$E_J = hc\tilde{B}J(J + 1) \quad [20.6b]$$

where  $B = (h/8\pi^2 I)$  and  $\tilde{B} = (h/8\pi^2 cI)$  are rotational constants, the former measured in Hz and the latter measured in  $\text{cm}^{-1}$ . Both units are widely used in rotational spectroscopy, and conversion between them is straightforward:  $1 \text{ cm}^{-1} = 30 \times 10^9 \text{ Hz}$  (30 GHz). A rotational absorption spectrum using microwave radiation, presented next, allows you to measure the rotational constant. Since  $\tilde{B} = (h/8\pi^2 cI)$  this gives you the moment of inertia  $I$ , and using  $I = \mu R_e^2$  you can derive the internuclear distance  $R_e$ ! This is how the equilibrium internuclear distance of HCl, and many other heteronuclear diatomic molecules, was first determined; decades later the measured  $R_e$ 's were confirmed by solving the Schrödinger equation for the potential energy curve depicted in Figure 20.1.

Microwave absorption spectroscopy has historically been one of our most important experimental methods for accurately measuring bond lengths in heteronuclear diatomic molecules. Microwave emission spectra are used to identify molecules in interstellar space as well as to monitor the concentrations of gases of importance in the atmospheric chemistry of the Earth. Absorption and emission of microwave radiation can be interpreted classically by considering the change in direction of the dipole moment of a heteronuclear diatomic molecule as it rotates. If you imagine that the diatomic molecule in Figure 20.8 is HCl, the H atom has a partial positive charge  $\delta+$  and the Cl atom has a partial negative charge  $\delta-$ , so as the HCl molecule rotates the dipole moment vector, pointing from the Cl atom to the H atom along the internuclear axis, rotates with it. This change in dipole moment direction is what allows the molecule to interact with the oscillating electric field of the microwave light, and absorb a photon. Thus molecules must have permanent dipole moments in order to absorb or emit microwave or far-infrared radiation as a result of rotational motion. Quantum mechanics imposes two additional requirements: conservation of energy and conservation of angular momentum. Conservation of energy is enforced by the familiar Bohr frequency rule  $|\Delta E| = h\nu$  that relates the photon frequency to the energy difference between the levels. Conservation of angular momentum

**FIGURE 20.8** The angular momentum of a photon (blue circular arrow) is transferred to a molecule (red circular arrows) upon absorption of microwave radiation. The straight black arrows show the instantaneous tangential velocities of the atoms in the molecule as it rotates. (Adapted from Peter Atkins and Julio de Paula, *Physical Chemistry*, W. H. Freeman and Company, New York, 2010, p. 457.)

requires that  $\Delta J = \pm 1$  for microwave absorption and emission, respectively, because the photon carries one unit of angular momentum. (Only  $J$  is changing, so the energy of the molecule increases when  $\Delta J = +1$ ; a photon is absorbed. We'll see in the next section on infrared spectroscopy that  $\Delta J = +1$  and  $\Delta J = -1$  are both possible when a molecule absorbs an infrared photon, as the change in energy is primarily determined by the change in the vibrational quantum number. The photon's unit of angular momentum may add to or subtract from the molecule's when the photon is absorbed.) Figure 20.8 shows one unit of angular momentum being transferred to a molecule upon absorption. The angular momentum of a molecule decreases by one unit when a photon is emitted, the angular momentum being carried away by the photon. This **selection rule**, based upon the conservation of angular momentum, is rigorous. There are other kinds of useful selection rules in spectroscopy that are somewhat weaker because they are based upon approximations, such as the harmonic oscillator approximation introduced later.

We can use Equation 20.6b to calculate the frequencies of the allowed transitions for microwave absorption in wave numbers, by letting  $J_i$  and  $J_f$  represent the rotational quantum numbers of the initial and final states and imposing the  $\Delta J = +1$  selection rule. Using the energy in rotation  $E_{\text{rot}} = hc\tilde{B}J(J+1)$  gives

$$\begin{aligned} E_{\text{photon}} &= hc\tilde{\nu} = E_{\text{rot},f} - E_{\text{rot},i} \\ \tilde{\nu} &= \tilde{B}[J_f(J_f + 1) - J_i(J_i + 1)] \\ &= \tilde{B}[(J_i + 1)(J_i + 2) - J_i(J_i + 1)] \\ &= 2\tilde{B}(J_i + 1) \end{aligned} \quad [20.7]$$

Equation 20.7 predicts that the microwave absorption spectrum of a heteronuclear diatomic molecule consists of a series of equally spaced lines separated by  $2\tilde{B}$ . Figure 20.9 shows the energy level diagram for a rigid rotor, with the allowed transitions represented by vertical arrows and the spectrum represented schematically by the stick diagram at the bottom of the figure. The microwave

**FIGURE 20.9** Rotational energy levels and allowed transitions for a heteronuclear diatomic molecule predicted by the rigid rotor model. The energy levels are given by  $E_J = hc\tilde{B}J(J+1)$  and the selection rule  $\Delta J = +1$  for absorption predicts a series of spectral lines equally spaced by  $2\tilde{B}$ , where  $\tilde{B}$  is the rotational constant in  $\text{cm}^{-1}$ .

**FIGURE 20.10** Microwave absorption spectrum of gas-phase carbon monoxide. The spacing between adjacent lines is  $3.8 \text{ cm}^{-1}$ , from which the rotational constant  $\tilde{B} = 1.9 \text{ cm}^{-1}$  is determined. (Adapted from G. W. Chantry, ed., *Modern Aspects of Microwave Spectroscopy*, Academic Press, 1979.)

absorption spectrum of carbon monoxide is shown in Figure 20.10. The separation between each pair of lines is  $3.8 \text{ cm}^{-1}$  from which we determine the rotational constant  $\tilde{B} = 1.9 \text{ cm}^{-1}$ . From this you can calculate the  $R_e$  of CO (see Example 20.4 below). The relative intensities of the lines observed in the experimental spectrum reflects both the increasing degeneracy of each energy level with increasing  $J$  as well as the exponentially decreasing populations of each  $(J, M_J)$  quantum state as determined by the Boltzmann distribution.

Bond lengths of heteronuclear diatomic molecules are simply calculated from the experimentally measured rotational constants and the atomic masses, as illustrated in Example 20.4.

#### EXAMPLE 20.4

The microwave absorption spectrum of gaseous NaH (isotope:  $^{23}\text{Na}^1\text{H}$ ) has been measured experimentally; microwaves with wavelengths of  $1.02 \text{ mm}$  excite the transition from  $J = 0$  to  $J = 1$ . Calculate the bond length of the NaH molecule. Use isotopic masses provided in Table 19.1.

#### Solution

The reduced mass is

$$\begin{aligned}\mu &= \frac{m_{\text{Na}}m_{\text{H}}}{m_{\text{Na}} + m_{\text{H}}} = \frac{(22.9898 \text{ u})(1.0078 \text{ u})}{22.9898 + 1.0078 \text{ u}} \\ &= 0.9655 \text{ u} = 1.603 \times 10^{-27} \text{ kg}\end{aligned}$$

The energy change is

$$\Delta E = h\nu = \frac{hc}{\lambda}$$

which in this case is

$$\begin{aligned}\Delta E_{\text{rot}} &= \frac{(6.626 \times 10^{-34} \text{ J s})(2.998 \times 10^8 \text{ m s}^{-1})}{1.02 \times 10^{-3} \text{ m}} = 1.95 \times 10^{-22} \text{ J} \\ &= \frac{h^2}{8\pi^2 I} [(1)(2) - (0)(1)] = \frac{h^2}{4\pi^2 I}\end{aligned}$$

Solving for the moment of inertia  $I$  gives

$$I = \frac{h^2}{4\pi^2 \Delta E_{\text{rot}}} = \frac{(6.626 \times 10^{-34} \text{ J s})^2}{4\pi^2 (1.95 \times 10^{-22} \text{ J})} = 5.70 \times 10^{-47} \text{ kg m}^2$$

(Continued)

The moment of inertia  $I$  is related to the bond length  $R_e$  by  $I = \mu R_e^2$  so

$$R_e^2 = \frac{I}{\mu} = \frac{5.70 \times 10^{-47} \text{ kg m}^2}{1.603 \times 10^{-27} \text{ kg}} = 3.56 \times 10^{-20} \text{ m}^2$$

$$R_e = 1.89 \times 10^{-10} \text{ m} = 1.89 \text{ \AA}$$

**Related Problems: 11, 12, 13, 14**

Microwave absorption cannot be used to measure bond lengths in homonuclear diatomic molecules because they have no permanent dipole moments. Rotational Raman spectroscopy, however, can be used to measure bond lengths in both heteronuclear and homonuclear diatomic molecules because it depends upon a different kind of interaction. Electromagnetic radiation from a polarized laser can induce a dipole moment in a molecule by displacing its electron density; the induced dipole moment is proportional to the component of the molecular **polarizability** that is oriented parallel to the electric field of the laser radiation. Polarizability (see Section 10.2) is a measure of the degree to which the electron distributions of atoms and molecules distort in the presence of electric fields; larger atoms, with more loosely bound electrons, have larger polarizabilities than smaller atoms, and molecules with delocalized electrons have larger polarizabilities than those that don't. Figure 20.11 shows that the polarizability of a diatomic molecule is generally larger when the molecule is aligned with the electric field than when it is oriented perpendicular to the field. The polarizability of a homonuclear diatomic molecule oscillates at twice the rotational frequency, producing an oscillating dipole moment that emits radiation at a frequency shifted from that of the incident radiation by that amount. We interpret Raman scattering using quantum mechanics as arising from the absorption of radiation from rotational levels of the ground electronic state to a set of "virtual" electronic states followed by emission to different rotational (or vibrational) levels of the ground electronic state, as shown in Figure 20.12.

We determine  $\Delta E_{\text{rot}}/hc$  for Raman transitions by measuring the differences in frequencies of the incident (laser) radiation and the observed scattered radiation  $\tilde{\nu} = \tilde{\nu}_i - \tilde{\nu}_s$ , where the negative of  $\tilde{\nu}$  is called the Raman shift and  $\tilde{\nu}_i$  and  $\tilde{\nu}_s$  are the frequencies of the incident and scattered radiation, respectively. The scattered radiation may appear either at higher or lower frequencies than the incident radiation, depending upon whether the final rotational level lies lower or higher in energy than the initial rotational level, as depicted in Figure 20.12. The selection rule for rotational Raman spectroscopy is  $\Delta J = 0, \pm 2$ ; transitions

**FIGURE 20.11** Schematic of the polarization induced in a diatomic molecule by polarized laser light with the electric field of the laser,  $\vec{E}_{\text{laser}}$ , pointing in the direction shown. The component of the molecular polarizability along the bond axis is, in general, larger than that perpendicular to the axis so the dipole moment that results oscillates at twice the rotational frequency. (We have chosen to represent the polarizability by an ellipse in which the magnitude is proportional to the lengths of the major and minor axes, which is more intuitive than the conventional representation.)

**FIGURE 20.12** Quantum mechanical picture of Raman scattering arising from absorption and emission by virtual electronic states.

for which  $\Delta J = 0$  produce Raman scattered radiation at the incident frequency, those for which  $\Delta J = +2$  produce Raman scattered radiation at lower frequencies (Stokes lines), and transitions for which  $\Delta J = -2$  produce Raman scattered radiation at higher frequencies (anti-Stokes lines). The selection rule for rotational Raman scattering is most easily understood by enforcing the conservation of angular momentum. Unlike absorption and emission, with only one photon involved, Raman scattering is a two-photon process that allows for several different combinations of the angular momenta of the incident and scattered photons. The projection of the angular momentum along the propagation direction of the light can have one of two values,  $+1$  or  $-1$  (in units of  $h/2\pi$ ). If the incident and scattered photons have parallel angular momentum vectors, then the change in the  $J$  quantum number of the molecule is zero, leading to the  $\Delta J = 0$  selection rule. If the incident and scattered photons have antiparallel angular momentum (think of two vectors, one the negative of the other), then two units of angular momentum must have been transferred to or from the molecule, leading to the  $\Delta J = \pm 2$  selection rule.

Figure 20.13 is a figure of some historical significance. The rotational Raman spectrum of  $O_2$  is shown on the left and that of  $N_2$  is shown on the right. These spectra were taken in 1929, just a year after the discovery of the Raman effect by the Indian physicist Sir C. V. Raman, for which he was awarded the

**FIGURE 20.13** First published rotational Raman spectra of  $O_2$  and  $N_2$ . The spectrum of  $N_2$  provided the first measurement of the bond length of that molecule. (Rasetti, F., *Proceedings of the National Academy of Sciences of the United States of America*, vol. 15, no. 6 (June 15, 1929), pp. 515–519.)

**FIGURE 20.14** The pure rotational Raman spectrum of  $\text{N}_2$ . The scattered photon has a smaller energy than the incident photon for the features on the right side, so the Raman shift  $\nu_s - \nu_i$  is negative,  $\Delta E_{\text{rot}}$  is positive, and  $\Delta J = +2$ .

Courtesy of Bryer Brooks, Department of Chemistry, University of Idaho

Nobel Prize. (The discovery of lasers decades later made these spectra much easier to obtain.) The spectra consist of a series of lines, analogous to those in the microwave spectrum of  $\text{CO}$ , from which the rotational constants, moments of inertia, and bond lengths of these molecules were determined. The rotational Raman spectrum of  $\text{N}_2$  provided the very first measurement of the equilibrium bond length ( $R_e$ ) of that molecule. Rotational Raman spectroscopy provided much, if not most, of the spectroscopic data shown in Figure 6.20 for the second period homonuclear diatomic molecules, which was of pivotal importance in developing an understanding of the nature of the chemical bond.

Figure 20.14 shows the pure rotational Raman spectrum of  $\text{N}_2$  recorded using a modern spectrometer. The Stokes lines appear as the envelope on the right, with negative Raman shifts, and the anti-Stokes lines appear as the envelope on the left, with positive Raman shifts. The overall shape of the envelopes is determined by the same factors as those for microwave absorption spectra, the degeneracy of the levels, and the Boltzmann factor. Note the interesting alternating intensities of the lines in the spectrum, which results from the effects of nuclear spin (see Section 20.4) on the effective symmetry of the molecule. Different patterns are observed for different nuclear spins: the pattern seen in the figure arises because each nitrogen atom in  $\text{N}_2$ ,  $^{14}\text{N}$ , has a nuclear spin of one. A different pattern appears for  $\text{H}_2$  because each H atom has a nuclear spin of  $\frac{1}{2}$ , and if you look closely at the spectrum of  $\text{O}_2$  shown in Figure 20.13 you will see that every other line is missing, because the spin of the  $^{16}\text{O}$  nucleus is zero.

### EXAMPLE 20.5

The rotational constant  $\tilde{B}$  for  $\text{H}_2$  is  $60.86 \text{ cm}^{-1}$ . Predict the rotational Raman spectrum of  $\text{H}_2$  and calculate the bond length of the molecule.

#### Solution

The rotational Raman spectrum of  $\text{H}_2$  consists of two envelopes of lines, a series of Stokes lines at lower frequencies than that of the excitation source and a series of anti-Stokes lines at higher frequencies. The separation between adjacent lines is  $4\tilde{B} = 243.4 \text{ cm}^{-1}$ , from which the rotational constant was determined. The intensity of the lines in each of the envelopes peaks at low values of  $J$ , because the rotational energies of  $\text{H}_2$

are comparable to thermal energies at 300 K and only the first few rotational levels are populated to a significant extent. The bond length is calculated from the moment of inertia, determined from the rotational constant, and the reduced mass by rearranging the equation for  $\tilde{B}$  below Equation 20.6b to get

$$I = (h/8\pi^2 c\tilde{B}) = 4.6 \times 10^{-46} \text{ kg m}^2$$

The reduced mass of  $\text{H}_2$  is  $\mu = 8.3 \times 10^{-28} \text{ kg}$  from which we calculate the bond length using  $I = \mu R_e^2$  to get  $R_e = 0.74 \text{ \AA}$ .

**Related Problems: 15, 16, 51, 52**

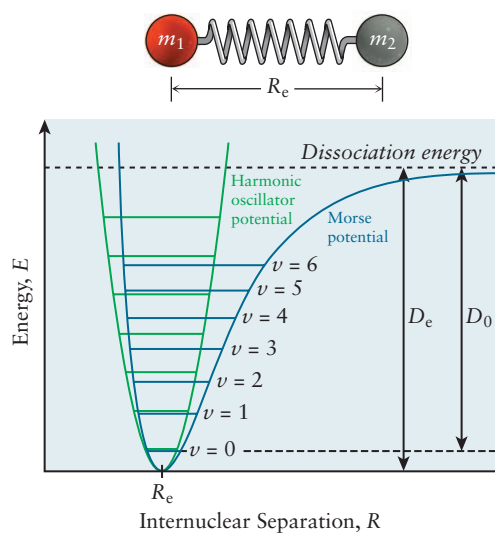

### Vibrational Spectroscopy

The vibrational motions of diatomic molecules are analogous to those of a pair of masses connected by a spring and they are analyzed using two simple mechanical potential energy functions, the harmonic oscillator and the Morse potential. The atoms oscillate about the equilibrium bond length at frequencies that depend upon the “stiffness” of the spring as well as the masses of the two atoms. Molecules are always vibrating, even at 0 K, but transitions between quantized vibrational states can be induced by absorption, emission, or scattering of electromagnetic radiation. The frequencies observed in the vibrational spectra of diatomic molecules, along with the known reduced masses, are used to calculate force constants such as those plotted in Figure 6.20, which correlate strongly with bond order and bond strength, as determined by bond dissociation energies. The importance of vibrational spectroscopy in developing an understanding of chemical bonding can hardly be overstated.

Figure 20.15 shows a more accurate potential energy function for a diatomic molecule, one called the Morse potential, along with the potential energy function for the harmonic oscillator model. Let's review the characteristics of potential energy functions before introducing the harmonic oscillator model. The potential energy of the atoms separated at infinity is often taken to be zero, but when one is studying molecular spectroscopy it is usual to shift the zero of potential energy to the minimum of the ground electronic state potential energy curve so that the expression for  $E_{\text{vib}}$  that we introduced in Section 12.8 may be used. If you start with the atoms far apart, large  $R$ , and move them toward each other, the potential energy decreases as the bond is formed, reaching its minimum value at the equilibrium bond length,  $R_e$ . The two atoms feel an attractive force between them in this region of the potential, between  $R = R_e$  and longer internuclear distances. At smaller internuclear distances than  $R = R_e$ , the two atoms feel a repulsive force between them. The potential energy curve near the minimum closely resembles a parabola, which is the potential energy function for the harmonic oscillator model, one of the most important mechanical models in physics. We discuss the classical and quantum harmonic oscillator models to provide a basis for interpreting the vibrational spectra of molecules. We introduced you to the harmonic oscillator model (without calling it that) in our discussion of blackbody radiation in Section 4.2. Our model for that problem was a mass connected to a wall by a spring. Hooke's law, which is empirical, states that the restoring force acting on that mass is directly proportional to the

**FIGURE 20.15** Potential energy curves for a diatomic molecule (represented by a ball and spring model) approximated by a Morse potential (blue) and a harmonic oscillator potential (green) that have the same equilibrium bond length  $R_e$ , and similar curvature near the minimum. The Morse potential leads to dissociation at long internuclear distances. The bond dissociation energy  $D_0$  and the energy difference  $D_e$  between the minimum of the potential energy curve and the dissociation limit are shown. They differ by  $\frac{1}{2} h\nu$ .

displacement of the mass from its equilibrium position but acting in the opposite direction. Let's now consider two masses connected by a spring, the masses representing the atoms of a diatomic molecule and the spring representing the chemical bond. For the case of two masses connected by a spring we simply replace the single mass used in our first model by the reduced mass of the system, which is given by

$$\mu = m_1 m_2 / (m_1 + m_2)$$

Let's apply Hooke's law to a diatomic molecule with reduced mass  $\mu$  and equilibrium bond length  $R_e$ . The restoring force is directly proportional to the change in bond length for small displacements from equilibrium

$$F(R) = -k(R - R_e) \quad [20.8]$$

where the **force constant**  $k$  is a measure of the stiffness of the bond, expressed in  $\text{N m}^{-1}$  and  $(R - R_e)$  is the displacement from the equilibrium bond length. The force constant  $k$  will be large for stiff bonds like the triple bond of CO, and smaller for single bonds. The potential energy function  $V(R)$  that results from this restoring force is obtained by integrating using Equation 20.8 with  $F(R) = -dV/dR$  to get

$$V(R) = \frac{1}{2} k(R - R_e)^2 \quad [20.9]$$

which is shown as the green parabolic curve in Figure 20.15. You can see that the harmonic oscillator potential approximates the real potential energy function in the region around the minimum closely, and also gives a good prediction for the energies of the lowest vibrational quantum states. This close agreement justifies the use of the harmonic oscillator approximation in vibrational spectroscopy of the low energy vibrational states of a molecule. If the two masses in the system just described are displaced from their equilibrium separation, they will begin to oscillate back and forth about that position with a characteristic frequency (in round-trip cycles per second) given by

$$\nu = \frac{1}{2\pi} \sqrt{\frac{k}{\mu}} \quad [20.10]$$

in which  $\mu$  is the reduced mass and  $k$  is the force constant of the harmonic oscillator. Classical harmonic oscillators vibrate at a natural frequency that is determined by Equation 20.10; they can vibrate with any amplitude (and energy, therefore) but the vibrational energies,  $E_{\text{vib}}$ , of quantum harmonic oscillators are restricted to fixed values as we now show.

The energies and wave functions for the quantum harmonic oscillator model are obtained by solving the one-dimensional Schrödinger equation with the harmonic oscillator potential energy term added to the kinetic energy term.

$$-\frac{\hbar^2}{8\pi^2 m} \frac{d^2\psi(x)}{dx^2} + \frac{1}{2} kx^2\psi(x) = E_{\text{vib}}\psi(x) \quad [20.11]$$

The  $x$  in this equation represents  $R - R_e$  for a diatomic molecule, and the mass  $m$  would be replaced by the reduced mass  $\mu$ . The method by which this equation is solved is beyond the scope of this textbook, but the wave functions and energy levels are easy to write down, graph, and interpret. You may verify the solutions by substituting them into the Schrödinger equation above. The first four wave functions for the quantum harmonic oscillator are listed in Table 20.2 and plotted in Figure 20.16. In this table and figure,  $x - x_0 = x - 0 = R - R_e$  for a diatomic, so if you plot the harmonic potential as a function of  $R$  instead of  $x$ , then the minimum of the harmonic potential is at  $R = R_e$ , as shown in Figure 20.15.

TABLE 20.2

## The First Four Harmonic Oscillator Wave Functions

$$\psi_3(x) = \left(\frac{\alpha^3}{9\pi}\right)^{1/4} (2\alpha x^3 - 3x) e^{-\alpha x^2/2}$$

$$\psi_2(x) = \left(\frac{\alpha}{4\pi}\right)^{1/4} (2\alpha x^2 - 1) e^{-\alpha x^2/2}$$

$$\psi_1(x) = \left(\frac{4\alpha^3}{\pi}\right)^{1/4} x e^{-\alpha x^2/2}$$

$$\psi_0(x) = \left(\frac{\alpha}{\pi}\right)^{1/4} e^{-\alpha x^2/2}$$

$$\text{with } \alpha = \frac{2\pi}{h} (k\mu)^{1/2}$$

FIGURE 20.16 Energy levels and wave functions for the lower energy states of the harmonic oscillator.

The frequency of a quantum harmonic oscillator is calculated using the same formula as that for the classical harmonic oscillator, Equation 20.10. The quantized energy levels of the harmonic oscillator are given by

$$E_\nu = h\nu \left( \nu + \frac{1}{2} \right) \quad [20.12]$$

where  $\nu$  is its fundamental vibrational frequency and  $\nu$  is a quantum number that can have the values 0, 1, 2, ... The energy levels are equally spaced, like the steps of a ladder, with adjacent levels being separated by  $\Delta E = h\nu$ . The higher energy vibrations may be thought of as harmonics of the fundamental, by analogy to the one-dimensional particle-in-a-box model, discussed in Section 4.6. Unlike the particle-in-a-box, however, the  $\nu = 0$  state of the harmonic oscillator is allowed because the term  $E = \frac{1}{2} h\nu$  ensures that the total energy of the oscillator never equals zero, which would violate the uncertainty principle. In the ground vibrational state all molecules have  $\frac{1}{2} h\nu$  of vibrational energy in each vibrational mode, even at 0 K; this motion is called **zero-point motion** and the energy is called the **zero-point energy**. Differences in zero-point energy account for very important isotope effects on reaction rates in chemical kinetics, as discussed in Section 18.6. Vibrational spectra are usually presented as a function of frequency expressed in wave numbers; the highest-frequency molecular vibration is that of  $\text{H}_2$ , at  $4400 \text{ cm}^{-1}$ , and the low-frequency end of the vibrational spectral region for molecules is generally around  $100 \text{ cm}^{-1}$ , frequencies that are characteristic of metal–metal stretching vibrations, for example.

Transitions between vibrational energy levels can occur by absorption or emission of infrared radiation, or by Raman scattering. Molecules must have dipole moments that change as they vibrate in order for them to absorb or emit infrared radiation, by the same classical argument presented for rotation earlier. Vibrational Raman scattering, on the other hand, requires a change in the molecular polarizability during vibration. The angular momentum selection rule introduced in Section 20.1 applies rigorously to vibrational spectroscopy as well, but it is a little harder to visualize than for rotational spectroscopy. The harmonic oscillator approximation introduces an additional, but weaker, quantum mechanical selection rule  $\Delta\nu = \pm 1$  for both infrared absorption and emission and for Raman scattering. That selection rule is relaxed for anharmonic potential energy functions, like the Morse potential for a diatomic molecule shown in Figure 20.15.

**EXAMPLE 20.6**

The infrared spectrum of gaseous NaH (isotope:  $^{23}\text{Na}^1\text{H}$ ) was determined via absorption spectroscopy. A single absorption band was observed at  $\lambda = 8.53\mu\text{m}$ . Calculate the vibrational force constant of the NaH molecule using the harmonic oscillator model using the masses of the isotopes provided in Table 19.1.

**Solution**

The vibrational frequency is

$$\nu = \frac{c}{\lambda} = \frac{2.998 \times 10^8 \text{ m s}^{-1}}{8.53 \times 10^{-6} \text{ m}} = 3.515 \times 10^{13} \text{ s}^{-1} = \frac{1}{2\pi} \sqrt{\frac{k}{\mu}}$$

Solving for the constant  $k$  (using the reduced mass from Example 20.4)

$$\begin{aligned} k &= \mu(2\pi\nu)^2 \\ &= (1.603 \times 10^{-27} \text{ kg})(2\pi)^2(3.515 \times 10^{13} \text{ s}^{-1})^2 \\ &= 78.2 \text{ kg s}^{-2} = 78.2 \text{ J m}^{-2} \end{aligned}$$

**Related Problems: 17, 18, 19, 20**

Force constants are a measure of the “stiffness” of chemical bonds. If you calculate the potential energy change from  $V = 0$  at equilibrium geometry to the  $V$  when  $R$  is  $0.1 \text{ \AA}$  larger than  $R_e$ , you will see that the potential energy  $V$  increases by a larger amount for bonds with a larger force constant  $k$ ; it requires more energy to stretch bond with a large force constant (the spring is stiffer) than a bond with a smaller  $k$ . Figure 6.20 shows a strong correlation between force constants and other properties such as bond lengths (if the valence electrons involved in bonding are from orbitals with the same principle quantum number in the comparison group) and bond dissociation energies. Example 20.7 shows how the force constants plotted in Figure 6.20 were determined from vibrational spectra.

**EXAMPLE 20.7**

Homonuclear diatomic molecules do not absorb infrared radiation but their vibrational spectra are readily obtained using Raman spectroscopy, as shown for  $\text{H}_2$ ,  $\text{N}_2$  and  $\text{O}_2$  in the *Connection to Instrumental Analysis* in Chapter 3. The measured vibrational frequencies for the second period diatomic molecules are:  $^7\text{Li}_2$  ( $351 \text{ cm}^{-1}$ );  $^{11}\text{B}_2$  ( $1051 \text{ cm}^{-1}$ );  $^{12}\text{C}_2$  ( $1855 \text{ cm}^{-1}$ );  $^{14}\text{N}_2$  ( $2358 \text{ cm}^{-1}$ );  $^{16}\text{O}_2$  ( $1580 \text{ cm}^{-1}$ );  $^{19}\text{F}_2$  ( $919 \text{ cm}^{-1}$ ). Calculate the force constants for each molecule, using the vibrational frequencies given and the atomic masses for the appropriate isotope provided in Table 19.1.

**Solution**

Let's calculate the force constant for  $\text{N}_2$  as an example, leaving the rest of the molecules for you to work out on your own. We modify the formula given in Example 20.6 to account for frequencies expressed in wave numbers and substitute the experimental values and the reduced mass for  $\text{N}_2$  to solve for the force constant.

$$\begin{aligned} \tilde{\nu} &= \frac{\nu}{c} = \frac{1}{2\pi c} \sqrt{\frac{k}{\mu}} \\ k &= \mu(2\pi c\tilde{\nu})^2 \\ &= [1.16 \times 10^{-26} \text{ kg}][ (2\pi)(3 \times 10^{10} \text{ cm s}^{-1})(2358 \text{ cm}^{-1}) ]^2 \\ &= 2292 \text{ N m}^{-1} \end{aligned}$$

which is in good agreement with the value plotted in Figure 6.20.

**Related Problems: 17, 18, 19, 20**

The differences in the vibrational frequencies observed for the series  $\text{C}_2 - \text{F}_2$  are dominated by the differences in force constants, the reduced masses varying by less than a factor of two. This allows us to determine the bond orders of individual

bonds in polyatomic molecules simply by inspection; single bonds between the second period elements give rise to bands in the  $1000\text{ cm}^{-1}$  region of the spectrum, double bonds around  $1600\text{ cm}^{-1}$ , and triple bonds around  $2300\text{ cm}^{-1}$ . These characteristic frequencies are very helpful in the analysis of the vibrational spectra of polyatomic molecules, as we show later. Examining trends in the vibrational frequencies of a series of diatomic hydrides reveals the importance of the reduced mass in determining vibrational frequencies and also allows us to establish the typical frequencies of C–H and O–H vibrations in an IR absorption spectrum. The vibrational frequencies of the hydrogen halides are:  ${}^1\text{H}{}^19\text{F}$  ( $4139\text{ cm}^{-1}$ );  ${}^1\text{H}{}^{35}\text{Cl}$  ( $2991\text{ cm}^{-1}$ );  ${}^1\text{H}{}^{81}\text{Br}$  ( $2449\text{ cm}^{-1}$ ); and  ${}^1\text{H}{}^{127}\text{I}$  ( $2308\text{ cm}^{-1}$ ). The reduced masses in each of these cases is essentially the mass of the hydrogen atom, which is why the vibrational frequencies are so high. The motion is that of the hydrogen atom vibrating against the more massive halogen atoms, which can be thought of as stationary. The vibrational frequencies of the gas-phase diatomic hydrides  ${}^{12}\text{C}{}^1\text{H}$  ( $2859\text{ cm}^{-1}$ ) and  ${}^{16}\text{O}{}^1\text{H}$  ( $3765\text{ cm}^{-1}$ ) are also typical for these bonds in polyatomic molecules; frequencies that are characteristic of particular bonds are extremely useful in the analysis of the vibrational spectra of polyatomic molecules.

While the harmonic oscillator model is very useful for predicting the energies of the low-lying vibrational energy levels,  $\nu = 0, 1$  or  $2$ , it does not predict the energies of the higher vibrational levels very well. The higher energy levels are much better reproduced using an anharmonic potential energy function like the **Morse potential energy function** shown in blue in Figure 20.15. The Morse potential (as it is often called) is a simple analytical expression that is widely used to describe the anharmonic potential energy function of a diatomic molecule, as it gives a better prediction for the actual vibrational energy levels observed spectroscopically. It is

$$V(R) = D_e[1 - \exp(-a(R - R_e))]^2 \quad [20.13]$$

where  $V(R)$  is the potential energy curve,  $R$  is the distance between the nuclei,  $R_e$  is the equilibrium bond length,  $D_e$  is the “depth” of the potential energy well, and  $a$  is a constant that determines the “width” of the potential energy well. (Note that the Morse potential energy function gives a good representation of a diatomic molecule’s potential energy in the bound region, but not at very short internuclear distances.) If you solve the Schrödinger equation for the vibrational energy levels in a Morse potential, the vibrational states become closer in energy as the energy in vibration is increased, as shown in Figure 20.15. This is represented mathematically by an anharmonic correction term to the equation for the vibrational energy levels. At the dissociation energy  $D_e$  the Morse potential predicts that the energy difference between two neighboring vibrational energy levels is reduced to zero.  $E_{\nu+1} - E_\nu$  is proportional to the vibrational quantum number  $\nu$  (decreasing as  $\nu$  increases) so a plot of the experimentally measured energy differences as a function of  $\nu + 1/2$ , called a *Birge–Sponer plot*, intercepts the horizontal axis when the vibrational spacing is zero at the dissociation limit. Calculating the area under the curve gives the sum of the energy differences between all the vibrational levels up to the dissociation limit, giving a very good estimate of the bond dissociation energy. This method is illustrated in Figure 20.17 and Example 20.8.

### EXAMPLE 20.8

Estimate the bond dissociation energy for  $\text{H}_2^+$  using Birge–Sponer extrapolation. The measured frequencies of the successive transitions ( $0 \rightarrow 1$ ,  $1 \rightarrow 2$ , etc.) in  $\text{cm}^{-1}$  are 2191, 2064, 1941, 1821, 1705, 1591, 1479, 1368, 1257, 1145, 1033, 918, 800, 677, 548, and 411. The  $0 \rightarrow 1$  vibrational transition is plotted at  $0 + 1/2$  in the Birge–Sponer plot so that the area under the curve gives the bond dissociation energy.

#### Solution

Plot the transition frequencies versus the lower quantum number  $+ 1/2$ , as illustrated in Figure 20.17. Fit to a straight line using the linear least squares function on your calculator or spreadsheet to determine  $y = -116.05x + 2237.7$ . The area under the curve (a triangle) is  $1/2(19.28)(2237.7\text{ cm}^{-1}) = 2.16 \times 10^4\text{ cm}^{-1}$ , very close to the actual  $D_0$ .

**FIGURE 20.17** Birge–Sponer plot used to determine the bond dissociation energy of  $\text{H}_2^+$ . (Adapted from Peter Atkins and Julio de Paula, *Physical Chemistry*, W. H. Freeman and Company, New York, 2010, p. 467.)

So far we have discussed low-resolution infrared absorption spectra, where the wavelength distribution of the light source used to excite the molecular vibration was not very narrow. If you use an infrared laser to excite the molecule, or take a Fourier transform infrared absorption spectrum you find that what appeared to be one absorption band peaked near the energy  $h\nu_{\text{vib}}$  actually consists of many sharp peaks. We have added the subscript “vib” so that we can distinguish the frequency of the photon absorbed,  $\nu_{\text{photon}}$ , and its energy  $h\nu_{\text{photon}}$ , from the frequency of the harmonic oscillator vibration,  $\nu_{\text{vib}}$ . They are different because the rotational quantum state of the molecule must also change when it absorbs a photon in order to obey the selection rule  $\Delta J = \pm 1$  for single photon absorption. (The same selection rule,  $\Delta J = \pm 1$ , applies to infrared emission spectra, but then of course the vibrational quantum number  $\nu$  decreases by 1.) Figure 20.18 shows a high-resolution infrared absorption spectrum of CO.

It is easy to calculate the energy of the absorbed photon if the infrared light promotes the molecule from an initial ro-vibrational quantum state labeled by the quantum numbers  $\nu_i$  and  $J_i$  to a final state labeled by the quantum numbers

**FIGURE 20.18** Vibration–rotation spectrum of carbon monoxide in the gas phase, measured using infrared absorption spectroscopy. Absorbance (see Eq. 20.3) is plotted as a function of the frequency in wave numbers of the incident photon. (Adapted from the work of Husheng Yang, Department of Chemistry, University of Idaho.)

$\nu_f$  and  $J_f$ . Using the rotational energy in the rigid-rotor approximation, Equation 20.6a, and the vibrational energy in the harmonic approximation, Equation 20.12, the absorbed photon energy would be

$$\begin{aligned} h\nu_{\text{photon}} &= \Delta E = E_f - E_i \\ h\nu_{\text{photon}} &= (E_{\text{vib},f} + E_{\text{rot},f}) - (E_{\text{vib},i} + E_{\text{rot},i}) \\ h\nu_{\text{photon}} &= h\nu_{\text{vib}} \left( \nu_f + \frac{1}{2} \right) + \frac{h^2}{8\pi^2 I} J_f(J_f + 1) - h\nu_{\text{vib}} \left( \nu_i + \frac{1}{2} \right) - \frac{h^2}{8\pi^2 I} J_i(J_i + 1) \\ h\nu_{\text{photon}} &= h\nu_{\text{vib}}(\nu_f - \nu_i) + \frac{h^2}{8\pi^2 I} [J_f(J_f + 1) - J_i(J_i + 1)] \end{aligned} \quad [20.14]$$

In an infrared absorption spectrum where  $\Delta\nu = +1$ ,  $\Delta J$  can be either  $+1$  or  $-1$ . If  $\Delta J = -1$ , Equation 20.14 gives the energy of the absorbed photon to be

$$\begin{aligned} h\nu_{\text{photon}} &= h\nu_{\text{vib}} + \frac{h^2}{8\pi^2 I} [(J_i - 1)(J_i) - J_i(J_i + 1)] \\ &= h\nu_{\text{vib}} - \frac{h^2}{4\pi^2 I} J_i \end{aligned} \quad [20.15]$$

In wave numbers, using  $h\nu_{\text{photon}} = hc\tilde{\nu}_{\text{photon}}$  and  $h\nu_{\text{vib}} = hc\tilde{\nu}_{\text{vib}}$  this becomes

$$\tilde{\nu}_{\text{photon}} = \tilde{\nu}_{\text{vib}} - 2\tilde{B}J_i \quad [20.16]$$

These photon energies excite transitions in what is called the P branch ( $\Delta J = -1$ ) of the infrared absorption spectrum. But of course, you can't have a transition where  $\Delta J = -1$  and  $J_i = 0$ , because that would give  $J_f = -1$  and no such quantum state exists! Also, an infrared absorption with  $\Delta J = 0$  is not observed as this does not satisfy angular momentum conservation when a single photon is absorbed (unless there is a change in electronic angular momentum, as in NO.) Thus, you can easily see why the spectrum of carbon monoxide in Figure 20.18 appears to be missing an absorption line right in the middle of the spectrum. The missing line would have been at the energy where  $h\nu_{\text{photon}} = h\nu_{\text{vib}}$ . Though the low-resolution infrared absorption spectrum shows a band centered roughly at  $h\nu_{\text{photon}} = h\nu_{\text{vib}}$  there is actually no absorption of light at this precise energy.

### EXAMPLE 20.9

Beginning with Equation 20.14, derive an expression for the energies of the transitions in the high energy half of the infrared absorption spectrum of CO; this portion of the spectrum is called the R branch and the transitions in this region follow the selection rules  $\Delta\nu = +1$ ,  $\Delta J = +1$ . Then calculate the energy of the absorbed photon for two absorption lines in the R branch, the one with  $J_i = 0$  and the one with  $J_i = 1$ . (These are labeled 0-1 and 1-2 in Figure 20.18.) The rotational constant of CO is  $1.92 \text{ cm}^{-1}$  and the vibrational frequency is  $2143 \text{ cm}^{-1}$ .

#### Solution

Substituting  $J_f = J_i + 1$  (for an R branch transition) and  $\nu_f = \nu_i + 1$  into Equation 20.14 gives

$$h\nu_{\text{photo}} = h\nu_{\text{vib}} + \frac{h^2}{8\pi^2 I} [(J_i + 1)(J_i + 2) - J_i(J_i + 1)] = h\nu_{\text{vib}} + \frac{h^2}{4\pi^2 I} (J_i + 1).$$

Expressing this in wave numbers gives  $\tilde{\nu}_{\text{photon}} = \tilde{\nu}_{\text{vib}} + 2\tilde{B}(J_i + 1)$ . When  $J_i = 0$ , an infrared photon of energy  $2143 \text{ cm}^{-1} + 2(1.92 \text{ cm}^{-1}) = 2147 \text{ cm}^{-1}$  can be absorbed

(Continued)

(adding a quantum of vibrational energy to the CO and changing its rotational state to  $J_f = 1$ ). When  $J_i = 1$ , an infrared photon of energy  $2143 \text{ cm}^{-1} + 4(1.92 \text{ cm}^{-1}) = 2151 \text{ cm}^{-1}$  can be absorbed. Note that the spacing between the two adjacent absorption lines is  $2\tilde{B}$ , the same as that in the pure rotational absorption spectrum of CO, so this infrared spectrum can also be used to determine the equilibrium bond length of CO.

**Related Problems: 19, 20**

## 20.3.2 Polyatomic Molecules

### Rotational Spectroscopy

Pure rotational spectra of polyatomic molecules are considerably more complicated than those of diatomic molecules because they may have up to three different moments of inertia that result from rotations about three different molecular axes (see Section 12.5 and Figure 12.13). The symmetry of the molecule determines the number of distinct values for the moments of inertia. Linear molecules have one unique axis and a single moment of inertia for rotation about any axis perpendicular to that axis. The analysis of pure rotational spectra for *linear* triatomic molecules is only slightly more complicated than that for diatomic molecules because there are two bond lengths and only one rotational constant (for the two rotational degrees of freedom). We can determine both bond lengths by measuring the rotational constants of at least two molecules in which one or more isotopic substitutions have been made and solving two equations for the two unknowns. The calculation is straightforward, but tedious, and examples can be found in standard physical chemistry textbooks. For a non-linear polyatomic molecule there are three rotational degrees of freedom, and three mutually perpendicular axes about which the molecule's rotation can be described. All axes are equivalent for spherically symmetric molecules such as  $\text{CH}_4$  and  $\text{SF}_6$ , with tetrahedral and octahedral symmetry, respectively; these spherical rotors have three moments of inertia that are equal to one another. Molecules such as  $\text{NH}_3$  and  $\text{CH}_3\text{Cl}$  have one unique axis and two different moments of inertia, one for rotation about the unique axis and one for rotations about any axis perpendicular to that axis. These molecules are called symmetric top rotors. Finally, molecules with three different moments of inertia, such as  $\text{H}_2\text{O}$ , are called asymmetric rotors. The analysis of rotational spectra for non-linear polyatomic molecules is significantly more complex than that for linear triatomic molecules, but it is carried out in the same way, and has enabled scientists to determine the geometries of many small polyatomic molecules, like those shown in Chapters 3, 6, 7 and 8, very accurately.

### Vibrational Spectroscopy

The number and frequencies of the bands observed in vibrational spectra are used to identify molecules, to characterize bonding, and to probe their local environments in complex systems such as those found in biology, geology, or materials science, for example. Molecules containing  $N$  atoms have  $3N$  degrees of freedom in total, corresponding to the three translational degrees of freedom for each atom if they were not bound together. Three of these degrees of freedom correspond to translations of a molecule through space, and there are either 2 (linear molecule) or 3 (nonlinear molecule) rotational degrees of freedom. Subtracting these motions from the total leaves  $3N - 5$  vibrational degrees of freedom for linear molecules and  $3N - 6$  vibrational degrees of freedom for nonlinear molecules. The vibrational motions of relatively small molecules, especially rather symmetric ones, can be represented as a superposition of a number of "normal modes" in which the motions of the atoms are arranged in uniquely

different ways. The normal modes of water include a symmetric H—O—H stretch (both bonds stretching and compressing in phase), an antisymmetric H—O—H stretch (both bonds stretching and compressing out of phase) and an H—O—H bending motion, for example. The energy in each vibrational mode is quantized (as it was for the single vibrational mode, the stretch, of a diatomic molecule). In the harmonic approximation, the total energy in vibration is then the sum of the vibrational energy in each normal mode

$$E_{\text{vib}} = h\nu_1 \left( \nu_1 + \frac{1}{2} \right) = h\nu_2 \left( \nu_2 + \frac{1}{2} \right) = h\nu_3 \left( \nu_3 + \frac{1}{2} \right)$$

where  $\nu_1$ ,  $\nu_2$  and  $\nu_3$  are the vibrational frequencies of the symmetric H—O—H stretch, H—O—H bending motion, and antisymmetric H—O—H stretch respectively and the numbers  $\nu_1$ ,  $\nu_2$ , and  $\nu_3$  are the number of quanta of vibration in each of these normal modes. Thus, to identify the vibrational quantum state of H<sub>2</sub>O you specify the values of three quantum numbers ( $\nu_1$ ,  $\nu_2$ ,  $\nu_3$ ).

It is instructive to examine the vibrations of a small polyatomic molecule, CO<sub>2</sub>, to get a feel for some characteristic vibrational motions, their frequencies, and their spectroscopic activity before turning our attention to the spectroscopy of more complicated polyatomic molecules. CO<sub>2</sub> is a linear triatomic molecule with  $3N - 5 = 4$  different “normal” modes of vibration, as shown in Figure 20.19. There are two stretching modes and two bending modes (only one of the two bending modes is shown in Figure 20.19, the other is identical except the motion is perpendicular to the plane of the page). Stretching modes are those in which the bond length changes without changing the bond angles, and bending modes are those in which the bond angles change without changing the bond lengths. The two oxygen atoms move in different directions (along the bond axis) during one cycle of the symmetric stretching vibration (a) whereas they move in the same direction (both to the right, then both to the left) during one cycle of the antisymmetric stretch (b). During the antisymmetric stretch motion the center C atom moves in the opposite direction of the O atoms to keep the center-of-mass of the molecule stationary. The bond angle changes during the two bending vibrations (c), which are degenerate. The two bending modes are distinct because the motions occur in two mutually perpendicular planes. If the dipole moment or polarizability of the molecule changes during each of these vibrations they may be observed in infrared or Raman spectra, respectively.

Let's examine how the dipole moment changes during each of the vibrations, beginning with the degenerate bending modes. The permanent dipole moment of CO<sub>2</sub> is zero by symmetry, but there is clearly an oscillating dipole moment associated with the bending mode so this mode is infrared active. The dipole moment of CO<sub>2</sub> does not change during the symmetric stretching motion, so that mode cannot be excited by infrared absorption. The dipole moment of the molecule clearly changes during the antisymmetric stretching vibration, so that mode can be excited by infrared absorption. The infrared spectrum of CO<sub>2</sub>

**FIGURE 20.19** The normal modes of vibration of CO<sub>2</sub>. The fourth mode, a second bending mode, is not shown as it is identical to the bend shown, except that the motion is perpendicular to the plane of the page.

TABLE 20.3

CO<sub>2</sub> Vibrational Modes, Frequencies, and Spectroscopic Activity

Mode	Frequency	Activity
Symmetric stretch	1354 cm <sup>-1</sup>	Raman
Bend (doubly degenerate)	673 cm <sup>-1</sup>	IR
Antisymmetric stretch	2396 cm <sup>-1</sup>	IR

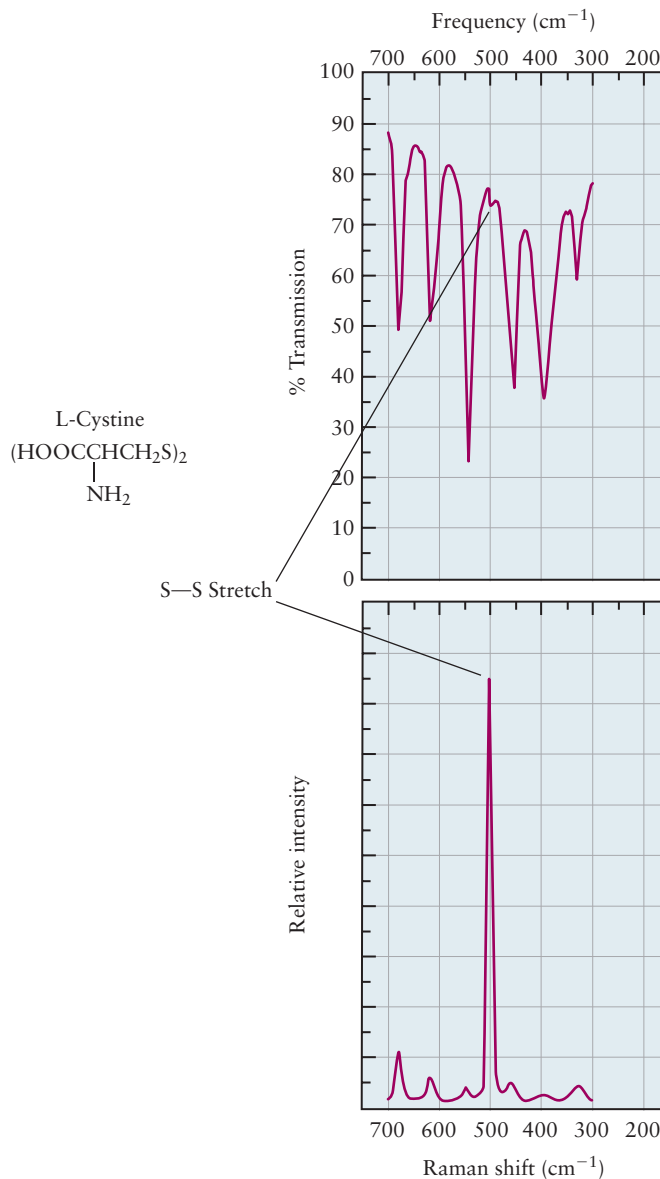

consists of two bands, one at 673 cm<sup>-1</sup>, which is assigned to the doubly degenerate bending mode and one at 2396 cm<sup>-1</sup>, which is assigned to the antisymmetric stretch.

Visualizing the change in polarizability during the vibrations is a little more difficult than visualizing the change in dipole moment. It is helpful to think about the polarizability of each of the bonds separately to see how the polarizability of the molecule changes during vibrations. We need to consider only the component of the polarizability that is parallel to the bond axis to understand the stretching modes. The polarizability increases as the bonds stretch and decreases as the bonds are compressed. The two C—O bonds oscillate in phase during the symmetric stretch, so the changes in the bond polarizability are additive. The bond polarizabilities oscillate out of phase during the antisymmetric stretch, and there is negligible change in the overall polarizability during that vibration. The symmetric stretch is Raman-active and the antisymmetric stretch is not. Understanding the Raman activity of the bending mode is not so easy to explain visually, so we just state the result; that mode is not Raman-active. The frequencies and IR or Raman activities of the three modes of CO<sub>2</sub> are summarized in Table 20.3. Note that none of the vibrational modes of CO<sub>2</sub> is both infrared active and Raman active; this is a consequence of inversion symmetry (see Section 6.1). There is a mutual exclusion rule for all centrosymmetric molecules: Modes that are infrared-active are not Raman-active, and vice versa.

Infrared and Raman spectroscopy tend to be complementary methods even for molecules that lack inversion symmetry, because the nature of the interactions between the molecules and electromagnetic radiation are different in the two cases. IR spectroscopy tends to emphasize vibrations involving polar bonds. Raman spectroscopy, on the other hand, is more sensitive to the motions of highly polarizable covalent bonds, such as those involving  $\pi$  bonds or conjugated systems, and rather less sensitive to the vibrations of very polar or ionic bonds, especially those involving the less polarizable lighter elements. The complementarity of the methods is illustrated by comparing the IR and Raman spectra of the amino acid cystine, as shown in Figure 20.20. Cystine is a dimer of the amino acid cysteine; the disulfide bond formed between two cysteine residues located in different regions of a protein cross-links the polymer chains and is a contributing factor to their tertiary structures. The S—S stretch observed near 500 cm<sup>-1</sup> is barely visible in the infrared spectrum whereas it dominates the Raman spectrum.

Vibrational spectra of polyatomic molecules with more than three atoms are considerably more complex than those of diatomic molecules or CO<sub>2</sub>. Fortunately, the vibrational modes of functional groups containing a few atoms are often independent of the rest of the molecule to which they are bound, in the same way that their chemical properties are quite similar in different molecules, as discussed in Section 7.6. Even the simplest amino acid glycine (H<sub>2</sub>NCH<sub>2</sub>COOH), for example, has 24 normal modes, but its spectrum can be analyzed by looking for vibrations that are characteristic of the carboxylic acid (—COOH) and amino (—NH<sub>2</sub>) groups. These complex spectra provide “fingerprints” that are

**FIGURE 20.20** Infrared and Raman spectrum of the amino acid L-cystine, showing the complementary nature of the techniques. (Adapted from Dana W. Mayo, Foil A. Miller, and Robert W. Hannah, *Course Notes on the Interpretation of Infrared and Raman Spectra*, John Wiley & Sons, Inc., Hoboken, New Jersey, 2004, p. 367.)

used to identify and characterize molecules. The vibrational spectra of larger molecules are generally analyzed by looking for characteristic frequencies of functional groups, which are largely independent of other features of the molecule of which they are a part. The characteristic frequencies of these functional groups can be interpreted as a set of “normal” or “local” modes that involve only the atoms of a particular group. The stretching vibrations of methyl ( $-\text{CH}_3$ ) or methylene ( $-\text{CH}_2$ ) groups can be thought of as “normal” modes of those groups, comprising symmetric and antisymmetric combinations of the individual C—H bond stretches. C—X stretching vibrations, where X is a halogen, the O—H stretch of an alcohol or the  $\text{C}\equiv\text{N}$  stretch of the nitrile functional group, on the other hand, can be thought of as “local” modes. Table 20.4 is an abbreviated version of a table of characteristic frequencies used to analyze infrared and Raman spectra and Example 20.10 shows how to use these characteristic group frequencies to analyze the infrared spectrum of a polyatomic molecule. Note that if the molecule is in solution, the O—H and N—H stretching frequencies may be dramatically changed by hydrogen bonding with solvent molecules.

TABLE 20.4

Characteristic Vibrational Frequencies and Infrared Absorption Intensities of Selected Vibrations and Functional Groups

Frequency ( $\text{cm}^{-1}$ )	Bond or Group	Vibration	Relative Intensity
3650–3200	O–H	Stretching	Weak to strong
3550–3100	N–H	Stretching	Medium
3300–2700	C–H	Stretching	Weak to medium
2250–2100	C $\equiv$ C	Stretching	Weak
1820–1630	C=O	Stretching	Strong
1680–1600	C=C	Stretching	Weak to medium
1430–1390	C–N	Stretching	Strong
1250–1000	C–O	Stretching	Strong

## EXAMPLE 20.10

Identify some characteristic group frequencies in the spectrum of an organic molecule shown below and identify the class of molecules to which it belongs. Propose a structure if you can.

## Solution

The highest frequency mode shown appears around  $3350\text{ cm}^{-1}$ , a region characteristic of N–H stretching vibrations, the stronger absorption appearing around  $2850\text{ cm}^{-1}$  is characteristic of C–H stretching vibrations in alkanes, and the very strong absorption band appearing near  $1650\text{ cm}^{-1}$  is characteristic of the carbonyl (C=O) stretching vibration. The absorption near  $1450\text{ cm}^{-1}$  is associated with a C–N stretching vibration and the one near  $1175\text{ cm}^{-1}$  is characteristic of a C–C single bond stretch. Taken together these observations suggest that the molecule is an amide, with the RC(O)N–functional group. The presence of the C–H stretching vibrations characteristic of an alkane as well as the C–C single bond stretch suggest that it is an alkyl amide. The molecule is  $\text{H}_3\text{CCH}_2\text{C(O)NHCH}_3$ .

## 20.4 Nuclear Magnetic Resonance Spectroscopy

Just as electrons have spin, so do some nuclei have spins, and the energies of their spin states are split apart by a magnetic field. Hydrogen ( $^1\text{H}$ ) nuclei have “spin up” and “spin down” states in which the proton behaves as if it were a tiny bar

magnet. The energies of these states are degenerate in the absence of a magnetic field, but when an external magnetic field is applied the protons with spin up align parallel to the magnetic field (lower energy configurations) and those with spin down align antiparallel to the field (higher energy configurations). The analogy with bar magnets suggests the difference in energy between these two states will be determined by the magnitude of the applied magnetic field,  $B$ , as shown in Figure 20.21. The magnitude of the energy splitting is  $\Delta E = g_N \mu_N B$  where  $g_N$  is the “nuclear g factor” for protons and  $\mu_N$  is a constant called the **nuclear magneton**. Figure 20.21 shows that both the spin up and the spin down nuclei have energy  $E_0$  when the magnitude  $B$  of the applied magnetic field, plotted on the horizontal axis, is 0, but when the magnitude of the applied magnetic field is increased to  $B_0$ , the energies split, so  $E_{\text{spin-down}} - E_{\text{spin-up}} = \Delta E = g_N \mu_N B_0$ . These nuclei can change spin state by absorbing or emitting photons with energy  $h\nu = g_N \mu_N B$ , which fall in the FM radio frequency (rf) region of the electromagnetic spectrum. In nuclear magnetic resonance (NMR) spectroscopy, low energy radio waves (photons with frequencies typically between 300 and 600 MHz) “tickle” the nuclei in a molecule, and cause spin transitions.

**FIGURE 20.21** (a) Energy level splitting diagram for a proton in an external magnetic field. The vertical line shows the absorption transition for a 7.05 T field. (b) Proton NMR spectrum obtained by scanning the magnetic field in a 300-MHz NMR spectrometer.

**FIGURE 20.22** Schematic of an FT NMR spectrometer.

The NMR spectrum can be recorded in various ways. The earliest commercial NMR spectrometers operated in continuous wave mode, in which the sample is irradiated at constant frequency  $\nu_0$  while the magnitude of the external magnetic field  $B$  is swept through a range of values. The rf power absorbed by the sample is recorded at each value of  $B$ . When the magnitude of the magnetic field is scanned to the value  $B_0 = h\nu_0/g_N\mu_N$ , satisfying the resonance condition, suddenly some of the rf power is absorbed by the sample, as shown in Figure 20.21b, and a peak appears in the spectrum. Newer instruments rely on Fourier Transform NMR spectroscopy (FT NMR) in which the magnetic field is fixed and the frequency of the radio waves is scanned; a schematic is shown in Figure 20.22. The sample is contained in a small (5 mm diameter) tube that is placed in a magnetic field created by a superconducting magnet. Radiofrequency radiation is transmitted to the sample by a set of coils placed around the sample, and a second set of coils detects the signal. The sample, held in a fixed magnetic field, is irradiated with a short, intense burst of rf power spanning a frequency range broad enough to stimulate many transitions. The specific frequencies of all the nuclear spin transitions in the polyatomic sample are measured simultaneously. A complete spectrum can be acquired within a few seconds. The measurements can be repeated many times and the results averaged in computer memory to reduce the effects of random background noise. FT NMR spectrometers detect numerous nuclei besides  $^1\text{H}$  ( $^{13}\text{C}$  holds special interest in organic chemistry and biochemistry), but our discussion is limited to  $^1\text{H}$ .

Nuclear spins are sensitive to the chemical environment of a nucleus. Electrons with non-zero angular momentum that are near the nucleus establish an internal magnetic field that modifies the local effective field felt by each proton to a value different from that of the externally applied field. The resulting **chemical shift** causes protons within different structural units of the molecule to show NMR peaks at different values of the applied magnetic field. All protons in chemically equivalent environments will contribute to a single absorption peak in the spectrum. The relative area under each absorption peak is proportional to the number of protons within each equivalent group. In order to standardize procedures, chemical shift values are reported relative to the selected reference compound tetramethylsilane (TMS) by adding a very small amount of

TMS to the sample. The chemical shift for each proton in the spectrum is then defined in parts per million (ppm) as

$$\delta = \frac{B_s - B_r}{B_r} \times 10^6 \quad [20.17]$$

where  $B_s$  is the value of the magnetic field at the peak in the sample spectrum and  $B_r$  is the value at the TMS peak. Extensive tables of chemical shift values relative to TMS aid the interpretation of spectra. For example, these considerations predict that the NMR spectrum of ethanol,  $\text{CH}_3\text{CH}_2\text{OH}$ , should have three peaks of relative area 3:2:1. This is exactly the result obtained when the spectrum is acquired with low resolution (Figure 20.23a).

Nuclear spins are also sensitive to other nearby nuclear spins. Because each spin behaves as if it were a small bar magnet, each influences the local value of the magnetic field felt by others nearby. The result is **spin-spin splitting**, which breaks the broad peak of each equivalent group of protons into a multiplet of narrower, sharper peaks. So long as the chemical shift between chemically non-equivalent groups of protons is large, the multiplet patterns can be interpreted by qualitative rules that we do not describe here. For example, when applied to ethanol, these rules predict splitting of the  $\text{CH}_3$  protons into a triplet and splitting of the  $\text{CH}_2$  protons into a quartet, as seen in high resolution experimental spectra (see Figure 20.23b). Through **chemical shifts** and **spin-spin coupling**, NMR spectroscopy offers a way to identify the bonding groups in a molecule and interpret molecular structure.

NMR spectroscopy is one of the most important techniques available for investigating structure and dynamics in many areas of chemistry, biology, and medicine. Synthetic chemists use NMR, along with mass spectrometry, to verify the identities of new products as well as those of intermediates formed in complex multistep reactions. Biologists use NMR to study the three-dimensional structures and reactions of proteins, enzymes, and nucleic acids (DNA and RNA). The method is complementary to X-ray diffraction (see Section 21.1); it does not require crystals to be grown, the molecules are studied in their native

**FIGURE 20.23** Proton NMR spectrum for ethanol. (a) The low-resolution spectrum shows a single broad peak for each chemically equivalent group of protons. (b) In high resolution, spin-spin splitting separates the peak for each chemically equivalent group of protons into a multiplet. The relative area under each peak, which is proportional to the number of protons responsible for the peak, is given by the number under the brackets below each peak.

environments, and it enables binding and other reactions to be studied that would be very difficult to accomplish using X-ray diffraction. An adaptation of NMR used in medical diagnosis is called magnetic resonance imaging (MRI). Images are obtained with millimeter spatial resolution, and specialized techniques have been developed for different applications that include imaging the major organs for function, identifying tumors, and monitoring blood flow to look for evidence of possible cardiovascular disease, for example.

## 20.5 Electronic Spectroscopy and Excited State Relaxation Processes

Figure 20.1 shows an excited electronic state of HCl that can support bound vibrational energy levels; the vibrational frequency in the excited state is typically different from that in the ground electronic state, as shown in Figure 20.1b. The total internal energy in a molecule may be represented as the sum of its rotational energy  $E_{\text{rot}}$ , its vibrational energy  $E_{\text{vib}}$ , and its electronic energy  $E_{\text{el}}$ . These are depicted in Figure 20.1b. The energetic separations between electronic states are relatively large (a few eV) so transitions between these states occur as a result of absorption or emission of electromagnetic radiation in the ultraviolet and visible regions of the spectrum. Electronic absorption spectroscopy is also widely used as an analytical method to measure the concentrations of species in solution because the measurements are easily quantified. Laser-induced fluorescence, described in Section 20.2, is a very sensitive analytical technique (detection limit  $\sim 1$  molecule); it is used for applications ranging from biological imaging to following the dynamics of energy and electron transfer processes on timescales as short as a few femtoseconds ( $1 \text{ fs} = 10^{-15} \text{ s}$ ).

In Section 20.1 we also briefly presented the radiative and nonradiative processes by which molecules in excited electronic states can lose energy. Figure 20.2 showed an electronically excited molecule returning to the ground electronic state by emitting fluorescence or phosphorescence, and through several nonradiative processes that dissipate the energy as heat. Energy and electron transfer to neighboring molecules are important processes that play central roles in a variety of natural phenomena and underlie a number of important technologies; examples of the former include photosynthesis (see Section 20.7) and examples of the latter include artificial photosynthesis (see Section 17.6 and the accompanying *Connection to Energy*). Understanding the factors that govern the rates of radiative and nonradiative processes is essential for the design and operation of lasers (see Section 20.8). Photoexcitation may also lead to photochemical reactions such as *cis-trans* isomerization, the first step in the vision process.

Molecular orbital (MO) theory, introduced in Chapter 6, provides the framework for understanding the electronic states of molecules and the nature of the transitions among them. We restrict our discussion in this section to the spectroscopy and photochemistry of a few representative organic molecules, having introduced you to the spectroscopy of inorganic compounds in Chapter 8. We use a simple model for electronic excitation, describing it in terms of an excitation of an electron in a molecule from a low energy orbital to a higher energy orbital; in reality the electronic configuration of an excited state molecule may be a linear combination of many such excited electronic configurations, and the dominant electronic configuration characterizing the excited state may change as a function of internuclear distance.

When light with a wavelength of 163 nm is absorbed by ethene, an electron is promoted from the  $\pi$  bonding molecular orbital to the higher energy  $\pi^*$  orbital.

These orbitals are depicted in Figure 6.16. Two excited states are possible, the lowest excited singlet state  $S_1$ , often labeled  $^1\pi\pi^*$  for ethene, and the corresponding triplet state  $T_1$ , labeled  $^3\pi\pi^*$  for ethene. (See Fig. 20.3 for the singlet and triplet spin states.)  $E_{el}$  for the triplet state is typically somewhat smaller than for the singlet state, similar to the  $\pi\pi^*$  excited singlet and triplet states of anthracene shown in Figure 20.6. Exciting an electron from a  $\pi$  to a  $\pi^*$  orbital changes the bond order of the carbon-carbon bond to 1 (it was a double bond in the ground electronic state  $S_0$ ), so the vibrational frequency of the C—C stretching vibration is smaller in the excited state than in the ground state. The equilibrium C—C internuclear distance is also longer in the excited state (typical C—C bond distances for single, double and triple bonds are given in Table 3.5.) Typically the lowest excited electronic state of a molecule is reached when an electron is promoted from the **highest occupied molecular orbital (HOMO)** (for ethene, the bonding  $\pi$  orbital) to the **lowest unoccupied molecular orbital (LUMO)** (for ethene, the anti-bonding  $\pi^*$  orbital). These orbitals are important in spectroscopy, photochemistry, and in many organic chemical reaction mechanisms because changes in the occupancy of these orbitals affect bond order and reactivity. The simple MO diagram of ethene suggests the possibility of other transitions at higher energies, for example a  $\sigma \rightarrow \sigma^*$  transition at very high energies, some of which have been observed experimentally.

The molar absorption coefficient for the strongest absorption band in ethene, which appears at  $\lambda_{\max} = 163 \text{ nm}$  is  $1.5 \times 10^4 \text{ L mol}^{-1} \text{ cm}^{-1}$ ; this value is characteristic of strong  $\pi \rightarrow \pi^*$  transitions. To give you a feeling for what strong absorption means let's calculate what fraction of a beam of 163 nm radiation is absorbed by ethene gas contained in a 1 cm path length cell at 0.001 atm and 300 K. Converting to molarity and using Beer's law, Equation 20.3, we find that  $A = 0.61$ , and that this dilute, but strongly absorbing, sample transmits only about 25% of the incident radiation.

Let's continue to focus on the  $\pi$  electrons and examine the energy level diagrams and transitions between singlet states in some conjugated polyenes and aromatic hydrocarbons to which you were introduced in Section 6.11. Conjugated polyenes are hydrocarbon chains with alternating single and double bonds. Resonance structures suggest, and simple MO theory confirms, that the  $\pi$  electrons in these systems are delocalized over the entire molecule. Figure 6.53 shows the four  $\pi$  orbitals of *trans*-1,3-butadiene, the simplest conjugated polyene. While the lowest  $\pi$  orbital of 1,3-butadiene, delocalized over all three carbon-carbon bonds, is lower in energy than the  $\pi$  orbital of ethene, the next higher  $\pi$  orbital is the HOMO. The LUMO of 1,3-butadiene is the lower of the two  $\pi^*$  molecular orbitals in Figure 6.53. Thus promoting an electron from the HOMO to the LUMO of 1,3-butadiene requires less energy than it did in ethene, and the absorption spectrum is shifted to correspondingly lower energies. Table 20.5 gives  $\lambda_{\max}$

TABLE 20.5

Absorption of Light by Molecules with Conjugated  $\pi$  Electron Systems

Molecule	Number of C=C Bonds	Wavelength of Maximum Absorption (nm)
$\text{C}_2\text{H}_4$	1	162
$\text{C}_4\text{H}_6$	2	217
$\text{C}_6\text{H}_8$	3	251
$\text{C}_8\text{H}_{10}$	4	304

**FIGURE 20.24** (a) Color wheel showing the colors of visible light and the corresponding complementary color at  $180^\circ$  from each color. (b) Schematic of the absorption of visible light by a solution of carotene. (c) Schematic of the absorption of visible light by a solution of indigo.

for several unsaturated hydrocarbon molecules with conjugated  $\pi$  electrons. Though all these molecules absorb in the ultraviolet, so appear colorless, the longest wavelength absorption bands of conjugated polyenes with eight or more double bonds appear in the visible region of the spectrum.

When a molecule absorbs light in the visible region of the electromagnetic spectrum (see Figure 4.3), the color we perceive is related to the absorption spectrum of the material, but only indirectly. What we see is the light transmitted through or reflected from the material, not the light absorbed. So, the color perceived is considered to be a **complementary color** to the color most strongly absorbed by the molecule, as shown in Figure 20.24. The color wheel shows the three primary colors, red, green, and blue (RGB), and their complementary colors, cyan, magenta, and yellow (CMY). The RGB system is used in computer displays and in television, and the CMYK system (K is black) is used in color printing, like that in this textbook. Figure 20.24b shows the spectrum of the transmitted light and the perceived color for carotene that absorbs in the blue-violet region of the spectrum, and Figure 20.24c shows the spectrum of the transmitted light and the perceived color (blue) for indigo, which absorbs in the yellow-orange region. Indigo is used to dye blue jeans; beta-carotene is responsible for the orange color of carrots, the colors of some processed foods, and the yellow and orange in certain bird feathers. The absorption spectra of these two compounds are shown in Figure 20.25.

**FIGURE 20.25** Absorption spectra for the dyes indigo (dark blue) and carotene (orange). The familiar mnemonic for remembering the colors in the visible region of the electromagnetic spectrum for the absorbed light is written on the top of the spectra.

**FIGURE 20.26** Approximate molecular orbitals and energy level diagram for formaldehyde. The O 2s,  $\sigma_{C-H}$  orbitals and the  $\sigma_{C-H}^*$  orbitals are omitted, as they are unimportant for the UV spectroscopy of formaldehyde.

### EXAMPLE 20.11

Suppose you set out to design a new green dye. Over what range of wavelengths would you want your trial compound to absorb light?

#### Solution

A good green dye must transmit green light and absorb all of the other colors to a significant extent so you should select a dye that absorbs in the violet–blue *and* orange–red regions of the spectrum (see Fig. 20.24).

The naturally occurring substance chlorophyll, which is responsible for the green colors of grass and leaves, absorbs light over just these wavelength ranges, converting solar energy to chemical energy stored as carbohydrates in plants. Chlorophyll is also used commercially as a green dye.

**Related Problems:** 37, 38

We now consider the electronic structure and spectra of formaldehyde, a prototype for molecules in which transitions involving nonbonding electrons are important. The Lewis dot model for formaldehyde shows 12 valence electrons, two C–H bonding pairs in  $\sigma$  orbitals at low energies, the four electrons in the C=O double bond (one pair in a low energy  $\sigma$  orbital and the other pair in the  $\pi_{C=O}$  orbital), and two lone pairs on the oxygen atom. One of the oxygen lone pairs resides in the O 2s orbital, which is at sufficiently low energy that we do not consider it when forming the MOs that are relevant to the spectroscopy and photochemistry of formaldehyde. The second lone pair on the oxygen atom resides in an O  $2p_y$  orbital that is oriented perpendicular to both the carbon–oxygen internuclear axis and the O  $2p_z$  orbital that we use to form  $\pi$  orbitals. Some of the orbitals and the associated energy level diagram for formaldehyde are shown in Figure 20.26.

The HOMO of formaldehyde is the nonbonding O  $2p_y$  orbital,  $n_O$ , and the LUMO is the  $\pi_{C=O}^*$  orbital, so the lowest energy transition is now an  $n \rightarrow \pi^*$  transition. The energy difference between the  $n_O$  and the  $\pi_{C=O}^*$  orbitals is not very large, however, so that  $n \rightarrow \pi^*$  and  $\pi \rightarrow \pi^*$  transitions are both important in the spectroscopy and photochemistry of formaldehyde. These transitions lead to  $(\sigma)^2(\pi)^2(n)^1(\pi^*)^1$  and  $(\sigma)^2(\pi)^1(n)^2(\pi^*)^1$  excited state configurations, respectively. The excited state configuration that results from an  $n \rightarrow \pi^*$  transition is

labeled simply the  $n\pi^*$  configuration and that resulting from a  $\pi \rightarrow \pi^*$  transition is labeled the  $\pi\pi^*$  configuration.

Photoelectron spectroscopy, discussed for atoms in Chapter 5 and for diatomic molecules in Chapter 6, provides important clues about the nature of these molecular orbitals; the photoelectron spectrum of formaldehyde is shown in Figure 20.27a. The three sets of peaks observed arise from photoionization in which the electron originated in three distinct molecular orbitals. The **vibrational fine structure** observed as a series of closely spaced lines in each band allows us to identify the orbitals involved and to confirm the validity of our energy level diagram. Energy in excess of the minimum necessary to ionize a molecule can excite vibrations in the positive ion left behind, and the nature of those excitations can be used to identify the orbital from which the electron was removed. Removing an electron from a bonding MO weakens the corresponding bond and lowers that bond's vibrational frequency in the ion from that in the parent molecule. The equilibrium bond length in the ion increases from that in the neutral, so the ion is formed in vibrational eigenstates with many quanta in that bond's stretching motion. (This is a result of what is called the **Franck-Condon principle**—the amplitude of the ion's vibrational wave function at the inner turning point of its C—O vibrational motion has internuclear distances similar to that of the neutral molecule's equilibrium geometry.) Removing an electron from an antibonding orbital strengthens the bond (increases its bond order), so the resulting ion has a larger vibrational frequency in the bond on which the antibonding orbital was localized. Photoelectron spectra from removing an electron from a nonbonding orbital does not affect bonding very much; the vibrational frequencies of the ion are very close

**FIGURE 20.27** (a) Photoelectron spectrum of formaldehyde. The lines labeled Ar and Xe are due to photoemission from residual rare gases in the sample chamber. (b) Formaldehyde vibrational modes and frequencies in the ground electronic state. (Adapted from D. W. Turner, C. Baker, A. D. Baker, and C. R. Brundle, *Molecular Photoelectron Spectroscopy*, John Wiley & Sons, London, 1970, p. 141.)

to those in the parent molecule and the equilibrium bond lengths in the neutral molecule and ion are similar, so the strongest transition does not involve vibrational excitation of the ion. These general characteristics are summarized in the *Connection to Instrumental Analysis* in Chapter 6. Let's use this approach to interpret the photoelectron spectrum of formaldehyde and identify the orbitals associated with each set of bands. The peak that appears at 10.88 eV arises from electrons that have the lowest binding energies and it is assigned, therefore, to the HOMO. There is very little vibrational fine structure, with most of the intensity appearing in the 10.88 eV peak. Two small peaks appear next to the 10.88 eV peak; they correspond to forming ions with a quantum in vibration in one of its vibrational modes, and the shifts in  $\text{cm}^{-1}$  from the 10.8 eV peak give the vibrational frequencies of the formaldehyde cation. The ion's vibrational frequencies observed agree closely with the C–H stretching, C=O stretching, and H–C–H bending vibrations of formaldehyde in its ground electronic state shown in Figure 20.27b. This allows us to confirm our assignment of the HOMO as the nonbonding orbital. Let's now examine the set of peaks between 14 and 15 eV. The frequency observed in the vibrational progression corresponds to multiple excitations of a single mode with a frequency of about  $1200 \text{ cm}^{-1}$  and deuterium isotope substitution has no effect on the frequency observed. We thus assign this mode to the C=O stretch in the ion and identify the orbital from which the electron was removed as the bonding  $\pi$  orbital on the basis of the decrease in vibrational frequency (the ground-state frequency is  $1744 \text{ cm}^{-1}$ ). The lower vibrational frequency is consistent with a reduction in the CO bond order that results from the removal of an electron from a bonding orbital localized on the CO bond. The vibrational frequency measured in the progression around 16 eV is lower than the frequency of the corresponding vibration in the ground state of formaldehyde. It is further reduced on deuterium substitution by almost exactly  $1/\sqrt{2}$ , so the vibration must involve H atom motion. These results suggest that the photoelectron produced in the 15.85-eV band came from one of the bonding CH  $\sigma$  orbitals.

Organic molecules with C=C double bonds, conjugated C=C double bonds, a carbonyl group (C=O), and aromatic functional groups like the phenyl group all evidence a strong  $\pi \rightarrow \pi^*$  transitions (molar absorption coefficients at the peak wavelength  $\lambda_{\text{max}}$  for the most intense peaks lie in the range  $10^3\text{--}10^5 \text{ M}^{-1} \text{ cm}^{-1}$ ). These functional groups are thus often referred to as chromophores. In molecules with nonbonding electron pairs on O, N or S atoms, such as formaldehyde, there is also an  $n \rightarrow \pi^*$  transition to a lower lying singlet excited state; these are generally weaker than  $\pi \rightarrow \pi^*$  transitions with  $\epsilon_{\text{max}}$  in the range  $10\text{--}10^3 \text{ M}^{-1} \text{ cm}^{-1}$ . They are central to the spectroscopy and photochemistry of molecules containing carbonyl and heteroaromatic chromophores, for example, like those found in amino acids and nucleic acids. In Section 20.1 and Figure 20.2 we presented the radiative (fluorescence and phosphorescence) and non-radiative **photophysical processes** that return excited molecules to their ground states. The nonradiative process that causes transitions between states of the same spin is called **internal conversion** whereas the nonradiative process that causes transitions between different spin states is called **intersystem crossing**. Molecules formed in excited vibrational levels after internal conversion or intersystem crossing can lose vibrational energy through collisions with solvent molecules in condensed phases, a process generally referred to as vibrational relaxation. This returns the molecules to a thermally equilibrated distribution, favoring the lower vibrational levels of that state.

When a molecule absorbs a high energy photon, the energy can also result in fission of a bond in the molecule. This is a **photochemical process** called **photodissociation**. Imagine exciting  $\text{H}_2^+$  to the repulsive excited electronic state

**FIGURE 20.28** Three electronic states of OH: the ground electronic state ( $\tilde{X}$ ), the lowest excited electronic state ( $\tilde{A}$ ), and a repulsive excited state that results in the OH molecules in the  $\tilde{A}$  state predissociating to H + O.

labeled  $1\sigma_u^*$  in Figure 6.6. The force on the excited state pushes the two atoms away from each other, and the molecule dissociates to H + H<sup>+</sup>. The excited state does not have a bound region of the potential, so it cannot support any bound vibrational states. Molecules may have both bound excited electronic states and repulsive ones. If you promote HCl to the excited state depicted in Figure 20.1, the absorption spectrum in this region has sharp features corresponding to exciting to different vibrational levels in the excited electronic state, but if you excite HCl at photon energies near 65,500 cm<sup>-1</sup> the absorption spectrum is broad and structureless. The excited state reached at these energies is directly repulsive (you have promoted an electron to the antibonding  $\sigma^*$  orbital of the H–Cl bond) and the molecule dissociates to H + Cl on this repulsive excited electronic state in less than a few fsec (it does not have time to undergo internal conversion to the ground electronic state). The excited state of OH reached at 32,477 cm<sup>-1</sup> (called the  $\tilde{A}$  state) shown in Figure 20.28 is formed from a bound excited state coupled to a repulsive excited state. The OH molecules in the higher rotational levels of  $v' = 1$  and all of the rotational states in  $v' = 2$  in the  $\tilde{A}$  state can couple to this repulsive excited state and undergo a process called predissociation. The typically sharp absorption features appear broadened for vibrational levels in the  $\tilde{A}$  state that are above the energy where the bound excited state crosses the repulsive excited state. Finally, even if the excited electronic state is a bound one, evidencing sharp peaks in the absorption spectrum spaced by the  $h\nu_{\text{vib}}$  for one of the excited state vibrational modes, the molecule can undergo internal conversion to high vibrational levels of the ground electronic state with enough energy to break a bond. A competition between vibrational relaxation and dissociation of the highly vibrationally excited molecules after internal conversion to  $S_0$  ensues if the vibrational energy is sufficient to break one of the bonds in the molecule. For example, when  $^1n\pi^*$  excited formaldehyde undergoes internal conversion to  $S_0$ , both dissociation to H<sub>2</sub> + CO and to H + HCO compete with vibrational relaxation. Spectroscopists describe this as predissociation via internal conversion to the high vibrational levels in the ground electronic state.

**EXAMPLE 20.12**

The ultraviolet absorption spectrum of methyl iodide evidences a broad structureless band centered near 260 nm, and a series of sharp, strong absorption lines at excitation wavelengths shorter than 200 nm. In which region of the spectrum are you likely to be exciting the molecule to a repulsive electronic state? What are the likely products of this direct dissociation? In which absorption band are you likely to detect fluorescence with a high quantum yield?

**Solution**

The broad absorption band near 260 nm cannot support vibrational states, so it is likely a repulsive excited state. The  $\sigma_{\text{C-H}}^*$  orbital is quite high in energy near the equilibrium geometry of methyl iodide, so the 260 nm photon likely excites

an electron to a  $\sigma^*$  orbital localized on the C—I bond. The molecules would feel a repulsive force between the I and the C atom on this excited state, so the likely photodissociation products are methyl ( $\text{CH}_3$ ) radicals and iodine atoms. Fluorescence must compete with this very fast dissociation process, so the **quantum yield** of I atoms would be close to 1 and the quantum yield of fluorescence would be very small. If you instead excite methyl iodide with 200 nm photons into one of the sharp features in the higher energy region of the UV absorption spectrum, this excited state can support bound vibrational states and you should be able to observe a substantial fluorescence quantum yield.

**Related Problems:** 43, 44

## 20.6 Introduction to Atmospheric Chemistry

A great deal of attention has been focused on three areas of atmospheric science in the last forty years or so: increased air pollution in the troposphere, the depletion of ozone in the stratosphere, and climate change. Oxides of nitrogen (collectively called  $\text{NO}_x$ ) and oxides of sulfur (collectively called  $\text{SO}_x$ ) come from the combustion of fuels, the former mostly from vehicles and the latter mostly from power plants. They lead to the production of ground-level ozone as well as to acid rain, both of which are serious environmental pollutants. Stratospheric ozone depletion is considered to be a contributing factor to the significant increases in the incidence of skin cancer observed over the past 30 years, based upon both epidemiology and animal model studies. Ozone depletion has been traced to a class of refrigerants and propellants called chlorofluorocarbons (CFCs), which have been banned by international agreement. Climate change has generally been attributed to increases in the concentrations of  $\text{CO}_2$ ,  $\text{CH}_4$ ,  $\text{N}_2\text{O}$ , and other atmospheric “greenhouse gases” over the past 150 years; these increases in concentration have been attributed to human activities.

Evidence for stratospheric ozone depletion began to appear globally in the early 1970s, and the existence of a dramatic “ozone hole” over Antarctica was confirmed by the mid 1980s. A mechanism for the catalytic destruction of ozone by chlorine radicals produced by photolysis of CFCs was first proposed in the early 1970s, and by 1987 the evidence was so convincing that the international community banned the production of these chemicals worldwide. In this section we discuss the chemistry and photochemistry central to stratospheric ozone depletion because the chemical mechanisms are now quite well established and those scientific advances led to an international solution to the problem.

### 20.6.1 The Atmosphere

Although the chemical composition of the atmosphere summarized in Table 9.1 describes the average makeup of the portion of the atmosphere closest to the Earth’s surface, it masks the variation in chemical composition with height, the dramatic role of local fluctuations in the concentrations of trace gases, and the dynamics underlying the observed average concentrations. The atmosphere is a complex chemical system that is far from equilibrium. Its properties are determined by an intricate combination of thermodynamic and kinetic factors. It is a multilayered structure, bathed in radiation from the sun, which interacts with

the oceans and landmasses at the Earth's surface. We generally identify four layers of the atmosphere, on the basis of characteristic temperatures, temperature profiles, and densities (Fig. 20.29). In the outer two layers (the **thermosphere** and the **mesosphere**, above 50 km), the density is low and the gases have been extensively ionized by intense, high-energy solar radiation. The third layer, the **stratosphere**, occupies the region from 12 km to 50 km (approximately) above the Earth's surface. The **troposphere** is the lowest region, reaching up to about 12 km from the Earth's surface. In the troposphere, warmer air lies beneath cooler air. This is a dynamically unstable situation because warmer air is less dense than cooler air and tends to rise so convection takes place, mixing the gases in the troposphere and determining the weather. In the stratosphere the temperature increases with height and there is little vertical mixing from convection. Mixing across the borders between the layers is also slow, so most chemical processes in each layer can be described separately.

The study of atmospheric chemistry dates back to the 18th century. Cavendish, Priestley, Lavoisier, and Ramsay were the first scientists to study the composition of the atmosphere. Recent advances in atmospheric science have come from the further development and integration of a number of scientific disciplines. The sensitivity of chemical analysis has greatly improved; concentrations of trace gases in the atmosphere are routinely measured at the part-per-trillion (ppt) level. We are now able to generate high-spatial-resolution maps of the distributions of chemical species across the globe daily using a combination of land-based, airborne, and satellite sensors. NASA's Aura satellite, for example, has four spectrometers that measure microwave, infrared, visible, and ultraviolet spectra of some 30 atmospheric constituents each day to map out the spatial distributions of these species in three dimensions. These maps provide important data that atmospheric chemists and meteorologists use to test and refine their climate models. Laboratory studies of the relevant reactions provide rate constants, activation energies, and mechanisms that must be included in these models. The role of heterogeneous chemical reactions in the atmosphere began

**FIGURE 20.29** Variation of temperature with altitude in the atmosphere, showing its layered structure.

to be appreciated about 15 years ago, and we have learned a great deal about the reactions of molecules like  $\text{ClONO}_2$  that occur on, and can be catalyzed by, particulates like ice crystals and sulfate aerosols, for example; these reactions are part of a series of reactions that lead to the formation of the ozone hole. Finally, large-scale computer simulations are now able to tackle the very difficult problem of analyzing systems of coupled chemical reactions including transport. Dynamic simulations of the reactions within and diffusion between the layers of the atmosphere have contributed a great deal to our understanding of atmospheric chemical processes.

### 20.6.2 Tropospheric Chemistry

The troposphere is the part of the atmosphere in contact with the Earth's surface. It is therefore most directly and immediately influenced by human activities, especially by the gases or small particles emitted into the air by motor vehicles, power plants, and factories. Some pollutants have long lifetimes and are spread fairly evenly over the Earth's surface; others are localized around cities or in regions where they are produced and where local weather patterns keep them from dispersing. Six pollutants are of the greatest concern: carbon monoxide, nitrogen oxides ( $\text{NO}_x$ ), ozone, sulfur oxides ( $\text{SO}_x$ ), particulate matter, and lead. We do not discuss particulate matter or lead, except to point out their effects on health, because the chemistry involved is unrelated to the chemistry of the other four pollutants. We begin by discussing the atmospheric chemistry and photochemistry of carbon monoxide, the nitrogen oxides, and ozone, because they arise mostly from vehicle emissions and because their reactions are coupled. Carbon monoxide, a product of incomplete combustion of fuels, is a poison at sufficiently high concentrations. Nitrogen oxides, generated at high temperatures in engines, lead to the production of both ground-level ozone and photochemical smog. Ozone is considered a secondary pollutant because it is generated by subsequent reactions of the primary pollutant, the nitrogen oxides. Finally, we discuss the atmospheric chemistry of sulfur oxides, which are produced primarily by the combustion of coal and oil to generate electricity. Sulfur oxides, and to a lesser extent nitrogen oxides, are precursors to acid rain. All of these criteria pollutants pose serious threats to human health as well as to the health of plants and animals.

Most of the anthropogenic carbon monoxide in the atmosphere is produced by incomplete combustion of fuel in motor vehicles; this source is responsible for about 60% of the CO produced across the United States, but up to 95% of the CO produced in urban areas with high densities of motor vehicle traffic. CO concentrations show seasonal variations with the highest levels occurring in the winter, due to a combination of increased combustion for heating as well as atmospheric conditions (inversion layers) that tend to trap CO and other pollutants.

Nitrogen oxides are major air pollutants. Although they are produced by natural sources such as volcanoes and lightning, most of the nitrogen oxides that enter the atmosphere are byproducts of combustion reactions used to generate energy for transportation or other purposes. About half come from motor vehicle emissions and half from industrial, commercial, and residential sources. The most important of these nitrogen oxides are NO and  $\text{NO}_2$ , which, along with their atmospheric oxidation products such as  $\text{HNO}_3$ , are collectively referred to as " $\text{NO}_x$ ." All of the oxides of nitrogen have positive free energies of formation at  $25^\circ\text{C}$ , making them thermodynamically unstable with respect to decomposition to the elements. The standard free energy of formation ( $\Delta G_f^\circ$ ) for NO, for example, is  $+86.6 \text{ kJ mol}^{-1}$ , which implies an equilibrium constant for the reaction  $K_{298} = 6 \times 10^{-16}$  for the reaction

giving equilibrium concentrations of NO of approximately  $10^{-10}$  ppm at room temperature. Nitrogen oxides form to a greater extent when air is heated to higher temperatures in industrial processes or in automobile engines; the equilibrium concentration of NO rises to about 100 ppm at  $800^{\circ}\text{C}$ , the operating temperature of an internal combustion engine, and to about 1000 ppm at  $1500^{\circ}\text{C}$ , the operating temperature of a gas turbine. Nitrogen oxides accumulate to concentrations much higher than their equilibrium concentrations at ambient temperatures because they decompose slowly. The long residence times of these oxides in the atmosphere demonstrate the greater importance of kinetics, relative to thermodynamics, in atmospheric chemistry.

$\text{NO}_2$  is the key player in the tropospheric chemistry of the nitrogen oxides.  $\text{NO}_2$  is the reddish-brown gas that obscures visibility on smoggy days in urban areas such as Los Angeles and Houston. The photolysis of  $\text{NO}_2$  is responsible for the generation of ground-level ozone, as well as for initiating a series of reactions that lead to photochemical smog, beginning with the following reactions.

where M is a third body that carries away some of the excess vibrational energy of the products (see Section 18.4). Ground-level ozone concentrations are controlled to some extent by the following reaction in which NO acts as a scavenger.

Ozone concentrations in metropolitan areas begin to increase in the mornings, as commuters head off to work, and then decrease during the evenings and overnight. The NO scavenging reaction reduces ozone concentrations, and the  $\text{NO}_2$  that is produced is not photolyzed during those hours. The  $\text{NO}_2$  and  $\text{O}_3$  concentrations predicted by the preceding mechanism are much lower than observed, so other mechanisms for producing these species must contribute. The most important of these involve the hydroxyl radical, which is produced in the atmosphere by photolysis of ozone and subsequent reaction of the photogenerated oxygen atom with water as follows. (The single dot represents a free radical; we add this indicator below only to OH and organic radicals, not other radicals such as NO and  $\text{NO}_2$ )

The hydroxyl radical is an extremely powerful oxidizing agent not only because it has an unfilled valence shell but also because of the extraordinary thermodynamic stability of the products created:  $\text{CO}_2$  from CO oxidation and  $\text{H}_2\text{O}$  from H atom abstraction reactions. The hydroxyl radical is sometimes called “the detergent of the atmosphere” because it cleans up harmful pollutants like CO and hydrocarbons. It also prevents hydrochlorofluorocarbons from leaving the troposphere and entering the stratosphere, where they have the potential to destroy ozone. Unfortunately, however, the hydroxyl radical also plays an important role in the generation of photochemical smog and in the reactions that lead to acid rain through the following series of reactions.

where RH is a hydrocarbon and  $\bullet\text{R}$  is the radical produced by hydrogen abstraction. The hydroperoxyl radical  $\bullet\text{OOH}$  and any number of peroxy

radicals  $\bullet\text{ROO}$  formed from various hydrocarbons oxidize  $\text{NO}$  to  $\text{NO}_2$  as follows

thus providing the source of the “extra”  $\text{NO}_2$  to account for the levels of ozone produced from its photolysis and subsequent reactions.

The last set of reactions we consider are those between peroxy radicals ( $\bullet\text{ROO}$ ), peroxyacyl radicals ( $\bullet\text{RC}(\text{O})\text{OO}$ ), and  $\text{NO}_2$  to form peroxyalkylnitrates and peroxyacylnitrates as follows

The latter class of compounds, the peroxyacylnitrates or **PANs**, are among the most abundant nitrogen-containing compounds in the troposphere, and they are distinct signatures of photochemical smog in polluted urban areas. The oxides of sulfur create pollution problems on regional and even global scales because they have longer lifetimes in the atmosphere than the nitrogen oxides. Some of the  $\text{SO}_2$  and  $\text{SO}_3$  in the air comes from biological processes and volcanoes, but about 70% of  $\text{SO}_2$  emissions have anthropogenic origins, the most important of which is the combustion of fossil fuels (coal in particular) to generate electricity in power plants. If the sulfur is not removed from the fuel or the exhaust gas,  $\text{SO}_2$  enters the atmosphere as a stable but reactive pollutant. Direct oxidation of  $\text{SO}_2$  by atmospheric oxygen is allowed thermodynamically, but the kinetics are so slow in the absence of a catalyst that the reaction does not contribute significantly to tropospheric  $\text{SO}_3$  concentrations. Further oxidation of  $\text{SO}_2$  by atmospheric radicals leads to sulfur trioxide by the following series of reactions, and the reaction of the atomic oxygen produced by the decomposition of the hydroperoxy ( $\bullet\text{OOH}$ ) radical can react with molecular oxygen in the third step to provide another source of ground-level ozone.

$\text{NO}_2$  and  $\text{SO}_3$  are both acid anhydrides that react with hydroxyl radicals and water vapor in the air to form nitric ( $\text{HNO}_3$ ) and sulfuric ( $\text{H}_2\text{SO}_4$ ) acids, respectively, which may deposit on the Earth in both wet and dry forms.

Acid deposition is the most general term for this set of processes; acid precipitation refers to the wet processes that include rain, snow, sleet, or hail, with **acid rain** being the process most familiar to the public. Even “pure” rainwater is slightly acidic due to the reaction of atmospheric  $\text{CO}_2$  with  $\text{H}_2\text{O}$  to form carbonic acid,  $\text{H}_2\text{CO}_3$ , resulting in a pH in the range 5.3–5.6 (the presence of other acidic species contributes to this variability). Acid rain, on the other hand, is characterized by pH values in the pH = 4–5 range, which is deleterious to both health and the environment. The pH of acid rain varies considerably across the United States, ranging from 5.7 in the West to less than 4.7 in parts of the Northeast in 2012. The acid rain problem in the Northeast is due to the large number of coal-fired power plants, steel mills, and other industries that rely on coal and emit  $\text{SO}_2$  in neighboring states such as Ohio and Pennsylvania. In the

years from 2002 to 2012 the pH of acid rain in the Northeast improved substantially (in 2002, it was more acidic, near 4.3). The environmental consequences are also more serious, particularly for aquatic species, because lakes in the Northeast tend to have granite beds, which do not provide any buffering capacity like lakes in which limestone ( $\text{CaCO}_3$ ) is the lakebed.

The oxides of nitrogen and sulfur are respiratory irritants that are especially problematic for those in “sensitive groups” that include children, the elderly, and individuals with respiratory problems. Health effects can be serious and even catastrophic. More than 4,000 people died in London during a five-day period in 1952. Cold weather necessitated burning large quantities of sulfur-rich coal, the emissions from which reacted with the typical London fog to form the deadly acid aerosol. As recently as 1982, the pH of the air in the Los Angeles basin fell to 1.5, in some areas leaving residents breathing nearly 0.1 M nitric acid. The Clean Air Act has substantially improved this situation.

### 20.6.3 Stratospheric Chemistry

Light emitted from the sun resembles that of a 5777 K black body (see Section 4.2). Although the intensity of the radiation drops rapidly toward shorter wavelengths in the UV region of the spectrum, a considerable number of very high-energy UV photons strikes the Earth’s atmosphere every second. The energy of a 200 nm photon (at the border between the ultraviolet and vacuum ultraviolet) is more than 6 eV, or about  $600 \text{ kJ mol}^{-1}$ , which is sufficient to break all but the strongest chemical bonds. Radiation at shorter wavelengths causes ionization, which is even more damaging to molecules and biological tissues. Fortunately, there is a substantial layer of ozone in the stratosphere (see Fig. 20.30) that absorbs most of the harmful ultraviolet radiation not absorbed by  $\text{O}_2$ , affording us substantial protection. In the mid-1970s, evidence began to accumulate that suggested that the concentration of stratospheric ozone was decreasing dramatically and that CFCs transported from the troposphere to the stratosphere were responsible. We describe the natural cycle for the production and destruction of  $\text{O}_3$  in the stratosphere, the mechanism by which it absorbs UV radiation, the role of Cl radicals in ozone depletion, the factors that led to the dramatic seasonal variation in the ozone concentrations over the Antarctic (and more recently, the Arctic) and, finally, the corrective steps that have been taken and the results observed to date.

**FIGURE 20.30** Variation in ozone concentrations with altitude in the atmosphere showing the stratospheric ozone layer and accumulation in the troposphere. (Adapted from Lucy Pryde Eubanks, Catherine H. Middlecamp, Carl E. Heltzel, and Steven W. Keller, *Chemistry in Context*, 6th ed., McGraw-Hill, New York, 2009, p. 58.)

**FIGURE 20.31** The Chapman cycle showing the key reactions for ozone formation and destruction in the stratosphere. (Adapted from Lucy Pryde Eubanks, Catherine H. Middlecamp, Carl E. Heltzel, and Steven W. Keller, *Chemistry in Context*, 6th ed., McGraw-Hill, New York, 2009, p. 74.)

The steady-state concentration of  $\text{O}_3$  in the stratosphere is reasonably well accounted for by the Chapman cycle (Fig. 20.31), named after the English physicist, Sydney Chapman. Chapman proposed the following series of coupled photochemical and thermal reactions: Photolysis of  $\text{O}_2$  by UV radiation ( $\lambda < 242 \text{ nm}$ ) produces oxygen atoms, which then react with  $\text{O}_2$  in the second step of the cycle to produce  $\text{O}_3$ . The second reaction may be reversed photochemically by the absorption of longer wavelength ( $\lambda < 340 \text{ nm}$ ) UV radiation, or the ozone produced may react thermally with oxygen atoms to regenerate  $\text{O}_2$ . The *steady state* concentration of  $\text{O}_3$  depends upon: (1) the  $\text{O}_2$  concentration at the altitude of interest and (2) the flux and wavelength distribution of UV radiation at that altitude. The average ozone concentration in the atmosphere is plotted as a function of altitude in Figure 20.30; note the accumulation of ozone over a rather broad region of the stratosphere. The Chapman cycle actually overestimates stratospheric ozone concentrations because it does not consider other naturally occurring pathways for ozone depletion, the most important being reactions with  $\bullet\text{H}$  and  $\bullet\text{OH}$  radicals formed by the photolysis of stratospheric water vapor, but also reactions catalyzed by  $\text{NO}$  and  $\text{NO}_2$ , natural sources of which include oxidation of  $\text{N}_2$  in forest fires, by lightning or volcanic eruptions.

UV radiation has been classified into three types based upon its absorption by a series of chosen glasses, rather like the three kinds of ionizing radiation were classified by their ability to penetrate three different kinds of matter. Ozone does not absorb appreciably at wavelengths longer than  $340 \text{ nm}$ , so the solar flux at the surface of the Earth over the region  $400 - 340 \text{ nm}$  is about the same as at the "top" of the atmosphere. Radiation from this region is called UV-A, and it is the least damaging to biological tissues.  $\text{O}_3$  begins to absorb strongly below  $340 \text{ nm}$ , whereas  $\text{O}_2$  begins to absorb strongly only below  $242 \text{ nm}$ . Radiation with wavelengths between  $340$  and  $280 \text{ nm}$  (where proteins begin to absorb) is called UV-B radiation, and it is more damaging to biological tissues. UV-B radiation can ionize molecules and form reactive free radicals, which are damaging to cells. It can also cause specific mutations in DNA that lead to skin cancers. UV-C radiation, with wavelengths less than  $280 \text{ nm}$ , is the most damaging of all but it is effectively absorbed by atmospheric  $\text{O}_2$ .

The extent of biological damage caused by UV radiation is a strong function of wavelength;  $280\text{-nm}$  radiation is a million times more damaging than  $340\text{-nm}$  radiation. The strongest of the ozone UV absorption bands begins at about  $350 \text{ nm}$ , reaching a peak at about  $280 \text{ nm}$ , as shown in Figure 20.32. The absorption cross section is significant,  $\sigma \approx 10^{-17} \text{ cm}^2$ , which corresponds to a molar extinction coefficient  $\epsilon \approx 10^3$ .

The German meteorologist Paul Crutzen at Mainz was the first to demonstrate the catalytic destruction of ozone by a free radical,  $\text{NO}$ , which was produced by natural processes. This discovery led Harold Johnston at Berkeley to propose that the  $\text{NO}$  produced by supersonic transports could pose a serious

**FIGURE 20.32** Ozone absorption in the visible and ultraviolet. (Adapted from J. Orphal, A critical review of the absorption cross-sections of  $O_3$  and  $NO_2$  in the ultraviolet and visible, *Journal of Photochemistry and Photobiology A: Chemistry* 157 (2003), 185–209.)

**FIGURE 20.33** Lewis dot structures of four chlorofluorocarbons (CFCs).

threat to the ozone layer, and scientists began to consider other potential ozone-depleting molecules. The American chemists Mario Molina and Sherwood Rowland, both then at the University of California at Irvine (Rowland went to high school, college, and graduate school at The University of Chicago), proposed that the photolysis of CFCs (see Figure 20.33) could produce reactive chlorine-containing free radicals that could also catalyze ozone destruction, by the mechanism proposed below. The Freons CFC-11 and CFC-12 shown are two of the most important CFCs developed commercially in the 1930s for use as refrigerants and propellants.

Photolysis of CFCs with UV light with wavelengths shorter than 220 nm produces chlorine atoms and radical fragments as shown below, for example

The chlorine atom is a very reactive free radical that is thought to destroy ozone by the catalytic mechanism shown below. The net reaction is the conversion of two  $O_3$  molecules into three  $O_2$  molecules.

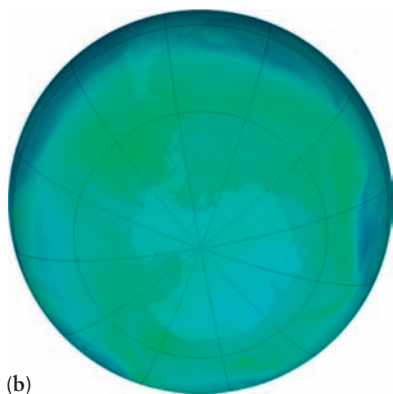

How were these reactions, which were studied in the laboratory, linked to the stratospheric ozone problem, and how did scientists rule out naturally occurring sources of Cl radicals as the active catalyst? Several lines of evidence supported the conclusion that the photolysis of CFCs was the source of the reactive Cl. First, an inverse correlation between  $ClO\bullet$  and ozone concentrations was established in an experiment in which a NASA jet measured the concentrations of these gases as it flew from Chile to Antarctica, entering the ozone hole as shown in Figure 20.34. (The seasonal depletion of the ozone layer over Antarctica is particularly dramatic, so this region was chosen for this experiment.) Although correlation does not prove causality, the level of detail shown in the mirror images was considered extremely good evidence that CFCs were

**FIGURE 20.34** Inverse correlation between stratospheric chlorine and stratospheric ozone levels as a function of latitude, as measured by a NASA jet flying into the Antarctic ozone hole. **FIGURE 20.35** (a) Image of the Antarctic ozone hole taken by the Ozone Monitoring Instrument on September 25, 2006. The hole (one of the largest ever recorded) covered an area greater than North America and the ozone levels were below 150 ppb, compared with the global annual average of about 350 ppb. (b) Ozone levels above Antarctica on December 25, 2006 showing substantial recovery.

responsible for ozone depletion. Second, satellites began to observe that the concentrations of halogen-containing compounds in the stratosphere were appreciable. Finally, the appearance of HF and other fluorine-containing compounds in the stratosphere and the correlation of their concentrations with the amounts and compositions of the CFCs provided the definitive proof. There are no naturally occurring sources of fluorine that could account for the HF appearing in the stratosphere. Detailed climate models, using accurate kinetic data measured in the laboratory, provided additional supporting evidence for the proposed mechanism. Molina, Rowland, and Crutzen were awarded the 1995 Nobel Prize in Chemistry for their pioneering work on this problem.

The ozone concentrations above Antarctica show dramatic seasonal variations in the ozone concentrations and depletion much greater than that averaged over the entire atmosphere. Figure 20.35 shows the ozone “hole” over Antarctica on September 25, 2006 and a corresponding image taken on December 25, 2006. The purple in the false color scale represents the lowest ozone concentrations, green is the average, and red the highest. A Dobson Unit is about 1 part per billion (ppb). Comparing the two images, we see that the ozone concentration over Antarctica during the Antarctic spring has dropped to less than a third of its average value. What mechanism causes such a dramatic variation? Several factors, acting in concert, are responsible. The Antarctic land mass is huge, and the region above the South Pole is the coldest spot on Earth. Circulating air masses prevent warmer air from entering the region during the Antarctic winter (July through September), creating conditions favorable for the formation of polar stratospheric clouds (PSCs). These PSCs are thought to catalyze the conversion of less reactive molecules like  $\text{ClONO}_2$  and  $\text{HCl}$  into more reactive species like  $\text{HOCl}$  and  $\text{Cl}_2$ , which are then stored on the surfaces of these clouds during the winter months, effectively “pre-concentrating” them. Sunlight returns in spring and photolyzes the accumulated store of chlorine-containing precursors, releasing relatively large amounts of  $\text{Cl}\cdot$  in a relatively short period of time. The hole appears quickly and dramatically. As spring turns into summer the clouds evaporate, the weather patterns change, and air from other regions of the atmosphere flows into the region, refilling the ozone hole. The situation is not as dramatic in the Arctic, presumably due to the smaller land mass, warmer temperatures, and lack of circulating winds, but ozone depletion over the North Pole is clearly evident and being closely monitored.

The international community quickly came together to address this problem globally, once the underlying science had been established and accepted. As

early as the late 1970s, just a few years after Rowland and Molina's pioneering work, the U.S. banned the use of CFCs as propellants in spray cans and, a decade later, as foaming agents. In 1987, the Montreal Protocol was signed by nearly 100 countries. It called for the reduction of global CFC production to half the 1986 levels by 1998; underdeveloped countries were given longer to comply. Replacing CFCs with hydrochlorofluorocarbons (HCFCs) caused the trend in the stratospheric chlorine concentrations to reverse, but even HCFCs can lead to ozone depletion. The 1993 Copenhagen amendment to the Montreal protocol requires discontinuing their production by 2030, so HCFCs are currently being replaced by hydrofluorocarbons (HFCs).

## 20.7 Photosynthesis

About 1% of the energy that reaches the Earth's surface is converted into chemical energy by **photosynthesis**—a remarkably efficient sequence of photophysical processes and oxidation–reduction reactions that leads to the formation of a six-carbon sugar molecule plus molecular oxygen as follows

This reaction is the reverse of the spontaneous oxidation of glucose to  $\text{CO}_2$  and  $\text{H}_2\text{O}$  by combustion or metabolism, and it requires an external driving force to occur as written. The energy of the light absorbed in the photosynthetic process increases the Gibbs free energy of the reactants and provides the necessary driving force. The end result of this carbon dioxide fixation reaction is the conversion of solar energy into chemical potential energy. We focus, in this section, on the elementary physical and chemical photosynthetic processes and do not discuss in any detail the structures and organization of the components of the photosynthetic membranes that carry out the reactions. These components include a number of membrane-bound enzyme complexes that are highly organized spatially to catalyze the various light-driven and dark-driven reactions of photosynthesis. The biochemistry required to understand the details of these enzyme-catalyzed reactions is beyond the scope of this textbook. Our primary objective is to show how the concepts we introduced at the beginning of this chapter, along with the molecular level picture of redox processes developed in Chapter 17, can be used to explain the initial steps of energy transduction in photosynthesis.

Photosynthesis occurs both in bacteria and in green plants by similar mechanisms, the differences being in the nature of their respective photosystems and reducing agents. Photosynthesis consists of a series of light reactions, discussed below, and dark reactions leading to  $\text{CO}_2$  fixation that we just touch upon. The light reactions and dark reactions have been shown to be independent of one another. Irradiating photosynthetic systems in the absence of  $\text{CO}_2$  generates  $\text{O}_2$ ; transferring a system prepared in this way into the dark and supplying it with  $\text{CO}_2$  results in  $\text{CO}_2$  fixation. The most general reaction for  $\text{CO}_2$  fixation can be written as

where  $\text{H}_2\text{A}$  is a hydrogen donor that is the reducing agent, and  $\text{CH}_2\text{O}$  is the carbohydrate group, the building block for sugars, starches, and cellulose in plants. The hydrogen donor in bacterial photosynthesis is often  $\text{H}_2\text{S}$ , and it is  $\text{H}_2\text{O}$  in plants. Isotope labeling experiments showed that the  $\text{O}_2$  produced in plant photosynthesis came from the water and not the  $\text{CO}_2$ , and we write the general photosynthetic reaction as shown so that we can track the source of the oxygen atoms through the process. The energy provided by light is ultimately

transduced in the form of the high-energy molecule ATP and a strong reducing agent called NADPH by the coupled reactions.

Hydrolysis of ATP to ADP is coupled to many otherwise nonspontaneous reactions in biochemistry because it provides a driving force ( $\Delta G$ ) of about  $50 \text{ kJ mol}^{-1}$ . ATP is synthesized as part of the photosynthetic process by an enzyme powered by a transmembrane proton gradient that is set up by a series of light-driven electron transfer reactions. It is used as a source of free energy that couples into the dark reactions leading to  $\text{CO}_2$  fixation. The reducing agent NADPH, the other primary product of photosynthesis, provides reducing equivalents for  $\text{CO}_2$  reduction to  $\text{CH}_2\text{O}$ .

The initial photosynthetic events are very similar in both bacteria and in plants. Light is absorbed by a number of pigments, the most important of which are the chlorophylls, which are shown along with their absorption spectra in Figure 20.36.

Chlorophylls are coordination complexes of magnesium and various substituted tetrapyrroles that are built around the large planar ring structure shown. The basic structure of chlorophyll is similar to that of heme, the iron-bearing component in myoglobin and hemoglobin (see the *Connection to Biology* in Chapter 8). The two strong absorption bands observed near  $650 \text{ nm}$  and  $450 \text{ nm}$  arise from  $\pi \rightarrow \pi^*$  transitions in the large aromatic ring, and they are responsible

**FIGURE 20.36** Chlorophyll structures (a) and spectra (b).

**FIGURE 20.37** Structures of the accessory pigments (a)  $\beta$ -carotene and (b) phycocyanobilin.

for the green color of plants. The structures of accessory pigments like carotene (which gives carrots their color) and phycocyanobilin are shown in Figure 20.37; their function is to absorb light that is not absorbed by chlorophyll, thereby utilizing the solar spectrum more efficiently.

We discussed various pathways for excited state relaxation in Sections 20.1 and 20.5 and alluded to the importance of energy transfer and electron transfer processes in photosynthesis. A photosynthetic unit comprises hundreds of chlorophyll molecules and accessory pigments whose purpose is to absorb large quantities of light and efficiently funnel the energy to a special pair of chlorophyll molecules called the reaction center. Most of the chlorophyll in the photosynthetic unit acts like a large antenna that captures light. Energy is transferred between the molecules that comprise the array by a dipole–dipole or Förster energy transfer mechanism, a nonradiative process by which excited molecules transfer energy to neighboring ground-state molecules without either emission by the donor or absorption by the acceptor. The mechanism is analogous to the coupling of two tuning forks by the air. A vibrating tuning fork will transfer energy to a quiet tuning fork if the two are placed close enough together. In a similar way the energy stored in the excited states of donor molecules is transferred to the ground states of acceptor molecules if they are near one another. The rate of Förster energy transfer falls off as the inverse sixth power of the distance between donors and acceptors (the same dependence as van der Waals forces) with a critical transfer distance  $R_0$  that gives a rough measure of the length over which energy is transferred efficiently.  $R_0$  is typically of the order of a few nm, which explains why the antenna chlorophyll molecules must be packed together pretty tightly for efficient energy transfer. Even though the process is not radiative, the rate of energy transfer depends on the overlap of the emission spectrum of the donor and the absorption spectrum of the acceptor. Figure 20.38 shows the energy transfer process and the overlap of the emission and absorption spectra.

Energy transferred to the special pair in the reaction center creates excited states that initiate a series of electron transfer reactions ultimately leading to oxygen evolution and/or  $\text{CO}_2$  fixation. The structure of the reaction center in the bacterium *Rhodospseudomonas viridis* is shown in Figure 20.39. The crystal structure shown was determined by X-ray diffraction (see Section 21.1) in 1984 by three German biochemists, Hartmut Michel, Johann Deisenhofer, and Robert Huber, for which they received the Nobel Prize in Chemistry. Not only did they locate the bacteriochlorophyll molecules that form the special pair, but they also

**FIGURE 20.38** Schematic of Förster energy transfer mechanism and spectral overlap.

identified the positions of the molecules involved in the subsequent steps in photosynthesis.

Figure 20.40 shows how photoexcitation of the special pair creates excited states of bacteriochlorophyll that are both reducing equivalents (the electron promoted to the LUMO) and oxidizing equivalents (the “hole” left behind in the HOMO). The energies of the species are plotted as electrode potentials, referenced to the standard hydrogen electrode (SHE). Recall that the electrical potential is the potential energy per unit charge (see Section 17.3), and “more negative potentials” in electrochemistry means “higher energy” in spectroscopy because the charge on the electron is negative. Electrons excited to the LUMO undergo a series of enzyme-catalyzed electron transfer reactions that ultimately reduce  $\text{NADP}^+$  to NADPH. Holes left behind in the HOMO oxidize a hydrogen donor,  $\text{H}_2\text{S}$ , in this example. The special pair in bacterial photosynthesis is called P780 because it absorbs light at 780 nm.

Returning to Figure 20.39 we see how the bacteriochlorophyll and related molecules are organized spatially to carry out these energy transfer reactions efficiently. A quinone is ultimately reduced to a hydroquinone that diffuses to the cytochrome shown, where it is oxidized back to quinone and the protons released generate a proton gradient that drives ATP synthesis as discussed.

Bacterial systems, in general, do not produce holes that are sufficiently oxidizing to oxidize water to  $\text{O}_2$ , so nature has created a second system that is used by

**FIGURE 20.39** Structure of the photosynthetic reaction center. (a) Artist's rendition of reaction center components and their organization in the cell membrane. (b) Crystal structure of the reaction center and associated cytochrome. (c) Structure of the reaction center with the proteins eliminated to show the relationships among the chlorophyll, heme, and quinone groups.

Note: The cytochrome subunit is membrane associated via a diacylglycerol moiety on its N-terminal Cys residue:

green plants for this purpose. The Z scheme of photosynthesis is illustrated schematically in Figure 20.41; it consists of two coupled photosystems called PSI and PSII that produce reducing equivalents sufficiently negative to reduce  $\text{NADP}^+$  to NADPH and oxidizing equivalents sufficiently positive to oxidize water. The oxygen evolving and the reducing functions of the photosynthetic system are separated and account for the existence of the light and dark reactions. The pigment in PSI absorbs light at 680 nm and is called P680, whereas that in PSII absorbs at

**FIGURE 20.40** Energy levels (shown as reduction potentials vs. SHE) and electron transfer processes in bacterial photosynthesis.

700 nm and is called P700. Not only does the absorption of two photons provide more energy than the absorption of one photon in bacterial photosynthesis, but the HOMO in P680 is at lower energy than either of the HOMOs in P780 or P700, and so the hole is sufficiently oxidizing to oxidize water. As illustrated in electrochemical terms, the potential is sufficiently positive.

The overall stoichiometry of photosynthesis depends on the pathways used by organisms to generate ATP from ADP when driven by light. The important key features of the process we emphasize can be summarized as follows:

1. Light is absorbed by chlorophylls and accessory pigments in bacteria and in green plants, and the energy is transferred in a few picoseconds ( $10^{-12}$  s) to a reaction center that contains a special pair of chlorophyll molecules.
2. Light absorbed by the special pair creates excited states that are both more strongly reducing and strongly oxidizing than the ground state. The basic mechanism of energy transduction is the creation of these oxidizing and reducing equivalents that initiate different series of redox reactions that ultimately lead to  $\text{CO}_2$  fixation and oxygen evolution.

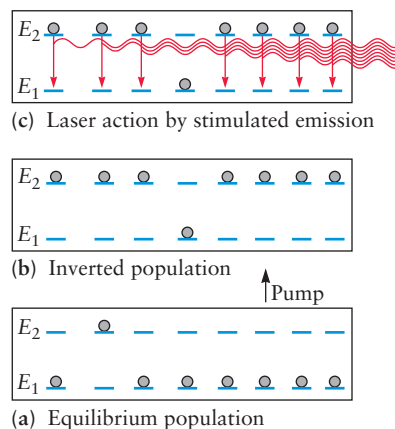

**FIGURE 20.41** The Z scheme of photosynthesis in green plants.

- Bacteria have a single photosynthetic system that absorbs longer wavelengths than plants and does not produce holes sufficiently oxidizing to oxidize water.
- Green plants have two photosystems that operate in tandem to generate more energy through the absorption of two photons and, more importantly, produce holes that can oxidize water to  $O_2$ .

## 20.8

## A DEEPER LOOK Lasers

**FIGURE 20.42** Operation of a laser device requires a pump source to change the equilibrium population (a) to one with a population inversion (b) and then stimulated emission (c), shown by the red downward arrows from the inverted population. (Adapted from P. W. Atkins, *Physical Chemistry*, 3rd ed., Oxford University Press, 1986.)

Lasers are devices that produce very intense beams of photons with a high degree of spatial coherence; they are the key elements in a number of important technologies with applications as diverse as machining, welding, communication, data storage, and surgery, to name a few. Fiber optic networks transmit huge volumes of digitized voice, video, and data across and between continents at nearly the speed of light. Data stored on CDs and DVDs are written by “burning” submicron size holes in the disks using a solid-state laser and read by measuring the reflectivity of the surface to locate the holes and smooth surfaces, which represent “ones” and “zeros”, respectively. There is enough energy delivered by the 192 beams of the National Ignition Facility laser (see Section 19.7) to heat a mixture of hydrogen isotopes to a few million degrees and initiate fusion. Although Einstein almost certainly did not foresee this enormously diverse range of applications, the possibility of light amplification through stimulated emission of radiation (giving rise to the acronym *laser*) was implicit in his treatment of the matter-radiation interaction and he is reported to have suggested that excess energy could be released as light, under certain circumstances. The key process of stimulated emission is depicted in Figure 20.42c. Once you have managed to get more molecules in the upper energy level than the lower energy level, then electromagnetic radiation in the laser cavity, perhaps selected to be of a certain wavelength by a diffraction grating, stimulates other excited molecules to emit a photon of exactly the same frequency.

Lasers have been constructed from many different materials and have a variety of different characteristics that make them suitable for particular applications. The lasing medium may be a gas, liquid, solid, or plasma, producing radiation from the far infrared to the X-ray region of the electromagnetic spectrum. Lasers may operate continuously, like laser pointers used in the classroom, or they may be pulsed for durations as short as 12 femtoseconds ( $12 \times 10^{-15}$  s).

Figure 20.43 shows the principle of operation of a Nd:YAG laser, a solid-state laser that produces light with a wavelength of 1064 nm. The principles of operation are similar to most other lasers. Before the laser is powered, the population of the excited state  $N_2$  is always less than that of the ground state  $N_1$ , as required by the Boltzmann distribution. When an excitation or “pump” source (electrically powered flashlamps, in the case of a Nd:YAG laser) is powered, the population  $N_2$  in the upper energy level shown in Figure 20.43 quickly increases—a situation in which  $N_2 > N_1$  is known as a *population inversion* (see also Figure 20.42b). While photons can be spontaneously emitted (as in fluorescence) to transfer molecules from the upper energy state to the lower energy state, a process called stimulated emission (see Figure 20.42c) in the optical cavity of the laser can produce a beam of radiation very different from that of ordinary spontaneous emission; it is highly collimated and the photons are travelling in phase with each other. (Explanations for the last two assertions are beyond the scope of this textbook, but are important characteristics of many lasers.) The trick, of course, is how to prepare a system that is not in thermal equilibrium. There are two general approaches. The first is to excite the system with a very short burst of intense radiation, intense enough to create the population

**FIGURE 20.43** Nd:YAG laser operation. (Adapted from Peter Atkins and Julio de Paula, *Physical Chemistry*, W. H. Freeman and Company, New York, 2010, p. 733.)

inversion but short enough to preclude significant spontaneous emission. The second is to use a medium with three or four states that provide a bottleneck that allows population to accumulate in the upper state. The latter is the approach used in a Nd:YAG laser. (In diode and excimer lasers, a population inversion is easily achieved because the ground electronic state of the molecules involved does not have a bound potential well.) Two other conditions are required for sustaining laser emission. The radiation must be confined in such a way to ensure that emitted photons stimulate emission from other excited atoms, ions, or molecules. This is generally accomplished by housing the lasing medium in a resonant cavity, terminated by a pair of highly reflective mirrors that keep the radiation circulating in the cavity, as well as to ensure that all of the photons are travelling in the same direction. A practical laser, however, must extract some of the radiation from the cavity to be useful; a partially transmitting mirror is generally used for this purpose, with a portion of the radiation being reflected back into the cavity to sustain the coherence in stimulated emission while allowing some of the radiation to escape as a laser beam. Some of the more common lasers with which you may be familiar include the continuous red HeNe gas laser, used in supermarket scanners, or the solid-state Nd:YVO<sub>4</sub> laser used in green laser pointers. Both of these lasers use multiple energy levels to achieve and maintain population inversions in the continuous mode of operation; the Nd:YAG laser can operate either in continuous or pulsed modes, the latter being used to generate the high powers necessary to initiate nuclear fusion.

Figure 20.43 shows an excitation source, the “pump” beam. Lasers are pumped by other lasers or by broadband emission from flash lamps or laser diodes; the lasing medium should have a large absorption coefficient at the pump wavelength(s) to create a significant population of excited states. Relaxation back to the ground state via emission or nonradiative processes must be slow. Non-radiative relaxation or energy transfer to the upper level of a second set of states, the level labeled with population  $N_2$ , must be fast, relaxation to the lower level, the level labeled with population  $N_1$ , must be slow, and, after a photon is produced from the stimulated emission process, transferring the system to the level labeled with population  $N_1$ , the relaxation back to the initial state (the initial state that the pump beam needs) must be fast; these conditions lead to the creation of a population inversion between the two levels on the right-hand side of the energy level diagram. Figure 20.43 shows the energy level diagram for the Nd:YAG laser in which the lasing medium consists of a particular yttrium aluminum garnet, Y<sub>3</sub>Al<sub>5</sub>O<sub>12</sub> in which about 1% of the Y<sup>3+</sup> ions have been replaced by Nd<sup>3+</sup> ions. Two excited states lying relatively close in energy are pumped either by diode lasers at the appropriate wavelengths or by broadband diode lasers or flash-lamps. Rapid nonradiative relaxation populates the  $N_2$  level (with 3 unpaired electrons) creating the population inversion that results in lasing at 1.06 μm. Relaxation from the  $N_1$  level back to the ground state of the system is rapid, as required to sustain the population inversion. Nd:YAG lasers are used in many of the applications cited earlier with the fundamental frequency (1.064 μm) multiplied in special crystals to produce radiation at shorter wavelengths. Frequency doubling produces the 532 nm green light of laser pointers whereas frequency tripling produces the 355 nm UV radiation used in the National Ignition Facility. A variant, the Nd<sup>3+</sup>:YVO<sub>4</sub> laser, produces the green light of laser pointers upon a frequency doubling.

## CHAPTER SUMMARY

Spectroscopy—understanding and exploiting the interactions between radiation and matter—has provided us with a suite of techniques with which to study the structures and reactions of molecules in environments that range from dilute

gases in interstellar space to those in living cells. Each of the different kinds of motions of a molecule is quantized, and each can be selectively excited by the absorption of electromagnetic radiation of the appropriate frequency. The energies of the transitions increase in the order: nuclear spin flips, molecular rotations, molecular vibrations, electronic excitations. They are excited by radiofrequency, microwave, infrared, and visible and ultraviolet radiation, respectively. We obtain bond lengths and angles, bond dissociation energies, and the energies of molecular orbitals from the spectra of molecules. Time-resolved methods allow us to follow molecular dynamics and chemical reactions on time scales as short as  $10^{-14}$  seconds and imaging techniques provide molecularly specific information on length scales as short as 100 nm. Absorption of ultraviolet and visible radiation produces electronically excited states of molecules, the first step in a number of important processes in spectroscopy and photochemistry. Fluorescence spectroscopy is one of our most sensitive tools for detecting and imaging molecules. Energy and electron transfer are key steps in solar energy conversion processes, including photosynthesis. Understanding atmospheric photochemistry in greater detail will enable us to address problems of truly global scope—air pollution, ozone destruction, and climate change.

## CONCEPTS AND SKILLS

### Section 20.1 – Introduction to Molecular Spectroscopy

*Identify the different kinds of spectroscopic techniques based upon the information provided and the region of the electromagnetic spectrum involved. See Table 20.1.*

*Identify and characterize the major radiative and nonradiative relaxation processes in molecules.*

- Radiative processes include fluorescence, the emission of light resulting from transitions between states of the same spin, and phosphorescence, the emission of light resulting from transitions between states of different spin. Nonradiative processes include internal conversion (relaxation between states of the same spin without emission) and intersystem crossing (relaxation between states of different spin). No light is absorbed or emitted during a nonradiative process.

### Section 20.2 – Experimental Methods in Molecular Spectroscopy

*State the Beer–Lambert law and use it to calculate the intensity of absorption, emission, or scattering (Problems 1–6).*

- The Beer–Lambert law is  $I_t = I_0 \exp[-(N/V)\sigma\ell]$  where  $(N/V)$  is the molecular number density,  $\sigma$  is a cross section measured in  $\text{cm}^2 \text{ molecule}^{-1}$  and  $\ell$  is a path length measured in cm.

*Describe how laser induced fluorescence can give you information on the vibrational frequencies of molecules in excited electronic states, and how dispersing the emission by wavelength can reveal the vibrational frequencies of the molecule in the ground electronic state (Problems 7, 8).*

- Starting with molecules in the  $v = 0$  level of the ground electronic state, you can tune the energy of the laser photon to excite the molecule to different vibrational levels in the excited electronic state. When the laser photon has the right energy to promote the molecule to a vibrational level in the excited electronic state, you see emitted photons coming from the sample. If you then leave the excitation laser tuned to excite one vibrational state in the excited state and disperse the emitted photons by their energy, you can, by subtracting the energy of the emitted photon from the energy of the absorbed photon, measure the vibrational energy levels in the ground electronic state.

*Identify the essential components of a molecular spectroscopy experiment.*

- Spectroscopy experiments require a source of electromagnetic radiation, an element that disperses the radiation spatially to select wavelengths, and a detector.

*Use the Boltzmann distribution to calculate the population differences between two levels as a function of their energy difference and the temperature (Problems 9, 10, 23, 24).*

- The Boltzmann distribution is  $N_i/N \propto g_i \exp(-E_i/k_B T)$  from which we calculate population ratios using Equation 20.4.

### Section 20.3 – Rotational and Vibrational Spectroscopy

*Calculate the energy levels and the separation between energy levels of a linear rigid rotor and predict the appearance of pure rotational spectra (Problems 11–14).*

- The energy levels of a linear rigid rotor are given by  $E_J = hc\tilde{B}J(J + 1)$  where  $\tilde{B}$  is a rotational constant in  $\text{cm}^{-1}$ . Only transitions for which  $\Delta J = 1$  are allowed in absorption so the spectrum consists of a series of lines separated by  $2\tilde{B}$  with relative intensities determined by the degeneracies of the two levels involved and their populations as given by the Boltzmann distribution.

*Calculate bond lengths from rotational spectral data or predict the energies of the photons absorbed in a pure rotational spectrum given the bond length of a diatomic molecule (Problems 11–14).*

- The rotational constant, which is determined from the spacing between adjacent levels, is related to the moment of inertia in Equation 20.6. The bond length is determined by substituting the reduced mass into the definition of the moment of inertia. See Example 20.4.

*Describe rotational Raman spectroscopy and the appearance of a rotational Raman spectrum (Problems 15–16).*

- Only those transitions for which  $\Delta J = 0, \pm 2$  are allowed in rotational Raman spectra of diatomic molecules. The appearance of the spectra depends upon the nuclear spins for homonuclear diatomic molecules as well as the relative populations of the levels that are determined by the degeneracies of the levels and the Boltzmann distribution.

*Describe the harmonic oscillator model, calculate force constants from vibrational frequencies and reduced masses for diatomic molecules, and interpret vibrational frequencies in terms of force constants and reduced masses (Problems 17–20, 25–28).*

- The harmonic oscillator model assumes that the potential energy function,  $V(x) = \frac{1}{2}kx^2$ , is given by Hooke's law, where  $x = R - R_e$  for a diatomic molecule.
- Solving the Schrödinger equation for this model problem gives a set of wave functions and a formula for calculating the quantized energy levels, which is  $E_v = h\nu(v + \frac{1}{2})$  where  $v$  is the vibrational quantum number and  $\nu$  is the vibrational frequency of the oscillator.  $v$  can be 0, 1, 2, 3... and the term  $\frac{1}{2}h\nu$  is the zero-point energy of the oscillator.
- The bond force constant is related to the vibrational frequency by  $k = \mu(2\pi\nu)^2$ .
- Vibrational frequencies are proportional to the square root of the force constant and inversely proportional to the square root of the reduced mass; they increase with increasing bond order, for a series of molecules with the same reduced mass, such as C–C single, double and triple bonds, and decrease with increasing reduced mass for a series of molecules with similar force constants.

*Describe the anharmonic oscillator model, the effects of anharmonicity on the appearance of infrared spectra, and how bond dissociation energies can be calculated from the spectra.*

- The energy levels of an anharmonic oscillator are not equally spaced, they decrease with increasing  $v$ , and the harmonic oscillator selection rule  $\Delta v = \pm 1$  is relaxed. A plot of the energy differences between adjacent levels as a function of the vibrational quantum number  $v + 1/2$  is approximately a straight line; extrapolating that straight line to the x intercept and taking the area under the curve gives the bond dissociation energy.

*Describe the characteristics of a high-resolution infrared absorption spectrum of a heteronuclear diatomic molecule (Problems 21–22).*

- When you excite a molecule with a laser photon characterized by a precise energy, what appeared a lower resolution to be a band centered at  $h\nu_{\text{photon}} = h\nu_{\text{vib}}$  is actually the envelope of two sets of sharp absorption features. The P branch of the absorption spectrum results from  $\Delta J = -1$  transitions to the excited vibrational state, while the R branch of the absorption spectrum results from  $\Delta J = +1$  transitions to the excited vibrational state.

*Describe the vibrational spectra of polyatomic molecules (Problems 29–32).*

- A polyatomic molecule with  $N$  atoms has  $3N - 5$  vibrational modes if the molecule is linear and  $3N - 6$  vibrational modes if it is not. The vibrational frequencies of functional groups tend to be similar in many molecules and can be used for qualitative analysis.

## 20.4 – Nuclear Magnetic Resonance Spectroscopy

*Describe the physical basis for NMR spectroscopy.*

- Many nuclei have intrinsic magnetic moments that arise from their nuclear spin. Acting as tiny bar magnets, the nuclear spins can align parallel or anti-parallel to an external magnetic field. The two nuclear spin states of a  $^1\text{H}$  atom nucleus have the same energy in the absence of an external magnetic field, but split in energy in the presence of an external magnetic field. The energy splitting is proportional to the strength of the applied magnetic field.

*Discuss what can be learned from NMR spectra (Problems 33–34).*

- Integrating the peaks in a low-resolution  $^1\text{H}$  NMR spectrum allows you to determine how many H atoms are in each functional group (e.g. 3 atoms in a  $\text{CH}_3$  group, one in an OH group). The chemical shift depends upon the charge density at the magnetic nucleus of interest as well as local fields induced by the interaction of the magnetic field with neighboring nuclei; it is characteristic of particular functional groups. The spin–spin splitting pattern identifies the number of protons on carbon atoms adjacent to the carbon atom to which the particular proton of interest is bound. Taken together, the chemical shifts and spin–spin splitting patterns allow chemists to locate functional groups within molecules and to determine molecular structures.

## 20.5 – Electronic Spectroscopy and Excited State Relaxation Processes

*Be able to identify the molecular orbitals of common chromophores, discuss the various kinds of transitions between them, and predict how the equilibrium bond length and the vibrational frequency of a bond might change if you promote an electron from a nonbonding orbital to a  $\pi^*$  orbital localized on that bond, or from a  $\pi$  orbital localized on that bond to a  $\pi^*$  orbital localized on that bond (Problems 35–36, 39–40, 58–59, 61).*

- The highest occupied and lowest unoccupied orbitals of organic chromophores may include the  $\sigma$ ,  $\sigma^*$ ,  $\pi$ ,  $\pi^*$ , and  $n$  orbitals.  $\sigma \rightarrow \sigma^*$  transitions typically occur in the UV while the lowest energy  $\pi \rightarrow \pi^*$  transitions for linear

polyenes begin in the UV and shift toward the visible as the number of carbon atoms increases.

*Describe how molecular photoelectron spectroscopy provides information about the bonding characteristics of molecular orbitals.*

- The number and frequencies of the vibrational bands observed in the spectra provide information about the nature of the molecular ion, from which we can deduce the characteristics of the orbital from which the electron was removed. Few bands with vibrational frequencies close to that of the parent molecule indicate that the electron was ionized from a nonbonding orbital, many bands with vibrational frequencies lower than that of the parent molecule indicate that the electron came from a bonding orbital, and an intermediate number of bands with frequencies somewhat larger than that of the parent molecule indicate that the orbital was antibonding.

*Define the Franck–Condon principle and provide a physical interpretation.*

- The Franck–Condon principle asserts that the most intense absorption band in a series that involves simultaneous electronic and vibrational excitation is the one in which the overlap of the vibrational wave functions in the ground and excited electronic states is the greatest. The principle is a consequence of the fact that nuclei move much more slowly than electrons and can be considered to be stationary during an electronic transition.

## 20.6 – Introduction to Atmospheric Chemistry

*Identify the different regions of the atmosphere, current areas of concern and the physical processes involved (Problems 5 and 45–48, but 45–48 focus only on the bonding of atmospherically relevant molecules).*

- We are mostly concerned with the chemistry of the troposphere, the region of the atmosphere that extends from the surface of the Earth to an altitude of about 15 km, and the stratosphere, the region between 15 and 30 km. Air pollution is the chief area of concern in the troposphere, with the dominant sources being vehicle emissions and emissions from power plants and manufacturing. Oxides of nitrogen and sulfur are respiratory irritants and precursors to acid rain, which is damaging both to human health and physical structures like buildings, roads, and bridges. CFCs produced for use as refrigerants and propellants have depleted stratospheric ozone through a series of photochemical reactions that result in catalysis of the reaction  $2\text{O}_3 \rightarrow 3\text{O}_2$ . Anthropogenic greenhouse gases, such as  $\text{CO}_2$ ,  $\text{CH}_4$ , and  $\text{N}_2\text{O}$  are thought to be largely responsible for the increase in the temperature of the Earth that has been observed since the Industrial Revolution.

## 20.7 – Photosynthesis

*Explain the mechanism by which photosynthetic bacteria and green plants convert light energy to chemical energy (Problems 49–50).*

- Visible light absorbed by chlorophyll molecules and accessory pigments is transferred to the photosynthetic reaction center where a series of light-driven and dark reactions produce carbohydrates and  $\text{O}_2$  from  $\text{CO}_2$  and  $\text{H}_2\text{O}$ .

## 20.8 – A Deeper Look . . . Lasers

*Explain what is meant by a population inversion and describe how stimulated emission produces an intense beam of laser photons, all with the same wavelength, from excited molecules that would normally fluoresce by emitting photons of disparate wavelengths.*

## CUMULATIVE EXERCISE

### Bromine

Elemental bromine is a brownish-red liquid that was first isolated in 1826. It is currently produced by oxidation of bromide ion in natural brines with elemental chlorine.

- What is the ground-state configuration of the valence electrons of bromine molecules ( $\text{Br}_2$ )? Is bromine paramagnetic or diamagnetic?
- What is the electron configuration of the  $\text{Br}_2^+$  molecular ion? Is its bond stronger or weaker than that in  $\text{Br}_2$ ? What is its bond order?
- Bromine compounds have been known and used for centuries. The deep purple color that symbolized imperial power in ancient Rome originated with the compound dibromoindigo, which was extracted in tiny quantities from purple snails (about 8000 snails per gram of compound). What color and maximum wavelength of *absorbed* light would give a deep purple (violet) color?
- What excited electronic state is responsible for the brownish-red color of bromine? Refer to Figure 6.18, but note the different row of the periodic table for Br.
- The two naturally occurring isotopes of bromine are  $^{79}\text{Br}$  and  $^{81}\text{Br}$ , with masses of 78.918 and 80.916 u, respectively. The wavelength of the  $J = 0$  to  $J = 1$  rotational transition in  $^{79}\text{Br}^{81}\text{Br}$  is measured to be 6.18 cm. Use this information to calculate the bond length in the  $\text{Br}_2$  molecule, and compare the result with that listed in Table 3.3.
- The wavelength of the vibrational transition in the  $^{79}\text{Br}^{81}\text{Br}$  molecule is  $3.09 \times 10^{-5}$  m. Calculate the force constant for the bond in this molecule.
- The action of light on bromine compounds released into the air (such as by leaded gasoline) causes the formation of the BrO radical. Give the bond order of this species by comparing it with the related radical OF.
- There is concern that synthetic bromine-containing compounds, in addition to chlorofluorocarbons, are helping to destroy ozone in the stratosphere. The BrO [see part (g)] can take part with ClO in the following catalytic cycle:

Write the overall equation for this cycle.

### Answers

- $(\sigma_{g4s})^2(\sigma_{u4s}^*)^2(\sigma_{g4p_z})^2(\pi_{u4p})^4(\pi_{g4p}^*)^4$ ; diamagnetic
- $(\sigma_{g4s})^2(\sigma_{u4s}^*)^2(\sigma_{g4p_z})^2(\pi_{u4p})^4(\pi_{g4p}^*)^3$ ; stronger; bond order is  $\frac{3}{2}$  versus 1
- Yellow light, near 530 nm (see Figure 4.3)
- The lowest energy excited state, which arises from the excitation of an electron from the filled  $\pi_{g4p}^*$  orbital to the unfilled  $\sigma_{u4p_z}^*$  orbital
- 2.28 Å (from Table 3.3; 2.286 Å)
- 247 J Nm<sup>-1</sup>
- $\frac{3}{2}$  order
- Overall:  $2 \text{O}_3 \rightarrow 3 \text{O}_2$

## PROBLEMS

Answers to problems whose numbers are red appear in Appendix G. Problems that are more challenging are indicated with asterisks.

### 20.2 Experimental Methods in Molecular Spectroscopy

- The percentage transmittance of light at 250 nm through a certain aqueous solution is 20.0% at 25°C. The experimental cell length is 1.0 cm, and the concentration of the solution is  $5 \times 10^{-4}$  mol L<sup>-1</sup>. Calculate the absorbance. Calculate the molar absorption coefficient.
- Beer's law is used to measure the concentration of species in solutions, once a "standardization curve" has been prepared for that species. In one such experiment, percent transmission was measured for a series of solutions with known concentrations and the results were as follows:

Concentration μg mL <sup>-1</sup>	1.0	2.0	3.0	4.0	5.0
Transmission, percent	66.8	44.7	29.2	19.9	13.3

Plot these results to obtain the standardization curve. An unknown concentration of the same species, measured in the same transmission cell, transmitted 35% of the incoming light. Calculate the concentration of the unknown solution.

- Beer's law can be used to determine the concentration of two substances A and B in solution, provided they do not react or interact, so they absorb radiation independently. The following data were obtained for A and B in three different solutions:

	[A] mol L <sup>-1</sup>	[B] mol L <sup>-1</sup>	% Transmittance at λ = 400 nm	% Transmittance at λ = 500 nm
Solution 1	0.0010	0	10.0	60.0
Solution 2	0	0.0050	80.0	20.0
Solution 3	?	?	40.0	50.0

Calculate the concentrations of A and B in Solution 3.

- The absorption of ultraviolet light by proteins at wavelength 280 nm is caused mostly by the amino acids tyrosine and tryptophan along the protein molecular chains. The molecular absorption coefficients for these two amino acids are:

$$\epsilon_{\text{tryp}}^{280} = 5690 \text{ L cm}^{-1} \text{ mol}^{-1}$$

$$\epsilon_{\text{tyro}}^{280} = 1280 \text{ L cm}^{-1} \text{ mol}^{-1}$$

Experiments are carried out on a protein with molecular weight 26,000, which contains two units of tryptophan and six units of tyrosine along the chain. The absorption is measured in a cell 1 cm long, and the protein concentration is 1.0 mg mL<sup>-1</sup>. Calculate the absorbance and the percent transmission.

- Stratospheric ozone absorbs ultraviolet radiation (UVB) that is known to cause cancer in humans. The onset of the UVB region of the spectrum is 320 nm and the absorption cross section for ozone (O<sub>3</sub>) that wavelength is about  $5 \times 10^{-20}$  cm<sup>2</sup> molecule<sup>-1</sup> (see Fig. 20.32). The average ozone number density in the stratosphere is about  $5 \times 10^{12}$  molecules cm<sup>-3</sup>. What thickness of the ozone layer is required to absorb 60% of the UV radiation at 320 nm?
- The absorption cross section for fluorescein, a dye that is used as a fluorescent probe for biological imaging (see the Chapter Opener image), is  $9.25 \times 10^{-16}$  cm<sup>2</sup> molecule<sup>-1</sup> at 500 nm. How much light is transmitted through a 1-cm path length by a standard  $10^{-6}$  M solution of fluorescein used to label biological samples?
- Laser-induced fluorescence is the technique of choice for detecting OH radicals in the atmosphere because the technique is so sensitive; it can detect OH radicals with concentrations of  $10^6$  molecules cm<sup>-3</sup>. (LIF instruments are mounted in aircraft!) The difference in energy between the minimum of the ground electronic state potential energy curve of OH and the minimum of the excited electronic  $\tilde{A}$  state is 32,684 cm<sup>-1</sup>. (This minimum to minimum energy difference is given the label  $E_{\text{el}}$  in Figure 20.1 and Equation 20.1, but in spectroscopic literature it is usually given by the symbol  $T_{\text{e}}$ .) Calculate the energy of the laser photon needed to excite an OH radical that is initially in the  $v'' = 0$  level of the ground electronic state,  $S_0$ , to the  $v' = 1$  level of the  $\tilde{A}$  state, using a harmonic approximation for the OH vibration. The vibrational frequency of the OH radical is 3738 cm<sup>-1</sup> in the ground electronic state and 3179 cm<sup>-1</sup> in the  $\tilde{A}$  state.
- If after laser exciting the OH radical to the  $v' = 1$  level of the  $\tilde{A}$  state as described in the prior problem, what energy photon would be emitted if the final vibrational state of the OH in the ground electronic state were  $v'' = 3$ ?
- The vibrational frequency  $\nu$  for H<sub>2</sub> is 4400 cm<sup>-1</sup> and the energy difference between its two lowest rotational energy levels,  $J = 0$  and  $J = 1$ , is 121.7 cm<sup>-1</sup>. Calculate the relative populations of the  $v = 1$  and  $v = 0$  vibrational energy levels and the relative populations of the two lowest rotational energy levels for H<sub>2</sub> at the operating temperature of the space shuttle's combustion chamber, which is 3300°C. Comment on your results.
- The vibrational frequency  $\nu$  for Br<sub>2</sub> is 323 cm<sup>-1</sup> and the energy difference between its two lowest rotational energy levels,  $J = 0$  and  $J = 1$ , is 0.164 cm<sup>-1</sup>. Calculate the relative populations of the  $v = 1$  and  $v = 0$  vibrational energy levels and the relative populations of the two lowest rotational energy levels for Br<sub>2</sub> at 300 K. Comment on your results.

### 20.3 Rotational and Vibrational Spectroscopy

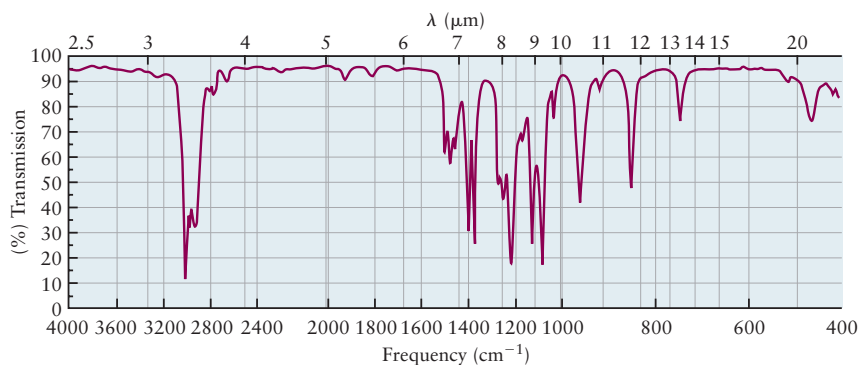

- Use data from Tables 19.1 and 3.3 to predict the energy spacing between the ground state and the first excited rotational state of the <sup>14</sup>N<sup>16</sup>O molecule.

12. Use data from Tables 19.1 and 3.3 to predict the energy spacing between the ground state and the first excited rotational state of the  $^1\text{H}^{19}\text{F}$  molecule.
13. The first three absorption lines in the pure rotational spectrum of gaseous  $^{12}\text{C}^{16}\text{O}$  are found to have the frequencies  $1.15 \times 10^{11}$ ,  $2.30 \times 10^{11}$ , and  $3.46 \times 10^{11} \text{ s}^{-1}$ . Calculate:
- The moment of inertia  $I$  of CO (in  $\text{kg m}^2$ )
  - The energies of the  $J = 1$ ,  $J = 2$ , and  $J = 3$  rotational levels of CO, measured from the  $J = 0$  state (in joules)
  - The C—O bond length (in angstroms)
14. Four consecutive absorption lines in the pure rotational spectrum of gaseous  $^1\text{H}^{35}\text{Cl}$  are found to have the frequencies  $2.50 \times 10^{12}$ ,  $3.12 \times 10^{12}$ ,  $3.74 \times 10^{12}$ , and  $4.37 \times 10^{12} \text{ s}^{-1}$ . Calculate:
- The moment of inertia  $I$  of HCl (in  $\text{kg m}^2$ )
  - The energies of the  $J = 1$ ,  $J = 2$ , and  $J = 3$  rotational levels of HCl, measured from the  $J = 0$  state (in joules)
  - The H—Cl bond length (in angstroms)
  - The initial and final  $J$  states for the observed absorption lines
15. The rotational constant  $\tilde{B} = 1.45 \text{ cm}^{-1}$  for  $\text{O}_2$ . Calculate the  $\text{O}_2$  bond length and predict the appearance of its rotational Raman spectrum, recalling that transitions between states with even  $J$  are forbidden due to nuclear spin statistics considerations.
16. The rotational constant  $\tilde{B}$  of  $^7\text{Li}_2$  is  $0.6727 \text{ cm}^{-1}$ . Calculate the  $^7\text{Li}_2$  bond length and predict the appearance of its rotational Raman spectrum without the effect of nuclear spin statistics on the relative intensities of the lines. Compare your results with those of Example 20.5.
17. The  $\text{Li}_2$  molecule ( $^7\text{Li}$  isotope) shows a very weak infrared line in its vibrational spectrum at a wavelength of  $2.85 \times 10^{-5} \text{ m}$ . Calculate the force constant for the  $\text{Li}_2$  molecule.
18. The  $\text{Na}_2$  molecule ( $^{23}\text{Na}$  isotope) shows a very weak infrared line in its vibrational spectrum at a wavelength of  $6.28 \times 10^{-5} \text{ m}$ . Calculate the force constant for the  $\text{Na}_2$  molecule, and compare your result with that of problem 17. Give a reason for any difference.
19. The “signature” infrared absorption that indicates the presence of a C—H stretching motion in a molecule occurs at wavelengths near  $3.4 \times 10^{-6} \text{ m}$ . Use this information to estimate the force constant of the C—H stretch. Take the reduced mass in this motion to be approximately equal to the mass of the hydrogen atom (a good approximation when the H atom is attached to a heavy atom).
20. Repeat the calculation of the problem 19 for the N—H stretch, where absorption occurs near  $2.9 \times 10^{-6} \text{ m}$ . Which bond is stiffer: N—H or C—H?
21. An HCl molecule initially in the  $(\nu, J) = (0, 2)$  quantum state can absorb infrared photons. What are the two most likely final quantum states after absorbing an infrared photon? Calculate the energy of the infrared photon absorbed for each of these transitions. Can it also absorb a microwave photon? If yes, calculate that photon energy also. The rotational constant of HCl is  $10 \text{ cm}^{-1}$  and its vibrational frequency is  $2990 \text{ cm}^{-1}$ .
22. A vibrationally excited CO molecule initially in the  $(\nu, J) = (1, 2)$  quantum state can emit a microwave photon, changing its rotational state, or it can emit infrared photons of two different energies. What is the final quantum state reached in these transitions? Calculate the energy of microwave photon and the infrared photon emitted in these three transitions. Example 20.9 has information on the rotational constant of CO and its vibrational frequency.
23. Estimate the ratio of the number of molecules in the first excited vibrational state of the molecule  $\text{N}_2$  to the number in the ground state, at a temperature of 450 K. The vibrational frequency of  $\text{N}_2$  is  $7.07 \times 10^{13} \text{ s}^{-1}$ .
24. The vibrational frequency of the ICl molecule is  $1.15 \times 10^{13} \text{ s}^{-1}$ . For every million ( $1.00 \times 10^6$ ) molecules in the ground vibrational state, how many will be in the first excited vibrational state at a temperature of 300 K?
25. The measured vibrational frequencies for the hydrogen halides given in Section 20.3 are:  $^1\text{H}^{19}\text{F}$  ( $4139 \text{ cm}^{-1}$ );  $^1\text{H}^{35}\text{Cl}$  ( $2991 \text{ cm}^{-1}$ );  $^1\text{H}^{81}\text{Br}$  ( $2449 \text{ cm}^{-1}$ ); and  $^1\text{H}^{127}\text{I}$  ( $2308 \text{ cm}^{-1}$ ). Calculate the force constants for each molecule, using the vibrational frequencies given and the atomic masses provided in Table 19.1. Which is the more important factor in determining the vibrational frequencies in this series of molecules—the force constants or the reduced masses?
26. The vibrational frequencies for the mixture of gases shown in the Chapter 3 *Connection to Instrumental Analysis* include:  $\text{H}_2$  ( $4160 \text{ cm}^{-1}$ )  $\text{N}_2$  ( $2331 \text{ cm}^{-1}$ )  $\text{CO}$  ( $2143 \text{ cm}^{-1}$ ), and  $\text{O}_2$  ( $1550 \text{ cm}^{-1}$ ). What can you conclude about the bond orders by inspection? Calculate the force constants for each molecule to check the accuracy of your estimate.
27. Substitution of hydrogen by deuterium is a convenient way to label organic molecules at specific sites for the purpose of investigating reaction mechanisms. At what frequency would the C—D stretch of a phenyl ring appear if the frequency of the C—H stretch is  $3062 \text{ cm}^{-1}$ ?
28. If the spacings between adjacent vibrational features in a photoelectron spectroscopy experiment decrease, changing by a factor of  $1/\sqrt{2}$ , when you deuterate the molecule being ionized, is it more likely that the orbital from which you are ejecting an electron is from a nonbonding orbital, a  $\pi$  orbital localized on a C—C or C—O bond, or a  $\sigma$  orbital localized on a C—H bond? Explain.
29. How many normal vibrational modes does each of the following molecules have?
- $\text{NH}_3$
  - $\text{C}_2\text{H}_4$
  - $\text{CCl}_2\text{F}_2$
  - $\text{CH}_3\text{CH}_2\text{OH}$
30. Consider the vibrations of the molecules in the previous problem from a localized point of view, as the vibrations of individual bonds. Infrared absorption is proportional to the permanent dipole moment of each individual bond. Which of the molecules will absorb IR radiation most strongly and why?

31. The IR spectra of nonane ( $C_9H_{20}$ ) and 1-hexanol ( $C_6H_{13}OH$ ) are shown below. Assign each spectrum to the correct compound and identify the frequencies and the functional groups used to support your assignment.

32. The IR spectrum of 2-methyl-1-butanol ( $H_3CCH_2CH(CH_3)CH_2OH$ ) and *tert*-butyl methyl ether [ $(CH_3)_3COCH_3$ ] are shown below. Assign each spectrum to the correct compound and identify the frequencies and the functional groups used to support your assignment.

## 20.4 Nuclear Magnetic Resonance Spectroscopy

33. Give the number of peaks and the relative peak areas that should be observed in the low-resolution proton magnetic resonance spectra of the following molecules:

34. The organic compound 1,4-dimethylbenzene (also known as *p*-xylene) has the formula  $(\text{CH}_3)_2\text{C}_6\text{H}_4$ . Its structure has two  $\text{CH}_3$  (methyl) groups substituted at opposite positions on the benzene ( $\text{C}_6\text{H}_6$ ) ring. Predict the number of peaks in the low-resolution proton NMR spectrum of this compound and the relative areas of the peaks.

## 20.5 Electronic Spectroscopy and Excited State Relaxation Processes

35. Suppose that an ethene molecule gains an additional electron to give the  $\text{C}_2\text{H}_4^-$  ion. Will the bond order of the carbon-carbon bond increase or decrease? Explain.
36. Suppose that an ethene molecule is ionized by a photon to give the  $\text{C}_2\text{H}_4^+$  ion. Will the bond order of the carbon-carbon bond increase or decrease? Explain.
37. The color of the dye “indanthrene brilliant orange” is evident from its name. In what wavelength range would you expect to find the maximum in the absorption spectrum of this molecule? Refer to the color spectrum in Figure 4.3.
38. In what wavelength range would you expect to find the maximum in the absorption spectrum of the dye “crystal violet”?
39. The structure of the molecule cyclohexene is shown below:

Does the absorption of ultraviolet light by cyclohexene occur at shorter wavelengths than in benzene? Explain.

40. The naphthalene molecule has a structure that corresponds to two benzene molecules fused together:

The  $\pi$ -electrons in this molecule are delocalized over the entire molecule. The wavelength of maximum absorption in the UV-visible part of the spectrum in benzene is 255 nm. Is the corresponding wavelength shorter or longer than 255 nm for naphthalene?

41. Use data from Table 3.3 to give an upper bound on the wavelengths of light that are capable of dissociating a molecule of  $\text{ClF}$ .

42. Use data from Table 3.3 to give an upper bound on the wavelengths of light that are capable of dissociating a molecule of  $\text{ICl}$ .
43. Plot a potential energy curve for the ground electronic state of methyl iodide and the excited electronic state reached when it absorbs a 260 nm photon, putting the potential energy  $V$  on the vertical axis and the distance between the carbon and iodine atom on the horizontal axis. The equilibrium internuclear distance of the  $\text{C-I}$  bond is about 200 pm and the  $\text{C-I}$  bond energy is about  $220 \text{ kJ mol}^{-1}$ . Assume the excited state potential energy curve at  $R_{\text{C-I}} = 200 \text{ pm}$  is reached by the 260 nm photon, in rough agreement with the Franck-Condon principle. The absorption spectrum is broad and structureless.
44. Plot a potential energy curve for the ground state of  $\text{HCl}$  and the excited state reached in the broad structureless absorption band peaking near  $65,500 \text{ cm}^{-1}$ . The equilibrium bond length of  $\text{HCl}$  and the bond energy is given in Table 3.3.

## 20.6 Introduction to Atmospheric Chemistry

45. The bond dissociation energy of a typical  $\text{C-F}$  bond in a chlorofluorocarbon is approximately  $440 \text{ kJ mol}^{-1}$ . Calculate the maximum wavelength of light that can photodissociate a molecule of  $\text{CCl}_2\text{F}_2$ , breaking such a  $\text{C-F}$  bond.
46. The bond dissociation energy of a typical  $\text{C-Cl}$  bond in a chlorofluorocarbon is approximately  $330 \text{ kJ mol}^{-1}$ . Calculate the maximum wavelength of light that can photodissociate a molecule of  $\text{CCl}_2\text{F}_2$ , breaking such a  $\text{C-Cl}$  bond.
47. Draw a Lewis diagram(s) for the ozone molecule ( $\text{O}_3$ ). Determine the steric number and hybridization of the central oxygen atom, and identify the molecular geometry. Describe the nature of the  $\pi$  bonds and give the bond order of the  $\text{O-O}$  bonds in ozone.
48. The compounds carbon dioxide ( $\text{CO}_2$ ) and sulfur dioxide ( $\text{SO}_2$ ) are formed by the burning of coal. Their apparently similar formulas mask underlying differences in molecular structure. Determine the shapes of these two types of molecules, identify the hybridization at the central atom of each, and compare the natures of their  $\pi$  bonds.

## 20.7 Photosynthesis

49. One way in which photosynthetic bacteria store chemical energy is through the conversion of a compound called adenosine diphosphate (ADP), together with hydrogen phosphate ion, to adenosine triphosphate (ATP):

Suppose some chlorophyll molecules absorb 1.00 mol of photons of blue light with wavelength 430 nm. If *all* this energy could be used to convert ADP to ATP at room conditions and pH 7, how many molecules of ATP would be produced per photon absorbed? (The actual number is smaller because the conversion is not 100% efficient.)

50. Repeat the calculation of problem 49 for red light with wavelength 700 nm.

## ADDITIONAL PROBLEMS

51. In Example 20.4, we determined that the moment of inertia of the NaH molecule is  $5.70 \times 10^{-47} \text{ kg m}^2$ .
- Calculate the relative population of the  $J = 5$  level and the ground state at  $25^\circ\text{C}$ .
  - Calculate the relative population of the  $J = 15$  level and the ground state at  $25^\circ\text{C}$ .
  - Calculate the relative population of the  $J = 25$  level and the ground state at  $25^\circ\text{C}$ .
52. The rotational constant for  $^{14}\text{N}_2$ , measured for the first time using rotational Raman spectroscopy (see Fig. 20.9), is  $1.99 \text{ cm}^{-1}$ . Calculate (a) the moment of inertia  $I$  of  $\text{N}_2$  in  $\text{kg m}^2$ , (b) the energies of the first three excited rotational levels, relative to that of the ground level, in wave numbers, and (c) the frequency of the  $J = 0 \rightarrow J = 1$  transition in GHz.
53. What are the moments of inertia of  $^1\text{H}^{19}\text{F}$  and  $^1\text{H}^{81}\text{Br}$ , expressed in  $\text{kg m}^2$ ? Compute the spacings  $\nu = \Delta E/h$  of the rotational states, in  $\text{s}^{-1}$ , between  $J = 0$  and 1 and between  $J = 1$  and 2. Explain, in one sentence, why the large change in mass from 19 to 81 causes only a small change in rotational energy differences.
54. The average bond length of a molecule can change slightly with vibrational state. In  $^{23}\text{Na}^{35}\text{Cl}$ , the frequency of light absorbed in a change from the  $J = 1$  to the  $J = 2$  rotational state in the ground vibrational state ( $n = 0$ ) was measured to be  $\nu = 2.60511 \times 10^{10} \text{ s}^{-1}$ , and that for a change from  $J = 1$  to  $J = 2$  in the first excited vibrational state ( $n = 1$ ) was  $\nu = 2.58576 \times 10^{10} \text{ s}^{-1}$ . Calculate the
59. One isomer of retinal is converted to a second isomer by the absorption of a photon:

This process is a key step in the chemistry of vision. Although free retinal (in the form shown to the left of the arrow) has an absorption maximum at 376 nm, in the ultraviolet region of the spectrum this absorption shifts into the visible range when the retinal is bound in a protein, as it is in the eye.

- How many of the  $\text{C}=\text{C}$  bonds are *cis* and how many are *trans* in each of the preceding structures? (When assigning labels, consider the relative positions of the two largest groups attached at each double bond.) Describe the motion that takes place upon absorption of a photon.
- If the ring and the  $-\text{CHO}$  group in retinal were replaced by  $-\text{CH}_3$  groups, would the absorption maximum in the molecule shift to longer or shorter wavelengths?

average bond lengths of NaCl in these two vibrational states, taking the relative atomic mass of  $^{23}\text{Na}$  to be 22.9898 and that of  $^{35}\text{Cl}$  to be 34.9689.

- The vibrational frequencies of  $^{23}\text{Na}^1\text{H}$ ,  $^{23}\text{Na}^{35}\text{Cl}$ , and  $^{23}\text{Na}^{127}\text{I}$  are  $3.51 \times 10^{13} \text{ s}^{-1}$ ,  $1.10 \times 10^{13} \text{ s}^{-1}$ , and  $0.773 \times 10^{13} \text{ s}^{-1}$ , respectively. Their bond lengths are 1.89 Å, 2.36 Å, and 2.71 Å. What are their reduced masses? What are their force constants? If NaH and NaD have the same force constant, what is the vibrational frequency of NaD? D is  $^2\text{H}$ .
- Recall that nuclear spin states in nuclear magnetic resonance are typically separated by energies of  $2 \times 10^{-5} \text{ kJ mol}^{-1}$  to  $2 \times 10^{-4} \text{ kJ mol}^{-1}$ . What are the ratios of occupation probability between a pair of such levels at thermal equilibrium and a temperature of  $25^\circ\text{C}$ ?
- The vibrational temperature of a molecule prepared in a supersonic jet can be estimated from the observed populations of its vibrational levels, assuming a Boltzmann distribution. The vibrational frequency of  $\text{HgBr}$  is  $5.58 \times 10^{12} \text{ s}^{-1}$ , and the ratio of the number of molecules in the  $n = 1$  state to the number in the  $n = 0$  state is 0.127. Estimate the vibrational temperature under these conditions.
- An electron in the  $\pi$  orbital of ethylene ( $\text{C}_2\text{H}_4$ ) is excited by a photon to the  $\pi^*$  orbital. Do you expect the equilibrium bond length in the excited ethene molecule to be greater or less than that in ground-state ethene? Will the vibrational frequency in the excited state be higher or lower than in the ground state? Explain your reasoning.

\*60. The ground-state electron configuration of the  $\text{H}_2^+$  molecular ion is  $(\sigma_{g1s})^1$ .

- A molecule of  $\text{H}_2^+$  absorbs a photon, promoting the electron to the  $\sigma_{u1s}^*$  molecular orbital. Predict what happens to the molecule.
  - Another molecule of  $\text{H}_2^+$  absorbs even more energy promoting the electron to the  $\sigma_{g2s}$  molecular orbital. Predict what happens to this molecule.
- \*61. (a) Draw a Lewis diagram for formaldehyde ( $\text{H}_2\text{CO}$ ), and decide the hybridization of the central carbon atom.
- Formulate the molecular orbitals for the molecule.
  - A strong absorption is observed in the ultraviolet region of the spectrum and is attributed to a  $\pi \rightarrow \pi^*$  transition. Another, weaker transition is observed at

- lower frequencies. What electronic excitation causes the weaker transition?
62. Write balanced chemical equations that describe the formation of nitric acid and sulfuric acid in rain, starting with the sulfur in coal and the oxygen, nitrogen, and water vapor in the atmosphere.
63. Compare and contrast the roles of ozone ( $O_3$ ) and nitrogen dioxide ( $NO_2$ ) in the stratosphere and in the troposphere.
64. Draw a schematic diagram of the steps in bacterial photosynthesis, numbering them in sequence and showing the approximate spatial relations of the involved molecules.
65. Do you expect the energy of the special pair of bacteriochlorophyll molecules to be higher or lower than the energy of an isolated bacteriochlorophyll? (*Hint*: Think about the analogy between the mixing of atomic orbitals to make molecular orbitals and the mixing of molecular orbitals on two nearby molecules.)

## CUMULATIVE PROBLEMS

66. At thermal equilibrium, is the rate as a molecule is excited from  $n = 0$  to the  $n = 1$  level greater than or less than the rate for the reverse process? What is the ratio of the rate constants? (*Hint*: Think of the analogy with the chemical equilibrium between two species.)
- \*67. It is important to know the dissociation constant of an indicator in order to use it properly in acid–base titrations. Spectrophotometry can be used to measure the concentration of these intensely colored species in acidic versus basic solutions, and from these data the equilibrium between the acidic and basic forms can be calculated. In one such study on the indicator *m*-nitrophenol, a  $6.36 \times 10^{-4}$  M solution was examined by spectrophotometry at 390 nm and 25°C in the following experiments. In highly acidic solution, where essentially all the indicator was in the form  $HIn$ , the absorbance was 0.142. In highly basic solution, where essentially all of the indicator was in the form  $In^-$ , the absorbance was 0.943. In a further series of experiments, the pH was adjusted using a buffer solution of ionic strength  $I$ , and absorbance was measured at each pH value. The following results were obtained:

pH	$I$	$A$
8.321	0.10	0.527
8.302	0.08	0.518
8.280	0.06	0.505
8.251	0.04	0.493
8.207	0.02	0.470

Calculate  $pK_a$  for the indicator at each value of ionic strength.

68. The hydroxyl radical has been referred to as the “chief clean-up agent in the troposphere.” Its concentration is approximately zero at night and becomes as high as  $1 \times 10^7$  molecules per  $cm^3$  in highly polluted air.
- (a) Calculate the maximum mole fraction and partial pressure of OH in polluted air at 25°C and atmospheric pressure.
- (b) Write an equation for the reaction of HO with  $NO_2$  in the atmosphere. How does the oxidation state of nitrogen change in this reaction? What is the ultimate fate of the product of this reaction?
69. In unpolluted air at 300 K, the hydroxyl radical OH reacts with CO with a bimolecular rate constant of  $1.6 \times 10^{11}$  L  $mol^{-1}$   $s^{-1}$  and with  $CH_4$  with a rate constant of  $3.8 \times 10^9$  L  $mol^{-1}$   $s^{-1}$ . Take the partial pressure of CO in air to be constant at  $1.0 \times 10^{-7}$  atm and that of  $CH_4$  to be  $1.7 \times 10^{-6}$  atm, and assume that these are the primary mechanisms by which OH is consumed in the atmosphere. Calculate the half-life of OH under these conditions.

Red dots represent the silicon atoms (only 2% are shown for clarity), and the gray spheres represent a native silicon dioxide layer located at the interface between the crystalline silicon substrate and layer of deposited polycrystalline silicon.

**T**hroughout history, the discovery of new materials from which to fashion the structures, machines, and devices of everyday life has set off great change in human affairs. Modern science and engineering—with chemistry in the central role—provide routes for modifying properties of materials to meet specific applications and for synthesizing and processing new materials designed from the beginning to have specific properties. The mechanical, thermal, electrical, and optical properties of a material depend on the extended nano-structural arrangement of chemical bonds within it. This arrangement can be created, modified, and tailored through chemical reactions. The contemporary disciplines of materials chemistry, solid state chemistry, and materials science and engineering—among the most active branches of chemistry today—all rely on the “properties ↔ structure ↔ reactions” correlation to make the leap from chemical bonding in isolated molecules (Unit II) to engineering applications.

## Unit Chapters

### CHAPTER 21

Structure and Bonding in Solids

### CHAPTER 22

Inorganic Materials

### CHAPTER 23

Polymeric Materials and Soft Condensed Matter

## Unit Goals

- To study the relationship between crystal symmetry and atomic-level structure as revealed by X-ray diffraction experiments
- To survey chemical bonding in classes of solids and correlate bonding with the properties of solids
- To explore three essential classes of materials—ceramics, optical and electronic materials, and polymers
- To illustrate the role of modern chemistry in measuring properties and identifying applications for both natural and manufactured materials

## 21

## CHAPTER

## Structure and Bonding in Solids

- 21.1 Crystal Symmetry and the Unit Cell
- 21.2 Crystal Structure
- 21.3 Cohesion in Solids
- 21.4 Defects and Amorphous Solids
- 21.5 **A Deeper Look . . .** Lattice Energies of Crystals

Pairs of silicon atoms separated by only 0.78 Å are clearly resolved in this ultrahigh-resolution electron microscope image.

In this chapter we begin a radical departure from the emphasis on the single molecule that permeates the previous 20 chapters. Unit II describes the chemical bonding and structure of single, isolated molecules. Unit III explains the macroscopic properties of gases and liquids through intermolecular forces that originate in the structures of individual molecules. While the behavior of many molecules contributes to these properties, the mechanism of their contribution is essentially that a few molecules come close enough to a “target” molecule to experience the intermolecular forces it sets up. Units IV and V deal with the equilibrium and rate aspects of chemical reactions as consequences of collisions between individual molecules.

The behavior of solids is a different story altogether. Chapter 10 identifies *rigidity* as the unique characteristic of solids, in dramatic contrast to the fluidity of gases and liquids. A rigid material retains its shape when an external mechanical force, called stress, is applied. A rigid material shows structural strength by not flowing under stress. All classes of solids behave this way because—with one

FIGURE 21.1 Calcite.

© Cengage Learning/Charles D. Winters

exception—they are not collections of molecules held together by intermolecular forces. Rather, solids are extended arrays of strong chemical bonds between atoms, almost as if they were “super-molecules.” These arrays extend over macroscopic distances, and it is the *collective behavior* of this set of chemical bonds that imparts strength and rigidity to solids.

A solid whose structure is highly ordered and symmetrical over macroscopic distances is called a **crystal**. Although the symmetry and beauty of crystals have always excited curiosity and wonder, the science of **crystallography** began only in the latter part of the 18th century. In those closing days of the Age of Enlightenment—while Lavoisier led the modern approach to chemistry—another brilliant French thinker established the fundamental laws of crystallography. René-Just Haüy was struck by the observation that when he accidentally dropped a crystal of calcite (a form of calcium carbonate), it fractured into smaller crystals with the same interfacial angles between their planar surfaces as in the original crystal. The statement that constant interfacial angles are observed when crystals are cleaved is now known as **Haüy's law**. Haüy concluded that the outward symmetry of crystals (Fig. 21.1) implies a highly regular internal structure and the existence of a smallest crystal unit. His inferences were correct. What distinguishes the crystalline state from the gaseous and liquid states is the nearly perfect positional order of the atoms, ions, or molecules in crystals. This crystalline order has been confirmed experimentally by X-ray diffraction and explained theoretically by the quantum theory of solids.

We begin this chapter with a look at the microscopic structure of a perfect crystal, and establish the methods for determining structure and the language for describing it. We then examine the types of chemical bonding in solids, identifying the forces that hold together different kinds of solids. The perfect crystal is the idealized model for investigations in solid state science, just as the ideal gas is the starting point for studies of fluid behavior. We use it as the point of reference for describing less ordered condensed phases of matter—defective crystals and amorphous solids—in terms of their deviations from perfect order and the consequent changes in properties. We end the chapter with a brief introduction to diffusion in solids, the mechanism by which a free atom migrates through an extended solid state structure. Diffusion has great influence on the rate and equilibrium of chemical reactions in the solid state and on tailoring the properties of the solids through carefully controlled incorporation of impurities.

## 21.1 Crystal Symmetry and the Unit Cell

The unifying aspect of crystal structure is the repetition, over long distances, of the same basic structural features in the arrangement of the atoms. The most fundamental way to characterize and classify these structures is based on the numbers and kinds of their **symmetry elements**. When the result of rotation, reflection, or inversion of an object can be exactly superimposed on the original object—that is, matched point for point to the original object—the structure is said to contain the corresponding symmetry element. Examples include an axis of rotation, a plane of reflection (mirror plane), or a central point (inversion center), as shown in Figure 21.2. These symmetry operations can be applied to geometrical shapes, to physical objects, and to molecular structures.

Consider a cube as an example. Suppose the center of the cube is placed at the origin of its coordinate system and the symmetry operations that transform it into identity with itself are counted (Fig. 21.3). The  $x$ ,  $y$ , and  $z$  coordinate axes are 4-fold axes of rotational symmetry, denoted by  $C_4$ , because a cube that is rotated through a multiple of  $90^\circ$  ( $= 360^\circ/4$ ) about any one of these axes is

**FIGURE 21.2** Three types of symmetry operation: rotation about an  $n$ -fold axis (with each axis going through the center of the structure and perpendicular to the plane of the page), reflection in a plane, and inversion through a point.

indistinguishable from the original cube. Similarly, a cube has four 3-fold axes of rotational symmetry, designated  $C_3$ , that are the body diagonals of the cube, connecting opposite vertices. In addition, a cube has six 2-fold rotational axes of symmetry, defined by the six axes that pass through the centers of edges and through the coordinate origin. Next, the cube has nine mirror planes of symmetry (designated by the symbol  $m$ ), which reflect any point in one half of the cube into an equivalent point in the other half. Finally, a cube has a center of inversion (inversion, designated  $i$ , is reflection through a point located at the center of the cube).

**FIGURE 21.3** Symmetry operations on a cube. There are three 4-fold axes, only two of which are shown, four 3-fold axes, only two of which are shown, and six 2-fold axes, only one of which is shown. The rest can be determined by connecting equivalent pairs of points by inspection. The nine planes of symmetry are also shown, as is the center of inversion.

**EXAMPLE 21.1**

Identify the symmetry elements of the ammonia molecule ( $\text{NH}_3$ ).

**Solution**

If the ammonia molecule is drawn as a pyramid with the nitrogen atom at the top (Fig. 21.4), then the only axis of rotational symmetry is a 3-fold axis passing downward through the N atom. Three mirror planes intersect at this 3-fold axis.

**Related Problems:** 3, 4

**FIGURE 21.4** An ammonia molecule has a 3-fold axis rotation axis and three mirror planes. The rotation axis is represented by the red dot, which indicates that the rotation occurs around an axis perpendicular to the plane of the page. The three mirror planes are also oriented perpendicular to the plane of the page.

### 21.1.1 Unit Cells in Crystals

The symmetry operations just described can be applied to crystals as well as to individual molecules or shapes. Identical sites within a crystal recur regularly because of long-range order in the organization of the atoms. The three-dimensional array made up of all the points within a crystal that have the same environment in the same orientation is a **crystal lattice**. Such a lattice is an abstraction “lifted away” from a real crystal, embodying the scheme of repetition at work in that crystal. The lattice of highest possible symmetry is that of the **cubic system**. This lattice is obtained by filling space with a series of identical cubes, each of which is called a **unit cell** of the system. A single unit cell contains all structural information about its crystal, because in principle the crystal could be constructed by making a great many copies of a single original unit cell and stacking them in a three-dimensional array. Unit cells fill space.

Other crystal systems besides cubic can be defined by their own unique unit cells. Constraints of symmetry permit only seven types of three-dimensional lattices. Each type has a unit cell with the shape of a parallelepiped (Fig. 21.5), whose size and shape are fully described by three edge lengths ( $a$ ,  $b$ , and  $c$ ) and the three angles between those edges ( $\alpha$ ,  $\beta$ , and  $\gamma$ ). These lengths and angles are the **cell constants**. The symmetry that defines each of the seven crystal systems imposes conditions on the shape of the unit cell summarized in relations among the cell constants (Table 21.1, Fig. 21.6). The unit cell chosen is the smallest unit that has all the symmetry elements of the crystal lattice; there is no benefit in using large cells once all the symmetry elements have been included. A unit cell of the minimum size is **primitive** and shares each of the eight *lattice points* at its corners with seven other unit cells, giving one lattice point per unit cell.

Other possible unit cells with the same volume (an infinite number, in fact) could be constructed, and each could generate the macroscopic crystal by repeated elementary translations, but only those shown in Figure 21.6 possess the symmetry elements of their crystal systems. Figure 21.7 illustrates a few of the infinite number of cells that can be constructed for a two-dimensional rectangular lattice. Only the rectangular cell B in the figure has three 2-fold rotation axes and two mirror planes. Although the other cells all have the same area, each of them has only one 2-fold axis and no mirror planes; they are therefore not acceptable unit cells.

**FIGURE 21.5** Unit cells always have three pairs of mutually parallel faces. Only six pieces of information are required to construct a scale model of a unit cell: the three cell edges ( $a$ ,  $b$ , and  $c$ ) and the three angles between the edges ( $\alpha$ ,  $\beta$ , and  $\gamma$ ). By convention,  $\gamma$  is the angle between edges  $a$  and  $b$ ,  $\alpha$  the angle between  $b$  and  $c$ , and  $\beta$  the angle between  $a$  and  $c$ .

TABLE 21.1

The Seven Crystal Systems

Crystal System	Minimum Essential Symmetry	Conditions on Unit-Cell Edges and Angles
Hexagonal	One 6-fold rotation	$a = b; \alpha = \beta = 90^\circ, \gamma = 120^\circ$
Cubic	Four independent 3-fold rotations <sup>†</sup>	$a = b = c; \alpha = \beta = \gamma = 90^\circ$
Tetragonal	One 4-fold rotation	$a = b; \alpha = \beta = \gamma = 90^\circ$
Trigonal	One 3-fold rotation	$a = b = c; \alpha = \beta = \gamma \neq 90^\circ$
Orthorhombic	Three mutually perpendicular 2-fold rotations	$\alpha = \beta = \gamma = 90^\circ$
Monoclinic	One 2-fold rotation	$\alpha = \beta = 90^\circ$
Triclinic	No symmetry required	None

<sup>†</sup>Each of these axes makes 70.53° angles with the other three.

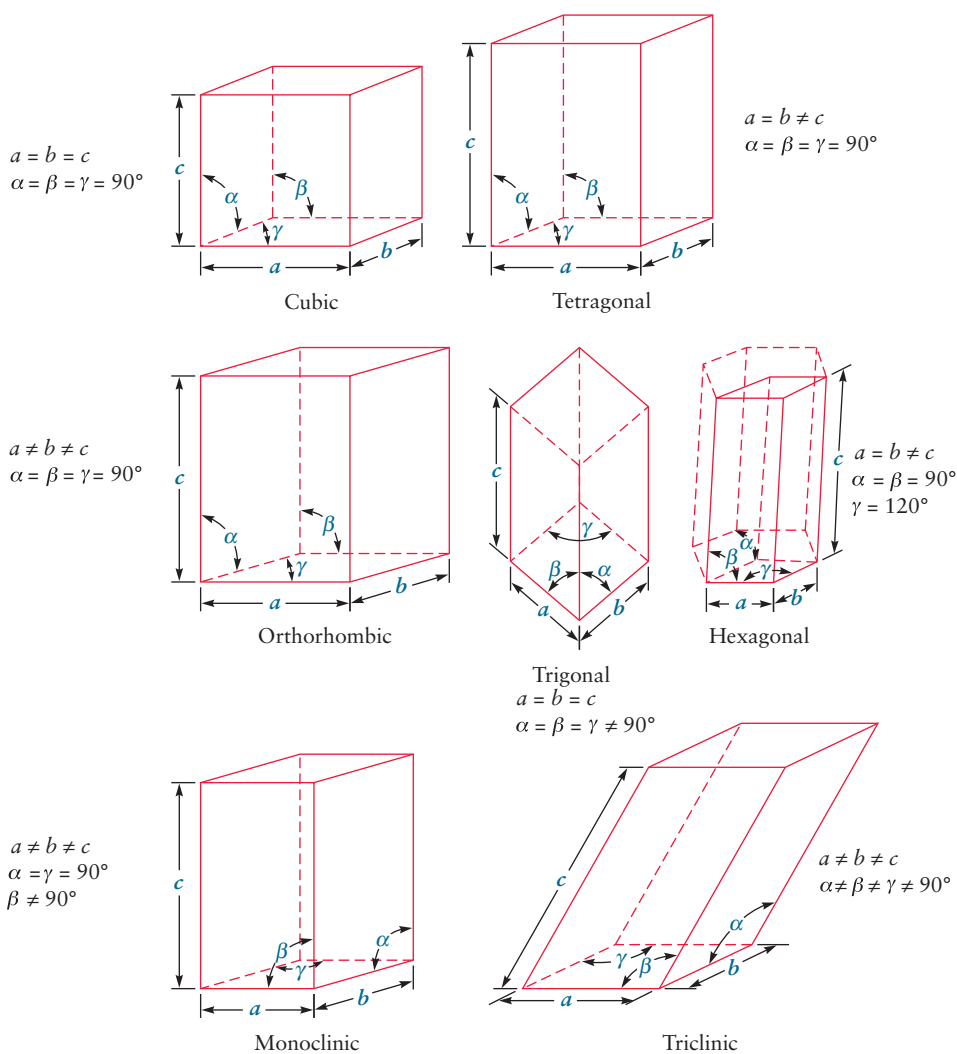

FIGURE 21.6 Shapes of the unit cells in the seven crystal systems. The more symmetric crystal systems have more symmetric cells.

FIGURE 21.7 Cells with and without mirror planes in a two-dimensional lattice. Each cell has the same area, but only cell B possesses mirror planes in addition to the 2-fold rotation axes required by the lattice.

**FIGURE 21.8** In this two-dimensional lattice, every lattice point is at the intersection of a horizontal mirror line and a vertical mirror line. It is possible to draw a primitive unit cell (red), but the larger, centered unit cell (blue) is preferred because it also has two mirror lines, the full symmetry of the lattice. A similar argument applies to the choice of unit cells on three-dimensional lattices.

Sometimes the smallest, or primitive, unit cell does not have the full symmetry of the crystal lattice. If so, a larger *nonprimitive* unit cell that does have the characteristic symmetry is deliberately chosen (Fig. 21.8). Only three types of nonprimitive cells are commonly used in the description of crystals: **body-centered**, **face-centered**, and **side-centered**. They are shown in Figure 21.9 for a cubic unit cell.

### 21.1.2 Scattering of X-Rays by Crystals

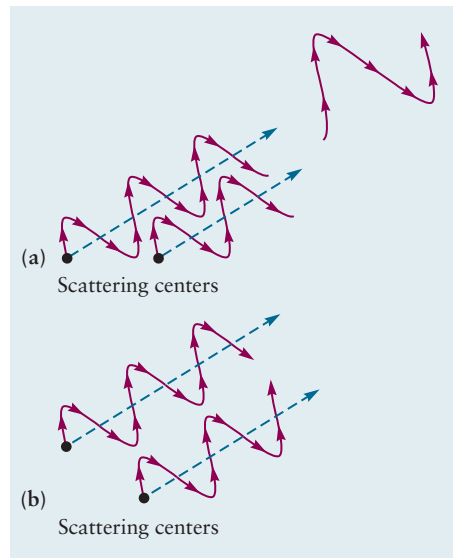

In the 19th century, crystallographers could classify crystals into the seven crystal systems only on the basis of their external symmetries. They could not measure the dimensions of unit cells or the positions of atoms within them. Several developments by German physicists changed this situation at the turn of the century. Wilhelm Roentgen's discovery of X-rays in 1895 provided a tool of enormous power for determining the structures of crystals. Max von Laue suggested that crystals might serve as three-dimensional gratings for the diffraction of electromagnetic radiation with a wavelength comparable to the distance between planes of atoms. Friedrich and Knipping demonstrated experimentally in 1912 that this was indeed the case, and von Laue was awarded the Nobel Prize in physics in 1914 for his theory of the diffraction of X-rays by crystals. At about the same time, W. H. Bragg and W. L. Bragg (father and son) at Cambridge University in England also demonstrated the diffraction of X-rays by crystals and shared the Nobel Prize in physics the following year. (W. L. Bragg was 22 years old and still a student at Cambridge when he discovered the diffraction law.) The formulation of the diffraction law proposed by the Braggs is equivalent to von Laue's suggestion and somewhat simpler to visualize. So we will follow an approach similar to theirs.

When electromagnetic radiation passes through matter, it interacts with the electrons in atoms, and some of it is scattered as spherical waves going out from the atoms in the solid. Suppose that X-radiation strikes two neighboring scattering centers. The expanding spheres of scattered waves soon encounter each other and interfere. In some directions, the waves are in phase and reinforce

**FIGURE 21.9** Centered lattices, like all lattices, have lattice points at the eight corners of the unit cell. A body-centered lattice has an additional lattice point at the center of the cell, a face-centered lattice has additional points at the centers of the six faces, and a side-centered lattice has points at the centers of two parallel sides of the unit cell. (**Note:** The colored dots in the lattice diagrams represent lattice points, not atoms.)

**FIGURE 21.10** A beam of X-rays (not shown) is striking two scattering centers, which emit scattered radiation. The difference in the lengths of the paths followed by the scattered waves determines whether they interfere (a) constructively or (b) destructively. This path difference depends on both the distance between the centers and the direction in which the scattered waves are moving. If the incoming waves travel a different distance to each scattering center, that must be accounted for as well (see Fig. 21.11).

each other, or interfere *constructively* (Fig. 21.10a); in others they are out of phase and cancel each other out, or interfere *destructively* (see Fig. 21.10b). Constructive interference occurs when the paths traversed by two waves differ in length by a whole number of wavelengths. The amplitudes of waves that interfere constructively add to one another, and the intensity of the scattered radiation in that direction is proportional to the square of the total amplitude.

Figure 21.11 illustrates the constructive interference of X-rays scattered by the electrons in atoms in equally spaced planes separated by the distance  $d$ . A parallel bundle of coherent X-rays of a single known wavelength is allowed to fall on the surface of a crystal, making an angle  $\theta$  with a set of parallel planes of atoms in the crystal. The scattering angle  $2\theta$  is then varied by rotating the crystal about an axis perpendicular to the plane of the figure. Line AD in Figure 21.11 represents a wave front of waves that are in phase as they approach the crystal. The wave that is scattered at B follows the path ABC, and the one that is scattered at F follows the path DFH. The second wave travels a greater distance than the first, and the difference in path length is the sum of the two segments EF and FG. To achieve constructive interference in the scattered waves (that is, for the phases to be the same along the wave front CH), this additional

**FIGURE 21.11** Constructive interference of X-rays scattered by atoms in lattice planes. Three beams of X-rays, scattered by atoms in three successive layers of a simple cubic crystal, are shown. Note that the phases of the waves are the same along the line CH, indicating constructive interference at this scattering angle  $2\theta$ .

distance traveled by the second wave must be an integral multiple of the X-ray wavelength  $\lambda$ :

$$EF + FG = n\lambda \quad n = 1, 2, 3, \dots$$

From trigonometry, the lengths of these two segments are equal to each other and to  $d \sin \theta$ , where  $d$  is the interplanar spacing. Therefore, constructive interference occurs only when

$$n\lambda = 2d \sin \theta \quad n = 1, 2, 3, \dots \quad [21.1]$$

It is easy to verify that for angles that meet this condition, the waves scattered from the third and subsequent planes are also in phase with the waves scattered from the first two planes.

The preceding condition on allowed wavelengths is called the **Bragg law**, and the corresponding angles are called *Bragg angles* for that particular set of parallel planes of atoms. It appears as though the beam of X-rays has been reflected symmetrically from those crystal planes, and we often speak colloquially of the “Bragg reflection” of X-rays. The X-rays have not been reflected, however, but have undergone constructive interference, more commonly called diffraction. The case  $n = 1$  is called first-order Bragg diffraction,  $n = 2$  is second-order, and so forth.

We now possess a tool of immense value for determining the interplanar spacings of crystals. If a crystal is turned through different directions, other parallel sets of planes with different separations are brought into the Bragg condition. The symmetry of the resulting diffraction pattern identifies the crystal system, and the Bragg angles determine the cell constants. Moreover, the *intensities* of the diffracted beams permit the locations of the atoms in the unit cell to be determined.

Analogous scattering techniques use beams of neutrons. In that case the scattering interaction is between the magnetic moments of the incident neutrons and nuclei in the solid, but the principles are the same as for X-ray diffraction. Of course, it is the wave character of neutrons (in particular, their de Broglie wavelength; see Chapter 4) that is responsible for neutron diffraction. Recall that the de Broglie wavelength and neutron momentum are related by  $\lambda = h/p$ .

### EXAMPLE 21.2

A diffraction pattern of aluminum is obtained by using X-rays with wavelength  $\lambda = 0.709 \text{ \AA}$ . The second-order Bragg diffraction from the parallel faces of the cubic unit cells is observed at the angle  $2\theta = 20.2^\circ$ . Calculate the lattice parameter  $a$ .

#### Solution

From the Bragg condition for  $n = 2$ ,

$$2\lambda = 2d \sin \theta$$

the spacing between planes, which is the lattice parameter, is

$$d = \frac{\lambda}{\sin \theta} = \frac{0.709 \text{ \AA}}{\sin (10.1^\circ)} = 4.04 \text{ \AA} = a$$

**Related Problems: 5, 6**

## 21.2 Crystal Structure

The crystal lattice is an abstract construction whose points of intersection describe the underlying symmetry of a crystal. To flesh out the description of a particular solid state structure, we must identify some structural elements that are “pinned” to the lattice points. These structural elements can be atoms, ions,

or even groups of atoms as we see in this and the next chapter. We begin with some illustrative simple cases. Some of the chemical elements crystallize in particularly simple solid structures, in which a single atom is situated at each point of the lattice.

Polonium is the only element known to crystallize in the **simple cubic lattice**, with its atoms at the intersections of three sets of equally spaced planes that meet at right angles. Each unit cell contains one Po atom, separated from each of its six nearest neighbors by  $3.35 \text{ \AA}$ .

The alkali metals crystallize in the **body-centered cubic (bcc) structure** at atmospheric pressure (Fig. 21.12). A unit cell of this structure contains two lattice points, one at the center of the cube and the other at any one of the eight corners. A single alkali-metal atom is associated with each lattice point. An alternative way to visualize this is to realize that each of the eight atoms that lie at the corners of a bcc unit cell is shared by the eight unit cells that meet at those corners. The contribution of the atoms to one unit cell is therefore  $8 \times \frac{1}{8} = 1$  atom, to which is added the atom that lies wholly within that cell at its center.

The metals aluminum, nickel, copper, and silver, among others, crystallize in the **face-centered cubic (fcc) structure** shown in Figure 21.13. This unit cell contains four lattice points, with a single atom associated with each point. No atom

**FIGURE 21.12** The bcc structure. An atom is located at the center of each cubic cell (orange) as well as at each corner of the cube (blue). The atoms are reduced slightly in size to make positions clear.

**FIGURE 21.13** The fcc structure. Atoms are located at the centers of the faces (orange) as well as at the corners of the cube (blue). The atoms are reduced slightly in size to make positions clear.

lies wholly within the unit cell; there are atoms at the centers of its six faces, each of which is shared with another cell (contributing  $6 \times \frac{1}{2} = 3$  atoms), and an atom at each corner of the cell (contributing  $8 \times \frac{1}{8} = 1$  atom), for a total of four atoms per unit cell.

The volume of a unit cell is given by the formula

$$V_c = abc \sqrt{1 - \cos^2\alpha - \cos^2\beta - \cos^2\gamma + 2 \cos \alpha \cos \beta \cos \gamma} \quad [21.2]$$

When the angles are all  $90^\circ$  (so that their cosines are 0), this formula reduces to the simple result  $V = abc$  for the volume of a rectangular box. If the mass of the unit cell contents is known, the theoretical cell density can be computed. This density must come close to the measured density of the crystal, a quantity that can be determined by entirely independent experiments. For an *element* whose crystal contains  $n_c$  atoms per unit cell, the calculated cell density is

$$\text{density} = \rho = \frac{\text{mass}}{\text{volume}} = \frac{n_c \left( \frac{\mathcal{M}}{N_A} \right)}{V_c} = \frac{n_c \mathcal{M}}{N_A V_c}$$

where we have used the fact that the molar mass  $\mathcal{M}$  of the element divided by Avogadro's number  $N_A$  is the mass of a single atom. This equation can also be used to calculate Avogadro's number from the measured density and cell constants, as the following example illustrates.

### EXAMPLE 21.3

Sodium has a density of  $\rho = 0.9700 \text{ g cm}^{-3}$  at  $20^\circ\text{C}$ , and its lattice parameter is  $a = 4.2856 \text{ \AA}$ . What is the value of Avogadro's number, given that the molar mass of sodium is  $22.9898 \text{ g mol}^{-1}$ ?

#### Solution

Sodium has two atoms per unit cell because its structure is bcc, and the volume of the unit cell is  $a^3$ . Solve the foregoing equation for Avogadro's number:

$$\begin{aligned} N_A &= \frac{n_c \mathcal{M}}{\rho a^3} \\ &= \frac{(2)(22.9898 \text{ g mol}^{-1})}{(0.9700 \text{ g cm}^{-3})(4.2856 \times 10^{-8} \text{ cm})^3} \\ &= 6.022 \times 10^{23} \text{ mol}^{-1} \end{aligned}$$

**Related Problems: 15, 16**

It is useful to define the locations of atoms in the unit cell with a set of three numbers measured in units of the lattice parameter(s). For this purpose, one corner of the unit cell is taken to be at the origin of the coordinate axes appropriate to the crystal system, and an atom at that lattice point has the coordinates  $(0, 0, 0)$ . Equivalent atoms at the seven remaining corners of the cell then have the coordinates  $(1, 0, 0)$ ,  $(0, 1, 0)$ ,  $(0, 0, 1)$ ,  $(1, 0, 1)$ ,  $(1, 1, 0)$ ,  $(0, 1, 1)$ , and  $(1, 1, 1)$ . These atom positions are generated from an atom at  $(0, 0, 0)$  by successive translations through unit distances along the three axes. An atom in a body-centered site has coordinates  $(\frac{1}{2}, \frac{1}{2}, \frac{1}{2})$  and the prescription for locating it is to proceed from the coordinate origin at  $(0, 0, 0)$  a distance  $a/2$  along  $a$ , then a distance  $b/2$  along  $b$ , and finally  $c/2$  along  $c$ . In the same way, an atom in a face-centered site has coordinates such as  $(\frac{1}{2}, \frac{1}{2}, 0)$ ,  $(\frac{1}{2}, 0, \frac{1}{2})$ , or  $(0, \frac{1}{2}, \frac{1}{2})$ .

So far, we have considered only cubic metals in which one atom corresponds to each lattice point. More complicated structures also occur, even for the elements, in which atoms occupy positions that are not lattice points. Diamond has an fcc structure with eight atoms (not four) per unit cell (see Fig. 21.22). Boron has a tetragonal structure with a very complex unit cell that contains 50 atoms. In molecular crystals the number of atoms per unit cell can be still greater; in a

protein with a molecular mass of  $10^5$ , there may be tens of thousands of atoms per unit cell. The computer-generated model of the protein myoglobin shown in Figure 23.21 is representative of the kinds of complex structures that are now routinely determined using modern X-ray crystallography.

### 21.2.1 Atomic Packing in Crystals

As we begin to add structural features like atoms onto crystal lattice sites, we have to pay attention to the size of the features. How efficiently can we pack atoms onto a lattice? We have already discussed two measures of the “size” of an atom or molecule. In Section 9.6, the van der Waals parameter  $b$  was related to the volume excluded per mole of molecules, so  $b/N_A$  is one measure of molecular size. In Section 5.5, we defined an approximate radius of an atom as the distance at which the electron density had fallen off to a particular value, or as the radius of a sphere containing a certain fraction of the total electron density. A third related measure of atomic size is based on the interatomic separations in a crystal. The radius of a noble-gas or metallic atom can be approximated as half the distance between the center of an atom and the center of its nearest neighbor in the crystal. We picture crystal structures as resulting from packing spheres in which nearest neighbors are in contact.

The nearest neighbor separation in a simple cubic crystal is equal to the lattice parameter  $a$ , so the atomic radius in that case is  $a/2$ . For the bcc lattice, the central atom in the unit cell “touches” each of the eight atoms at the corners of the cube, but those at the corners do not touch one another, as Figure 21.12 shows. The nearest-neighbor-distance is calculated from the Cartesian coordinates of the atom at the origin  $(0, 0, 0)$  and that at the cell center  $(a/2, a/2, a/2)$ . By the Pythagorean theorem, the distance between these points is  $\sqrt{(a/2)^2 + (a/2)^2 + (a/2)^2} = a\sqrt{3}/2$ , so the atomic radius is  $a\sqrt{3}/4$ . Figure 21.13 shows that in an fcc crystal the atom at the center of a face [such as at  $(0, a/2, a/2)$ ] touches each of the neighboring corner atoms [such as at  $(0, 0, 0)$ ], so the nearest-neighbor distance is  $\sqrt{(a/2)^2 + (a/2)^2} = a\sqrt{2}/2$  and the atomic radius is  $a\sqrt{2}/4$ . Table 21.2 summarizes the results for cubic lattices.

What is the most dense crystal packing that can be achieved? To answer this question, construct a crystal by first putting down a plane of atoms with the highest possible density, shown in Figure 21.14a. Each sphere is in contact with six other spheres in the plane. Then put down a second close-packed plane on top of the first one (see Fig. 21.14b) in such a way that each sphere in the second plane is in contact with three spheres in the plane below it; that is, each sphere in the second plane forms a tetrahedron with three spheres beneath. When the third plane is laid down, there are two possibilities. In Figure 21.14c, the atoms

**TABLE 21.2**  
Structural Properties of Cubic Lattices

	Simple Cubic	Body-Centered Cubic	Face-Centered Cubic
Lattice points per cell	1	2	4
Number of nearest neighbors	6	8	12
Nearest-neighbor distance	$a$	$a\sqrt{3}/2 = 0.866a$	$a\sqrt{2}/2 = 0.707a$
Atomic radius	$a/2$	$a\sqrt{3}/4 = 0.433a$	$a\sqrt{2}/4 = 0.354a$
Packing fraction	$\frac{\pi}{6} = 0.524$	$\frac{\sqrt{3}\pi}{8} = 0.680$	$\frac{\sqrt{2}\pi}{6} = 0.740$

**FIGURE 21.14** Close-packing of spheres. (a) One layer, with each atom surrounded by six nearest neighbors. (b) Two layers, with the atoms of the second layer centered on top of indentations in the layer below. (c) The third layer can be placed on sites that are not directly above the sites in the first layer (note that the red spheres show through). If this pattern is repeated as *abcabc* . . . it gives cubic close-packing. (d) Alternatively, the third layer can be placed directly over the sites in the first layer (note that the white triangular spaces show through). The repeated pattern *ababab* . . . gives hexagonal close-packing.

in the third plane lie on sites not directly over those in the first layer, whereas in Figure 21.14d the third-plane atoms are directly over the first-plane atoms.

Clearly, there are two choices for placing each plane, and an infinite number of crystal structures can be generated that have the same atomic packing density. The two simplest such structures correspond to the periodic layer sequences *abcabcab* . . . and *abababa* . . . The first of these is the fcc structure already discussed, and the second is a close-packed structure in the hexagonal crystal system termed **hexagonal close-packed (hcp) structure**. In each of these simple structures, atoms occupy 74.0% of the unit cell volume, as the following example shows. (Atoms that crystallize in the bcc structure occupy only 68.0% of the crystal volume, and the packing fraction for a simple cubic array is only 52.4%.)

#### EXAMPLE 21.4

Calculate (a) the atomic radius of an aluminum atom and (b) the fraction of the volume of aluminum that is occupied by its atoms.

#### Solution

(a) Aluminum crystallizes in the fcc crystal system, and its unit cell therefore contains four atoms. Because a face-centered atom touches each of the atoms at the corners of its face, the atomic radius  $r_1$  (see the triangle in Fig. 21.15) can be expressed by

$$4r_1 = a\sqrt{2}$$

Using the value  $a = 4.04 \text{ \AA}$  derived from X-ray diffraction (see Example 21.2) and solving for  $r_1$  gives

$$r_1 = 1.43 \text{ \AA}$$

(b) The fraction of the volume of an aluminum single crystal that is occupied by its atoms is

$$f = \frac{4 \left[ \frac{4}{3} \pi r_1^3 \right]}{a^3} = \frac{4 \frac{4}{3} \pi \left[ \frac{a\sqrt{2}}{4} \right]^3}{a^3} = 0.740$$

**Related Problem: 23**

### 21.2.2 Interstitial Sites

The ways in which the empty volume is distributed in a crystal are both interesting and important. For the close-packed fcc structure, two types of **interstitial sites**, upon which the free volume in the unit cell is centered, are identifiable. An *octahedral site* is surrounded at equal distances by six nearest-neighbor atoms. Figure 21.15 shows that such sites lie at the midpoints of the edges of the fcc unit cell. A cell has twelve edges, each of which is shared by four unit cells, so the edges contribute three octahedral interstitial sites per cell. In addition, the site at the center of the unit cell is also octahedral, so the total number of

**FIGURE 21.15** Octahedral sites in an fcc lattice. The geometric procedure for relating the site radius  $r_2$  to the atom radius  $r_1$  is shown.

octahedral sites per fcc unit cell is four, the same as the number of atoms in the unit cell.

With a bit of simple geometry, we can calculate the size of an octahedral site in an fcc structure or, more precisely, the radius  $r_2$  of a smaller atom that would fit in the site without overlapping its neighboring atoms. Figure 21.15 represents a cell face in which the length of the diagonal is  $4r_1$  and the length of the cell edge is  $2r_1 + 2r_2$ , where  $r_1$  is the radius of the host atoms and  $r_2$  is the radius of the octahedral site. From the figure,

$$r_1 = a \frac{\sqrt{2}}{4}$$

$$a = 2r_2 + 2r_1 = 2r_2 + 2a \frac{\sqrt{2}}{4}$$

$$r_2 = \frac{a}{2} - a \frac{\sqrt{2}}{4} = 0.146a$$

and the ratio of the octahedral-site radius to the host-atom radius is

$$\frac{r_2}{r_1} = \frac{0.146a}{a\sqrt{2}/4} = 0.414$$

The second type of interstitial site, known as a *tetrahedral site*, lies at the center of the space defined by four touching spheres. In an fcc cell, a tetrahedral site occurs in the volume between a corner atom and the three face-centered atoms nearest to it. Geometrical reasoning like that used for the octahedral site gives the following ratio of the radius of a tetrahedral site to that of a host atom:

$$\frac{r_2}{r_1} = 0.225$$

The fcc unit cell contains eight tetrahedral sites, twice the number of atoms in the cell.

Interstitial sites are important when a crystal contains atoms of several kinds with considerably different radii. We will return to this shortly when we consider the structures of ionic crystals.

## 21.3 Cohesion in Solids

In addition to symmetry, the nature of the bonding forces between atoms provides a useful way to classify solids. This classification does indeed lead to an understanding of the remarkable differences in the chemical and physical properties of different materials. We now consider crystals held together through ionic, metallic, or covalent bonding interactions, and the one class of solids held together by intermolecular forces.

### 21.3.1 Ionic Crystals

Compounds formed by atoms with significantly different electronegativities are largely ionic, and to a first approximation the ions can be treated as hard, charged spheres that occupy positions on the crystal lattice (see the ionic radii in Appendix F). All the elements of Groups I and II of the periodic table react with Group VI and VII elements to form ionic compounds, the great majority of which crystallize in the cubic system. The alkali-metal halides (except for the cesium halides), the ammonium halides, and the oxides and sulfides of the alkaline-earth metals all crystallize in the *rock-salt*, or **sodium chloride structure**

**FIGURE 21.16** The sodium chloride, or rock-salt, structure. On the left, the sizes of the  $\text{Na}^+$  ions (purple) and the  $\text{Cl}^-$  ions (green) are drawn to scale. On the right, the ions are reduced in size to allow a unit cell (shown by red lines) to be outlined clearly.

**FIGURE 21.17** The structure of cesium chloride. On the left, the sizes of the  $\text{Cs}^+$  ions (purplish pink) and the  $\text{Cl}^-$  ions (green) are drawn to scale. On the right, they are reduced in size to allow a unit cell (shown by red lines) to be outlined clearly. Note that the lattice in this structure is simple cubic, with one  $\text{Cs}^+$  ion and one  $\text{Cl}^-$  ion per unit cell.

(a) Sphalerite ( $\text{ZnS}$ )

(b) Fluorite ( $\text{CaF}_2$ )

**FIGURE 21.18** Two ionic lattices in the fcc system. A single (nonprimitive) cubic unit cell of each is shown.

of ionic crystals shown in Figure 21.16. It may be viewed as an fcc lattice of anions whose octahedral sites are all occupied by cations or, equivalently, as an fcc lattice of cations whose octahedral sites are all occupied by anions. Either way, each ion is surrounded by six equidistant ions of the opposite charge. The rock-salt structure is a stable crystal structure when the cation-anion radius ratio lies between 0.414 and 0.732, if cations and anions are assumed to behave as incompressible charged spheres.

When the hard-sphere cation-anion radius ratio exceeds 0.732, as it does for the cesium halides, a different crystal structure called the **cesium chloride structure of ionic crystals**, is more stable. It may be viewed as two interpenetrating simple cubic lattices, one of anions and the other of cations, as shown in Figure 21.17. When the cation-anion radius ratio is less than 0.414, the *zinc blende*, or *sphalerite*, structure (named after the structure of  $\text{ZnS}$ ) results. This crystal consists of an fcc lattice of  $\text{S}^{2-}$  ions, with  $\text{Zn}^{2+}$  ions occupying half of the available tetrahedral sites in alternation, as Figure 21.18a illustrates. Fluorite ( $\text{CaF}_2$ ) has yet another structure; the unit cell is based on an fcc lattice of  $\text{Ca}^{2+}$  ions. The  $\text{F}^-$  ions occupy all eight of the tetrahedral sites, so the unit cell contains four  $\text{Ca}^{2+}$  and eight  $\text{F}^-$  ions (see Fig. 21.18b). The radius ratios (0.414 and 0.732) at which crossovers from one type of crystal to another occur are not accidental numbers. Recall from Section 21.2 that 0.414 is the ratio of the octahedral-site radius to the host-atom radius for an fcc lattice; only when this size ratio is exceeded does the ion inserted into that site come into contact with ions of the opposite sign in the rock-salt structure. The number 0.732 comes from a corresponding calculation of the radius ratio of the interstitial site at the center of a simple cubic unit cell (see problem 25). It is important to realize that the radius-ratio criterion for the stability limits of the structures of binary ionic compounds assumes that the ions are incompressible and that the wave functions do not overlap. The criterion fails when these approximations are not met.

The strength and range of the electrostatic attractions make ionic crystals hard, high-melting, brittle solids that are electrical insulators. Melting an ionic crystal, however, disrupts the lattice and sets the ions free to move, so ionic liquids are good electrical conductors.

### 21.3.2 Metallic Crystals

The type of bonding found in metals is quite different from that in other crystals. As we compare the various main group and transition metals in the periodic table we see only small differences in electronegativity. So, there is little tendency for ionic bonding in metals. The electronic configurations of metal atoms, even in the transition metals, do not have nearly-filled subshells, so there is little tendency to form covalent bonds by sharing electrons to achieve a stable octet. The familiar classical models of chemical bonding (see Chapter 3) do not extend to metals.

Prior to quantum mechanics, bonding in metals was described by the Drude model, named for the German physicist Paul Drude. The solid was viewed as a fixed array of positively charged metal ions, each localized at a site of the crystal lattice. These fixed ions were surrounded by a sea of mobile electrons, one contributed by each of the atoms in the solid. The number density of electrons was equal to the number density of positively charged ions, so the metal was electrically neutral. The sea of delocalized electrons would interact with the stable ions to give a strong cohesive force keeping the metal bound together. The Drude model accounts for the malleability (deformation in response to mechanical force, like hammering) and ductility (ease of drawing into a fine wire) of metals. As some ions move to new positions in response to these mechanical disturbances, delocalized electrons can rapidly adjust to maintain metallic bonding in the deformed or drawn solid. The ease with which metals conduct electricity is explained because these delocalized electrons can respond to any applied electric fields.

The delocalized sea of electrons picture of metal bonding survives in the quantum theory of solids, which is an extension of the molecular orbital description of molecular bonding (see Chapter 6). The valence electrons in a metal are delocalized in huge molecular orbitals that extend over the entire crystal and provide the “glue” that holds together the positively charged ion cores of the metal atoms. To understand the origin of these molecular orbitals, suppose just two sodium atoms are brought together, each in its electronic ground state with the configuration  $1s^2 2s^2 2p^6 3s^1$ . As the atoms approach each other, the wave functions of their 3s electrons combine to form two molecular orbitals—one in which their phases are symmetric ( $\sigma_{3s}$ ) and another in which they are antisymmetric ( $\sigma_{3s}^*$ ). Solving the Schrödinger equation yields two energy states, one above and the other below the energy of the atomic 3s levels, analogous to the formation of a hydrogen molecule from two hydrogen atoms described in Chapter 6. If both valence electrons are put into the level of lower energy with spins opposed, the result is a  $\text{Na}_2$  molecule. If a third sodium atom is added, the 3s atomic levels of the atoms split into three sublevels (Fig. 21.19). Two electrons occupy the lowest level with their spins opposed, and the third electron occupies the middle level. The three energy levels and the three electrons belong collectively to the three sodium atoms. A fourth sodium atom could be added so that there would be four closely spaced energy sublevels, and this process could be carried on without limit.

The foregoing is not a mere “thought experiment.” Sodium vapor contains about 17%  $\text{Na}_2$  molecules at its normal boiling point. Larger sodium clusters have been produced in molecular beam experiments, and mass spectrometry

**FIGURE 21.19** As sodium atoms are brought together, the molecular orbitals formed from their 3s atomic orbitals spread out into a band of levels, half occupied by electrons.

shows that such clusters can contain any desired number of atoms. For each added Na atom, another energy sublevel is added. Because the sublevels are so very closely spaced in a solid (with, say,  $10^{23}$  atoms), the collection of sublevels can be regarded as an *energy band*. Figure 21.19 depicts the formation of bands of sublevels that broaden (become delocalized) as the spacing between the nuclear centers decreases, and the 3s electrons go into these bands. The electrons that belong to the 1s, 2s, and 2p atomic levels of sodium are only very slightly broadened at the equilibrium internuclear separation of the crystal, so they retain their distinct, localized character as the core levels of the ions at the lattice sites. Chapter 22 explores the electrical properties of metals, which arise from this band structure.

Most metals have crystal structures of high symmetry and crystallize in bcc, fcc, or hcp lattices (Fig. 21.20). Relatively few metals (Ga, In, Sn, Sb, Bi, and Hg) have more complex crystal structures. Many metals undergo phase transitions to other structures when the temperature or pressure is changed. Both liquid and crystal phases can be metals; in fact, the conductivity usually drops by only a small amount when a metal melts. The electron sea provides very strong binding in most metals, as shown by their high boiling points. Metals have a very large range of melting points. Gallium melts at  $29.78^\circ\text{C}$  (Fig. 21.21), and mercury stays liquid at temperatures that freeze water. Many transition metals require temperatures in excess of  $1000^\circ\text{C}$  to melt, and tungsten, the highest melting elemental metal, melts at  $3410^\circ\text{C}$  (see Section 8.1).

**FIGURE 21.22** The structure of diamond. Each carbon atom has four nearest neighbors surrounding it at the corners of a tetrahedron.

### 21.3.4 Molecular Crystals

Molecular crystals include the noble gases; oxygen; nitrogen; the halogens; compounds such as carbon dioxide; metal halides of low ionicity such as  $\text{Al}_2\text{Cl}_6$ ,  $\text{FeCl}_3$ , and  $\text{BiCl}_3$ ; and the vast majority of organic compounds. All these molecules are held in their lattice sites by the intermolecular forces discussed in Sections 9.6 and 10.2. The trade-off between attractive and repulsive forces among even small molecules in a molecular crystal is complex because so many atoms are involved. A useful simplification is to picture a molecule as a set of fused spheres centered at each nucleus. The radius of each sphere is the van der Waals radius of the element involved. In molecular crystals, such shapes pack together so that no molecules overlap but empty space is minimized. Figure 21.23 depicts such a “space-filling model” of cyanuric triazide ( $\text{C}_3\text{N}_12$ ), showing how nature solves the problem of efficiently packing many copies of the rather complicated molecular shape of  $\text{C}_3\text{N}_{12}$  in a single layer. In the three-dimensional molecular crystal of  $\text{C}_3\text{N}_{12}$ , many such layers stack up with a slight offset that minimizes unfilled space between layers.

Van der Waals forces are much weaker than the forces that operate in ionic, metallic, and covalent crystals. Consequently, molecular crystals typically have low melting points and are soft and easily deformed. Although at atmospheric pressure the noble-gas elements crystallize in the highly symmetric fcc lattice shown in Figure 21.13, molecules (especially those with complex geometries) more often form crystals of low symmetry in the monoclinic or triclinic systems. Molecular crystals are of great scientific value. If proteins and other macromolecules are obtained in the crystalline state, their structures can be determined by X-ray diffraction. Knowing the three-dimensional structures of biological molecules is the starting point for understanding their functions.

**FIGURE 21.23** The van der Waals radii of the carbon and nitrogen atoms superimposed on an outline of the molecular structure of cyanuric triazide,  $\text{C}_3\text{N}_{12}$ , to show the volume of space from which each molecule excludes the others. Van der Waals forces in the molecular crystal hold the molecules in contact in a pattern that minimizes empty space. The thin white lines emphasize the 3-fold symmetry of the pattern.

### 21.3.5 Crystal Structures of the Elements

The chemical elements provide examples of three of the four classes of crystalline solids described in this section. Only ionic solids are excluded, because a single element cannot have the two types of atoms of different electronegativities needed to form an ionic material. We have already discussed some of the structures formed by metallic elements, which are sufficiently electropositive that their atoms readily give up electrons to form the electron sea of metallic bonding. The nonmetallic elements are more complex in their structures, reflecting a competition between intermolecular and intramolecular bonding and producing molecular or covalent solids with varied properties.

Each halogen atom has seven valence electrons and can react with one other halogen atom to form a diatomic molecule. Once this single bond forms, there is no further bonding capacity; the halogen diatomic molecules interact with one another only through relatively weak van der Waals forces and form molecular solids with low melting and boiling points.

The Group VI elements oxygen, sulfur, and selenium display dissimilar structures in the solid state. Each oxygen atom (with six valence electrons) can form one double or two single bonds. Except in ozone, its high-free-energy form, oxygen uses up all its bonding capacity with an intramolecular double bond, forming a molecular liquid and a molecular solid that are only weakly bound. In contrast, diatomic sulfur molecules ( $S_2$ ) are relatively rare, being encountered only in high-temperature vapors. The favored forms of sulfur involve the bonding of every atom to two other sulfur atoms. This leads to either rings or chains, and both are observed. The stable form of sulfur at room temperature consists of  $S_8$  molecules, with eight sulfur atoms arranged in a puckered ring (Fig. 21.24). The weak interactions between  $S_8$  molecules make elemental sulfur a rather soft molecular solid. Above  $160^\circ\text{C}$  the rings in molten sulfur break open and re-link to form long, tangled chains, producing a highly viscous liquid. An unstable ring form of selenium ( $Se_8$ ) is known, but the thermodynamically stable form of this element is a gray crystal of metallic appearance that consists of very long spiral chains with weak interchain interaction. Crystalline tellurium has a similar structure. The Group VI elements thus show a trend (moving down the periodic table) from the formation of multiple bonds toward the chains and rings characteristic of atoms that each form two single bonds.

**FIGURE 21.24** The structure of the  $S_8$  sulfur molecule. The orthorhombic unit cell of rhombic sulfur, the most stable form of elemental sulfur at room temperature, is large and contains 16 of these  $S_8$  molecules for a total of 128 atoms of sulfur.

A similar trend is evident in Group V. Only nitrogen forms diatomic molecules with triple bonds, in which all the bonding capacity is used between pairs of atoms. Elemental phosphorus exists in three forms, in all of which each phosphorus atom forms three single bonds rather than one triple bond. White phosphorus (Fig. 21.25a) consists of tetrahedral  $P_4$  molecules, which interact with each other through weak van der Waals forces. Black phosphorus and red phosphorus (see Fig. 21.25b, c) are higher melting network solids in which the three bonds formed by each atom connect it directly or indirectly with all the other atoms in the sample. Unstable solid forms of arsenic and antimony that consist of  $As_4$  or  $Sb_4$  tetrahedra like those in white phosphorus can be prepared by rapid cooling of the vapor. The stable forms of these elements have structures related to that of black phosphorus.

The elements considered so far lie on the border between covalent and molecular solids. Other elements, those of intermediate electronegativity, exist as solids on the border between metallic and covalent; these are called *metalloids*. Antimony has a metallic luster, for example, but is a rather poor conductor of electricity and heat. Silicon and germanium are each an example of a **semiconductor**, with electrical conductivities far lower than those of metals but still significantly higher than those of true insulators such as diamond. Section 22.7 examines the special properties of these materials more closely.

**FIGURE 21.25** Structures of elemental phosphorus.

**FIGURE 21.26** The structure of graphite.

Some elements of intermediate electronegativity exist in two crystalline forms with very different properties. White tin has a tetragonal crystal structure and is a metallic conductor. Below  $13^{\circ}\text{C}$  it crumbles slowly to form a powder of gray tin (with the diamond structure) that is a poor conductor. Its formation at low temperature is known as the “tin disease” and can be prevented by the addition of small amounts of bismuth or antimony. The thermodynamically stable form of carbon at room conditions is not the insulator diamond, but graphite. Graphite consists of sheets of fused hexagonal rings with only rather weak interactions between layers (Fig. 21.26). Each carbon atom shows  $sp^2$  hybridization, with its remaining  $p$  orbital (perpendicular to the graphite layers) taking part in extended  $\pi$ -bonding interactions over the whole plane. Graphite can be pictured as a series of interlocked benzene rings, with  $\pi$ -electron delocalization contributing significantly to its stability. The delocalized electrons give graphite a significant value for conductivity in the planes of fused hexagons approaching that of the metallic elements. The conductivity and relative chemical inertness of graphite make it useful for electrodes in electrochemistry.

## 21.4 Defects and Amorphous Solids

Although real crystals display beautiful symmetries to the eye, they are not perfect. As a practical matter, it is impossible to rid a crystal of all impurities or to ensure that it contains perfect periodic ordering. So, we describe real crystals as “perfect crystals with defects,” and define means to characterize these defects. If so many defects are present that crystalline order is destroyed, we describe the material as an **amorphous solid**.

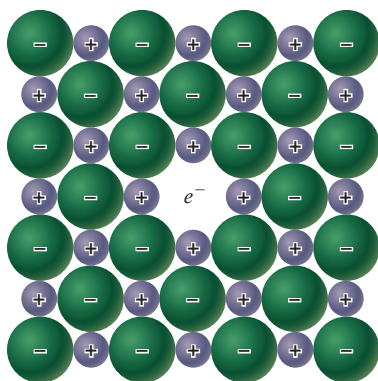

### 21.4.1 Point Defects

Point defects in a pure crystalline substance include *vacancies*, in which atoms are missing from lattice sites, and **interstitials**, in which atoms are inserted in

**FIGURE 21.27** Point imperfections in a lattice. The red X's denote vacancies.

**FIGURE 21.28** An F-center in a crystal.

sites different from their normal sites. In real crystals, a small fraction of the normal atom sites remain unoccupied. Such a vacancy is called a **Schottky defect**, and their concentration depends on temperature:

$$N = N_s \exp(-\Delta G/RT)$$

where  $N$  is the number of lattice vacancies per unit volume,  $N_s$  is the number of atom sites per unit volume, and  $\Delta G$  is the molar free energy of formation of vacancies. Figure 21.27a illustrates Schottky defects in the crystal structure of a metal or noble gas. Schottky defects also occur in ionic crystals but with the restriction that the imperfect crystals remain electrically neutral. Thus, in sodium chloride, for every missing  $\text{Na}^+$  ion there must also be a missing  $\text{Cl}^-$  ion (see Fig. 21.27b).

In certain kinds of crystals, atoms or ions are displaced from their regular lattice sites to interstitial sites, and the crystal defect consists of the lattice vacancy plus the interstitial atom or ion. Figure 21.27c illustrates this type of lattice imperfection, known as a **Frenkel defect**. The silver halides ( $\text{AgCl}$ ,  $\text{AgBr}$ ,  $\text{AgI}$ ) are examples of crystals in which Frenkel disorder is extreme. The crystal structures of these compounds are established primarily by the anion lattice, and the silver ions occupy highly disordered, almost random, sites. The rate of diffusion of silver ions in these solids is exceptionally high, as studies using radioactive isotopes of silver have shown. Both Frenkel and Schottky defects in crystals are mobile, jumping from one lattice site to a neighboring site with frequencies that depend on the temperature and the strengths of the atomic forces. Diffusion in crystalline solids is due largely to the presence and mobility of point defects; it is a thermally activated process, just like the rates of chemical reactions considered in Chapter 18. The coefficient of self-diffusion has the form

$$D = D_0 \exp[-E_a/RT] \quad [21.3]$$

where  $E_a$  is the activation energy. The rates of diffusive motion in crystalline solids vary enormously from one substance to another. In a crystal of a low-melting metal such as sodium, an average atom undergoes about  $10^8$  diffusive jumps per second at  $50^\circ\text{C}$ , whereas in a metal such as tungsten that melts at  $3410^\circ\text{C}$ , an average atom jumps to another lattice site less than once per year at  $1000^\circ\text{C}$ !

If an alkali halide crystal such as  $\text{NaCl}$  is irradiated with X-rays, ultraviolet radiation, or high-energy electrons, some  $\text{Cl}^-$  ions may lose an electron:

The resulting  $\text{Cl}$  atom, being uncharged and much smaller than a  $\text{Cl}^-$  ion, is no longer strongly bound in the crystal and can diffuse to the surface and escape. The electron can migrate through the crystal quite freely until it encounters an anion vacancy and is trapped in the Coulomb field of the surrounding cations (Fig. 21.28). This crystal defect is called an **F-center** (from the German word *Farbenzentrum*, meaning *color center*). It is the simplest of a family of electronic crystal defects. As the name suggests, it imparts a color to ionic crystals (Fig. 21.29).

## 21.4.2 Nonstoichiometric Compounds

As Chapter 1 emphasizes, the law of definite proportions was one of the principal pieces of evidence that led to the acceptance of Dalton's atomic theory. It is now recognized that a great many solid-state binary compounds do *not* have fixed and unvarying compositions but exist over a range of compositions in a

**FIGURE 21.29** Pure calcium fluoride,  $\text{CaF}_2$ , is white but the natural sample of calcium fluoride (fluorite) shown here is a rich purple because F-centers are present. These are lattice sites where the  $\text{F}^-$  anion is replaced by an electron only.

© Cengage Learning/Leon Lewandowski

single phase. Thus, FeO (wüstite) has the composition range  $\text{Fe}_{0.85}\text{O}_{1.00}$  to  $\text{Fe}_{0.95}\text{O}_{1.00}$  and is never found with its nominal 1:1 composition. The compounds NiO and  $\text{Cu}_2\text{S}$  also deviate considerably from their nominal stoichiometries.

The explanation depends on the existence of more than one oxidation state for the metal. In wüstite, iron can exist in either the +2 or the +3 oxidation state. Suppose a solid were to begin at the hypothetical composition of  $\text{Fe}_{1.00}\text{O}_{1.00}$ , with iron entirely in the +2 oxidation state. For every two  $\text{Fe}^{3+}$  ions introduced, three  $\text{Fe}^{2+}$  ions must be removed to maintain overall charge neutrality. The total number of moles of iron is then less than that in the ideal FeO stoichiometry. The departure from the nominal stoichiometry can be far more extreme than that found in wüstite. The composition of “TiO” ranges from  $\text{Ti}_{0.75}\text{O}$  to  $\text{Ti}_{1.45}\text{O}$ . Nickel oxide varies only from  $\text{Ni}_{0.97}\text{O}$  to NiO in composition, but the variation is accompanied by a dramatic change in properties. When the compound is prepared in the 1:1 composition, it is pale green and is an electrical insulator. When it is prepared in an excess of oxygen, it is black and conducts electricity fairly well. In the black material, a small fraction of  $\text{Ni}^{2+}$  ions are replaced by  $\text{Ni}^{3+}$  ions, and compensating vacancies occur at some nickel atom sites in the crystal.

### EXAMPLE 21.5

The composition of a sample of wüstite is  $\text{Fe}_{0.930}\text{O}_{1.00}$ . What percentage of the iron is in the form of iron(III)?

#### Solution

For every 1.00 mol of oxygen atoms in this sample, there is 0.930 mol of iron atoms. Suppose  $y$  mol of the iron is in the +3 oxidation state and  $0.930 - y$  is in the +2 oxidation state. Then the total positive charge from the iron (in moles of electron charge) is

$$+3y + 2(0.930 - y)$$

This positive charge must exactly balance the 2 mol of negative charge carried by the mole of oxygen atoms (recall that each oxygen atom has oxidation number  $-2$ ). We conclude that

$$3y + 2(0.930 - y) = +2$$

Solving this equation for  $y$  gives

$$y = 0.140$$

The percentage of iron in the form of  $\text{Fe}^{3+}$  is then the ratio of this number to the total number of moles of iron, 0.930, multiplied by 100%:

$$\% \text{ iron in form of } \text{Fe}^{3+} = \frac{0.140}{0.930} \times 100\% = 15.1\%$$

**Related Problems: 37, 38**

### 21.4.3 Alloys

The nonstoichiometric compounds just described are ionic materials with compositional disorder. A related type of disorder is exhibited by an **alloy**, a mixture of elements that displays metallic properties.

There are two types of alloys. In a **substitutional alloy**, some of the metal atoms in a crystal lattice are replaced by other atoms (usually of comparable size). Examples are brass, in which approximately one third of the atoms in a copper crystal are replaced by zinc atoms, and pewter, an alloy of tin that contains 7% copper, 6% bismuth, and 2% antimony. In an **interstitial alloy**, atoms of one or more additional elements enter the interstitial sites of the host metal lattice. An example is steel, in which carbon atoms occupy interstitial sites of an iron crystal, making the material stronger and harder than pure iron. Mild steel contains less than 0.2% C and is used for nails, whereas high-carbon steels can contain up to 1.5% C and are used in specialty applications such as tools and springs. *Alloy steels* are both substitutional and interstitial; atoms from metals such as chromium and vanadium substitute for iron atoms, with carbon remaining in interstitial sites. Alloy steels have a variety of specialized purposes, ranging from cutlery to bicycle frames.

### 21.4.4 Amorphous Solids and Glasses

The arrangements of atoms, ions, or molecules in crystalline solids exhibit high degrees of spatial order. Now let us briefly consider solids that lack this characteristic. An **amorphous solid**, commonly called a **glass**, resembles a crystalline solid in many respects. They may have chemical compositions, mechanical properties such as hardness and elasticity, and electrical and magnetic properties that are similar to those of crystals. Like crystals, glasses may have molecular, ionic, covalent, or metallic bonding. On an atomic scale, however, amorphous solids lack the regular periodic structure of crystals. They are states of matter in which so many defects are present that crystalline order is destroyed.

Some substances have a strong tendency to solidify as glasses. The best example is the material used in common window panes, with the approximate chemical formula  $\text{Na}_2\text{O}\cdot\text{CaO}\cdot(\text{SiO}_2)_6$ . This is a partly ionic, partly covalent material with  $\text{Na}^+$  and  $\text{Ca}^{2+}$  ions distributed through a covalently bonded Si—O network. Glass-forming ability is not restricted to a few special materials, however. If a substance can be liquefied, it can almost certainly be prepared in an amorphous state. Even metals, which are known primarily in the crystalline state, have been made into amorphous solids. The trick is to bypass crystallization by cooling molten material very fast. One technique involves shooting a jet of liquid metal at a rapidly rotating cold cylinder, which produces a continuous ribbon of amorphous metal at a rate up to 2 km per minute.

On the molecular level, a strong tendency to form glasses is associated with the presence of long or irregularly shaped molecules that can easily become tangled and disordered. Even slowly cooling a liquid assembly of such molecules may not afford enough time for them to organize into a crystalline lattice before solidification. Instead of a sharp liquid-to-crystal transition, such glass-formers transform continuously, over a range of temperature, into amorphous solids. They lend themselves to fabrication into articles of every conceivable shape, because the flow properties of the work piece can be managed by controlling its temperature. This plasticity is the reason that glass has played an indispensable role in science, industry, and the arts.

One of the most exciting uses of a glass is the transmission of voice messages, television images, and data as light pulses. Tens of thousands of audio messages can be transmitted simultaneously through glass fibers no greater in diameter than a human hair. This is done by encoding the audio signal into

© Stockbyte Silver/Getty Images

**FIGURE 21.30** Optical fibers (extremely thin glass fibers of specialized composition) carry information in the form of light waves.

electronic impulses that modulate light from a laser source. The light then passes down the glass fiber as though it were a tube. Chemical control of the glass composition reduces light loss and permits messages to travel many kilometers without amplification (Fig. 21.30).

## 21.5 A DEEPER LOOK Lattice Energies of Crystals

The **lattice energy** of a crystal is the energy required to separate the crystal into its component atoms, molecules, or ions at 0 K. In this section we examine the calculation and measurement of lattice energies for molecular and ionic crystals.

### 21.5.1 Lattice Energy of a Molecular Crystal

The lattice energy of a molecular crystal can be estimated by using the simple Lennard–Jones potential of Section 9.6:

$$V_{\text{LJ}}(R) = 4\epsilon \left[ \left( \frac{\sigma}{R} \right)^{12} - \left( \frac{\sigma}{R} \right)^6 \right]$$

Table 9.4 lists the values of  $\epsilon$  and  $\sigma$  for various atoms and molecules. Note that this potential is most useful when the species in the crystal are noble gas atoms or nonpolar molecules like methane that interact due to van der Waals forces. To obtain the total potential energy for 1 mol, sum over all pairs of atoms or molecules:

$$V_{\text{tot}} = \frac{1}{2} \sum_{i=1}^{N_A} \sum_{j=1}^{N_A} V_{\text{LJ}}(R_{ij})$$

where  $R_{ij}$  is the distance between atom  $i$  and atom  $j$ . The factor  $\frac{1}{2}$  arises because each interaction between a pair of atoms should be counted only once, not twice. For a crystal of macroscopic size, this can be rewritten as

$$V_{\text{tot}} = \frac{N_A}{2} \sum_{j=1}^{N_A} V_{\text{LJ}}(R_{ij})$$

where  $i$  is taken to be some atom in the middle of the crystal. Taking the nearest neighbor distance to be  $R_0$ , we define a ratio of distances  $p_{ij} = R_{ij}/R_0$  and rewrite  $V_{\text{tot}}$  for the Lennard–Jones potential as

$$\begin{aligned} V_{\text{tot}} &= \frac{N_A}{2} (4\epsilon) \left[ \sum_j \left( \frac{\sigma}{p_{ij}R_0} \right)^{12} - \sum_j \left( \frac{\sigma}{p_{ij}R_0} \right)^6 \right] \\ &= 2\epsilon N_A \left[ \left( \frac{\sigma}{R_0} \right)^{12} \sum_j (p_{ij})^{-12} - \left( \frac{\sigma}{R_0} \right)^6 \sum_j (p_{ij})^{-6} \right] \end{aligned}$$

The two summations are dimensionless properties of the lattice structure, and accurate values can be obtained by summing over the first few sets of nearest neighbors (Table 21.3). The resulting total energy for the fcc lattice is

$$V_{\text{tot}} = 2\epsilon N_A \left[ 12.132 \left( \frac{\sigma}{R_0} \right)^{12} - 14.454 \left( \frac{\sigma}{R_0} \right)^6 \right]$$

The equilibrium atomic spacing at  $T = 0$  K should be close to the one that gives a minimum in  $V_{\text{tot}}$ , which can be calculated by differentiating the preceding expression with respect to  $R_0$  and setting the derivative to 0. The result is

$$R_0 = 1.09\sigma$$

TABLE 21.3

Lattice Sums for Molecular Crystals (fcc Structure)

	Number, $n$	$\rho_{ij}$	$n(\rho_{ij})^{-12}$	$n(\rho_{ij})^{-6}$
Nearest neighbors	12	1	12	12
Second nearest neighbors	6	$\sqrt{2}$	0.0938	0.750
Third nearest neighbors	24	$\sqrt{3}$	0.0329	0.889
Fourth nearest neighbors	12	2	0.0029	0.188
Fifth nearest neighbors	24	$\sqrt{5}$	0.0015	0.192
	$\vdots$	$\vdots$	$\vdots$	$\vdots$
Total			12.132	14.454

TABLE 21.4

Properties of Noble-Gas Crystals<sup>†</sup>

	$R_0$ (Å)		Lattice Energy (kJ mol <sup>-1</sup> )	
	Predicted	Observed	Predicted	Observed
Ne	3.00	3.13	1.83	1.88
Ar	3.71	3.76	7.72	7.74
Kr	3.92	4.01	11.50	11.20
Xe	4.47	4.35	15.20	16.00

<sup>†</sup>All data are extrapolated to 0 K and zero pressure.and the value of  $V_{\text{tot}}$  at this value of  $R_0$  is

$$V_{\text{tot}} = -8.61\epsilon N_A$$

The corresponding potential energy when the atoms or molecules are completely separated from one another is zero. The lattice energy is the difference between these quantities and is a positive number:

$$\text{lattice energy} = -V_{\text{tot}} = 8.61\epsilon N_A$$

This overestimates the true lattice energy because of the quantum effect of zero-point energy (see Section 4.6). When a quantum correction is applied, the binding energy is reduced by 28%, 10%, 6%, and 4% for Ne, Ar, Kr, and Xe, respectively. Table 21.4 shows the resulting predictions for crystal lattice energies and nearest neighbor distances. The agreement with experiment is quite reasonable, considering the approximations inherent in the use of a Lennard-Jones potential derived entirely from gas-phase data. For helium the amplitude of zero-point motion is so great that if a crystal did form, it would immediately melt. Consequently, helium remains liquid down to absolute zero at atmospheric pressure.

### 21.5.2 Lattice Energy of an Ionic Crystal

In Section 3.8, we calculated the potential energy of a gaseous diatomic ionic molecule relative to the separated ions by means of Coulomb's law:

$$V = \frac{q_1 q_2}{4\pi\epsilon_0 R_0}$$

where  $R_0$  is the equilibrium internuclear separation. Coulomb's law can also be used to calculate the lattice energies of ionic compounds in the crystalline state.

**FIGURE 21.31** Lattice energy for a one-dimensional ionic crystal.

For simplicity, consider a hypothetical one-dimensional crystal (Fig. 21.31), in which ions of charge  $+e$  and  $-e$  alternate with an internuclear separation of  $R_0$ . One ion, selected to occupy an arbitrary origin, will interact attractively with all ions of opposite sign to make the following contribution to the crystal energy:

$$V_{\text{attraction}} = -\frac{e^2}{4\pi\epsilon_0 R_0} [2(1) + 2(\frac{1}{3}) + 2(\frac{1}{5}) + \dots]$$

Here the factors of 2 come from the fact that there are *two* ions of opposite sign at a distance  $R_0$  from a given ion, two at a distance  $3R_0$ , two at  $5R_0$ , and so forth. The negative sign occurs because the ions that occupy odd-numbered sites have a charge opposite that of the ion at the origin, and their interaction with the ion at the origin is attractive. The ion at the origin also interacts repulsively with all ions of the same sign to make the following contribution to the crystal energy:

$$V_{\text{repulsion}} = +\frac{e^2}{4\pi\epsilon_0 R_0} [2(\frac{1}{2}) + 2(\frac{1}{4}) + 2(\frac{1}{6}) + \dots]$$

The net interaction of  $N_A$  such ions of each sign with one another is:

$$V_{\text{net}} = -\frac{N_A e^2}{4\pi\epsilon_0 R_0} \left[ 2 - \frac{2}{2} + \frac{2}{3} - \frac{2}{4} + \frac{2}{5} - \frac{2}{6} + \dots \right]$$

We must be very careful with factors of 2. To obtain the potential energy for the interaction of  $N_A$  positive ions with  $N_A$  negative ions, it is necessary to multiply the total potential energy of a given ion due to all others by  $2N_A$  and then divide by 2 to avoid counting the interaction of a given pair of ions twice. This gives the preceding result.

If such a calculation is carried out for a real three-dimensional crystal, the result is a series (such as that just given in brackets) whose value sums to a dimensionless number that depends upon the crystal structure. That number is called the **Madelung constant**,  $M$ , and its value is independent of the unit-cell dimensions. Table 21.5 lists the values of the Madelung constant for several crystal structures. The lattice energy is again the opposite of the total potential energy. Expressed in terms of the Madelung constant, it is

**TABLE 21.5**

Madelung Constants

Lattice	$M$
Rock salt	1.7476
CsCl	1.7627
Zinc blende	1.6381
Fluorite	2.5194

$$\text{lattice energy} = \frac{N_A e^2 M}{4\pi\epsilon_0 R_0} \quad [21.4]$$

**EXAMPLE 21.6**

Calculate the electrostatic part of the lattice energy of sodium chloride, given that the internuclear separation between  $\text{Na}^+$  and  $\text{Cl}^-$  ions is  $2.82 \text{ \AA}$ .

**Solution**

Using the Madelung constant of 1.7476 for this structure gives

$$\frac{(6.02 \times 10^{23} \text{ mol}^{-1})(1.602 \times 10^{-19} \text{ C})^2(1.7476)}{(4\pi)(8.854 \times 10^{-12} \text{ C}^2 \text{ J}^{-1} \text{ m}^{-1})(2.82 \times 10^{-10} \text{ m})} = 8.61 \times 10^5 \text{ J mol}^{-1} = 861 \text{ kJ mol}^{-1}$$

**Related Problems:** 39, 40

Ionic lattice energies are measured experimentally by means of a thermodynamic cycle developed by Max Born and Fritz Haber. The **Born–Haber cycle** is an application of Hess’s law (the first law of thermodynamics). It is illustrated by a determination of the lattice energy of sodium chloride, which is  $\Delta U$  for the reaction

This reaction can be represented as a series of steps, each with a measurable energy or enthalpy change. In the first step, the ionic solid is converted to the elements in their standard states:

In the second step, the elements are transformed into gas-phase atoms:

Finally, in the third step, electrons are transferred from the sodium atoms to the chlorine atoms to give ions:

Here  $EA(\text{Cl})$  is the electron affinity of Cl, and  $IE_1(\text{Na})$  is the first ionization energy of Na. The total energy change is

$$\Delta U = \Delta U_1 + \Delta U_2 + \Delta U_3 = 411 + 229 + 147 = +787 \text{ kJ}$$

The small differences between  $\Delta U$  and  $\Delta H$  were neglected in this calculation. If their difference is taken into account (using  $\Delta H = \Delta U + RT\Delta n_g$ , where  $\Delta n_g$  is the change in the number of moles of gas molecules in each step of the reaction), then  $\Delta U_2$  is decreased by  $\frac{3}{2}RT$  and  $\Delta U_1$  by  $\frac{1}{2}RT$ , giving a net decrease of  $2RT$  and changing  $\Delta U$  to  $+782 \text{ kJ mol}^{-1}$ . Comparing this experimental lattice energy with the energy calculated in Example 21.6 shows that the latter is approximately 10% greater, presumably because short-range repulsive interactions and zero-point energy were not taken into account in the lattice energy calculation.

## CHAPTER SUMMARY

This chapter describes the distinctive properties of solids as the consequences of the collective behavior of an extended array of chemical bonds. The chemical bonds involved are already familiar in the context of isolated molecules. What is new here is the extended array of these bonds in the solid state. We can determine the array experimentally by X-ray diffraction. To describe the array we introduce the concepts of local symmetry and repetitive, long-range order; together, these define the unit cell and the crystal lattice. By placing structural elements at the points of the lattice, we complete the description of the structure of a perfect crystal. The number of atoms per unit cell depends on packing density of the atoms in the lattice. The properties of different classes of solids depend on the type of bonding involved: ionic, covalent, metallic, or molecular.

The perfect crystal is the fundamental starting point for investigations in the solid state. Practical materials can be described and categorized by the nature and extent of their deviations from perfect crystal structure.

## CONCEPTS AND SKILLS

### Section 21.1 – Crystal Symmetry and the Unit Cell

*Relate the general properties of solids to the nature of the bonds between atoms and to the spatial arrangement of atoms in a solid.*

- Solids differ from gases and liquids because they are rigid objects that retain their shapes even when external forces are applied. The rigidity and mechanical strength of solids are due to strong, directional bonds between atoms.
- Solids whose structures are highly ordered and symmetrical over macroscopic distances are called crystals with structures that are defined mathematically and measured experimentally.
- Crystal structure is defined in terms of the crystal lattice, a mathematical abstraction that represents the ordered and repetitive nature of the structure. A crystal lattice is constructed from a set of specific displacements along different directions. Each individual displacement generates a new lattice point; repeating this process many times generates the crystal lattice.

*Identify the symmetry elements of different crystal systems (Problems 1–4).*

- A symmetry element is an operation of rotation, reflection, or inversion which produces a new orientation of an object that can be exactly superimposed on the original orientation.
- The lattice embodies all the symmetry in the structure. Lattice points are identified by the fundamental symmetry operations of rotation, reflection, and inversion.
- The unit cell is the smallest region of a crystal lattice that contains all the structural information about the crystal. Each unit cell has characteristic lengths and angles. There are seven types of crystal structures (the seven crystal systems—see Table 21.1), each defined by the properties of its unit cell: hexagonal, cubic, tetragonal, trigonal, orthorhombic, monoclinic, and triclinic. The crystal lattice may be visualized as a three-dimensional stack of unit cells.

### Section 21.2 – Crystal Structure

*Explain how X-rays and neutrons are diffracted by crystals, and use information from such experiments to calculate lattice spacings (Problems 5–10).*

- X-rays and neutrons have wavelengths comparable to the distance  $d$  between lattice planes in solids. Waves scattered from atoms in the solid experience constructive and destructive interference to produce a diffraction pattern in which peaks in the diffracted intensity appear at angles  $\theta$  that satisfy the diffraction condition.

$$n\lambda = 2d \sin \theta \quad n = 1, 2, 3, \dots$$

- The distance  $d$  between planes in a crystal can be measured experimentally by X-ray diffraction once the diffraction angle ( $\theta$ ) and  $n$ , the order of diffraction, are known.

*Describe the packing of atoms in simple crystal lattices (Problems 11–24).*

- Once the crystal lattice has been identified, description of the structure is completed by specifying the structural elements that are located at lattice

points. The resulting structures are named by characteristics of the unit cell. Three examples are displayed by the elemental metals.

Simple cubic (one atom per unit cell)	Po
Body-centered cubic (two atoms per unit cell)	alkali metals
Face-centered cubic (four atoms per unit cell)	Al, Ni, Cu, Ag

- The volume of a unit cell is given by

$$V_c = abc \sqrt{1 - \cos^2\alpha - \cos^2\beta - \cos^2\gamma + 2 \cos\alpha \cos\beta \cos\gamma} \quad [21.2]$$

The efficiency of packing atoms onto lattice sites is determined by the size of the atom and the dimensions of the unit cell. Table 21.2 lists the fractional volume occupied by the atoms (packing fraction) for cubic lattices.

### Section 21.3 – Cohesion in Solids

*Compare the natures of the forces that hold atoms or molecules in their lattice sites in ionic, metallic, covalent, and molecular crystals (Problems 27–32).*

- Different types of chemical bonding appear in solids and are responsible for the differences in mechanical and structural properties of different types of solids.
- Because electrostatic forces are strong and operate over large distances, ionic crystals are hard, brittle solids that have high melting points and are poor conductors of heat and electricity. They crystallize in structures determined primarily by atomic packing density.
  - Zinc blende structure for cation–anion radius ratio smaller than 0.414
  - Rock-salt structure for cation–anion radius ratio between 0.414 and 0.732
  - Cesium chloride structure for cation–anion radius ratio greater than 0.732
- Bonding in metallic crystals is explained as a sea of delocalized electrons around positively charged ions located at the lattice sites. The number density of electrons is equal to the number density of positive ions, so the metal is electrically neutral. The bonds are quite strong, evidenced by the high melting and boiling points of metals. Metals are malleable and ductile because the highly mobile electrons can rapidly adjust when lattice ions are pushed to new locations by external mechanical forces. Metals are good conductors of heat and electricity because the delocalized electrons respond easily to applied external fields.
- Covalent crystals are held together by strong, highly directional bonds usually described by the valence bond hybrid orbital method. Because of the nature of their bonds, covalent crystals have very high melting points and are hard and brittle.
- Molecular crystals are held together by van der Waals forces, the same as the intermolecular forces in gases and liquids. Because these are much weaker than ionic, metallic, and covalent bonds, the molecular crystals are usually soft, easily deformed, and have low melting points.

### Section 21.4 – Defects and Amorphous Solids

*Describe the kinds of equilibrium defects that are present in crystalline solids and the properties of amorphous solids (Problems 35–36). Real-world crystals do not have perfect symmetry and order. It is useful to characterize practical*

materials by the ways in which they deviate from the structure of the perfect crystal models described earlier.

- Point defects where atoms are missing from lattice sites are called vacancies, or Schottky defects. Their number density depends on the temperature and on the Gibbs free energy of formation of defects.
- Point defects where atoms are located between lattice sites are called interstitials. If a lattice atom is displaced to an interstitial site, the combination of the vacancy and the interstitial is called a Frenkel defect.
- Diffusion in solids occurs as Schottky or Frenkel defects hop from one lattice site to another by a thermally activated process akin to chemical reactions. The diffusion constant is given by

$$D = D_0 \exp[-E_a/RT] \quad [21.3]$$

- Amorphous solids, or glasses, may have chemical compositions and mechanical properties similar to crystalline materials, and they may have ionic, metallic, covalent, or molecular bonding. But at the microscopic level they lack crystalline order. This arises from kinetic effects during solidification that reduce the mobility of atoms or molecules and prevent them from achieving ordered structures. Long or irregularly shaped molecules that are easily entangled lead to glass formation.

Determine the amount of different oxidation states present in nonstoichiometric solids (Problems 37–38).

- Determine the empirical formula for a nonstoichiometric metal oxide. Assuming the mixed oxide was initially 1:1, let  $y$  be the number of moles of metal ions in the +2 state that must be removed in order to accommodate each metal ion of the other oxidation state; the remaining metal ions must be in the +2 state. Enforce charge balance between the two states of metal and the total negative charge in the oxide anions to evaluate  $y$ . The method is illustrated in Example 21.5.

### Section 21.5 – A Deeper Look . . . Lattice Energies of Crystals

Calculate lattice energies of molecular and ionic crystals (Problems 39–42).

- The lattice energy of a crystal is the energy required to separate the crystal into its component ions, atoms, or molecules at 0 K. The lattice energy is the negative of the total potential energy in the lattice. The total potential energy in an ionic crystal is calculated by adding up the pairwise Coulomb interactions among a mole of positive and negative ions separated by distance  $R_0$  throughout the crystal. The geometry of the lattice is accounted for by the Madelung constant  $M$ , which multiplies the pairwise interaction.

$$\text{lattice energy} = \frac{N_A e^2 M}{4\pi\epsilon_0 R_0} \quad [21.4]$$

**FIGURE 21.32** Two forms of elemental phosphorus: white and red.

## CUMULATIVE EXERCISE

### The Many States of Phosphorus

Solid elemental phosphorus appears in a rich variety of forms (Fig. 21.32), with crystals in all seven crystal systems reported under various conditions of temperature, pressure, and sample preparation.

- (a) The thermodynamically stable form of phosphorus under room conditions is black phosphorus. Its unit cell is orthorhombic with edges of lengths

- 3.314, 4.376, and 10.48 Å. Calculate the volume of one unit cell, and determine the number of phosphorus atoms per unit cell, if the density of this form of phosphorus is 2.69 g cm<sup>-3</sup>.
- (b) The form of phosphorus that is easiest to prepare from the liquid or gaseous state is white phosphorus, which consists of P<sub>4</sub> molecules in a cubic lattice. When X-rays of wavelength 2.29 Å are scattered from the parallel faces of its unit cells, the first-order Bragg diffraction is observed at an angle 2θ of 7.10°. Calculate the length of the unit-cell edge for white phosphorus. At what angle will third-order Bragg diffraction be seen?
- (c) Amorphous red phosphorus has been reported to convert to monoclinic, triclinic, tetragonal, and cubic red forms with different heat treatments. Identify the changes in the shape of the unit cell as a cubic lattice is converted first to tetragonal, then monoclinic, then triclinic.
- (d) A monoclinic form of red phosphorus has been studied that has cell edge lengths 9.21, 9.15, and 22.60 Å, with an angle β of 106.1°. Each unit cell contains 84 atoms of phosphorus. Estimate the density of this form of phosphorus.
- (e) Phosphorus forms many compounds with other elements. Describe the nature of the bonding in the solids white elemental phosphorus (P<sub>4</sub>), black elemental phosphorus, sodium phosphate (Na<sub>3</sub>PO<sub>4</sub>), and phosphorus trichloride (PCl<sub>3</sub>).

### Answers

- (a) Volume is 152.0 Å<sup>3</sup>; eight atoms per unit cell
- (b) 18.5 Å; angle 2θ = 21.4°
- (c) Cubic to tetragonal: One cell edge is stretched or shrunk. Tetragonal to monoclinic: A second cell edge is stretched or shrunk, and the angles between two adjacent faces (and their opposite faces) are changed from 90°. Monoclinic to triclinic: The remaining two angles between faces are deformed from 90°.
- (d) 2.36 g cm<sup>-3</sup>
- (e) P<sub>4</sub>(white) and PCl<sub>3</sub> are molecular solids; P(black) is covalent; Na<sub>3</sub>PO<sub>4</sub> is ionic.

## PROBLEMS

Answers to problems whose numbers are red appear in Appendix G. Problems that are more challenging are indicated with asterisks.

### 21.1 Crystal Symmetry and the Unit Cell

- Which of the following has 3-fold rotational symmetry? Explain.
  - An isosceles triangle
  - An equilateral triangle
  - A tetrahedron
  - A cube
- Which of the following has 4-fold rotational symmetry? Explain.
  - A cereal box (exclusive of the writing on the sides)
  - A stop sign (not counting the writing)
  - A tetrahedron
  - A cube
- Identify the symmetry elements of the CCl<sub>2</sub>F<sub>2</sub> molecule (see Fig. 12.20).
- Identify the symmetry elements of the PF<sub>5</sub> molecule (see Fig. 3.37a).

5. The second-order Bragg diffraction of X-rays with  $\lambda = 1.660 \text{ \AA}$  from a set of parallel planes in copper occurs at an angle  $2\theta = 54.70^\circ$ . Calculate the distance between the scattering planes in the crystal.
6. The second-order Bragg diffraction of X-rays with  $\lambda = 1.237 \text{ \AA}$  from a set of parallel planes in aluminum occurs at an angle  $2\theta = 35.58^\circ$ . Calculate the distance between the scattering planes in the crystal.
7. The distance between members of a set of equally spaced planes of atoms in crystalline lead is  $4.950 \text{ \AA}$ . If X-rays with  $\lambda = 1.936 \text{ \AA}$  are diffracted by this set of parallel planes, calculate the angle  $2\theta$  at which fourth-order Bragg diffraction will be observed.
8. The distance between members of a set of equally spaced planes of atoms in crystalline sodium is  $4.28 \text{ \AA}$ . If X-rays with  $\lambda = 1.539 \text{ \AA}$  are diffracted by this set of parallel planes, calculate the angle  $2\theta$  at which second-order Bragg diffraction will be observed.
9. The members of a series of equally spaced parallel planes of ions in crystalline LiCl are separated by  $2.570 \text{ \AA}$ . Calculate all the angles  $2\theta$  at which diffracted beams of various orders may be seen, if the X-ray wavelength used is  $2.167 \text{ \AA}$ .
10. The members of a series of equally spaced parallel planes in crystalline vitamin B<sub>12</sub> are separated by  $16.02 \text{ \AA}$ . Calculate all the angles  $2\theta$  at which diffracted beams of various orders may be seen, if the X-ray wavelength used is  $2.294 \text{ \AA}$ .
15. At room temperature, the edge length of the cubic unit cell in elemental silicon is  $5.431 \text{ \AA}$ , and the density of silicon at the same temperature is  $2.328 \text{ g cm}^{-3}$ . Each cubic unit cell contains eight silicon atoms. Using only these facts, perform the following operations.
  - (a) Calculate the volume (in cubic centimeters) of one unit cell.
  - (b) Calculate the mass (in grams) of silicon present in a unit cell.
  - (c) Calculate the mass (in grams) of an atom of silicon.
  - (d) The mass of an atom of silicon is  $28.0855 \text{ u}$ . Estimate Avogadro's number to four significant figures.
16. One form of crystalline iron has a bcc lattice with an iron atom at every lattice point. Its density at  $25^\circ\text{C}$  is  $7.86 \text{ g cm}^{-3}$ . The length of the edge of the cubic unit cell is  $2.87 \text{ \AA}$ . Use these facts to estimate Avogadro's number.
17. Sodium sulfate ( $\text{Na}_2\text{SO}_4$ ) crystallizes in the orthorhombic system in a unit cell with  $a = 5.863 \text{ \AA}$ ,  $b = 12.304 \text{ \AA}$ , and  $c = 9.821 \text{ \AA}$ . The density of these crystals is  $2.663 \text{ g cm}^{-3}$ . Determine how many  $\text{Na}_2\text{SO}_4$  formula units are present in the unit cell.
18. The density of turquoise,  $\text{CuAl}_6(\text{PO}_4)_4(\text{OH})_8(\text{H}_2\text{O})_4$ , is  $2.927 \text{ g cm}^{-3}$ . This gemstone crystallizes in the triclinic system with cell constants  $a = 7.424 \text{ \AA}$ ,  $b = 7.629 \text{ \AA}$ ,  $c = 9.910 \text{ \AA}$ ,  $\alpha = 68.61^\circ$ ,  $\beta = 69.71^\circ$ , and  $\gamma = 65.08^\circ$ . Calculate the volume of the unit cell, and determine how many copper atoms are present in each unit cell of turquoise.
19. An oxide of rhenium has a structure with a Re atom at each corner of the cubic unit cell and an O atom at the center of each edge of the cell. What is the chemical formula of this compound?
20. The mineral perovskite has a calcium atom at each corner of the unit cell, a titanium atom at the center of the unit cell, and an oxygen atom at the center of each face. What is the chemical formula of this compound?
21. Iron has a body-centered cubic structure with a density of  $7.86 \text{ g cm}^{-3}$ .
  - (a) Calculate the nearest neighbor distance in crystalline iron.
  - (b) What is the lattice parameter for the cubic unit cell of iron?
  - (c) What is the atomic radius of iron?
22. The structure of aluminum is fcc and its density is  $\rho = 2.70 \text{ g cm}^{-3}$ .
  - (a) How many Al atoms belong to a unit cell?
  - (b) Calculate  $a$ , the lattice parameter, and  $d$ , the nearest neighbor distance.
23. Sodium has the body-centered cubic structure, and its lattice parameter is  $4.28 \text{ \AA}$ .
  - (a) How many Na atoms does a unit cell contain?
  - (b) What fraction of the volume of the unit cell is occupied by Na atoms, if they are represented by spheres in contact with one another?

## 21.2 Crystal Structure

11. A crucial protein at the photosynthetic reaction center of the purple bacterium *Rhodospseudomonas viridis* (see Section 20.7) has been separated from the organism, crystallized, and studied by X-ray diffraction. This substance crystallizes with a primitive unit cell in the tetragonal system. The cell dimensions are  $a = b = 223.5 \text{ \AA}$  and  $c = 113.6 \text{ \AA}$ .
  - (a) Determine the volume, in cubic angstroms, of this cell.
  - (b) One of the crystals in this experiment was box-shaped, with dimensions  $1 \times 1 \times 3 \text{ mm}$ . Compute the number of unit cells in this crystal.
12. Compute the volume (in cubic angstroms) of the unit cell of potassium hexacyanoferrate(III) ( $\text{K}_3\text{Fe}(\text{CN})_6$ ), a substance that crystallizes in the monoclinic system with  $a = 8.40 \text{ \AA}$ ,  $b = 10.44 \text{ \AA}$ , and  $c = 7.04 \text{ \AA}$  and with  $\beta = 107.5^\circ$ .
13. The compound  $\text{Pb}_4\text{In}_3\text{B}_{17}\text{S}_{18}$  crystallizes in the monoclinic system with a unit cell having  $a = 21.021 \text{ \AA}$ ,  $b = 4.014 \text{ \AA}$ ,  $c = 18.898 \text{ \AA}$ , and the only non- $90^\circ$  angle equal to  $97.07^\circ$ . There are two molecules in every unit cell. Compute the density of this substance.
14. Strontium chloride hexahydrate ( $\text{SrCl}_2 \cdot 6\text{H}_2\text{O}$ ) crystallizes in the trigonal system in a unit cell with  $a = 8.9649 \text{ \AA}$  and  $\alpha = 100.576^\circ$ . The unit cell contains three formula units. Compute the density of this substance.

24. Nickel has an fcc structure with a density of  $8.90 \text{ g cm}^{-3}$ .
- Calculate the nearest neighbor distance in crystalline nickel.
  - What is the atomic radius of nickel?
  - What is the radius of the largest atom that could fit into the interstices of a nickel lattice, approximating the atoms as spheres?
25. Calculate the ratio of the maximum radius of an interstitial atom at the center of a simple cubic unit cell to the radius of the host atom.
26. Calculate the ratio of the maximum radius of an interstitial atom at the center of each face of a bcc unit cell to the radius of the host atom.

### 21.3 Cohesion in Solids

27. Classify each of the following solids as molecular, ionic, metallic, or covalent.
- $\text{BaCl}_2$
  - $\text{SiC}$
  - $\text{CO}$
  - $\text{Co}$
28. Classify each of the following solids as molecular, ionic, metallic, or covalent.
- Rb
  - $\text{C}_3\text{H}_{12}$
  - B
  - $\text{Na}_2\text{HPO}_4$
29. The melting point of cobalt is  $1495^\circ\text{C}$ , and that of barium chloride is  $963^\circ\text{C}$ . Rank the four substances in problem 27 from lowest to highest in melting point.
30. The boiling point of pentane ( $\text{C}_5\text{H}_{12}$ ) is slightly less than the melting point of rubidium. Rank the four substances in problem 28 from lowest to highest in melting point.
31. Explain the relationship between the number of bonds that can be formed by a typical atom in a crystal and the possibility of forming linear, two-dimensional, and three-dimensional network structures.
32. Although large crystals of sugar (rock candy) and large crystals of salt (rock salt) have different geometric shapes, they look much the same to the untrained observer. What physical tests other than taste might be performed to distinguish between these two crystalline substances?
33. By examining Figure 21.17, determine the number of nearest neighbors, second nearest neighbors, and third nearest neighbors of a  $\text{Cs}^+$  ion in crystalline  $\text{CsCl}$ . The nearest neighbors of the  $\text{Cs}^+$  ion are  $\text{Cl}^-$  ions, and the second nearest neighbors are  $\text{Cs}^+$  ions.

34. Repeat the determinations of the preceding problem for the  $\text{NaCl}$  crystal, referring to Figure 21.16.

### 21.4 Defects and Amorphous Solids

35. Will the presence of Frenkel defects change the measured density of a crystal?
36. What effect will the (unavoidable) presence of Schottky defects have on the determination of Avogadro's number via the method described in problems 15 and 16?
37. Iron(II) oxide is nonstoichiometric. A particular sample was found to contain 76.55% iron and 23.45% oxygen by mass.
- Calculate the empirical formula of the compound (four significant figures).
  - What percentage of the iron in this sample is in the +3 oxidation state?
38. A sample of nickel oxide contains 78.23% Ni by mass.
- What is the empirical formula of the nickel oxide to four significant figures?
  - What fraction of the nickel in this sample is in the +3 oxidation state?

### 21.5 A Deeper Look . . . Lattice Energies of Crystals

39. Calculate the energy needed to dissociate 1.00 mol of crystalline  $\text{RbCl}$  into its gaseous ions if the Madelung constant for its structure is 1.7476 and the radii of  $\text{Rb}^+$  and  $\text{Cl}^-$  are  $1.48 \text{ \AA}$  and  $1.81 \text{ \AA}$ , respectively. Assume that the repulsive energy reduces the lattice energy by 10% from the pure Coulomb energy.
40. Repeat the calculation of problem 39 for  $\text{CsCl}$ , taking the Madelung constant from Table 21.5 and taking the radii of  $\text{Cs}^+$  and  $\text{Cl}^-$  to be  $1.67 \text{ \AA}$  and  $1.81 \text{ \AA}$ .
41.
  - Use the Born–Haber cycle, with data from Appendices D and E, to calculate the lattice energy of  $\text{LiF}$ .
  - Compare the result of part (a) with the Coulomb energy calculated by using an  $\text{Li–F}$  separation of  $2.014 \text{ \AA}$  in the  $\text{LiF}$  crystal, which has the rock-salt structure.
42. Repeat the calculations of problem 41 for crystalline  $\text{KBr}$ , which has the rock-salt structure with a  $\text{K–Br}$  separation of  $3.298 \text{ \AA}$ .

## ADDITIONAL PROBLEMS

43. Some water waves with a wavelength of 3.0 m are diffracted by an array of evenly spaced posts in the water. If the rows of posts are separated by 5.0 m, calculate the angle  $2\theta$  at which the first-order “Bragg diffraction” of these water waves will be seen.
44. A crystal scatters X-rays of wavelength  $\lambda = 1.54 \text{ \AA}$  at an angle  $2\theta$  of  $32.15^\circ$ . Calculate the wavelength of the X-rays in another experiment if this same diffracted beam from the same crystal is observed at an angle  $2\theta$  of  $34.46^\circ$ .
45. The number of beams diffracted by a single crystal depends on the wavelength  $\lambda$  of the X-rays used and on the volume associated with one lattice point in the crystal—that is, on the volume  $V_p$  of a primitive unit cell. An approximate formula is

$$\text{number of diffracted beams} = \frac{4}{3} \pi \left( \frac{2}{\lambda} \right)^3 V_p$$

- (a) Compute the volume of the conventional unit cell of crystalline sodium chloride. This cell is cubic and has an edge length of 5.6402 Å.
- (b) The NaCl unit cell contains four lattice points. Compute the volume of a primitive unit cell for NaCl.
- (c) Use the formula given in this problem to estimate the number of diffracted rays that will be observed if NaCl is irradiated with X-rays of wavelength 2.2896 Å.
- (d) Use the formula to estimate the number of diffracted rays that will be observed if NaCl is irradiated with X-rays having the shorter wavelength 0.7093 Å.
46. If the wavelength  $\lambda$  of the X-rays is too large relative to the spacing of planes in the crystal, no Bragg diffraction will be seen because  $\sin \theta$  would be larger than 1 in the Bragg equation, even for  $n = 1$ . Calculate the longest wavelength of X-rays that can give Bragg diffraction from a set of planes separated by 4.20 Å.
47. The crystal structure of diamond is fcc, and the atom coordinates in the unit cell are  $(0, 0, 0)$ ,  $(\frac{1}{2}, \frac{1}{2}, 0)$ ,  $(\frac{1}{2}, 0, \frac{1}{2})$ ,  $(0, \frac{1}{2}, \frac{1}{2})$ ,  $(\frac{1}{4}, \frac{1}{4}, \frac{1}{4})$ ,  $(\frac{3}{4}, \frac{1}{4}, \frac{3}{4})$ ,  $(\frac{3}{4}, \frac{3}{4}, \frac{1}{4})$ , and  $(\frac{1}{4}, \frac{3}{4}, \frac{3}{4})$ . The lattice parameter is  $a = 3.57$  Å. What is the C—C bond distance in diamond?
48. Polonium is the only element known to crystallize in the simple cubic lattice.
- (a) What is the distance between nearest neighbor polonium atoms if the first-order diffraction of X-rays with  $\lambda = 1.785$  Å from the parallel faces of its unit cells appears at an angle of  $2\theta = 30.96^\circ$  from these planes?
- (b) What is the density of polonium in this crystal (in  $\text{g cm}^{-3}$ )?
49. At room temperature, monoclinic sulfur has the unit-cell dimensions  $a = 11.04$  Å,  $b = 10.98$  Å,  $c = 10.92$  Å, and  $\beta = 96.73^\circ$ . Each cell contains 48 atoms of sulfur.
- (a) Explain why it is not necessary to give the values of the angles  $\alpha$  and  $\gamma$  in this cell.
- (b) Compute the density of monoclinic sulfur (in  $\text{g cm}^{-3}$ ).
50. A compound contains three elements: sodium, oxygen, and chlorine. It crystallizes in a cubic lattice. The oxygen atoms are at the corners of the unit cells, the chlorine atoms are at the centers of the unit cells, and the sodium atoms are at the centers of the faces of the unit cells. What is the formula of the compound?
- \*51. Show that the radius of the largest sphere that can be placed in a tetrahedral interstitial site in an fcc lattice is  $0.225r_1$ , where  $r_1$  is the radius of the atoms making up the lattice. (*Hint*: Consider a cube with the centers of four spheres placed at alternate corners, and visualize the tetrahedral site at the center of the cube. What is the relationship between  $r_1$  and the length of a diagonal of a face? The length of a body diagonal?)
52. What is the closest packing arrangement possible for a set of thin circular discs lying in a plane? What fraction of the area of the plane is occupied by the discs? Show how the same reasoning can be applied to the packing of infinitely long, straight cylindrical fibers.
53. Name two elements that form molecular crystals, two that form metallic crystals, and two that form covalent crystals. What generalizations can you make about the portions of the periodic table where each type is found?
54. The nearest-neighbor distance in crystalline LiCl (rock-salt structure) is 2.570 Å; the bond length in a gaseous LiCl molecule is significantly shorter, 2.027 Å. Explain.
55. (a) Using the data of Table 9.4, estimate the lattice energy and intermolecular separation of nitrogen in its solid state, assuming an fcc structure for the solid lattice.
- (b) The density of cubic nitrogen is  $1.026 \text{ g cm}^{-3}$ . Calculate the lattice parameter  $a$  and the nearest neighbor distance. Compare your answer with that from part (a).
- \*56. Solid  $\text{CuI}_2$  is unstable relative to  $\text{CuI}$  at room temperature, but  $\text{CuBr}_2$ ,  $\text{CuCl}_2$ , and  $\text{CuF}_2$  are all stable relative to the copper(I) halides. Explain by considering the steps in the Born–Haber cycle for these compounds.
57. A crystal of sodium chloride has a density of  $2.165 \text{ g cm}^{-3}$  in the absence of defects. Suppose a crystal of NaCl is grown in which 0.15% of the sodium ions and 0.15% of the chloride ions are missing. What is the density in this case?
58. The activation energy for the diffusion of sodium atoms in the crystalline state is  $42.22 \text{ kJ mol}^{-1}$ , and  $D_0 = 0.145 \text{ cm}^2 \text{ s}^{-1}$ .
- (a) Calculate the diffusion constant  $D = D_0 \exp(-E_a/RT)$  of sodium in the solid at its melting point ( $97.8^\circ\text{C}$ ).
- (b) What is the root-mean-square displacement of an average sodium atom from an arbitrary origin after the lapse of 1.0 hour at  $t = 97.8^\circ\text{C}$ ? (*Hint*: Use Equation 9.32 in Chapter 9.)
59. A compound of titanium and oxygen contains 28.31% oxygen by mass.
- (a) If the compound's empirical formula is  $\text{Ti}_x\text{O}$ , calculate  $x$  to four significant figures.
- (b) The nonstoichiometric compounds  $\text{Ti}_x\text{O}$  can be described as having a  $\text{Ti}^{2+}-\text{O}^{2-}$  lattice in which certain  $\text{Ti}^{2+}$  ions are missing or are replaced by  $\text{Ti}^{3+}$  ions. Calculate the fraction of  $\text{Ti}^{2+}$  sites in the nonstoichiometric compound that are vacant and the fraction that are occupied by  $\text{Ti}^{3+}$  ions.
60. Classify the bonding in the following amorphous solids as molecular, ionic, metallic, or covalent.
- (a) Amorphous silicon, used in photocells to collect light energy from the sun
- (b) Polyvinyl chloride, a plastic of long-chain molecules composed of  $-\text{CH}_2\text{CHCl}-$  repeating units, used in pipes and siding
- (c) Soda-lime-silica glass, used in windows
- (d) Copper-zirconium glass, an alloy of the two elements with approximate formula  $\text{Cu}_3\text{Zr}_2$ , used for its high strength and good conductivity

## CUMULATIVE PROBLEMS

---

61. Sodium hydride (NaH) crystallizes in the rock-salt structure, with four formula units of NaH per cubic unit cell. A beam of monoenergetic neutrons, selected to have a velocity of  $2.639 \times 10^3 \text{ m s}^{-1}$ , is scattered in second order through an angle of  $2\theta = 36.26^\circ$  by the parallel faces of the unit cells of a sodium hydride crystal.
- Calculate the wavelength of the neutrons.
  - Calculate the edge length of the cubic unit cell.
  - Calculate the distance from the center of a  $\text{Na}^+$  ion to the center of a neighboring  $\text{H}^-$  ion.
  - If the radius of a  $\text{Na}^+$  ion is  $0.98 \text{ \AA}$ , what is the radius of an  $\text{H}^-$  ion, assuming the two ions are in contact?
62. Chromium(III) oxide has a structure in which chromium ions occupy two-thirds of the octahedral interstitial sites in a hexagonal close-packed lattice of oxygen ions. What is the *d*-electron configuration on the chromium ion?
63. A useful rule of thumb is that in crystalline compounds every nonhydrogen atom occupies  $18 \text{ \AA}^3$ , and the volume occupied by hydrogen atoms can be neglected. Using this rule, estimate the density of ice (in  $\text{g cm}^{-3}$ ). Explain why the answer is so different from the observed density of ice.
64. Estimate, for the F-centers in  $\text{CaF}_2$ , the wavelength of maximum absorption in the visible region of the spectrum that will give rise to the color shown in Figure 21.29.

Azurite is a basic copper carbonate with chemical formula  $\text{Cu}_3(\text{CO}_3)_2(\text{OH})_2$ .

Having laid the conceptual foundation for relating properties of solids to chemical bonding in Chapter 21, we turn now to applications of these concepts to three important classes of materials: ceramics, electronic materials, and optical materials. All of these are synthetic materials fashioned from inorganic, nonmetallic substances by chemical methods of synthesis and processing.

Ceramics are one of the oldest classes of materials prepared by humankind. New discoveries in ceramics are occurring at a startling rate, and major new technologic advances will certainly come from these discoveries. Ceramics have value both as structural materials—the role emphasized in this chapter—and for their wide range of electronic and optical properties.

High-speed computing, fast communication, and rapid display of information were major technologic achievements in the second half of the 20th century. These developments will grow even more rapidly in the 21st century, when

every home will be digitally connected to the Internet and every cell phone will display images requiring broadband transmission. These developments were made possible by the “microelectronics revolution,” beginning with the first integrated circuits fabricated on microchips by Jack Kilby at Texas Instruments and Robert Noyce at Fairchild in 1958 to 1959.<sup>1</sup> The speed of computers increased dramatically through advances in transistor design; advances in the solid-state laser enabled high-speed communication via fiber optics. All these advances in device design relied critically on equally dramatic accomplishments in the growth and processing of materials, which in every case involved making and breaking chemical bonds in solid-state materials. Our goals in this chapter are to introduce the optical and electronic properties of materials and to show how they depend on chemical structure.

Electronic properties describe the movement of charged particles in a material in response to an applied electric field. If the charges are free to move throughout the material, the process is *electrical conduction*, measured by the *electrical conductivity* of the material. Differences in the magnitude of the conductivity distinguish metals, semiconductors, and insulators. If the charges can move only limited distances and are then halted by opposing binding forces, separation of positive and negative charges leads to *electric polarization* of the material, measured by its *dielectric constant*. Conduction involves dissipation of energy as heat, whereas polarization involves storage of potential energy in the material.

Optical properties describe the response of a material to electromagnetic radiation, particularly visible light. The list of optical properties is long, including reflection of light from a surface, refraction (bending the direction) of light as it passes from one medium into another, absorption, and transmission. We limit the discussion here to the generation and detection of light in solid materials, as extensions of the molecular processes of emission and excitation already described in Chapter 20. The absorption of light creates the bright colors of inorganic pigments and the conversion of solar energy into electrical energy in solar cells.

In this survey of mechanical, electrical, and optical properties, keep two questions in mind: (1) How does a material respond on an atomic level to applied mechanical stress and to electrical and optical fields? (2) If the chemical structure is modified, how does this change influence the response of the material to these forces?

## 22.1 Minerals: Naturally Occurring Inorganic Materials

This chapter begins with a survey of the naturally occurring inorganic, nonmetallic minerals that are the starting materials for synthesis and processing of inorganic materials.

### 22.1.1 Silicates

Silicon and oxygen make up most of the earth’s crust, with oxygen accounting for 47% and silicon for 28% of its mass. The silicon–oxygen bond is strong and partially ionic. It forms the basis for a class of minerals called **silicates**, which make up the bulk of the rocks, clays, sand, and soils in the earth’s crust. From time

<sup>1</sup>Kilby was awarded the Nobel Prize in Physics in 2000, but Noyce, who had died, did not share the award. The Nobel Prize is not awarded posthumously.

**FIGURE 22.1** In silicates, four O atoms (red) are arranged in a tetrahedron around an Si atom. The stoichiometry is changed when one or more O atoms is shared with neighboring tetrahedra.

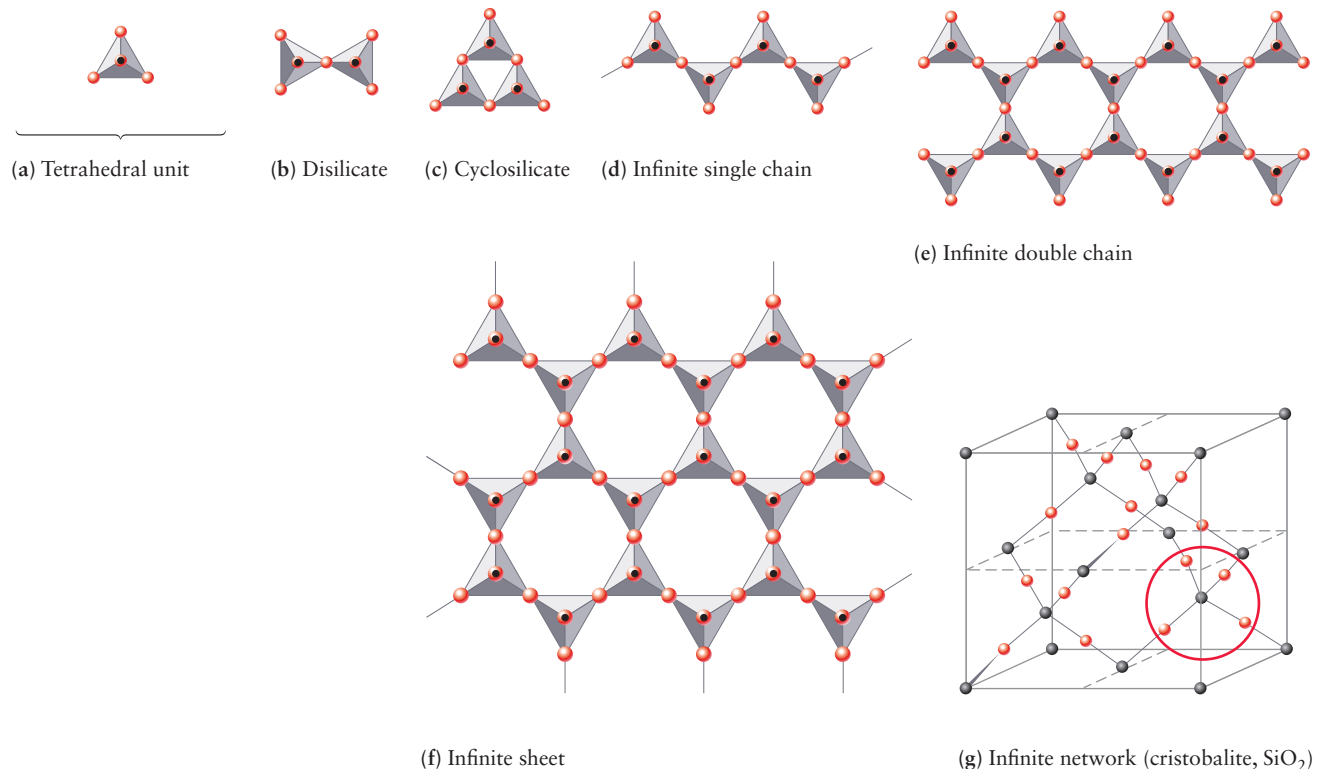

**TABLE 22.1**

Silicate Structures

Structure	Figure Number	Corners Shared at Each Si Atom	Repeat Unit	Si : O Ratio	Example
Tetrahedra	22.2a	0	$\text{SiO}_4^{4-}$	1:4	Olivines
Pairs of tetrahedra	22.2b	1	$\text{Si}_2\text{O}_7^{6-}$	1:3 $\frac{1}{2}$	Thortveitite
Closed rings	22.2c	2	$\text{SiO}_3^{2-}$	1:3	Beryl
Infinite single chains	22.2d	2	$\text{SiO}_3^{2-}$	1:3	Pyroxenes
Infinite double chains	22.2e	2 $\frac{1}{2}$	$\text{Si}_4\text{O}_{11}^{6-}$	1:2 $\frac{3}{4}$	Amphiboles
Infinite sheets	22.2f	3	$\text{Si}_2\text{O}_5^{2-}$	1:2 $\frac{1}{2}$	Talc
Infinite network	22.2g	4	$\text{SiO}_2$	1:2	Quartz

immemorial, silicates have provided the ingredients for building materials such as bricks, cement, concrete, and glass (which are considered later in this chapter).

The structure-building properties of silicates (Table 22.1 and Fig. 22.1) originate in the tetrahedral orthosilicate anion ( $\text{SiO}_4^{4-}$ ), in which the negative charge of the silicate ion is balanced by the compensating charge of one or more cations. The simplest silicates consist of individual  $\text{SiO}_4^{4-}$  anions (Fig. 22.2a), with cations arranged around them on a regular crystalline lattice. Such silicates are properly called *orthosilicates*. Examples are forsterite ( $\text{Mg}_2\text{SiO}_4$ ) and fayalite ( $\text{Fe}_2\text{SiO}_4$ ),

**FIGURE 22.2** Classes of silicate structures. (a) Symbol used for the  $\text{SiO}_4^{4-}$  tetrahedron. This top view of the symbol shows a red circle to represent the fourth oxygen atom at the top of the tetrahedron. The black dot represents the silicon atom at the center of the tetrahedron. Bear in mind that all of these structures are actually three-dimensional. Planar projections are used here for convenience of representation. (b) Disilicate. (c) Cyclosilicate. (d) Infinite single chain. (e) Infinite double chain. (f) Infinite sheet. (g) Infinite network (cristobalite,  $\text{SiO}_2$ ) with an example of the tetrahedral arrangement of O atoms about a silicon atom circled.

which are the extreme members of a class of minerals called **olivines**,  $[\text{Mg,Fe}]_2\text{SiO}_4$ . There is a continuous range of proportions of magnesium and iron in the olivines.

Other silicate structures form when two or more  $\text{SiO}_4^{4-}$  tetrahedra link and share oxygen vertices. The simplest such minerals are the **disilicates**, such as thortveitite,  $\text{Sc}_2(\text{Si}_2\text{O}_7)$ , in which two tetrahedra are linked (see Fig. 22.2b). Additional linkages of tetrahedra create the ring, chain, sheet, and network structures shown in Figure 22.2 and listed in Table 22.1. In each of these, the fundamental tetrahedron is readily identified, but the Si:O ratio is no longer 4 because oxygen (O) atoms are shared at the linkages.

### EXAMPLE 22.1

By referring to Table 22.1, predict the structural class in which the mineral Egyptian blue ( $\text{CaCuSi}_4\text{O}_{10}$ ) belongs. Give the oxidation state of each of its atoms.

#### Solution

Because the silicon/oxygen (Si:O) ratio is 4:10, or  $1:2\frac{1}{2}$ , this mineral should have an infinite sheet structure with the

repeating unit  $\text{Si}_2\text{O}_5^{2-}$ . The oxidation states of Si and O are +4 and -2, as usual, and that of calcium (Ca) is +2. For the total oxidation number per formula unit to sum to 0, the oxidation state of copper (Cu) must be +2.

**Related Problems: 3, 4**

**FIGURE 22.3** The mineral quartz is one form of silica,  $\text{SiO}_2$ .

© Cengage Learning/Charles D. Winters

**FIGURE 22.4** The fibrous structure of asbestos is apparent in this sample.

The physical properties of the silicates correlate closely with their structures. Talc,  $\text{Mg}_3(\text{Si}_4\text{O}_{10})(\text{OH})_2$ , is an example of an infinite layered structure (see Fig. 22.2f). In talc, all of the bonding interactions among the atoms occur in a single layer. Layers of talc sheets are attracted to one another only by van der Waals interactions, which (being weak) permit one layer to slip easily across another. This accounts for the slippery feel of talc (called talcum powder). When all four vertices of each tetrahedron are linked to other tetrahedra, three-dimensional network structures such as cristobalite (see Fig. 22.2g) or quartz (Fig. 22.3) result. Note that the quartz network carries no charge; consequently, there are no cations in its structure. Three-dimensional network silicates such as quartz are much stiffer and harder than the linear and layered silicates, and they resist deformation well.

**Asbestos** is a generic term for a group of naturally occurring, hydrated silicates that can be processed mechanically into long fibers (Fig. 22.4). Some of these silicates, such as tremolite,  $\text{Ca}_2\text{Mg}_5(\text{Si}_4\text{O}_{11})_2(\text{OH})_2$ , show the infinite double-chain structure of Figure 22.2e. Another kind of asbestos mineral is chrysotile,  $\text{Mg}_3(\text{Si}_2\text{O}_5)(\text{OH})_4$ . As the formula indicates, this mineral has a sheet structure (see Fig. 22.2f), but the sheets are rolled into long tubes. Asbestos minerals are fibrous because the bonds along the strandlike tubes are stronger than those that hold different tubes together. Asbestos is an excellent thermal insulator that does not burn, resists acids, and is strong. For many years, it was used in cement for pipes and ducts and woven into fabric to make fire-resistant roofing paper and floor tiles. Its use has decreased significantly in recent years because inhalation of its small fibers can cause the lung disease asbestosis. The risk comes with breathing asbestos dust that is raised during mining and manufacturing processes or that is released in buildings in which asbestos-containing materials are fraying, crumbling, or being removed.

## 22.1.2 Aluminosilicates

An important class of minerals called **aluminosilicates** results from the replacement of some of the Si atoms in silicates with aluminum (Al) atoms. Aluminum is the third most abundant element in the earth's crust (8% by mass), where it occurs largely in the form of aluminosilicates. Aluminum in minerals can be a

**FIGURE 22.5** Naturally occurring muscovite mica. The mechanical properties of crystals of mica are quite anisotropic. Thin sheets can be peeled off a crystal of mica by hand, but the sheets resist stresses in other directions more strongly. Transparent, thin sheets of mica, sometimes called isinglass, have been used for heat-resistant windows in stoves or in place of window glass.

simple cation ( $\text{Al}^{3+}$ ), or it can replace silicon in tetrahedral coordination. When it replaces silicon, it contributes only three electrons to the bonding framework in place of the four electrons of Si atoms. The additional required electron is supplied by the ionization of a metal atom such as sodium (Na) or potassium (K); the resulting alkali-metal ions occupy nearby sites in the aluminosilicate structure.

The most abundant and important of the aluminosilicate minerals in the earth's surface are the *feldspars*, which result from the substitution of aluminum for silicon in three-dimensional silicate networks such as quartz. The Al ions must be accompanied by other cations such as sodium, potassium, or calcium to maintain overall charge neutrality. Albite is a feldspar with the chemical formula  $\text{NaAlSi}_3\text{O}_8$ . In the high-temperature form of this mineral, the Al and Si atoms are distributed at random (in 1 : 3 proportion) over the tetrahedral sites available to them. At lower temperatures, other crystal structures become thermodynamically stable, with partial ordering of the Al and Si sites.

If one of the four Si atoms in the structural unit of talc,  $\text{Mg}_3(\text{Si}_4\text{O}_{10})(\text{OH})_2$ , is replaced by an Al atom and a K atom is furnished to supply the fourth electron needed for bonding in the tetrahedral silicate framework, the result is the composition  $\text{KMg}_3(\text{AlSi}_3\text{O}_{10})(\text{OH})_2$ , which belongs to the family of **micas** (Fig. 22.5). Mica is harder than talc, and its layers slide less readily over one another, although the crystals still cleave easily into sheets. The cations occupy sites between the infinite sheets, and the van der Waals bonding that holds adjacent sheets together in talc is augmented by an ionic contribution. The further replacement of the three  $\text{Mg}^{2+}$  ions in  $\text{KMg}_3(\text{AlSi}_3\text{O}_{10})(\text{OH})_2$  with two  $\text{Al}^{3+}$  ions gives the mineral muscovite,  $\text{KAl}_2(\text{AlSi}_3\text{O}_{10})(\text{OH})_2$ . Writing its formula in this way indicates that there are Al atoms in two kinds of sites in the structure: One Al atom per formula unit occupies a tetrahedral site, substituting for one Si atom, and the other two Al atoms are between the two adjacent layers. The formulas that mineralogists and crystallographers use convey more information than the usual empirical chemical formula of a compound.

### 22.1.3 Clay Minerals

**Clays** are minerals produced by the weathering action of water and heat on primary minerals. Their compositions can vary widely as a result of the replacement of one element with another. Invariably, they are microcrystalline or powdered in form and are usually hydrated. Often, they are used as supports for catalysts, as fillers in paint, and as ion-exchange vehicles. The clays that readily absorb water and swell are used as lubricants and bore-hole sealers in the drilling of oil wells.

The derivation of clays from talcs and micas provides a direct way to understand the structures of the clays. The infinite-sheet mica pyrophyllite,  $\text{Al}_2(\text{Si}_4\text{O}_{10})(\text{OH})_2$ , serves as an example. If one of six  $\text{Al}^{3+}$  ions in the pyrophyllite structure is replaced by one  $\text{Mg}^{2+}$  ion and one  $\text{Na}^+$  ion (which together carry the same charge), a type of clay called montmorillonite,  $\text{MgNaAl}_5(\text{Si}_4\text{O}_{10})_3(\text{OH})_6$ , results. This clay readily absorbs water, which infiltrates between the infinite sheets and hydrates the  $\text{Mg}^{2+}$  and  $\text{Na}^+$  ions there, causing the montmorillonite to swell (Fig. 22.6).

A different clay derives from the layered mineral talc,  $\text{Mg}_3(\text{Si}_4\text{O}_{10})(\text{OH})_2$ . If iron(II) and aluminum replace magnesium and silicon in varying proportions and water molecules are allowed to take up positions between the layers, the swelling clay vermiculite results. When heated, vermiculite pops like popcorn, as the steam generated by the vaporization of water between the layers puffs the flakes up into a light, fluffy material with air inclusions. Because of its porous structure, vermiculite is used for thermal insulation or as an additive to loosen soils.

**FIGURE 22.6** Structure of the clay mineral montmorillonite. Insertion of variable amounts of water causes the distance between layers to swell from 9.6 Å to more than 20 Å. When 1  $\text{Al}^{3+}$  ion is replaced by an  $\text{Mg}^{2+}$  ion, an additional ion such as  $\text{Na}^+$  is introduced into the water layers to maintain overall charge neutrality.

### 22.1.4 Zeolites

**Zeolites** are a class of three-dimensional aluminosilicates. Like the feldspars, they carry a negative charge on the aluminosilicate framework that is compensated by neighboring alkali-metal or alkaline-earth cations. Zeolites differ from feldspars in having much more open structures that consist of polyhedral cavities connected by tunnels (Fig. 22.7). Many zeolites are found in nature, but they can also be synthesized under conditions controlled to favor cavities of uniform size and shape. Most zeolites accommodate water molecules in their cavities, where they provide a mobile phase for the migration of the charge-compensating cations. This enables zeolites to serve as ion-exchange materials (in which one kind of positive ion can be readily exchanged for another) and is the key to their ability to soften water. Water “hardness” arises from soluble calcium and magnesium salts such as  $\text{Ca}(\text{HCO}_3)_2$  and  $\text{Mg}(\text{HCO}_3)_2$ . Such salts are converted to insoluble carbonates (boiler scale) when the water is heated and form objectionable precipitates (bathtub ring) with soaps. When hard water is passed through a column packed with a zeolite that has Na ions in its structure, the Ca and Mg ions exchange with the Na ions and are removed from the water phase:

**FIGURE 22.7** Structure of the synthetic zeolite Li-ABW [ $\text{Li}_4(\text{Si}_4\text{Al}_4\text{O}_{16}) \cdot 4\text{H}_2\text{O}$ ].

C. Baerlocher, L.B. McCusker: Atlas of Zeolite Structure Types. <http://www.iza-sc.cethz.ch/>  
IZA-SC/Atlas/AtlasHome.html

When the ion-exchange capacity of the zeolite is exhausted, this reaction can be reversed by passing a concentrated solution of sodium chloride through the zeolite to regenerate it in the sodium form.

A second use of zeolites derives from the ease with which they adsorb small molecules. Their spongelike affinity for water makes them useful as drying agents; they are put between the panes of double-pane glass windows to prevent moisture from condensing on the inner surfaces. The pore size of zeolites can be selected to allow molecules that are smaller than a certain size to pass through but hold back larger molecules. Such zeolites serve as “molecular sieves” for gas purification.  $\text{Ca}^+$  exchange zeolites can also preferentially trap nitrogen, with its large quadrupole moment, allowing oxygen molecules in an air stream to pass through.

Perhaps the most exciting use of zeolites is as catalysts. Molecules of varying sizes and shapes have different rates of diffusion through a zeolite; this feature enables chemists to enhance the rates and yields of desired reactions and suppress unwanted reactions. The most extensive applications of zeolites currently are in the catalytic cracking of crude oil, a process that involves breaking down long-chain hydrocarbons and re-forming them into branched-chain molecules of lower molecular mass for use in high-octane unleaded gasoline. A relatively new process uses “shape-selective” zeolite catalysts to convert methanol ( $\text{CH}_3\text{OH}$ ) to high-quality gasoline. Plants have been built to make gasoline by this process, using methanol derived from coal or from natural gas.

## 22.2 Properties of Ceramics

A **ceramic** is a synthetic material that has as its essential components inorganic, nonmetallic materials. This broad definition includes cement, concrete, and glass, in addition to the more traditional fired clay products such as bricks, roof tiles, pottery, and porcelain. The use of ceramics predates recorded history; the emergence of civilization from a primitive state is chronicled in fragments of pottery. No one knows when small vessels were first shaped by human hands from moist clay and left to harden in the heat of the sun. Such containers held nuts, grains, and berries well, but they lost their shape and slumped into formless mud when water was poured into them. Then someone discovered (perhaps by accident) that if clay was placed in the glowing embers of a fire, it became as hard as rock and withstood water well. Molded figures (found in what is now the Czech Republic) that were made 24,000 years ago are the earliest fired ceramic objects discovered so far, and fired clay vessels from the Near East date from 8000 B.C. With the action of fire on clay, the art and science of ceramics began.

Ceramics offer stiffness, hardness, resistance to wear, and resistance to corrosion (particularly by oxygen and water), even at high temperature. They are less dense than most metals, which makes them desirable metal substitutes when weight is a factor. Most are good electrical insulators at ordinary temperatures, a property that is exploited in electronics and power transmission. Ceramics retain their strength well at high temperatures. Several important structural metals soften or melt at temperatures 1000°C below the melting points of their chemical compounds in ceramics. Aluminum, for example, melts at 660°C, whereas aluminum oxide ( $\text{Al}_2\text{O}_3$ ), an important compound in many ceramics, does not melt until a temperature of 2051°C is reached.

Against these advantages must be listed some serious disadvantages. Ceramics are generally brittle and low in tensile strength. They tend to have high thermal expansion but low thermal conductivity, making them subject to **thermal shock**, in which sudden local temperature change causes cracking or shattering. Metals and plastics dent or deform under stress, but ceramics cannot

**FIGURE 22.8** Microstructures of aluminosilicate ceramics, viewed by the different colors of light emitted after bombardment by electrons. (a) Forsterite (red), spinel (green), and periclase (dark brown) grains. (b) Periclase (blue) and oldhamite (yellow) grains.

Musa Karakus and Richard Hagini

absorb stress in this way: instead, they break. A major drawback of ceramics as structural materials is their tendency to fail unpredictably and catastrophically in use. Moreover, some ceramics lose mechanical strength as they age, an insidious and serious problem.

### 22.2.1 Composition and Structure of Ceramics

Ceramics use a variety of chemical compounds, and useful ceramic bodies are nearly always mixtures of several compounds. **Silicate ceramics**, which include the commonplace pots, dishes, and bricks, are made from aluminosilicate clay minerals. All contain the tetrahedral  $\text{SiO}_4$  grouping discussed in Section 22.1. In **oxide ceramics**, silicon is a minor or nonexistent component. Instead, a number of metals combine with oxygen to give compounds such as alumina ( $\text{Al}_2\text{O}_3$ ), magnesia ( $\text{MgO}$ ), or yttria ( $\text{Y}_2\text{O}_3$ ). **Nonoxide ceramics** contain compounds that are free of oxygen as principal components. Some important compounds in nonoxide ceramics are silicon nitride ( $\text{Si}_3\text{N}_4$ ), silicon carbide ( $\text{SiC}$ ), and boron carbide (approximate composition  $\text{B}_4\text{C}$ ).

One important property of ceramics is their porosity. Porous ceramics have small openings into which fluids (typically air or water) can infiltrate. Fully dense ceramics have no channels of this sort. Two ceramic pieces can have the same chemical composition but quite different densities if the first is porous and the second is not.

A **ceramic phase** is any portion of the whole body that is physically homogeneous and bounded by a surface that separates it from other parts. Distinct phases are visible at a glance in coarse-grained ceramic pieces; in a fine-grained piece, phases can be seen with a microscope. When examined on a still finer scale, most ceramics, like metals, are microcrystalline, consisting of small crystalline grains cemented together (Fig. 22.8). The **microstructure** of such objects includes the sizes and shapes of the grains, the sizes and distribution of voids (openings between grains) and cracks, the identity and distribution of impurity grains, and the presence of stresses within the structure. Microstructural variations have enormous importance in ceramics because slight changes at this level strongly influence the properties of individual ceramic pieces. This is less true for plastic and metallic objects.

The microstructure of a ceramic body depends markedly on the details of its fabrication. The techniques of forming and firing a ceramic piece are as important as its chemical composition in determining ultimate behavior because they confer a unique microstructure. This fact calls attention to the biggest problem with ceramics as structural materials: inconsistent quality. Ceramic engineers can produce parts that are harder than steel (Fig. 22.9), but not reliably so because of the difficulties of monitoring and controlling microstructure. Gas turbine engines fabricated of silicon nitride, for example, run well at  $1370^\circ\text{C}$ ,

© david page photography/Alamy

**FIGURE 22.9** Silicon carbide ball bearings are harder, stiffer, and have smoother surfaces than steel bearings, resulting in improved performance due to reduced friction and less heat. Their high melting points make them the bearings of choice for demanding, high temperature applications.

which is hot enough to soften or melt most metals. The higher operating temperature increases engine efficiency, and the ceramic turbines weigh less, which further boosts fuel economy. Despite these advantages, there is no commercial ceramic gas turbine. Acceptable ceramic turbines have to be built from selected, pretested components. The testing costs and rejection rates are so high that economical mass production has been impossible so far.

### 22.2.2 Making Ceramics

The manufacture of most ceramics involves four steps: (1) the preparation of the raw material; (2) the forming of the desired shape, often achieved by mixing a powder with water or other binder and molding the resulting plastic mass; (3) the drying and firing of the piece, also called its **densification**, because pores (voids) in the dried ceramic fill in; and (4) the finishing of the piece by sawing, grooving, grinding, or polishing.

The raw materials for traditional ceramics are natural clays that come from the earth as powders or thick pastes and become plastic enough after adjustment of their water content to be formed freehand or on a potter's wheel. Special ceramics (both oxide and nonoxide) require chemically pure raw materials that are produced synthetically. Close control of the purity of the starting materials for these ceramics is essential to produce finished pieces with the desired properties. In addition to being formed by hand or in open molds, ceramic pieces are shaped by the squeezing (compacting) of the dry or semidry powders in a strong, closed mold of the desired shape, at either ordinary or elevated temperatures (hot pressing).

Firing a ceramic causes **sintering** to occur. In sintering, the fine particles of the ceramic start to merge together by diffusion at high temperatures. The density of the material increases as the voids between grains are partially filled. Sintering occurs below the melting point of the material and shrinks the ceramic body. In addition to the merging of the grains of the ceramic, firing causes partial melting, chemical reactions among different phases, reactions with gases in the atmosphere of the firing chamber, and recrystallization of compounds with an accompanying growth in crystal size. All of these changes influence the microstructure of a piece and must be understood and controlled. Firing accelerates physical and chemical changes, of course, but thermodynamic equilibrium in a fired ceramic piece is rarely reached. Kinetic factors—including the rate of heating, the length of time at which each temperature is held, and the rate of cooling—influence microstructure. As a result, the use of microwave radiation (as in microwave ovens) rather than kilns to fire ceramics is under development in ceramic factories, because it promises more exact control of the heating rate, and thereby more reliable quality.

## 22.3 Silicate Ceramics

The silicate ceramics include materials that vary widely in composition, structure, and use. They range from simple earthenware bricks and pottery to cement, fine porcelain, and glass. Their structural strength is based on the same linking of silicate ion tetrahedra that gives structure to silicate minerals in nature.

### 22.3.1 Pottery and Structural Clay Products

Aluminosilicate clays are products of the weathering of primary minerals. When water is added to such clays in moderate amount, a thick paste results that is easily molded into different shapes. Clays expand as water invades the space

between adjacent aluminosilicate sheets of the mineral, but they release most of this water to a dry atmosphere and shrink. A small fraction of the water or hydroxide ions remains rather tightly bound by ion–dipole forces to cations between the aluminosilicate sheets and is lost only when the clay is heated to a high temperature. The firing of aluminosilicate clays simultaneously causes irreversible chemical changes to occur. The clay kaolinite ( $\text{Al}_2\text{Si}_2\text{O}_5(\text{OH})_4$ ) undergoes the following reaction:

The fired ceramic body is a mixture of two phases: mullite and silica. Mullite, a rare mineral in nature, takes the form of needlelike crystals that interpenetrate and confer strength on the ceramic. When the temperature is above  $1470^\circ\text{C}$ , the silica phase forms as minute grains of cristobalite, one of the several crystalline forms of  $\text{SiO}_2$ .

If chemically pure kaolinite is fired, the finished ceramic object is white. Such purified clay minerals are the raw material for fine china. As they occur in nature, clays contain impurities, such as transition-metal oxides, that affect the color of both the unfired clay and the fired ceramic object if they are not removed. The colors of the metal oxides arise from their absorption of light at visible wavelengths, as explained by crystal field theory (see Section 8.4). Common colors for ceramics are yellow or greenish yellow, brown, and red. Bricks are red when the clay used to make them has high iron content.

Before a clay is fired in a kiln, it must first be freed of moisture by slowly heating to about  $500^\circ\text{C}$ . If a clay body dried at room temperature were to be placed directly into a hot kiln, it would literally explode from the sudden, uncontrolled expulsion of water. A fired ceramic shrinks somewhat as it cools, causing cracks to form. These imperfections limit the strength of the fired object and are undesirable. The occurrence of imperfections can be reduced by coating the surface of a partially fired clay object with a **glaze**, a thin layer that minimizes crack formation in the underlying ceramic by holding it in a state of tension as it cools. Glazes, as their name implies, are glasses that have no sharp melting temperature, but rather harden and develop resistance to shear stresses increasingly as the temperature of the high-fired clay object is gradually reduced. Glazes generally are aluminosilicates that have high aluminum content to raise their viscosity, and thereby reduce the tendency to run off the surface during firing. They also provide the means of coloring the surfaces of fired clays and imparting decorative designs to them. Transition-metal oxides (particularly those of titanium [Ti], vanadium [V], chromium [Cr], manganese [Mn], iron [Fe], cobalt [Co], nickel [Ni], and Cu) are responsible for the colors. The oxidation state of the transition metal in the glaze is critical in determining the color produced and is controlled by regulating the composition of the atmosphere in the kiln; atmospheres rich in oxygen give high oxidation states, and those poor or lacking in oxygen give low oxidation states.

### 22.3.2 Glass

Glassmaking probably originated in the Near East about 3500 years ago. It is one of the oldest domestic arts, but its beginnings, like those of metallurgy, are obscure. Both required high-temperature, charcoal-fueled ovens and vessels made of materials that did not easily melt to initiate and contain the necessary chemical reactions. In the early period of glassmaking, desired shapes were fabricated by sculpting them from solid chunks of glass. At a later date, molten glass was poured in successive layers over a core of sand. A great advance was the invention of glassblowing, which probably occurred in the first century B.C. A long iron tube was dipped into molten glass and a rough ball of viscous

**FIGURE 22.10** Handcrafted glassware is trimmed after being blown into the desired shape.

© Charles D. Winters/Science Source

material was caused to accumulate on its end by rotating the tube. Blowing into the iron tube forced the soft glass to take the form of a hollow ball (Fig. 22.10) that could be further shaped into a vessel and severed from the blowing tube with a blade. Artisans in the Roman Empire developed glassblowing to a high degree, but with the decline of that civilization, the skill of glassmaking in Europe deteriorated until the Venetians redeveloped the lost techniques a thousand years later.

Glasses are amorphous solids of widely varying composition (see Section 21.4 for a discussion of the physical properties of glass). In this chapter, the term *glass* is used in the restricted and familiar sense to refer to materials formed from silica, usually in combination with metal oxides. The absence of long-range order in glasses has the consequence that they are **isotropic**—that is, their physical properties are the same in all directions. This has advantages in technology, including that glasses expand uniformly in all directions with an increase in temperature. The mechanical strength of glass is intrinsically high, exceeding the tensile strength of steel, provided the surface is free of scratches and other imperfections. Flaws in the surface provide sites where fractures can start when the glass is stressed. When a glass object of intricate shape and non-uniform thickness is suddenly cooled, internal stresses are locked in; these stresses may be relieved catastrophically when the object is heated or struck (Fig. 22.11). Slowly heating a strained object to a temperature somewhat below its softening point and holding it there for a while before allowing it to cool slowly is called **annealing**; it gives short-range diffusion of atoms a chance to occur and to eliminate internal stresses.

The softening and annealing temperatures of a glass and other properties, such as density, depend on its chemical composition (Table 22.2). Silica itself ( $\text{SiO}_2$ ) forms a glass if it is heated above its melting point and then cooled

**FIGURE 22.11** The strains associated with internal stresses in rapidly cooled glass can be made visible by viewing the glass in polarized light. They appear as colored regions.

1.459	1.512	1.474	1.530	1.560

<sup>†</sup>The coefficient of linear thermal expansion is defined as the fractional increase in length of a body when its temperature is increased by  $1^{\circ}\text{C}$ .

<sup>‡</sup>The refractive index is a vital property of glass for optical applications. It is defined by  $n = \sin \theta_i / \sin \theta_r$ , where  $\theta_i$  is the angle of incidence of a ray of light on the surface of the glass and  $\theta_r$  is the angle of refraction of the ray of light in the glass.

**FIGURE 22.12** Structure of a soda-lime glass. Note the tetrahedral coordination of oxygen atoms around each silicon atom.

rapidly to avoid crystallization. The resulting vitreous (glassy) silica has limited use because the high temperatures required to shape it make it quite expensive. Sodium silicate glasses are formed in the high-temperature reaction of silica sand with anhydrous sodium carbonate (soda ash,  $\text{Na}_2\text{CO}_3$ ):

The melting point of the nonvolatile product is about  $900^\circ\text{C}$ , and the glassy state results if cooling through that temperature is rapid. The product, called “water glass,” is water-soluble; thus, it is unsuitable for making vessels. Its aqueous solutions, however, are used in some detergents and as adhesives for sealing cardboard boxes.

An insoluble glass with useful structural properties results if lime ( $\text{CaO}$ ) is added to the sodium carbonate–silica starting materials. **Soda-lime glass** is the resulting product, with the approximate composition  $\text{Na}_2\text{O} \cdot \text{CaO} \cdot (\text{SiO}_2)_6$ . Soda-lime glass is easy to melt and shape and is used in applications ranging from bottles to window glass. It accounts for more than 90% of all the glass manufactured today. The structure of this ionic glass is shown schematically in Figure 22.12. It is a three-dimensional network of the type discussed in Section 22.1, but with random coordination of the silicate tetrahedra. The network is a giant “polyanion,” with  $\text{Na}^+$  and  $\text{Ca}^{2+}$  ions distributed in the void spaces to compensate for the negative charge on the network.

Replacing lime and some of the silica in a glass by other oxides ( $\text{Al}_2\text{O}_3$ ,  $\text{B}_2\text{O}_3$ ,  $\text{K}_2\text{O}$ , or  $\text{PbO}$ ) modifies its properties noticeably. For example, the thermal conductivity of ordinary (soda-lime) glass is quite low, and its coefficient of thermal expansion is high. This means that internal stresses are created when its surface is subjected locally to extreme heat or cold, and it may shatter. The coefficient of thermal expansion is appreciably lower in certain borosilicate glasses, in which many of the silicon sites are occupied by boron. Pyrex, the most familiar of these glasses, has a coefficient of linear expansion about one-third that of ordinary soda-lime glass and is the preferred material for laboratory glassware and household ovenware. Vycor has an even smaller coefficient of expansion (approximating that of fused silica) and is made by chemical treatment of a borosilicate glass to leach out its sodium. This leaves a porous structure that is densified by increasing the temperature and shrinking the glass to its final volume.

### 22.3.3 Cements

Hydraulic cement was first developed by the ancient Romans, who found that a mixture of lime ( $\text{CaO}$ ) and dry volcanic ash reacts slowly with water, even at low temperatures, to form a durable solid. They used this knowledge to build the Pantheon in Rome, a circular building whose concrete dome, spanning 143 feet without internal support, still stands nearly 2000 years after its construction! The knowledge of cement making was lost for centuries after the fall of the Roman Empire. It was rediscovered in 1824 by an English bricklayer, Joseph Aspdin, who patented a process for calcining a mixture of limestone and clay. He called the product **Portland cement** because, when mixed with water, it hardened to a material that resembled a kind of limestone found on the Isle of Portland. Portland cement is now manufactured in every major country, and annual worldwide production is currently about 800 million metric tons, exceeding the production of all other materials. Portland cement opened up a new age in the methods of constructing highways and buildings: Rock could be crushed and then molded in cement, rather than shaped with cutting tools.

Portland cement is a finely ground, powdered mixture of compounds produced by the high-temperature reaction of lime, silica, alumina, and iron oxide. The lime ( $\text{CaO}$ ) may come from limestone or chalk deposits, and the silica ( $\text{SiO}_2$ ) and alumina ( $\text{Al}_2\text{O}_3$ ) are often obtained in clays or slags. The blast

TABLE 22.3

## Composition of Portland Cement

Oxide	Percentage by Mass
Lime (CaO)	61–69
Silica (SiO <sub>2</sub> )	18–24
Alumina (Al <sub>2</sub> O <sub>3</sub> )	4–8
Iron(III) oxide (Fe <sub>2</sub> O <sub>3</sub> )	1–8
Minor oxides (MgO, Na <sub>2</sub> O, K <sub>2</sub> O, SO <sub>3</sub> )	2–4

furnaces of steel mills are a common source of slag, which is a byproduct of the smelting of iron ore. The composition of slag varies, but it can be represented as a calcium aluminum silicate of approximate formula  $\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot (\text{SiO}_2)_2$ . Molten slag solidifies into “blast furnace clinkers” on quenching in water. This material is crushed and ground to a fine powder, blended with lime in the correct proportion, and burned again in a horizontal rotary kiln at temperatures up to 1500°C to produce “cement clinker.” A final stage of grinding and the addition of about 5% gypsum ( $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ ) to lengthen the setting time completes the process of manufacture. Table 22.3 presents the composition of a typical Portland cement and gives percentages of the separate oxides; these simple materials, which are the “elements” of cement making, combine in the cement in more complex compounds such as tricalcium silicate,  $(\text{CaO})_3 \cdot \text{SiO}_2$ , and tricalcium aluminate,  $(\text{CaO})_3 \cdot \text{Al}_2\text{O}_3$ .

Cement *sets* when the semiliquid slurry first formed by the addition of water to the powder becomes a solid of low strength. Subsequently, it gains strength in a slower *hardening* process. Setting and hardening involve a complex group of exothermic reactions in which several hydrated compounds form. Portland cement is a **hydraulic cement**, because it hardens not by loss of admixed water, but by chemical reactions that incorporate water into the final body. The main reaction during setting is the hydration of the tricalcium aluminate, which can be approximated by the following equation:

The product forms after 5 or 6 hours as a microscopic forest of long crystalline needles that lock together to solidify the cement. Later, the calcium silicates react with water to harden the cement. For example:

The hydrated calcium silicates develop as strong tendrils that coat and enclose unreacted grains of cement, each other, and other particles that may be present, binding them in a robust network. Most of the strength of cement comes from these entangled networks, which, in turn, depend ultimately for strength on chains of O—Si—O—Si silicate bonds. Hardening is slower than setting; it may take as long as 1 year for the final strength of a cement to be attained.

Portland cement is rarely used alone. Generally, it is combined with sand, water, and lime to make **mortar**, which is applied with a trowel to bond bricks or stone together in an assembled structure. When Portland cement is mixed with sand and aggregate (crushed stone or pebbles) in the proportions of 1:3.75:5 by volume, the mixture is called **concrete**. Concrete is outstanding in its resistance to compressive forces and is therefore the primary material in use for the foundations of buildings and the construction of dams, in which the compressive loads are enormous. The stiffness (resistance to bending) of concrete is high, but its fracture toughness (resistance to impact) is substantially lower and its tensile strength is relatively poor. For this reason, concrete is usually reinforced with steel rods when it is used in structural elements such as beams that are subject to transverse or tensile stresses.

As excess water evaporates from cement during hardening, pores form that typically comprise 25% to 30% of the volume of the solid. This porosity weakens concrete, and recent research has shown that the fracture strength is related inversely to the size of the largest pores in the cement. A new material, called “macro defect-free” (MDF) cement, has been developed in which the size of the pores is reduced from about a millimeter to a few micrometers by the addition of water-soluble polymers that make a doughlike “liquid” cement that is moldable with the use of far less water. Unset MDF cement is mechanically kneaded and extruded into the desired shape. The final result possesses substantially

increased bending resistance and fracture toughness. MDF cement can even be molded into springs and shaped on a conventional lathe. When it is reinforced with organic fibers, its toughness is further increased. The development of MDF cement is a good illustration of the way in which chemistry and engineering collaborate to furnish new materials.

## 22.4 Nonsilicate Ceramics

Many useful ceramics exist that are *not* based on the Si—O bond and the SiO<sub>4</sub> tetrahedron. They have important uses in electronics, optics, and the chemical industry. Some of these materials are oxides, but others contain neither silicon nor oxygen.

### 22.4.1 Oxide Ceramics

Oxide ceramics are materials that contain oxygen in combination with any of a number of metals. These materials are named by adding an *-ia* ending to the stem of the name of the metallic element. Thus, if the main chemical component of an oxide ceramic is Be<sub>2</sub>O<sub>3</sub>, it is a *beryllia* ceramic; if the main component is Y<sub>2</sub>O<sub>3</sub>, it is an *yttria* ceramic; and if it is MgO, it is a *magnesia* ceramic. As Table 22.4 shows, the melting points of these and other oxides are substantially higher than the melting points of the elements themselves. Such high temperatures are hard to achieve and maintain, and the molten oxides corrode most container materials. Oxide ceramic bodies are therefore not shaped by melting the appropriate oxide and pouring it into a mold. Instead, these ceramics are fabricated by sintering, like the silicate ceramics.

**Alumina** (Al<sub>2</sub>O<sub>3</sub>) is the most important nonsilicate ceramic material. It melts at a temperature of 2051°C and retains strength even at temperatures of 1500°C to 1700°C. Alumina has a large electrical resistivity and withstands both thermal shock and corrosion well. These properties make it a good material for spark plug insulators, and most spark plugs now use a ceramic that is 94% alumina.

High-density alumina is fabricated in such a way that open pores between the grains are nearly completely eliminated; the grains are small, with an average diameter as low as 1.5 μm. Unlike most others, this ceramic has good mechanical strength against impact, which has led to its use in armor plating. The ceramic absorbs the energy of an impacting projectile by breaking; thus, penetration does not occur. High-density alumina is also used in high-speed cutting tools for machining metals. The temperature resistance of the ceramic allows much faster cutting speeds, and a ceramic cutting edge has no tendency to weld to the metallic work piece, as metallic tools do. These properties make

**TABLE 22.4**

Melting Points of Some Metals and Their Oxides

Metal	Melting Point (°C)	Oxide	Melting Point (°C)
Be	1287	BeO	2570
Mg	651	MgO	2800
Al	660	Al <sub>2</sub> O <sub>3</sub>	2051
Si	1410	SiO <sub>2</sub>	1723
Ca	865	CaO	2572
Y	1852	Y <sub>2</sub> O <sub>3</sub>	2690

**FIGURE 22.13** The socket in this artificial hip is made of high-density alumina.

© SIU/Science Source

alumina cutting tools superior to metallic tools, as long as they do not break too easily. High-density alumina is also used in artificial joints (Fig. 22.13).

If  $\text{Al}_2\text{O}_3$  doped with a small percentage of  $\text{MgO}$  is fired in a vacuum or a hydrogen atmosphere (instead of air) at a temperature of  $1800^\circ\text{C}$  to  $1900^\circ\text{C}$ , even very small pores, which scatter light and make the material white, are removed. The resulting ceramic is translucent. This material is used to contain the sodium in high-intensity sodium discharge lamps. With envelopes of high-density alumina, these lamps can be operated at temperatures of  $1500^\circ\text{C}$  to give a whiter and more intense light. Old-style sodium-vapor lamps with glass envelopes were limited to a temperature of  $600^\circ\text{C}$  because the sodium vapor reacted with the glass at higher temperatures. At low temperatures, the light from a sodium-vapor lamp has an undesirable yellow color.

*Magnesia* ( $\text{MgO}$ ) is mainly used as a **refractory**—a ceramic material that withstands a temperature of more than  $1500^\circ\text{C}$  without melting ( $\text{MgO}$  melts at  $2800^\circ\text{C}$ ). A major use of magnesia is as insulation in electrical heating devices, because it combines high thermal conductivity with excellent electrical resistance. Magnesia is prepared from magnesite ores, which consist of  $\text{MgCO}_3$  and a variety of impurities. When purified magnesite is heated to  $800^\circ\text{C}$  to  $900^\circ\text{C}$ , carbon dioxide is driven off to form  $\text{MgO}(s)$  in fine grains:

After cooling, fine-grained  $\text{MgO}$  reacts vigorously with water to form magnesium hydroxide:

Heating fine-grained  $\text{MgO}(s)$  to  $1700^\circ\text{C}$  causes the  $\text{MgO}$  grains to sinter, giving a “dead-burned magnesia” that consists of large crystals and does not react with water. The  $\Delta G^\circ$  of the reaction between  $\text{MgO}$  and  $\text{H}_2\text{O}$  does not change when magnesia is dead burned. The altered microstructure (larger crystals vs. small) makes the reaction with water exceedingly slow, however.

## 22.4.2 Superconducting Ceramics

The oxide ceramics discussed so far in this chapter all consisted of single chemical compounds, except for minor additives. A natural idea for new ceramics is to make materials that contain two (or more) oxides in equal or nearly equal molar amounts. Thus, if  $\text{BaCO}_3$  and  $\text{TiO}_2$  are mixed and heated to high temperature, they react to give the ceramic barium titanate:

Barium titanate, which has many novel properties, is a **mixed oxide ceramic**. It has the same structure as the mineral *perovskite*,  $\text{CaTiO}_3$  (Fig. 22.14), except, of course, that Ba replaces Ca. Perovskites typically have two metal atoms for every three O atoms, giving them the general formula  $\text{ABO}_3$ , where A stands for a metal atom at the center of the unit cube and B stands for an atom of a different metal at the cube corners.

Research interest in perovskite ceramic compositions has grown explosively after the discovery that some of them are able to act as a **superconductor** at relatively high temperatures. A superconducting material offers no resistance whatsoever to the flow of an electric current. The phenomenon was discovered by the Dutch physicist Heike Kamerlingh-Onnes in 1911, when he cooled mercury below its superconducting transition temperature of 4 K. Such low temperatures are difficult to achieve and maintain, but if practical superconductors could be made to work at higher temperatures (or even at room temperature!), then power transmission, electronics, transportation, medicine, and many other aspects of human life would be transformed. More than 60 years of research

**FIGURE 22.14** Structure of perovskite ( $\text{CaTiO}_3$ ). A stack of three unit cells is shown, with some additional O atoms (red) from neighboring cells. Each Ti atom (gray) is surrounded by six O atoms; each Ca atom (white) has eight O atoms as nearest neighbors.

**FIGURE 22.15** Levitation of a small magnet above a disk of superconducting material. A superconducting substance cannot be penetrated by an external magnetic field. At room temperature, the magnet rests on the ceramic disk. When the disk is cooled with liquid nitrogen, it becomes superconducting and excludes the magnet's field, forcing the magnet into the air.

with metallic systems culminated in 1973 with the discovery of a niobium–tin alloy with a world-record superconducting transition temperature of 23.3 K. Progress toward higher temperature superconductors then stalled until 1986, when K. Alex Müller and J. Georg Bednorz, who had had the inspired notion to look for higher transition temperatures among perovskite ceramics, found a Ba–La–Cu–O perovskite phase having a transition temperature of 35 K. This result motivated other scientists, who soon discovered another rare-earth-containing perovskite ceramic that became a superconductor at 90 K. This result was particularly exciting because 90 K exceeds the boiling point of liquid nitrogen (77 K), a relatively cheap refrigerant (Fig. 22.15). This 1-2-3 compound (so called because its formula,  $\text{YBa}_2\text{Cu}_3\text{O}_{9-x}$ , has one Y, two Ba, and three Cu atoms per formula unit) is not an ideal perovskite because it has fewer than nine O atoms in combination with its six metal atoms. The deficiency makes  $x$  in the formula somewhat greater than 2, depending on the exact method of preparation. The structure of this nonstoichiometric solid is shown in Figure 22.16. More recently, the maximum superconducting transition temperature has increased to 125 K in another class of ceramics that does not contain rare-earth elements.

A crucial concern in the application of superconducting ceramics is to devise ways to fabricate the new materials in desired shapes such as wires. This will be quite a challenge because these superconductors are ceramics and have the brittleness and fragility typical of ceramic materials.

### 22.4.3 Nonoxide Ceramics

In nonoxide ceramics, nitrogen (N) or carbon (C) takes the place of oxygen in combination with silicon or boron. Specific substances are boron nitride (BN), boron carbide ( $\text{B}_4\text{C}$ ), the silicon borides ( $\text{SiB}_4$  and  $\text{SiB}_6$ ), silicon nitride ( $\text{Si}_3\text{N}_4$ ), and silicon carbide (SiC). All of these compounds possess strong, short covalent bonds. They are hard and strong, but brittle. Table 22.5 lists the enthalpies of the chemical bonds in these compounds.

Much research has aimed at making gas-turbine and other engines from ceramics. Of the oxide ceramics, only alumina and zirconia ( $\text{ZrO}_2$ ) are strong enough, but both resist thermal shock too poorly for this application. Attention has therefore turned to the nonoxide **silicon nitride** ( $\text{Si}_3\text{N}_4$ ). In this **network solid** (Fig. 22.17), every Si atom bonds to four N atoms that surround it at the corners of a tetrahedron; these tetrahedra link into a three-dimensional network by sharing corners. The Si–N bond is covalent and strong (the bond enthalpy is  $439 \text{ kJ mol}^{-1}$ ). The similarity to the joining of  $\text{SiO}_4$  units in silicate minerals (see Section 22.1) is clear.

**FIGURE 22.16** The structure of  $\text{YBa}_2\text{Cu}_3\text{O}_{9-x}$  is a layered perovskite. Each Cu atom (orange) is bonded to O atoms (red). The layers differ because one-third of them contain Y atoms (blue-gray), whereas two-thirds contain Ba atoms (green). This structure is a variation of the perovskite structure in Figure 22.14. In a hypothetical “ $\text{BaCuO}_3$ ” structure, every third Ba has been replaced by a Y, and the O atoms in the layer containing the Y have been removed.

**TABLE 22.5**

Bond Enthalpies in Nonoxide Ceramics

Bond	Bond Enthalpy ( $\text{kJ mol}^{-1}$ )
B–N	389
B–C	448
Si–N	439
Si–C	435
B–Si	289
C–C	350

**FIGURE 22.17** Structure of silicon nitride ( $\text{Si}_3\text{N}_4$ ). Each Si atom is bonded to four N atoms, and each N atom is bonded to three Si atoms. The result is a strong network.

At first, silicon nitride appears chemically unpromising as a high-temperature structural material. It is unstable in contact with water because the following reaction has a negative  $\Delta G^\circ$ :

In fact, this reaction causes finely ground  $\text{Si}_3\text{N}_4$  powder to give off an odor of ammonia in moist air at room temperature. Silicon nitride is also thermodynamically unstable in air, reacting spontaneously with oxygen:

The reaction has a  $\Delta G^\circ$  of  $-1927 \text{ kJ mol}^{-1}$ . In practice, neither reaction occurs at a perceptible rate when  $\text{Si}_3\text{N}_4$  is in bulk form. Initial contact of oxygen or water with  $\text{Si}_3\text{N}_4(\text{s})$  forms a surface film of  $\text{SiO}_2(\text{s})$  that protects the bulk of the  $\text{Si}_3\text{N}_4(\text{s})$  from further attack. When *strongly* heated in air (to about  $1900^\circ\text{C}$ ),  $\text{Si}_3\text{N}_4$  does decompose, violently, but until that temperature is reached, it resists attack.

Fully dense silicon nitride parts are stronger than metallic alloys at high temperatures. Ball bearings made of dense silicon nitride work well without lubrication at temperatures up to  $700^\circ\text{C}$ ; for example, they last longer than steel ball bearings. Because the strength of silicon nitride increases with the density attained in the production process, the trick is to form a dense piece of silicon nitride in the desired shape. One method for making useful shapes of silicon nitride is “reaction bonding.” Powdered silicon is compacted in molds, removed, and then fired under an atmosphere of nitrogen at  $1250^\circ\text{C}$  to  $1450^\circ\text{C}$ . The following reaction forms the ceramic:

The parts neither swell nor shrink significantly during the chemical conversion from Si to  $\text{Si}_3\text{N}_4$ , making it possible to fabricate complex shapes reliably. Unfortunately, reaction-bonded  $\text{Si}_3\text{N}_4$  is still somewhat porous and is not strong enough for many applications. In the “hot-pressed” forming process,  $\text{Si}_3\text{N}_4$  powder is prepared in the form of exceedingly small particles by reaction of silicon tetrachloride with ammonia:

The solid  $\text{Si}_3\text{N}_4$  forms as a smoke. It is captured as a powder, mixed with a carefully controlled amount of MgO additive, placed in an enclosed mold, and sintered at  $1850^\circ\text{C}$  under a pressure of 230 atm. The resulting ceramic shrinks to nearly full density (no pores). Because the material does not flow well (to fill a complex mold completely), only simple shapes are possible. Hot-pressed

silicon nitride is impressively tough and can be machined only with great difficulty and with diamond tools.

In the silicate minerals of Section 22.1,  $\text{AlO}_4^{5-}$  units routinely substitute for  $\text{SiO}_4^{4-}$  tetrahedra as long as positive ions of some type are present to balance the electric charge. This fact suggests that in silicon nitride some  $\text{Si}^{4+}$  ions, which lie at the centers of tetrahedra of N atoms, could be replaced by  $\text{Al}^{3+}$  if a compensating replacement of  $\text{O}^{2-}$  for  $\text{N}^{3-}$  were simultaneously made. Experiments show that ceramic alloying of this type works well, giving many new ceramics with great potential called **sialons** (named for the four elements Si–Al–O–N). These ceramics illustrate the way a structural theme in a naturally occurring material guided the search for new materials.

Boron has one fewer valence electron than carbon, and nitrogen has one more valence electron. *Boron nitride* (BN) is therefore isoelectronic with  $\text{C}_2$ , and it is not surprising that it has two structural modifications that resemble the structures of graphite and diamond. In hexagonal boron nitride, the B and N atoms take alternate places in an extended “chicken-wire” sheet in which the B–N distance is 1.45 Å. The sheets stack in such a way that each B atom has a N atom directly above it and directly below it, and vice versa. The cubic form of boron nitride has the diamond structure, is comparable in hardness to diamond, and resists oxidation better. Boron nitride is often prepared by **chemical vapor deposition**, a method used in fabricating several other ceramics as well. In this method, a controlled chemical reaction of gases on a contoured, heated surface gives a solid product of the desired shape. If a cup made of BN is needed, a cup-shaped mold is heated to a temperature exceeding 1000°C and a mixture of  $\text{BCl}_3(\text{g})$  and  $\text{NH}_3(\text{g})$  is passed over its surface. The reaction

deposits a cup-shaped layer of BN(s). Boron nitride cups and tubes are used to contain and evaporate molten metals.

*Silicon carbide* (SiC) is diamond in which half of the C atoms are replaced by Si atoms. Also known by its trade name of Carborundum, silicon carbide was developed originally as an abrasive, but it is now used primarily as a refractory and as an additive in steel manufacture. It is formed and densified by methods similar to those used with silicon nitride. Silicon carbide is often produced in the form of small plates or whiskers to reinforce other ceramics. Fired silicon carbide whiskers are quite small (0.5 μm in diameter and 50 μm long) but are strong. They are mixed with a second ceramic material before that material is formed. Firing then gives a **composite ceramic**. Such composites are stronger and tougher than unreinforced bodies of the same primary material. Whiskers serve to reinforce the main material by stopping cracks; they either deflect advancing cracks or soak up their energy, and a widening crack must dislodge them to proceed (Fig. 22.18). Recently, SiC has been used in high-power, high-temperature semiconductor devices (Section 22.7).

**FIGURE 22.18** Microstructure of a composite ceramic. The light-colored areas are  $\text{TiB}_2$ , the gray areas are SiC, and the dark areas are voids. The  $\text{TiB}_2$  acts to toughen the SiC matrix. Note that the crack shown passing through from left to right is forced to deflect around the  $\text{TiB}_2$  particles.

## 22.5 Electrical Conduction in Materials

Electronic properties describe the movement of charged particles in a material in response to an applied electric field. If the charges are free to move throughout the material, the process is *electrical conduction*, measured by the *electrical conductivity* of the material. Differences in the magnitude of the conductivity distinguish metals, semiconductors, and insulators. If the charges can move only limited distances and are then halted by opposing binding forces, separation of positive and negative charges leads to *electric polarization* of the material, measured by its *dielectric constant*. Conduction involves dissipation of energy as heat, whereas polarization involves storage of potential energy in the material.

An electric field applied to a material that has free charged particles causes these particles to flow through the material and into the external circuit. How do we define and measure the conductivity of a material? On what macroscopic properties does it depend? How does it relate to the detailed chemical structure of the material?

### 22.5.1 Measurement of Conductivity

The electrical conductivity of a material is measured by placing a cylindrical sample of cross-sectional area,  $A$ , and length,  $\ell$ , in a simple electrical circuit as a resistor in series with a power supply and ammeter; a voltmeter measures the actual voltage across the sample (Fig. 22.19). If the voltage,  $V$ , is varied and the resulting current,  $I$ , is measured at each voltage, a plot of  $I$  versus  $V$  is a straight line (Fig. 22.20):

**FIGURE 22.20** Plot of current against voltage is a straight line whose slope is the conductance  $G$ .

$$I = GV \quad [22.1]$$

The resulting slope is called the **conductance** and is denoted by  $G$ . If  $V$  is measured in volts and  $I$  in amperes (A), then  $G$  has units of siemens ( $1 \text{ siemens} = 1 \text{ A/V}$ ). If the value of  $G$  is constant, the material follows Ohm's law

$$V = IR$$

and  $G$  is the reciprocal of the **resistance**  $R$ , which is measured in ohms ( $\Omega$ ;  $1 \Omega = 1 \text{ V/A}$ ). So far, the measurement depends on the size and shape of the material sample, in addition to its composition. To remove these geometric effects, we note

TABLE 22.6

Electrical Conductivity of Selected Metals at Room Temperature

Metal	Conductivity [[ $\Omega \text{ m}$ ] <sup>-1</sup> ]
Silver	$6.8 \times 10^7$
Copper	$6.0 \times 10^7$
Gold	$4.3 \times 10^7$
Aluminum	$3.8 \times 10^7$
Iron	$1.0 \times 10^7$
Platinum	$0.94 \times 10^7$
Stainless steel	$0.2 \times 10^7$

from experiment that  $R$  increases as  $\ell$  increases, and it decreases as  $A$  increases. Therefore, we define the material property **resistivity**, denoted by  $\rho$ , as the proportionality constant that summarizes these two effects:

$$R = \frac{\ell}{A} \rho \quad [22.2]$$

From this definition,  $\rho$  has dimensions of  $\Omega \text{ m}$ . Finally, we define the material property **conductivity**,  $\sigma$ , as the reciprocal of the resistivity:

$$\sigma = \frac{1}{\rho} = \frac{\ell}{RA} \quad [22.3]$$

from which  $\sigma$  has units of  $(\Omega \text{ m})^{-1}$  or  $\text{S m}^{-1}$ . We now rewrite Ohm's law in a form independent of sample geometry. First, define the current density  $J$  ( $\text{A m}^{-2}$ ) through the sample as  $I/A$  and define the electric field  $E$  ( $\text{V m}^{-1}$ ) through the sample as  $V/\ell$ . Inserting these definitions and the definition of  $\sigma$  from Equation 22.3 into Equation 22.1 gives:

$$J = \sigma E \quad [22.4]$$

According to Equation 22.4, the current density flowing through a material sample is proportional to the electric field applied to the sample, and the proportionality constant is the conductivity of the material of which the sample is made. This is the equation we use to relate the conductivity of a material to its microstructural properties. Table 22.6 lists conductivities for several common metals at room temperature.<sup>2</sup>

## 22.5.2 Microscopic Origins of the Conductivity

Insight into the conductivity is provided by measuring the electrical conductivity of aqueous ionic solutions (Fig. 22.21; this topic is referred to in Chapters 11 and 15). The conductivity of pure water, multiply distilled to remove all impurities, is about  $0.043 \times 10^{-6} (\Omega \text{ cm})^{-1}$ . Exposed to the air, pure water dissolves  $\text{CO}_2$ , which forms carbonic acid,  $\text{H}_2\text{CO}_3$ ; dissociation produces  $\text{H}_3\text{O}^+$  and  $\text{HCO}_3^-$ , which increase the conductivity to about  $1 \times 10^{-6} (\Omega \text{ cm})^{-1}$ . As ionic

<sup>2</sup>Because the meter is inconveniently large for measuring the dimensions of most samples in material studies, you will frequently see  $\rho$  expressed in units of  $\Omega \text{ cm}$  and  $\sigma$  in units of  $(\Omega \text{ cm})^{-1}$ . In base International System of Units (SI), resistivity has units expressed as  $\text{kg m}^3 \text{ s}^{-3} \text{ A}^{-2}$ .

FIGURE 22.21 Apparatus for measuring the conductivity of an aqueous solution of NaCl.

solutes are added to water, the conductivity increases rapidly; a 1.0-M solution in NaOH has conductivity of about  $0.180 (\Omega \text{ cm})^{-1}$  at  $25^\circ\text{C}$ . The conductivity depends strongly on both concentration and ionic species. The concentration dependence is summarized by the **molar conductivity**, defined by  $\Lambda_m = \sigma/c$ , where  $c$  is the concentration of the ion measured in moles per liter. To gain fundamental understanding of the conduction mechanism, we relate  $\Lambda_m$  to the details of the ionic motion in dilute solutions in response to the electric field. This leads to the concept of *mobility* of the ion, denoted by  $\mu$ , which shows how its surroundings influence the response of an ion to an applied field.

As the electric field is turned on, each ion is accelerated by the field and experiences a force whose magnitude and direction are given by the vector relation

$$\vec{F} = ze\vec{E}$$

where  $z$  is the charge on the ion in units of the elementary charge,  $e$ , and the expression is valid for either cations or anions (the force points in opposite directions in the two cases). As the ion is accelerated by the field, however, its forward motion is retarded by friction from the surrounding solvent molecules. This retarding force  $\vec{F}'$  opposes the direction of motion of the ion and is proportional to its velocity,  $\vec{v}$ :

$$\vec{F}' = -f\vec{v}$$

where  $f$  is the frictional drag coefficient. In due course, these forces balance and the ion achieves its steady drift velocity  $\vec{v}_d$ . This force balance condition provides the following relation:

$$\vec{v}_d = ze \frac{\vec{E}}{f}$$

This equation shows that the electric field increases the drift velocity, whereas the drag coefficient reduces it. We define the proportionality constant between the *drift speed* (the magnitude of the drift velocity) and the field to be the **mobility**,  $\mu$ , of the ion (a positive number), giving the following relation:

$$|\vec{v}_d| = \mu |\vec{E}| \quad [22.5]$$

Mobility has physical units of  $\text{m}^2 \text{V}^{-1} \text{s}^{-1}$ . For ions in solution, the mobility is given by

$$\mu = \frac{|z|e}{f}$$

In more advanced work, it is possible to estimate the drag coefficient,  $f$ , and provide a theoretical prediction of the mobility. Experimentally, the mobility for ions is obtained from the molar conductivity through the following equation, which we do not justify:

$$\Lambda_m = |z| \mu F \quad [22.6]$$

where  $F$  is the Faraday constant,  $96,485.34 \text{ C mol}^{-1}$  (the Faraday constant is introduced in Chapter 17).

Mobilities are shown in Table 22.7 for several ions in aqueous solution. One interesting feature is that the smaller cations have lower mobilities than the larger cations; for example,  $\mu$  for  $\text{Na}^+$  is smaller than that for  $\text{K}^+$ , and  $\mu$  for  $\text{Mg}^{2+}$  is smaller than that for  $\text{Ca}^{2+}$ . One might expect that the smaller ions would have larger mobility, because their smaller size should encounter less

**TABLE 22.7**

Mobilities of Selected Ions in Aqueous Solution at  $25^\circ\text{C}$

Ion	Mobility ( $\text{cm}^2 \text{V}^{-1} \text{s}^{-1}$ )
$\text{Li}^+$	$4.01 \times 10^{-4}$
$\text{Na}^+$	$5.19 \times 10^{-4}$
$\text{K}^+$	$7.62 \times 10^{-4}$
$\text{Mg}^{2+}$	$5.50 \times 10^{-4}$
$\text{Ca}^{2+}$	$6.17 \times 10^{-4}$
$\text{Ba}^{2+}$	$6.60 \times 10^{-4}$
$\text{Cl}^-$	$7.91 \times 10^{-4}$
$\text{Br}^-$	$8.10 \times 10^{-4}$
$\text{NO}_3^-$	$7.40 \times 10^{-4}$
$\text{ClO}_4^-$	$6.98 \times 10^{-4}$
$\text{CH}_3\text{COO}^-$	$4.24 \times 10^{-4}$

frictional drag when moving through the solvent. However, the greater charge density on the smaller cations attracts a larger solvation shell than occurs on the larger cations (see Section 11.2 and Fig. 11.5). The entity moving through the solution in response to the electric field is not the “bare” cation but the cation “dressed” with its solvation shell. The larger solvation shell on the smaller ions causes more frictional drag and lower mobility.

It can be shown that the conductivity of an ion is related to its mobility by the following equation:

$$\sigma_{\text{ion}} = |z|en_{\text{ion}}\mu_{\text{ion}} \quad [22.7]$$

where  $n_{\text{ion}}$  is the number density of ions present, expressed in number per cubic meter. The conductivity depends on two fundamental microscopic variables: the number density of carriers and the carrier mobility. Both positive and negative ions can respond to the electric field in the solution, so the total conductivity must include a contribution from each:

$$\sigma_{\text{tot}} = |z_{\text{cation}}|en_{\text{cation}}\mu_{\text{cation}} + |z_{\text{anion}}|en_{\text{anion}}\mu_{\text{anion}} \quad [22.8]$$

Equations 22.7 and 22.8 are valid for non-superconducting electrical conduction processes: motion of positive and negative ions in solution and in ionic solids, and motion of electrons in solids. These equations are used in subsequent sections to discuss conduction in a variety of materials. These equations should remind you that the conductivity in any material depends on two separate microscopic parameters: the number of charge carriers present and their mobilities.

### EXAMPLE 22.2

The molar conductivity of  $\text{Na}^+$  ions in aqueous solution at  $25^\circ\text{C}$  has been determined to be  $5.01 \times 10^{-2} (\Omega \text{ cm})^{-1} \text{ mol}^{-1} \text{ L}$ . Assume an electric field of  $1.0 \times 10^2 \text{ V cm}^{-1}$  is applied to the solution. Calculate the mobility and the drift velocity of  $\text{Na}^+$  ions.

#### Solution

From Equation 22.6, the mobility and molar conductivity are related by

$$\begin{aligned} \mu &= \frac{\Lambda_m}{|z|F} \\ &= \frac{5.01 \times 10^{-2} \Omega^{-1} \text{ cm}^{-1} \text{ mol}^{-1} \text{ L}}{(1)(96,485 \text{ C mol}^{-1})} \\ &= 5.19 \times 10^{-4} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1} \end{aligned}$$

We used Ohm's law  $V = IR$  or  $V = C \text{ s}^{-1} \Omega$  to simplify the units, and we took  $1 \text{ L} = 10^3 \text{ cm}^3$ .

From Equation 22.5, the drift velocity is given by

$$\begin{aligned} v_d &= \mu E \\ &= (5.19 \times 10^{-4} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1})(1.0 \times 10^2 \text{ V cm}^{-1}) \\ &= 5.19 \times 10^{-2} \text{ cm s}^{-1} \end{aligned}$$

### 22.5.3 Illustration: Conductivity in Metals

Before the quantum theory of solids (see description in Chapter 21), microscopic descriptions of metals were based on the Drude model, named for the German physicist Paul Drude. The solid was viewed as a fixed array of positively charged metal ions, each localized to a site on the solid lattice. These fixed ions were surrounded by a sea of mobile electrons, one contributed by each of the atoms in the solid. The number density of the electrons,  $n_{\text{el}}$ , is then equal to the number density of atoms in the solid. As the electrons move through the ions in response to an applied electric field, they can be scattered away from their

straight-line motions by collisions with the fixed ions; this influences the mobility of the electrons. As temperature increases, the electrons move more rapidly and the number of their collisions with the ions increases; therefore, the mobility of the electrons decreases as temperature increases. Equation 22.7 applied to the electrons in the Drude model gives

$$\sigma_{\text{el}} = en_{\text{el}}\mu_{\text{el}} \quad [22.9]$$

which predicts that the electrical conductivity of a metal will decrease as temperature increases, because the electron mobility decreases with temperature, whereas the electron number density is independent of temperature. This simple model prediction agrees with the experimental fact that the resistivity of metals increases as temperature increases.

## 22.6 Band Theory of Conduction

The characteristic property of metals is their good ability to conduct electricity and heat. Both phenomena are due to the ease with which valence electrons move. Electrical conduction is a result of the flow of electrons from regions of high potential energy to those of low potential energy. Collisions of high-kinetic-energy electrons and low-kinetic-energy electrons between high- and low-temperature regions of the metal, as well as the collisional excitation of lattice vibrations, facilitate heat conduction. Why are electrons so mobile in a metal but so tightly bound to atoms in an insulating solid, such as diamond or sodium chloride?

Figure 21.19 shows how the quantum energy levels of Na atoms in a crystal are spread out into a continuous band of states, which is half-occupied by electrons. Now, suppose a small electric potential difference is applied across a sodium crystal. The spin-paired electrons that lie deep in the band cannot be accelerated by a weak electric field because occupied levels exist just above them. They have no place to go (recall the Pauli principle, which states that an energy level contains at most two electrons). At the top of the “sea” of occupied levels, however, there is an uppermost electron-occupied or half-occupied level called the **Fermi level**. Electrons that lie near that level have the highest kinetic energy of all the valence electrons in the crystal and can be accelerated by the electric field to occupy the levels above. They are free to migrate in response to the electric field so that they conduct an electric current. These same electrons at the Fermi level are responsible for the high thermal conductivities of metals. They are also the electrons freed by the photoelectric effect when a photon gives them sufficient kinetic energy to escape from the metal (see Section 4.4).

A natural question arises: Why are the alkaline-earth elements metals, given the argument just presented? A metal such as magnesium contains two 3s electrons, and one might expect the band derived from the broadened 3s level to be completely filled. The answer to this question is that the energies of the 3s orbitals and 3p orbitals for magnesium are not greatly different. When the internuclear separation becomes small enough, the 3p band overlaps the 3s band, and many unoccupied sublevels are then available above the highest filled level.

### 22.6.1 Band Picture of Bonding in Silicon

An analogous procedure to that shown in Figure 21.19 can be used to construct a band picture for silicon. In this case, the  $4N_{\text{A}}$  valence atomic orbitals (both 3s and 3p) from 1 mol ( $N_{\text{A}}$  atoms) silicon split into *two* bands in the silicon crystal, each containing  $2N_{\text{A}}$  closely spaced levels (Fig. 22.22). The lower band is called the **valence band** and the upper one the **conduction band**. Between the top of the valence band and the bottom of the conduction band is an energy region that is

**FIGURE 22.22** The valence orbitals of the silicon atom combine in crystalline silicon to give two bands of closely spaced levels. The valence band is almost completely filled, and the conduction band is almost empty.

forbidden to electrons. The magnitude of the separation in energy between the valence band and the lowest level of the conduction band is called the **band gap**,  $E_g$ , which for pure silicon is  $1.94 \times 10^{-19}$  J. This is the amount of energy that an electron must gain to be excited from the top of the valence band to the bottom of the conduction band. For 1 mol of electrons to be excited in this way, the energy is larger by a factor of Avogadro's number  $N_A$ , giving  $117 \text{ kJ mol}^{-1}$ . (Another unit used for band gaps is the *electron volt*, defined in Section 3.3 as  $1.60218 \times 10^{-19}$  J. In this unit, the band gap in Si is 1.21 eV.)

Each Si atom in the crystal contributes four valence electrons to the bands of orbitals in Figure 22.22, for a total of  $4N_A$  per mole. This is a sufficient number to place two electrons in each level of the valence band (with opposing spins) and leave the conduction band empty. There are no low-lying energy levels for those electrons at the top of the valence band to enter if given a small increment in their energy. The band gap means that an electron at the top of the filled valence band must acquire an energy of at least  $1.94 \times 10^{-19}$  J, equivalent to  $117 \text{ kJ mol}^{-1}$ , to jump to the lowest empty level of the conduction band. This is a large amount of energy. If it were to be supplied by a thermal source, the temperature of the source would have to be on the order of

$$T = \frac{\Delta E}{R} = \frac{117,000 \text{ J mol}^{-1}}{8.315 \text{ J K}^{-1} \text{ mol}^{-1}} = 14,000 \text{ K}$$

which is far above the temperature at which a crystalline sample could exist. At room temperature, only a few electrons per mole in the extreme tail of the Boltzmann distribution have enough energy to jump the gap; therefore, the conduction band in pure silicon is sparsely populated with electrons. The result is that silicon is not a good conductor of electricity; good electrical conductivity requires a net motion of many electrons under the impetus of a small electric potential difference. Silicon has an electrical conductivity that is 11 orders of magnitude smaller than that of copper at room temperature. These are called

**semiconductors**, because their electrical conductivity, although smaller than that of a metal, is far greater than that of an **insulator** such as diamond, which has a larger band gap. The conductivity of a semiconductor is increased by increasing the temperature, which excites more electrons into levels in the conduction band. Another way to increase the conductivity of a semiconductor is to irradiate it with a beam of electromagnetic radiation with a frequency high enough to excite electrons from the valence band to the conduction band. This process resembles the photoelectric effect described in Section 4.4, with the difference that now the electrons are not removed from the material but only moved into the conduction band, ready to conduct a current if a potential difference is imposed.

### EXAMPLE 22.3

Calculate the longest wavelength of light that can excite electrons from the valence to the conduction band in silicon. In what region of the spectrum does this wavelength fall?

#### Solution

The energy carried by a photon is  $h\nu = hc/\lambda$ , where  $h$  is Planck's constant,  $\nu$  the photon frequency,  $c$  the speed of light, and  $\lambda$  the photon wavelength. For a photon to just excite an electron across the band gap, this energy must be equal to that band gap energy,  $E_g = 1.94 \times 10^{-19}$  J, where

$$\frac{hc}{\lambda} = E_g$$

Solving for the wavelength gives

$$\begin{aligned}\lambda &= \frac{hc}{E_g} = \frac{(6.626 \times 10^{-34} \text{ J s}) \times (2.998 \times 10^8 \text{ m s}^{-1})}{1.94 \times 10^{-19} \text{ J}} \\ &= 1.02 \times 10^{-6} \text{ m} = 1020 \text{ nm}\end{aligned}$$

This wavelength falls in the infrared region of the spectrum. Photons with shorter wavelengths (for example, visible light) carry more than enough energy to excite electrons to the conduction band in silicon.

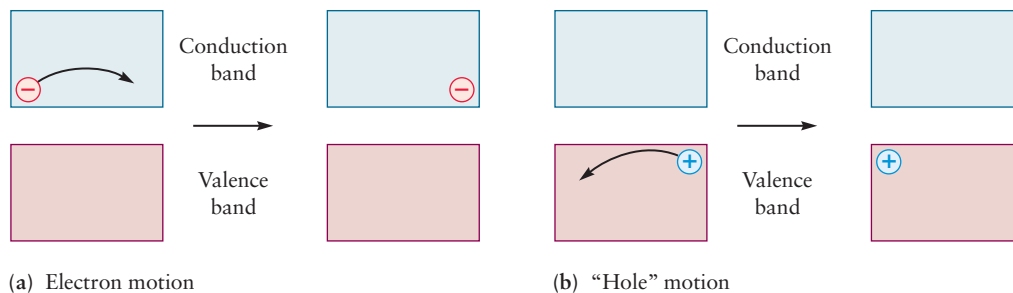

**Related Problems: 27, 28**

## 22.7 Semiconductors

Silicon in very high purity is said to display its **intrinsic properties**. When certain other elements are added to pure silicon in a process called **doping**, it acquires interesting electronic properties. For example, if atoms of a Group V element such as arsenic or antimony are diffused into silicon, they substitute for Si atoms in the network. Such atoms have five valence electrons, so each introduces one more electron into the silicon crystal than is needed for bonding. The extra electrons occupy energy levels just below the lowest level of the conduction band. Little energy is required to promote electrons from such a **donor impurity level** into the conduction band, and the electrical conductivity of the silicon crystal is increased without the necessity of increasing the temperature. Silicon doped with atoms of a Group V element is called an ***n*-type semiconductor** to indicate that the charge carrier is negative.

However, if a Group III element such as gallium is used as a dopant, there is one fewer electron in the valence band per dopant atom because Group III elements have only three valence electrons, not four. This situation corresponds to creating one *hole* in the valence band, with an effective charge of +1, for each Group III atom added. If a voltage difference is impressed across a crystal that is doped in this way, it causes the positively charged holes to move toward the negative source of potential. Equivalently, a valence band electron next to the (positive) hole will move in the opposite direction (that is, toward the positive source of potential). Whether we think of holes or electrons as the mobile charge carrier in the valence band, the result is the same; we are simply using different words to describe the same physical phenomenon (Fig. 22.23). Silicon that has been doped with a Group III element is called a ***p*-type semiconductor** to indicate that the carrier has an effective positive charge.

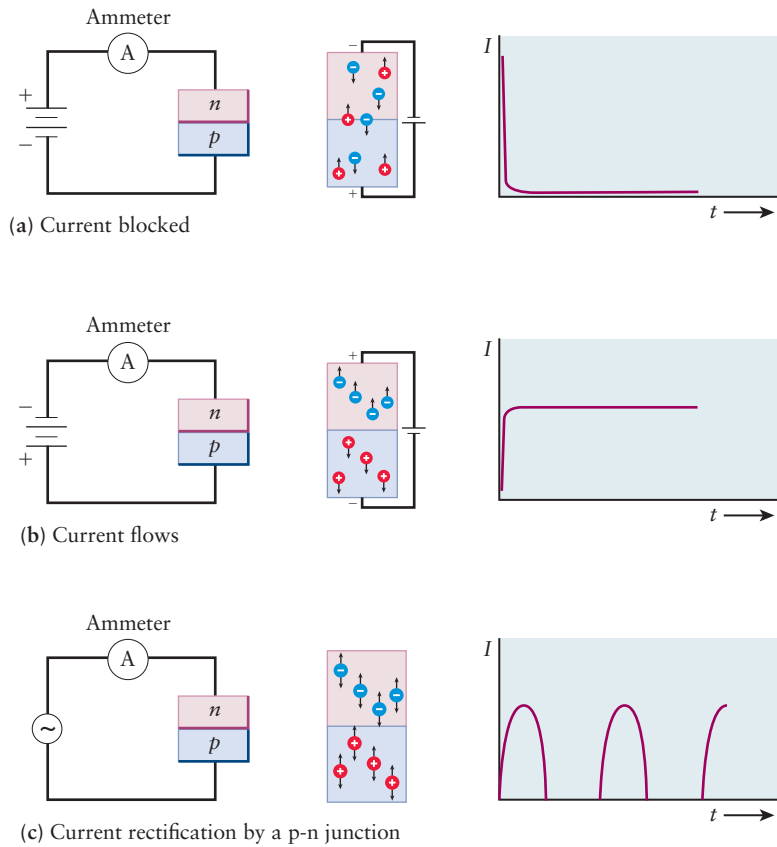

**FIGURE 22.23** (a) In an  $n$ -type semiconductor, a small number of electrons occupy levels in the conduction band. When an electric field is imposed, each electron moves (black arrows) into one of the numerous nearby vacant energy levels in the conduction band. (b) In a  $p$ -type semiconductor, a small number of levels in the valence band are unoccupied. Conduction occurs as electrons in the numerous occupied levels of the valence band jump into the sparsely distributed unoccupied levels. The arrow shows the motion of an electron to occupy a previously empty level. The process can also be described as the motion of positively charged holes in the opposite direction.

A different class of semiconductors is based not on silicon, but on equimolar compounds of Group III with Group V elements. Gallium arsenide, for example, is isoelectronic to the Group IV semiconductor germanium. When GaAs is doped with the Group VI element tellurium, an  $n$ -type semiconductor is produced; doping with zinc, which has one *fewer* valence electron than gallium, gives a  $p$ -type semiconductor. Other III–V combinations have different band gaps and are useful in particular applications. Indium antimonide (InSb), for example, has a small enough band gap that absorption of infrared radiation causes electrons to be excited from the valence to the conduction band, and an electric current then flows when a small potential difference is applied. This compound is therefore used as a detector of infrared radiation. Still other compounds formed between the zinc group (zinc, cadmium, and mercury) and Group VI elements such as sulfur also have the same average number of valence electrons per atom as silicon and make useful semiconductors.

### 22.7.1 $p$ – $n$ Junctions and Device Performance

Of what value is it to have a semiconductor that can conduct an electric current by the flow of electrons if it is  $n$ -type or by the flow of holes if it is  $p$ -type? Many electronic functions can be fulfilled by semiconductors that possess these properties, but the simplest is **rectification**—the conversion of alternating current into direct current. Suppose thin crystals of  $n$ - and  $p$ -type silicon are placed in contact with one another and connected to a battery. In Figure 22.24a, the positive pole of the battery is connected to the  $n$ -type silicon, and the  $p$ -type silicon is connected to the negative pole. Only a small transient current can flow through the circuit in this case, because when the electrons in the conduction band of the  $n$ -type silicon have flowed out to the positive pole of the battery, there is none to take their place and current ceases to flow. However, if the negative pole of the battery is connected to the  $n$ -type silicon and the positive pole to the  $p$ -type silicon (see Fig. 22.24b), a steady current flows because electrons and holes move in opposite directions and recombine at the  $n$ – $p$  junction. In effect, electrons flow toward the  $n$ – $p$  junction in the  $n$ -type material, holes flow toward the  $n$ – $p$  junction in the  $p$ -type material, and the junction is a “sink” where electrons fill the holes in the valence band and neutralize one another. If, instead of a galvanic cell, an alternating current source was connected to the  $n$ – $p$  rectifier, current would flow in one direction only, creating pulsed direct current (see Fig. 22.24c).

**FIGURE 22.24** Current rectification by a  $p$ - $n$  junction.

Gallium arsenide and other semiconductors also provide materials for making solid-state lasers, which have applications ranging from reading compact discs to performing delicate eye surgery. When an electric current is passed through a material containing  $n$ - $p$  junctions, electrons from the  $n$  regions and holes from the  $p$  regions flow toward the junctions, where they recombine and emit light. The light moves through the material, stimulating additional recombinations at other junctions and the emission of additional photons (Fig. 22.25). Critical to the operation of a laser is that these photons are coherent (in phase with one another),

**FIGURE 22.25** (a) In this solid-state laser, photons are emitted as electrons and holes recombine. (b) An emitted photon can stimulate the emission of additional photons. (c) Then reflection by a mirror on the right side sends coherent waves back through the laser medium and further amplification occurs by stimulated emission. (d) Some of the waves pass through a partially reflecting mirror on the left side.

Andrei Kudryusov/Photodisc/Getty Images

**FIGURE 22.26** An integrated circuit, like the microprocessor in a laptop computer, can contain hundreds of millions of transistors in a chip whose area is about  $1 \text{ cm}^2$ . The integrated circuit shown in this figure is connected to a printed circuit board by rows of wires on all four sides.

**FIGURE 22.27** Silicon solar collectors are used on a large scale to harvest energy from the sun in this photovoltaic power plant located on one of the Tremiti Islands in Italy.

so the corresponding electric fields add constructively to create a plane wave. The light is reflected by a mirror at one end of the material and sets up a standing wave inside the semiconductor. At the other end, a partially reflecting mirror allows an intense beam of coherent light with a fixed wavelength to leave.

Semiconductors perform a wide range of electronic functions that formerly required the use of vacuum tubes. Vacuum tubes occupy much more space, generate large amounts of heat, and require considerably more energy to operate than a **transistor** does, their semiconductor counterparts. More important, semiconductors can be built into integrated circuits (Fig. 22.26) and made to store information and process it at great speeds.

Solar cells based on silicon or gallium arsenide provide a way to convert the radiant energy of the sun directly into electrical work by a technology that is virtually nonpolluting (Fig. 22.27). The high capital costs of solar cells make them uncompetitive with conventional fossil fuel sources of energy at this time, but as reserves of fossil fuels dwindle, solar energy will become an important option.

## 22.8 Pigments and Phosphors: Optical Displays

© Kurt Nassau/Phototake

**FIGURE 22.28** Mixed crystals of two semiconductors with different band gaps, CdS (yellow) and CdSe (black), show a range of colors, illustrating a decrease in the band gap energy as the composition of the mixture becomes richer in Se.

The band gap of an insulator or semiconductor has a significant effect on its color. Pure diamond has a large band gap, so even blue light does not have enough energy to excite electrons from the valence band to the conduction band. As a result, light in the visible region of the electromagnetic spectrum (see Fig. 4.3) passes through diamonds without being absorbed and the diamonds are colorless. Cadmium sulfide ( $\text{CdS}$ ; Fig. 22.28) has a band gap of  $3.8 \times 10^{-19} \text{ J}$ , which corresponds to a wavelength of 510 nm in the visible region of the spectrum. The absorption cross section of CdS increases as the incident photon wavelength is decreased to 450 nm. Cadmium sulfide thus primarily absorbs violet and blue light but strongly transmits yellow, giving it a deep yellow color. Cadmium sulfide is the pigment called cadmium yellow. Cinnabar ( $\text{HgS}$ , Fig. 22.29) has a smaller band gap of  $3.2 \times 10^{-19} \text{ J}$  and absorbs all light except red. It has a deep red color and is the pigment vermilion. Semiconductors with band gaps of less than  $2.8 \times 10^{-19} \text{ J}$  absorb all wavelengths of visible light and appear black. These include silicon (see Example 22.2), germanium, and gallium arsenide.

Doping silicon brings donor levels close enough to the conduction band or acceptor levels close enough to the valence band that thermal excitation can

**FIGURE 22.29** Crystalline cinnabar, HgS.

© Cengage Learning/Charles D. Winters

cause electrons to move into a conducting state. The corresponding doping of *insulators* or wide band-gap semiconductors can bring donor or acceptor states into positions where *visible light* can be absorbed or emitted. This changes the colors and optical properties of the materials. Nitrogen doped in diamond gives a donor impurity level in the band gap. Transitions to this level can absorb some blue light, giving the diamond an undesirable yellowish color. In contrast, boron doped into diamond gives an acceptor level that absorbs red light most strongly and gives the highly prized and rare “blue diamond.”

**Phosphors** are wide band-gap materials with dopants selected to create new levels such that particular colors of light are emitted. Electrons in these materials are excited by light of other wavelengths or by electrons hitting their surfaces, and light is then emitted as they return to lower energy states. A fluorescent lamp, for example, is a mercury-vapor lamp in which the inside of the tube has been coated with phosphors. The phosphors absorb the violet and ultraviolet light emitted by mercury vapor and emit at lower energies and longer wavelengths, giving a nearly white light that is more desirable than the bluish light that comes from a mercury-vapor lamp without the phosphors.

Phosphors are also used in television screens. The picture is formed by scanning a beam of electrons (from an electron gun) over the screen. The electrons strike the phosphors coating the screen, exciting their electrons and causing them to emit light. In a black-and-white television tube, the phosphors are a mixture of silver doped into ZnS, which gives blue light, and silver doped into  $Zn_xCd_{1-x}S$ , which gives yellow light. The combination of the two provides a reasonable approximation of white. A color television uses three different electron guns, with three corresponding types of phosphor on the screen. Silver doped in ZnS gives blue, manganese doped in  $Zn_2SiO_4$  is used for green, and europium doped in  $YVO_4$  gives red light. Masks are used to ensure that each electron beam encounters only the phosphors corresponding to the desired color.

## CHAPTER SUMMARY

The properties of solid materials are determined by their microscopic structure, which in turn depends on the nature of the chemical bonds created during synthesis and processing. Mechanical and structural properties originate in strong ionic and covalent bonding. Electrical conductivity measures the movement of charged particles throughout the material. Metals, semiconductors, and insulators are distinguished by differences in conductivity values, as explained by the differences in their band gaps. In effect, this difference measures the extent to which some valence electrons from the atoms comprising the solid are delocalized while the remainder are involved in formation of localized bonds. Optical properties measure the response of the solid to visible light. The magnitude of the band gap determines what wavelength of light is absorbed, and therefore the color of the material.

## CONCEPTS AND SKILLS

### Section 22.1 – Minerals: Naturally Occurring Inorganic Materials

*Show how the fundamental silicate tetrahedral unit ( $SiO_4^{4-}$ ) links to other silicate tetrahedra to form rings, chains, double chains, sheets, and space-filling crystalline networks (Problems 1–4).*

- Two or more tetrahedra may link together by sharing oxygen vertices. Several examples are shown in Figure 22.2 and Table 22.1. In these linked structures the Si:O ratio is no longer 1:4 because oxygen atoms are shared at each of the linked points.

*Describe the chemical compositions and structures of aluminosilicates, clays, and zeolites (Problems 5–6).*

- Aluminosilicates are produced when Al atoms replace some of the Si atoms in silicates. Because the Al has only three electrons, one additional electron is provided by an alkali metal. Both the Al and alkali ions occupy tetrahedral sites in the aluminosilicate structure.
- Zeolites are aluminosilicate materials with extended three-dimensional structures that enclose polyhedral cavities. The very large surface area of these cavities makes these very effective as ion exchange materials for water purification, absorbing small molecules, and as catalysts.
- Clays are produced from primary materials by the weathering action of water and heat. The structures and properties of clays can be understood from the structure of the primary materials from which they derive, such as talcs and micas.

### Section 22.2 – Properties of Ceramics

*Describe the structure of ceramic materials and the ways in which they are formed.*

- Ceramics are synthetic materials fabricated from inorganic, nonmetallic materials. Ceramics are mixtures that include silicates, oxides of elements other than silicon, and non-oxide materials such as carbides and nitrides. The microstructure of ceramics includes grains, voids, and cracks of various sizes and orientations. The microstructure can be controlled by sintering and densification to reduce the size of pores and voids.
- The mechanical properties of solid materials are determined by their internal structure, which in turn depends on the nature of the chemical bonds created during synthesis and processing.

### Section 22.3 – Silicate Ceramics

*Outline the properties of pottery, glass, and cement and the chemical reactions that give them structural strength (Problems 7–14).*

- Silicate ceramics are well suited for structural applications because of their strength, which originates in the partially ionic, strong silicon–oxygen bonds in the tetrahedral orthosilicate anion. This structural unit appears in naturally occurring minerals and clays, which are fashioned into ceramic pieces through sintering and densification processes.

### Section 22.4 – Nonsilicate Ceramics

*List several important oxide and mixed oxide ceramics and give some of their uses (Problems 15–16).*

- Nonsilicate ceramics derive comparable properties from other inorganic structural units.
- Oxide ceramics are made from oxides of numerous metals including beryllium, aluminum, calcium, and yttrium; these metal-oxide bonds are essentially ionic.

*Discuss the special properties of nonoxide ceramics and the kinetic and thermodynamic factors that make them useful (Problems 17–20).*

- Nonoxide ceramics are based on the nitrogen and carbon compounds of silicon and boron. These compounds have short, strong, highly directional covalent bonds, so the materials have great structural strength but are brittle.

### Section 22.5 – Electrical Conduction in Materials

Explain how the conductivity of a material is measured, and relate it to the number and mobility of charge carriers (Problems 21–26).

- The electrical properties measure the movement of charged particles in a material in response to an applied electric field. If the particles are free to move throughout the materials, electrical conduction is the result, and the magnitude is characterized as the electrical conductivity of the material.
- The resistance of a cylindrical sample of material is measured as in Ohm's law. Geometrical factors are included to define the resistivity  $\rho$ , and the conductivity  $\sigma$  is defined as the reciprocal of the resistivity.

$$\sigma = \frac{1}{\rho} = \frac{\ell}{RA} \quad [22.3]$$

- Ohm's law can be rewritten to state that the current density flowing through a sample is proportional to the applied electrical field, and the proportionality constant is the electrical conductivity. This expression is used to relate the conductivity of a material to its microstructural properties

$$J = \sigma E \quad [22.4]$$

### Section 22.6 – Band Theory of Conduction

Use the band model to describe the conductivity of metals, semiconductors, and insulators (Problems 27–30).

- Electrical conductivity depends on the product of two separate microscopic parameters of a material: the number density of charge carriers present and the mobility of the carriers.
- The band theory of solids explains the three broad classes of electronic conductivity seen in nature in terms of the number density of charge carriers available in classes of solids.
- Metals have high conductivity values because the number density of free, mobile electrons is quite high—at least one per atom in the solid is in the conduction band. The “electron sea” is delocalized throughout the solid, and the free electrons respond easily to applied electric fields.
- Insulating materials, such as the ceramics, have very low electrical conductivity because they have essentially no free electrons to carry current. There are no electrons in the conduction band, and the band gap is too large for electrons to be promoted from the valence band to the conduction band.
- Semiconductors have conductivity values intermediate between metals and insulators because their bandgaps are small enough that electrons can be promoted from the valence band to the conduction band with modest thermal or optical excitation.

### Section 22.7 – Semiconductors

Describe the mechanism of action of intrinsic, n-type, and p-type semiconductors (Problems 31–34).

- Doping a semiconductor by adding an electron donor impurity creates new states very near the bottom of the conduction band, so electrons can be promoted from the donor into the conduction band without increasing the temperature. These promoted electrons are now free to respond to an applied electric field. This doping process leads to an n-type semiconductor, in which the charge carrier is an electron.

- Doping a semiconductor by adding an electron acceptor impurity creates new states very near the top of the valence band. An electron can move to this impurity state from the valence band, leaving a positively charged hole in the valence band. The hole can move in response to an applied electric field. This doping process leads to a *p*-type semiconductor, in which the charge carrier is a hole.
- When a *p*-type semiconductor is placed in contact with an *n*-type semiconductor and the resulting *p*-*n* junction is placed in an electrical circuit, the junction can either pass or block DC current, or rectify AC current depending on details of the circuit. The device can emit light due to recombination of holes and electrons at the junction.

### Section 22.8 – Pigments and Phosphors: Optical Displays

Relate the band gap of a semiconductor or phosphor to the frequencies of electromagnetic radiation absorbed or emitted when electrons make transitions between the valence and conduction bands (Problems 35–36).

- Optical properties describe the response of a material to light in the visible range of the electromagnetic spectrum.
- The band gap of an insulator or semiconductor determines the wavelength of light absorbed by the materials. Because the remaining portions of white light are transmitted through the materials, the color of the materials is complementary to the wavelength of the light absorbed.
- Many insulators are not colored because their band gaps are so large that no visible light is absorbed. Adding dopants can introduce donor or acceptor states that enable absorption of visible light, so the doped materials are colored.
- Phosphors are wide band gap materials doped to emit light at specific wavelengths upon excitation by electron impact or incident light at other wavelengths. Phosphors are used to generate visible light in fluorescent fixtures, and to display signals on video monitors.

## PROBLEMS

Answers to problems whose numbers are red appear in Appendix G. Problems that are more challenging are indicated with asterisks.

### 22.1 Minerals: Naturally Occurring Inorganic Materials

1. Draw a Lewis electron-dot diagram for the disilicate ion ( $\text{Si}_2\text{O}_7^{6-}$ ). What changes in this structure would be necessary to produce the structure of the pyrophosphate ion ( $\text{P}_2\text{O}_7^{4-}$ ) and the pyrosulfate ion ( $\text{S}_2\text{O}_7^{2-}$ )? What is the analogous compound of chlorine?
2. Draw a Lewis electron-dot diagram for the cyclosilicate ion ( $\text{Si}_6\text{O}_{18}^{12-}$ ), which forms part of the structures of beryl and emerald.
3. Using Table 22.1, predict the structure of each of the following silicate minerals (network, sheets, double chains, and so forth). Give the oxidation state of each atom.
  - (a) Andradite,  $\text{Ca}_3\text{Fe}_2(\text{SiO}_4)_3$
  - (b) Vlasovite,  $\text{Na}_2\text{ZrSi}_4\text{O}_{10}$
  - (c) Hardystonite,  $\text{Ca}_2\text{ZnSi}_2\text{O}_7$
  - (d) Chrysotile,  $\text{Mg}_3\text{Si}_2\text{O}_5(\text{OH})_4$
4. Using Table 22.1, predict the structure of each of the following silicate minerals (network, sheets, double chains, and so forth). Give the oxidation state of each atom.
  - (a) Tremolite,  $\text{Ca}_2\text{Mg}_5(\text{Si}_4\text{O}_{11})_2(\text{OH})_2$
  - (b) Gillespite,  $\text{BaFeSi}_4\text{O}_{10}$
  - (c) Uvarovite,  $\text{Ca}_3\text{Cr}_2(\text{SiO}_4)_3$
  - (d) Barysilate,  $\text{MnPb}_8(\text{Si}_2\text{O}_7)_3$

5. Using Table 22.1, predict the structure of each of the following aluminosilicate minerals (network, sheets, double chains, and so forth). In each case, the Al atoms grouped with the Si and O in the formula substitute for Si in tetrahedral sites. Give the oxidation state of each atom.
- Keatite,  $\text{Li}(\text{AlSi}_2\text{O}_6)$
  - Muscovite,  $\text{KAl}_2(\text{AlSi}_3\text{O}_{10})(\text{OH})_2$
  - Cordierite,  $\text{Al}_3\text{Mg}_2(\text{AlSi}_5\text{O}_{18})$
6. Using Table 22.1, predict the structure of each of the following aluminosilicate minerals (network, sheets, double chains, and so forth). In each case, the Al atoms grouped with the Si and O in the formula substitute for Si in tetrahedral sites. Give the oxidation state of each atom.
- Amesite,  $\text{Mg}_2\text{Al}(\text{AlSi}_5\text{O}_{15})(\text{OH})_4$
  - Phlogopite,  $\text{KMg}_3(\text{AlSi}_3\text{O}_{10})(\text{OH})_2$
  - Thomsonite,  $\text{NaCa}_2(\text{Al}_3\text{Si}_5\text{O}_{20}) \cdot 6 \text{H}_2\text{O}$

### 22.3 Silicate Ceramics

7. A ceramic that has been much used by artisans and craftsmen for the carving of small figurines is based on the mineral steatite (commonly known as soapstone). Steatite is a hydrated magnesium silicate that has the composition  $\text{Mg}_3\text{Si}_4\text{O}_{10}(\text{OH})_2$ . It is remarkably soft—a fingernail can scratch it. When heated in a furnace to about  $1000^\circ\text{C}$ , chemical reaction transforms it into a hard, two-phase composite of magnesium silicate ( $\text{MgSiO}_3$ ) and quartz in much the same way that clay minerals are converted into mullite ( $\text{Al}_2\text{Si}_2\text{O}_7$ ) and cristobalite ( $\text{SiO}_2$ ) on firing. Write a balanced chemical equation for this reaction.
8. A clay mineral that is frequently used together with or in place of kaolinite is pyrophyllite ( $\text{Al}_2\text{Si}_4\text{O}_{10}(\text{OH})_2$ ). Write a balanced chemical equation for the production of mullite and cristobalite on the firing of pyrophyllite.
9. Calculate the volume of carbon dioxide produced at standard temperature and pressure when a sheet of ordinary glass of mass 2.50 kg is made from its starting materials—sodium carbonate, calcium carbonate, and silica. Take the composition of the glass to be  $\text{Na}_2\text{O} \cdot \text{CaO} \cdot (\text{SiO}_2)_6$ .
10. Calculate the volume of steam produced when a 4.0-kg brick made from pure kaolinite is completely dehydrated at  $600^\circ\text{C}$  and a pressure of 1.00 atm.
11. A sample of soda-lime glass for tableware is analyzed and found to contain the following percentages by mass of oxides:  $\text{SiO}_2$ , 72.4%;  $\text{Na}_2\text{O}$ , 18.1%;  $\text{CaO}$ , 8.1%;  $\text{Al}_2\text{O}_3$ , 1.0%;  $\text{MgO}$ , 0.2%;  $\text{BaO}$ , 0.2%. (The elements are not actually present as binary oxides, but this is the way compositions are usually given.) Calculate the chemical amounts of Si, Na, Ca, Al, Mg, and Ba atoms per mole of O atoms in this sample.
12. A sample of Portland cement is analyzed and found to contain the following percentages by mass of oxides:  $\text{CaO}$ , 64.3%;  $\text{SiO}_2$ , 21.2%;  $\text{Al}_2\text{O}_3$ , 5.9%;  $\text{Fe}_2\text{O}_3$ , 2.9%;  $\text{MgO}$ , 2.5%;  $\text{SO}_3$ , 1.8%;  $\text{Na}_2\text{O}$ , 1.4%. Calculate the chemical amounts of Ca, Si, Al, Fe, Mg, S, and Na atoms per mole of O atoms in this sample.
13. The most important contributor to the strength of hardened Portland cement is tricalcium silicate,  $(\text{CaO})_3 \cdot \text{SiO}_2$ , for which the measured standard enthalpy of formation is  $-2929.2 \text{ kJ mol}^{-1}$ . Calculate the standard enthalpy change for the production of 1.00 mol tricalcium silicate from quartz and lime.
14. One of the simplest of the heat-generating reactions that occur when water is added to cement is the production of calcium hydroxide (slaked lime) from lime. Write a balanced chemical equation for this reaction, and use data from Appendix D to calculate the amount of heat generated by the reaction of 1.00 kg lime with water at room conditions.

### 22.4 Nonsilicate Ceramics

15. Calculate the average oxidation number of the copper in  $\text{YBa}_2\text{Cu}_3\text{O}_{9-x}$  if  $x = 2$ . Assume that the rare-earth element yttrium is in its usual +3 oxidation state.
16. The mixed oxide ceramic  $\text{Tl}_2\text{Ca}_2\text{Ba}_2\text{Cu}_3\text{O}_{10+x}$  has zero electrical resistance at 125 K. Calculate the average oxidation number of the copper in this compound if  $x = 0.50$  and thallium is in the +3 oxidation state.
17. Silicon carbide (SiC) is made by the high-temperature reaction of silica sand (quartz) with coke; the byproduct is carbon monoxide.
- Write a balanced chemical equation for this reaction.
  - Calculate the standard enthalpy change per mole of SiC produced.
  - Predict (qualitatively) the following physical properties of silicon carbide: conductivity, melting point, and hardness.
18. Boron nitride (BN) is made by the reaction of boron trichloride with ammonia.
- Write a balanced chemical equation for this reaction.
  - Calculate the standard enthalpy change per mole of BN produced, given that the standard molar enthalpy of formation of  $\text{BN}(s)$  is  $254.4 \text{ kJ mol}^{-1}$ .
  - Predict (qualitatively) the following physical properties of boron nitride: conductivity, melting point, and hardness.
19. The standard free energy of formation of cubic silicon carbide (SiC) is  $62.8 \text{ kJ mol}^{-1}$ . Determine the standard free energy change when 1.00 mol SiC reacts with oxygen to form  $\text{SiO}_2(s, \text{quartz})$  and  $\text{CO}_2(g)$ . Is silicon carbide thermodynamically stable in the air at room conditions?
20. The standard free energy of formation of boron carbide ( $\text{B}_4\text{C}$ ) is  $71 \text{ kJ mol}^{-1}$ . Determine the standard free energy change when 1.00 mol  $\text{B}_4\text{C}$  reacts with oxygen to form  $\text{B}_2\text{O}_3(s)$  and  $\text{CO}_2(g)$ . Is boron carbide thermodynamically stable in the air at room conditions?

## 22.5 Electrical Conduction in Materials

- A cylindrical sample of solid germanium has length 55.0 mm and diameter 5.0 mm. In a test circuit, 0.150 A of current flowed through this sample when the voltage applied between its ends was 17.5 V. What is the electrical conductivity of this sample?
- A gold wire 4.0 mm in diameter and 1.5 m in length is to be used in a test circuit. (a) Calculate the resistance of the wire. (b) Calculate the current density in the wire when the voltage applied between its ends is 0.070 V. (c) Calculate the electric field in the wire.
- The mobilities for  $\text{Na}^+$  and  $\text{Cl}^-$  in aqueous solution are given in Table 22.7. Calculate the conductivity of a 0.10-M solution of NaCl in water at 25°C.
- Explain why the ionic mobility of  $\text{CH}_3\text{COO}^-$  is smaller than that for  $\text{Cl}^-$ .
- The electrical conductivity for copper is given in Table 22.6. The electron mobility in copper at room temperature is  $3.0 \times 10^{-3} \text{ m}^2 \text{ V}^{-1} \text{ s}^{-1}$ . Using the Drude model for metallic conductivity, calculate the number of free electrons per Cu atom. The density of copper is  $8.9 \text{ g cm}^{-3}$ .
- A variety of useful metallic alloys can be prepared by dissolving Ni in Cu. The room temperature resistivity of pure copper is  $1.6 \times 10^{-8} \Omega \text{ m}$ . As nickel is dissolved in copper up to 50% mass, the resistivity increases in a nearly linear fashion to the value  $47.0 \times 10^{-8} \Omega \text{ m}$ . Explain this increase qualitatively.

## 22.6 Band Theory of Conduction

- Electrons in a semiconductor can be excited from the valence band to the conduction band through the absorption of photons with energies exceeding the band gap. At room temperature, indium phosphide (InP) is a semiconductor that absorbs light only at wavelengths less than 920 nm. Calculate the band gap in InP.
- Both GaAs and CdS are semiconductors that are being studied for possible use in solar cells to generate electric current from sunlight. Their band gaps are  $2.29 \times 10^{-19} \text{ J}$  and  $3.88 \times 10^{-19} \text{ J}$ , respectively, at room temperature. Calculate the longest wavelength of light that is capable of exciting electrons across the band gap in each of these substances. In which region of the electromagnetic spectrum do these wavelengths fall? Use this result to explain why CdS-based sensors are used in some cameras to estimate the proper exposure conditions.
- The number of electrons excited to the conduction band per cubic centimeter in a semiconductor can be estimated from the following equation:

$$n_e = (4.8 \times 10^{15} \text{ cm}^{-3} \text{ K}^{-3/2}) T^{3/2} e^{-E_g/(2RT)}$$

where  $T$  is the temperature in kelvins and  $E_g$  the band gap in joules *per mole*. The band gap of diamond at 300 K is  $8.7 \times 10^{-19} \text{ J}$ . How many electrons are thermally excited to the conduction band at this temperature in a  $1.00\text{-cm}^3$  diamond crystal?

- The band gap of pure crystalline germanium is  $1.1 \times 10^{-19} \text{ J}$  at 300 K. How many electrons are excited from the valence band to the conduction band in a  $1.00\text{-cm}^3$  crystal of germanium at 300 K? Use the equation given in the preceding problem.

## 22.7 Semiconductors

- Describe the nature of electrical conduction in (a) silicon doped with phosphorus and (b) indium antimonide doped with zinc.
- Describe the nature of electrical conduction in (a) germanium doped with indium and (b) cadmium sulfide doped with arsenic.
- In a light-emitting diode (LED), which is used in displays on electronic equipment, watches, and clocks, a voltage is imposed across an  $n$ - $p$  semiconductor junction. The electrons on the  $n$  side combine with the holes on the  $p$  side and emit light at the frequency of the band gap. This process can also be described as the emission of light as electrons fall from levels in the conduction band to empty levels in the valence band. It is the reverse of the production of electric current by illumination of a semiconductor.

Many LEDs are made from semiconductors that have the general composition  $\text{GaAs}_{1-x}\text{P}_x$ . When  $x$  is varied between 0 and 1, the band gap changes and, with it, the color of light emitted by the diode. When  $x = 0.4$ , the band gap is  $2.9 \times 10^{-19} \text{ J}$ . Determine the wavelength and color of the light emitted by this LED.

- When the LED described in Problem 33 has the composition  $\text{GaAs}_{0.14}\text{P}_{0.86}$  (i.e.,  $x = 0.86$ ), the band gap has increased to  $3.4 \times 10^{-19} \text{ J}$ . Determine the wavelength and color of the light emitted by this LED.

## 22.8 Pigments and Phosphors: Optical Displays

- The pigment zinc white ( $\text{ZnO}$ ) turns bright yellow when heated, but the white color returns when the sample is cooled. Does the band gap increase or decrease when the sample is heated?
- Mercury(II) sulfide ( $\text{HgS}$ ) exists in two different crystalline forms. In cinnabar, the band gap is  $3.2 \times 10^{-19} \text{ J}$ ; in metacinnabar, it is  $2.6 \times 10^{-19} \text{ J}$ . In some old paintings with improperly formulated paints, the pigment vermilion (cinnabar) has transformed to metacinnabar on exposure to light. Describe the color change that results.

## ADDITIONAL PROBLEMS

37. Predict the structure of each of the following silicate minerals (network, sheets, double chains, and so forth). Give the oxidation state of each atom.
- Apophyllite,  $\text{KCa}_4(\text{Si}_8\text{O}_{20})\text{F} \cdot 8 \text{H}_2\text{O}$
  - Rhodonite,  $\text{CaMn}_4(\text{Si}_5\text{O}_{15})$
  - Margarite,  $\text{CaAl}_2(\text{Al}_2\text{Si}_2\text{O}_{10})(\text{OH})_2$
38. Using Table 22.1, predict the kind of structure formed by manganpyrosmalite, a silicate mineral with chemical formula  $\text{Mn}_{12}\text{FeMg}_3(\text{Si}_{12}\text{O}_{30})(\text{OH})_{10}\text{Cl}_{10}$ . Give the oxidation state of each atom in this formula unit.
39. A reference book lists the chemical formula of one form of vermiculite as
- $$[(\text{Mg}_{2.36}\text{Fe}_{0.48}\text{Al}_{0.16})(\text{Si}_{2.72}\text{Al}_{1.28})\text{O}_{10}(\text{OH})_2] \cdot [\text{Mg}_{0.32}(\text{H}_2\text{O})_{4.32}]$$
- Determine the oxidation state of the iron in this mineral.
40. The most common feldspars are those that contain potassium, sodium, and calcium cations. They are called, respectively, orthoclase ( $\text{KAlSi}_3\text{O}_8$ ), albite ( $\text{NaAlSi}_3\text{O}_8$ ), and anorthite ( $\text{CaAl}_2\text{Si}_2\text{O}_8$ ). The solid solubility of orthoclase in albite is limited, and its solubility in anorthite is almost negligible. Albite and anorthite, however, are completely miscible at high temperatures and show complete solid solution. Offer an explanation for these observations, based on the tabulated radii of the  $\text{K}^+$ ,  $\text{Na}^+$ , and  $\text{Ca}^{2+}$  ions from Appendix F.
41. The clay mineral kaolinite ( $\text{Al}_2\text{Si}_2\text{O}_5(\text{OH})_4$ ) is formed by the weathering action of water containing dissolved carbon dioxide on the feldspar mineral anorthite ( $\text{CaAl}_2\text{Si}_2\text{O}_8$ ). Write a balanced chemical equation for the reaction that occurs. The  $\text{CO}_2$  forms  $\text{H}_2\text{CO}_3$  as it dissolves. As the pH is lowered, will the weathering occur to a greater or a lesser extent?
42. Certain kinds of zeolite have the general formula  $\text{M}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot \gamma\text{SiO}_2 \cdot w\text{H}_2\text{O}$ , where M is an alkali metal such as sodium or potassium,  $\gamma$  is 2 or more, and  $w$  is any integer. Compute the mass percentage of aluminum in a zeolite that has  $\text{M} = \text{K}$ ,  $\gamma = 4$ , and  $w = 6$ .
43. (a) Use data from Tables 15.2 and 16.2 to calculate the solubility of  $\text{CaCO}_3$  in water at pH 7.  
 (b) Will the solubility increase or decrease if the pH is lowered and the water becomes more acidic?  
 (c) Calculate the maximum amount of limestone (primarily calcium carbonate) that could dissolve per year in a river at pH 7 with an average flow rate of  $1.0 \times 10^6 \text{ m}^3/\text{h}$ .
44. Silica ( $\text{SiO}_2$ ) exists in several forms, including quartz (molar volume  $22.69 \text{ cm}^3 \text{ mol}^{-1}$ ) and cristobalite (molar volume  $25.74 \text{ cm}^3 \text{ mol}^{-1}$ ).  
 (a) Use data from Appendix D to calculate  $\Delta H^\circ$ ,  $\Delta S^\circ$ , and  $\Delta G$  at  $25^\circ\text{C}$ .  
 (b) Which form is thermodynamically stable at  $25^\circ\text{C}$ ?  
 (c) Which form is stable at very high temperatures, provided that melting does not occur first?
45. Talc,  $\text{Mg}_3\text{Si}_4\text{O}_{10}(\text{OH})_2$ , reacts with forsterite ( $\text{Mg}_2\text{SiO}_4$ ) to form enstatite ( $\text{MgSiO}_3$ ) and water vapor.  
 (a) Write a balanced chemical equation for this reaction.  
 (b) If the water pressure is equal to the total pressure, will formation of products be favored or disfavored with increasing total pressure?  
 (c) The entropy change for this reaction is positive. Will the slope of the coexistence curve (pressure plotted against temperature) be positive or negative?
46. In what ways does soda-lime glass resemble and in what ways does it differ from a pot made from the firing of kaolinite? Include the following aspects in your discussion: composition, structure, physical properties, and method of preparation.
47. Iron oxides are red when the average oxidation state of iron is high and black when it is low. To impart each of these colors to a pot made from clay that contains iron oxides, would you use an air-rich or a smoky atmosphere in the kiln? Explain.
48. Refractories can be classified as acidic or basic, depending on the properties of the oxides in question. A basic refractory must not be used in contact with acid, and an acidic refractory must not be used in contact with a base. Classify magnesia and silica as acidic or basic refractories.
49. Dolomite bricks are used in the linings of furnaces in the cement and steel industries. Pure dolomite contains 45.7%  $\text{MgCO}_3$  and 54.3%  $\text{CaCO}_3$  by mass. Determine the empirical formula of dolomite.
50. Beryllia ( $\text{BeO}$ ) ceramics have some use but show only poor resistance to strong acids and bases. Write likely chemical equations for the reaction of  $\text{BeO}$  with a strong acid and with a strong base.
51. Silicon nitride resists all acids except hydrofluoric, with which it reacts to give silicon tetrafluoride and ammonia. Write a balanced chemical equation for this reaction.
52. Compare oxide ceramics such as alumina ( $\text{Al}_2\text{O}_3$ ) and magnesia ( $\text{MgO}$ ), which have significant ionic character, with covalently bonded nonoxide ceramics such as silicon carbide ( $\text{SiC}$ ) and boron carbide ( $\text{B}_4\text{C}$ ; see Problems 19 and 20) with respect to thermodynamic stability at ordinary conditions.

53. Compare the hybridization of Si atoms in Si(s) with that of C atoms in graphite (see Fig. 21.26). If silicon were to adopt the graphite structure, would its electrical conductivity be high or low?
54. Describe how the band gap varies from a metal to a semiconductor to an insulator.
55. Suppose some people are sitting in a row at a movie theater, with a single empty seat on the left end of the row. Every 5 minutes, a person moves into a seat on his or her left if it is empty. In what direction and with what speed does the empty seat “move” along the row? Comment on the connection with hole motion in *p*-type semiconductors.
56. A sample of silicon doped with antimony is an *n*-type semiconductor. Suppose a small amount of gallium is added to such a semiconductor. Describe how the conduction properties of the solid will vary with the amount of gallium added.

A false-color scanning tunneling micrograph (STM) of a DNA double-helix molecule adsorbed on a graphite substrate.

The organic compounds discussed in Chapter 7 were relatively small molecules, ranging from four or five atoms (such as methane or formaldehyde) to long-chain hydrocarbons up to 30 carbon atoms with relative molecular masses of several hundred. In addition to these smaller molecules, carbon atoms string together in stable chains of essentially unlimited length. Such chains provide the backbones of truly huge molecules that may contain hundreds of thousands or even millions of atoms. Such a compound, called a **polymer**, is formed by linking numerous separate small **monomer units** in strands and webs.

Although many polymers are based on the ability of carbon to form stable long-chain molecules with various functional groups attached, carbon is not unique in this ability. Recall from Chapter 22 the chains, sheets, and networks found in natural silicates, in which the elements silicon and oxygen join together to form extended structures. This chapter focuses on organic polymers, whose

chemical and physical properties depend on the bonding and functional group chemistry discussed in Section 7.6. We examine both synthetic polymers, which are built largely from the hydrocarbon raw materials discussed in Section 7.1, and naturally occurring biopolymers such as starch, proteins, and nucleic acids, which are built from products of biological synthesis.

## 23.1 Polymerization Reactions for Synthetic Polymers

To construct a polymer, very many monomers must add to a growing polymer molecule, and the reaction must not falter after the first few molecules have reacted. This is achieved by having the polymer molecule retain highly reactive functional groups at all times during its synthesis. The two major types of polymer growth are addition polymerization and condensation polymerization.

In **addition polymerization**, monomers react to form a polymer chain without net loss of atoms. The most common type of addition polymerization involves the free-radical chain reaction of molecules that have C=C bonds. As in the chain reactions considered in Section 18.4, the overall process consists of three steps: initiation, propagation (repeated many times to build up a long chain), and termination. As an example, consider the polymerization of vinyl chloride (chloroethene, CH<sub>2</sub>=CHCl) to polyvinyl chloride (Fig. 23.1). This process can be initiated by a small concentration of molecules that have bonds weak enough to be broken by the action of light or heat, giving radicals. An example of such an **initiator** is a peroxide, which can be represented as R—O—O—R', where R and R' represent alkyl groups. The weak O—O bonds break

to give radicals, whose oxygen valence shells are incomplete. The radicals remedy this by reacting readily with vinyl chloride, accepting electrons from the C=C bonds to reestablish a closed-shell electron configuration on the oxygen atoms:

One of the two  $\pi$  electrons in the vinyl chloride double bond has been used to form a single bond with the R—O· radical. The other remains on the second carbon atom, leaving it as a seven-valence-electron atom that will react with another vinyl chloride molecule:

At each stage, the end group of the lengthening chain is one electron short of a valence octet and remains quite reactive. The reaction can continue, building up long-chain molecules of high molecular mass. The vinyl chloride monomers always attach to the growing chain with their CH<sub>2</sub> group because the odd electron is more stable on a CHCl end group. This gives the polymer a regular alternation of —CH<sub>2</sub>— and —CHCl— groups. Its chemical formula is (—CH<sub>2</sub>CHCl—)<sub>n</sub>.

© Cengage Learning/Charles D. Winters

**FIGURE 23.1** A pipefitting of polyvinyl chloride.

Termination occurs when the radical end groups on two different chains encounter each other and the two chains couple to give a longer chain:

Alternatively, a hydrogen atom may transfer from one end group to the other:

The latter termination step leaves a double bond on one chain end and a  $-\text{CH}_2\text{Cl}$  group on the other. When the polymer molecules are long, the exact natures of the end groups have little effect on the physical and chemical properties of the material. A different type of hydrogen transfer step often has a much greater effect on the properties of the resulting polymer. Suppose that a hydrogen atom transfers not from the monomer unit on the *end* of a second chain but from a monomer unit in the middle of that chain (Fig. 23.2). Then the first chain stops growing, but the radical site moves to the middle of the second chain, and growth resumes from that point, forming a *branched* polymeric chain with very different properties.

Addition polymerization can be initiated by ions as well as by free radicals. An example is the polymerization of acrylonitrile:

**FIGURE 23.2** Chain branching can occur when a hydrogen atom is transferred (abstracted) from the middle of one chain to the free radical end of a second chain, thus terminating the growth of the second chain. The newly generated free radical in the middle of the polymer chain provides a site for the growth of a branched chain via continued monomer addition polymerization.

A suitable initiator for this process is butyl lithium,  $(\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2)^-\text{Li}^+$ . The butyl anion (abbreviated  $\text{Bu}^-$ ) reacts with the end carbon atom in a molecule of acrylonitrile to give a new anion:

The new anion then reacts with an additional molecule of acrylonitrile:

The process continues, building up a long-chain polymer.

Ionic polymerization differs from free-radical polymerization because the negatively charged end groups repel one another, ruling out termination by the coupling of two chains. The ionic group at the end of the growing polymer is stable at each stage. Once the supply of monomer has been used up, the polymer can exist indefinitely with its ionic end group, in contrast with the free-radical case, in which some reaction must take place to terminate the process. Ion-initiated polymers are called “living” polymers because, when additional monomer is added (even months later), they resume growth and increase in molecular mass. Termination can be achieved by adding water to replace the  $\text{Li}^+$  with a hydrogen ion:

A second important mechanism of polymerization is **condensation polymerization**, in which a small molecule (frequently water) is split off as each monomer unit is attached to the growing polymer.<sup>1</sup> An example is the polymerization of 6-aminohexanoic acid. The first two molecules react upon heating according to

An amide linkage and water form from the reaction of an amine with a carboxylic acid. The new molecule still has an amine group on one end and a carboxylic acid group on the other; it can therefore react with two more molecules of 6-aminohexanoic acid. The process repeats to build up a long-chain molecule.

<sup>1</sup>Condensation reactions have appeared several times outside the context of polymer synthesis in this text. For example, two molecules of  $\text{H}_2\text{SO}_4$  condense to form disulfuric acid ( $\text{H}_2\text{S}_2\text{O}_7$ ), and a carboxylic acid condenses with an alcohol to form an ester (see Section 7.6).

For each monomer unit added, one molecule of water is split off. The final polymer in this case is called nylon 6 and is used in fiber-belted radial tires and in carpets.

Both addition and condensation polymerization can be carried out with mixtures of two or more types of monomers present in the reaction mixture. The result is a **random copolymer** that incorporates both types of monomers in an irregular sequence along the chain. For example, a 1:6 molar ratio of styrene to butadiene monomers is used to make styrene–butadiene rubber (SBR) for automobile tires, and a 2:1 ratio gives a copolymer that is an ingredient in latex paints.

### 23.1.1 Cross-Linking: Nonlinear Synthetic Polymers

If every monomer forming a polymer has only two reactive sites, then only chains and rings can be made. The 6-aminohexanoic acid used in making nylon 6 has one amine group and one carboxylic acid group per molecule. When both functional groups react, one link is forged in the polymer chain, but that link cannot react further. If some or all of the monomers in a polymer have three or more reactive sites, however, then cross-linking to form sheets or networks is possible.

One important example of cross-linking involves phenol–formaldehyde copolymers (Fig. 23.3). When these two compounds are mixed (with the phenol in excess in the presence of an acid catalyst), straight-chain polymers form. The first step is the addition of formaldehyde to phenol to give methylolphenol:

Molecules of methylolphenol then undergo condensation reactions (releasing water) to form a linear polymer called novalac:

**FIGURE 23.3** When a mixture of phenol ( $\text{C}_6\text{H}_5\text{OH}$ ) and formaldehyde ( $\text{CH}_2\text{O}$ ) dissolved in acetic acid is treated with concentrated hydrochloric acid, a phenol–formaldehyde polymer grows.

If, on the other hand, the reaction is carried out with an excess of formaldehyde, dimethylolphenols and trimethylolphenols form:

Each of these monomers has more than two reactive sites and can react with up to three others to form a cross-linked polymer that is much stronger and more impact-resistant than the linear polymer. The very first synthetic plastic, Bakelite, was made in 1907 from cross-linked phenol and formaldehyde. Modern phenol–formaldehyde polymers are used as adhesives for plywood; more than a billion kilograms are produced per year in the United States.

Cross-linking is often desirable because it leads to a stronger material. Sometimes cross-linking agents are added deliberately to form additional bonds between polymer chains. Polybutadiene contains double bonds that can be linked upon addition of appropriate oxidizing agents. One especially important kind of cross-linking occurs through sulfur chains in rubber, as we will see.

## 23.2 Applications for Synthetic Polymers

The three largest uses for polymers are in fibers, plastics, and elastomers (rubbers). We can distinguish between these three types of materials on the basis of their physical properties, especially their resistance to stretching. A typical fiber strongly resists stretching and can be elongated by less than 10% before breaking. Plastics are intermediate in their resistance to stretching and elongate 20% to 100% before breaking. Finally, elastomers stretch readily, with elongations of 100% to 1000% (that is, some types of rubber can be stretched by a factor of 10 without breaking). A fourth important class is the more recently developed electrically conducting polymers, which combine the optical and electronic properties of inorganic semiconductors with the processibility of conventional polymers. This section examines the major kinds of synthetic polymers and their uses.

### 23.2.1 Fibers

Many important fibers, including cotton and wool, are naturally occurring polymers. The first commercially successful synthetic polymers were made not by polymerization reactions but through the chemical regeneration of the natural polymer cellulose, a condensation polymer of the sugar glucose that is made by plants:

In the viscose rayon process, still used today, cellulose is digested in a concentrated solution of NaOH to convert the  $-\text{OH}$  groups to  $-\text{O}^- \text{Na}^+$  ionic

**FIGURE 23.4** Filter paper (cellulose) will dissolve in a concentrated ammonia solution containing  $[\text{Cu}(\text{NH}_3)_4]^{2+}$  ions. When the solution is extruded into aqueous sulfuric acid, a dark blue thread of rayon (regenerated cellulose) precipitates.

groups. Reaction with  $\text{CS}_2$  leads to the formation of about one “xanthate” group for every two glucose monomer units:

Such substitutions reduce the hydrogen-bond forces holding polymer chains together. In the ripening step, some of these xanthate groups are removed with regeneration of  $\text{CS}_2$ , and others migrate to the  $-\text{CH}_2\text{OH}$  groups from the ring  $-\text{OH}$  groups. Afterward, sulfuric acid is added to neutralize the  $\text{NaOH}$  and to remove the remaining xanthate groups. At the same time, the viscose rayon is spun out to form fibers (Fig. 23.4) while new hydrogen bonds form.

Rayon is a “semisynthetic” fiber because it is prepared from a natural polymeric starting material. The first truly synthetic polymeric fiber was nylon, developed in the 1930s by the American chemist Wallace Carothers at DuPont Company. He knew of the condensation of an amine with a carboxylic acid to form an amide linkage (see Section 7.6) and noted that, if each molecule had *two* amine or carboxylic acid functional groups, long-chain polymers could form. The specific starting materials upon which Carothers settled, after numerous attempts, were adipic acid and hexamethylenediamine:

The two react with loss of water, according to the equation

The resulting molecule has a carboxylic acid group on one end (which can react with another molecule of hexamethylenediamine) and an amine group on the other end (which can react with another molecule of adipic acid). The process can continue indefinitely, leading to a polymer with the formula

called nylon 66 (Fig. 23.5). The nylon is extruded as a thread or spun as a fiber from the melt. The combination of well-aligned polymer molecules and  $\text{N}-\text{H}\cdots\text{O}$  hydrogen bonds between chains makes nylon one of the strongest materials known. The designation “66” indicates that this nylon has six carbon atoms on the starting carboxylic acid and six on the diamine. Other nylons can be made with different numbers of carbon atoms.

Just as a carboxylic acid reacts with an amine to give an amide, it also reacts with an alcohol to give an ester. This suggests the possible reaction of a

**FIGURE 23.5** Hexamethylenediamine is dissolved in water (lower layer), and adipyl chloride, a derivative of adipic acid, is dissolved in hexane (upper layer). At the interface between the layers, nylon forms and is drawn out onto the stirring bar.

TABLE 23.1

## Fibers

Name	Structural Units	Properties	Sample Uses
Rayon	Regenerated cellulose	Absorbent, soft, easy to dye, poor wash and wear	Dresses, suits, coats, curtains, blankets
Acetate	Acetylated cellulose	Fast drying, supple, shrink-resistant	Dresses, shirts, draperies, upholstery
Nylon	Polyamide	Strong, lustrous, easy to wash, smooth, resilient	Carpeting, upholstery, tents, sails, hosiery, stretch fabrics, rope
Dacron	Polyester	Strong, easy to dye, shrink-resistant	Permanent-press fabrics, rope, sails, thread
Acrylic (Orlon)	$-(\text{CH}_2-\underset{\text{C}\equiv\text{N}}{\text{CH}})_n-$	Warm, lightweight, resilient, quick-drying	Carpeting, sweaters, baby clothes, socks

dicarboxylic acid and a glycol (dialcohol) to form a polymer. The polymer produced most extensively in this way is polyethylene terephthalate, which is built up from terephthalic acid (a benzene ring with  $-\text{COOH}$  groups on both ends) and ethylene glycol. The first two molecules react according to

Further reaction then builds up the polymer, which is called polyester and sold under trade names such as Dacron. The planar benzene rings in this polymer make it stiffer than nylon, which has no aromatic groups in its backbone, and help make polyester fabrics crush-resistant. The same polymer formed in a thin sheet rather than a fiber becomes Mylar, a very strong film used for audio and video tapes.

Table 23.1 summarizes the structures, properties, and uses of some important fibers.

### 23.2.2 Plastics

**Plastics** are loosely defined as polymeric materials that can be molded or extruded into desired shapes and that harden upon cooling or solvent evaporation. Rather than being spun into threads in which their molecules are aligned, as in fibers, plastics are cast into three-dimensional forms or spread into films for packaging applications. Although celluloid articles were fabricated by plastic processing by the late 1800s, the first important synthetic plastic was Bakelite, the phenol-formaldehyde resin whose cross-linking was discussed earlier in this section. Table 23.2 lists some of the most important plastics and their properties.

Ethene ( $\text{CH}_2=\text{CH}_2$ ) is the simplest monomer that will polymerize. (In industrial settings, ethene is typically referred to by its common name ethylene. Thus

TABLE 23.2

## Plastics

Name	Structural Units	Properties	Sample Uses
Polyethylene	$\text{-(CH}_2\text{-CH}_2\text{)}_n\text{-}$	High density: hard, strong, stiff Low density: soft, flexible, clear	Molded containers, lids, toys, pipe Packaging, trash bags, squeeze bottles
Polypropylene	$\text{-(CH}_2\text{-CH)}_n\text{-}$   CH <sub>3</sub>	Stiffer, harder than high-density polyethylene, higher melting point	Containers, lids, carpeting, luggage, rope
Polyvinyl chloride	$\text{-(CH}_2\text{-CH)}_n\text{-}$   Cl	Nonflammable, resistant to chemicals	Water pipes, roofing, credit cards, records
Polystyrene	$\text{-(CH}_2\text{-CH)}_n\text{-}$   	Brittle, flammable, not resistant to chemicals, easy to process and dye	Furniture, toys, refrigerator linings, insulation
Phenolics	Phenol-formaldehyde copolymer	Resistant to heat, water, chemicals	Plywood adhesive, Fiberglass binder, circuit boards

the common name for a polymer of ethene is polyethylene. The IUPAC name polyethene is not yet in widespread use, so we will refer to such polymers by their common names herein.) Through free-radical-initiated addition polymerization at high pressures (1000 atm to 3000 atm) and temperatures (300°C to 500°C), it forms polyethylene:

The polyethylene formed in this way is not the perfect linear chain implied by this simple equation. Free radicals frequently abstract hydrogen from the middles of chains in this synthesis, so the polyethylene is heavily branched with hydrocarbon side chains of varying length. It is called *low-density polyethylene* (LDPE) because the difficulty of packing the irregular side chains gives it a lower density ( $<0.94 \text{ g cm}^{-3}$ ) than that of perfectly linear polyethylene. This irregularity also makes it relatively soft, so its primary uses are in coatings, plastic packaging, trash bags, and squeeze bottles in which softness is an advantage, not a drawback.

A major breakthrough occurred in 1954, when the German chemist Karl Ziegler showed that ethene could also be polymerized with a catalyst consisting of  $\text{TiCl}_4$  and an organoaluminum compound [for example,  $\text{Al}(\text{C}_2\text{H}_5)_3$ ]. The addition of ethene takes place at each stage within the coordination sphere of the titanium atom, so monomers can add only at the end of the growing chain. The result is linear polyethylene, also called *high-density polyethylene* (HDPE) because of its density ( $0.96 \text{ g cm}^{-3}$ ). Because its linear chains are regular, HDPE contains large crystalline regions, which make it much harder than LDPE and thus suitable for molding into plastic bowls, lids, and toys.

A third kind of polyethylene introduced in the late 1970s is called *linear low-density polyethylene* (LLDPE). It is made by the same metal-catalyzed reactions as HDPE, but it is a deliberate copolymer with other 1-alkenes such as 1-butene. It has some side groups (which reduce the crystallinity and density), but they

have a controlled short length instead of the irregular, long side branches in LDPE. LLDPE is stronger and more rigid than LDPE; it is also less expensive because lower pressures and temperatures are used in its manufacture.

If one of the hydrogen atoms of the ethene monomer unit is replaced with a different type of atom or functional group, the plastics that form upon polymerization have different properties. Substitution of a methyl group (that is, the use of propylene as monomer) leads to polypropylene:

This reaction cannot be carried out successfully by free-radical polymerization. It was first achieved in 1953–1954 by Ziegler and the Italian chemist Giulio Natta, who used the Ziegler catalyst later employed in making HDPE. In polypropylene, the methyl groups attached to the carbon backbone can be arranged in different conformations (Fig. 23.6). In the **isotactic form**, all the methyl groups are arranged on the same side, whereas in the **syndiotactic form** they alternate in a regular fashion. The **atactic form** shows a random positioning of methyl groups. Natta showed that the Ziegler catalyst led to isotactic polypropylene, and he developed another catalyst, using  $\text{VCl}_4$ , that gave the syndiotactic form. Polypropylene plastic is stiffer and harder than HDPE and has a higher melting point, so it is particularly useful in applications requiring high temperatures (such as the sterilization of medical instruments).

In polystyrene, a benzene ring replaces one hydrogen atom of each ethene monomer unit. Because such a ring is bulky, atactic polystyrene does not crystallize to any significant extent. The most familiar application of this polymer is in the polystyrene foam used in disposable containers for food and drinks and as insulation. A volatile liquid or a compound that dissociates to gaseous products on heating is added to the molten polystyrene. It forms bubbles that remain as the polymer is cooled and molded. The gas-filled pockets in the final product make it a good thermal insulator.

Synthetic polymers with other elements beyond carbon and hydrogen offer many additional possibilities for making plastics. Polyvinylchloride was already discussed in Section 23.1. Another well-known plastic is the solid perfluorocarbon

**FIGURE 23.6** The structures of (a) isotactic, (b) syndiotactic, and (c) atactic polypropylene.

**FIGURE 23.7** A model of the molecular structure of Teflon shows that the fluorine atoms shield the carbon chain very effectively. Note that the chain must twist to accommodate the bulk of the fluorine atoms, completing a full spiral every 26 C atoms along the chain.

called polytetrafluoroethylene (Teflon), formulated as  $(-\text{CF}_2-\text{CF}_2)_n$ , where  $n$  is a large number. Chemically, this compound is nearly completely inert, resisting attack from boiling sulfuric acid, molten potassium hydroxide, gaseous fluorine, and other aggressive chemicals. Physically, it has excellent heat stability (a working temperature up to  $260^\circ\text{C}$ ), is a very good electrical insulator, and has a low coefficient of friction that makes it useful for bearing surfaces in machines as well as coating frying pans (“non-stick” Teflon). In Teflon the carbon atoms lie in a long chain that is encased by tightly bound fluorine atoms (Fig. 23.7). Even reactants with a strong innate ability to disrupt C—C bonds (such as fluorine itself) fail to attack Teflon at observable rates because there is no way to get past the surrounding fluorine atoms and their tightly held electrons.

### 23.2.3 Rubber

An **elastomer** is a polymer that can be deformed to a great extent and still recover its original form when the deforming stress is removed. The term *rubber* was introduced by Joseph Priestley, who observed that such materials can be used to rub out pencil marks. Natural rubber is a polymer of isoprene (2-methylbutadiene). The isoprene molecule contains two double bonds of which polymerization removes only one; natural rubber is therefore unsaturated, containing one double bond per isoprene unit. In polymeric isoprene, the geometry at each double bond can be either *cis* or *trans* (Fig. 23.8). Natural rubber is all-*cis* polyisoprene. The all-*trans* form also occurs in nature in the sap of certain trees and is called gutta-percha. This material is used to cover golf balls because it is particularly tough. Isoprene can be polymerized by free-radical addition polymerization, but the resulting polymer contains a mixture of *cis* and *trans* double bonds and is useless as an elastomer.

Even pure natural rubber has limited utility because it melts, is soft, and does not fully spring back to its original form after being stretched. In 1839 the American inventor Charles Goodyear discovered that if sulfur is added to rubber and the mixture is heated, the rubber hardens, becomes more resilient, and does not melt. This process is referred to as **vulcanization** and involves the formation of sulfur bridges between the methyl side groups on different chains. Small amounts of sulfur (<5%) yield an elastic material in which sulfur links between chains remain after stretching and enable the rubber to regain its original form when the external force is removed. Large amounts of sulfur give the very hard, nonelastic material ebonite.

Research on synthetic substitutes for natural rubber began in the United States and Europe before World War II. Attention focused on copolymers of butadiene with styrene (now called SBR rubber) and with acrylonitrile (NBR rubber). The Japanese occupation of the rubber-producing countries of Southeast Asia sharply curtailed the supply of natural rubber to the Allied nations, and rapid steps were taken to increase production of synthetic rubber.

**FIGURE 23.8** In the polymerization of isoprene, a *cis* or *trans* configuration can form at each double bond in the polymer. The blue arrows show the redistribution of the electrons upon bond formation.

The initial production goal was 40,000 tons per year of SBR. By 1945, U.S. production had reached an incredible total of more than 600,000 tons per year. During those few years, many advances were made in production techniques, quantitative analysis, and basic understanding of rubber elasticity. Styrene-butadiene rubber production continued after the war, and in 1950 SBR exceeded natural rubber in overall production volume for the first time. More recently, several factors have favored natural rubber: the increasing cost of the hydrocarbon feed stock for synthetic rubber, gains in productivity of natural rubber, and the growing preference for belted radial tires, which use more natural rubber.

The development of the Ziegler–Natta catalysts has affected rubber production as well. First, it facilitated the synthesis of all-*cis* polyisoprene and the demonstration that its properties were nearly identical to those of natural rubber. (A small amount of “synthetic natural rubber” is produced today.) Second, a new kind of synthetic rubber was developed: all-*cis* polybutadiene. It now ranks second in production after styrene-butadiene rubber.

### 23.2.4 Electrically Conducting Polymers

Electrically conducting polymers, sometimes called *synthetic metals*, have a backbone that is a  $\pi$ -conjugated system, with alternating double and single bonds. This system is formed by overlap of carbon  $2p_z$ -orbitals, as in Figure 7.12. The polymers are named after the monomer units on which their structures are based. The simplest conducting polymer is polyacetylene, which is a continuation of the 1,3-butadiene structure in Figure 6.53 to much longer chain lengths. Other conducting polymers include ring structures in the conjugated backbone. The monomeric units are shown below for *trans*-polyacetylene, polythiophene, poly(*para*-phenylene), and poly(*para*-pyridine).

As the chain length increases, the energy levels shown in Figure 6.53 for 1,3-butadiene increase in number and coalesce into bands. Thus, the conjugated electronic structure for the individual linear polymer molecule is described by bands, which previously we have seen only for extended three-dimensional solids (see Figs. 21.20 and 22.22). The ground state for the polymer chain is that of an insulator, with an energy gap between occupied and empty levels.

The pure polymers are made conductive by doping; the conductivity increases as the doping level increases. Room temperature conductivity for polyacetylene doped with iodine has reached values of  $5 \times 10^4 \text{ S cm}^{-1}$ , which is about one-tenth the value for copper. (See Section 23.1 for the definition and dimensions of conductivity.) Doping of conductive polymers does not involve substitutional replacement of lattice atoms as in the inorganic semiconductors (see Section 22.7). Rather, doping proceeds by partial oxidation or reduction of the polymer. Electron-donating dopants like Na, K, and Li produce *n*-type material (partly reduced), whereas electron acceptors like  $\text{I}_2$ ,  $\text{PF}_6$ , and  $\text{BF}_4$  produce *p*-type material (partly oxidized). The dopant ions appear interstitially between the polymer chains and promote conductivity by exchanging charges with the

conjugated polymer backbones. A wide variety of interesting structural arrangements of polymer chains and dopants can be produced. The details of the conduction process depend strongly on structure and on the degree of ordering of the polymer chains. Research in this area is a fascinating interplay between concepts of solid state physics and synthetic organic chemistry.

Applications of conductive polymers rely on their combination of electrical and optical properties (comparable to metallic conductors and inorganic semiconductors) with the mechanical flexibility and the chemical processibility of organic polymers. Applications have already appeared in packaging materials for items that are sensitive to electrostatic discharges, in flexible materials for shielding against electromagnetic interference (previously achieved only with rigid metal enclosures), and in rechargeable batteries. Applications are envisioned for electrochemical drug delivery in medicine. Very recent applications include light-emitting diodes, transistors, and memory cells. This field holds rich opportunity for cross-disciplinary developments in chemistry, physics, materials science and engineering, and electrical engineering.

**FIGURE 23.9** Different states of structural order for rod-shaped molecules. The figure is only schematic; in a real sample, the lining up of the molecules would not be so nearly perfect.

## 23.3 Liquid Crystals

A **liquid crystal** constitutes an interesting state of matter with properties intermediate between those of true liquids and those of crystals. Unlike glasses, liquid-crystal states are thermodynamically stable. Many organic materials do not show a single solid-to-liquid transition but rather a cascade of transitions involving new intermediate phases. In recent years, liquid crystals have been used in a variety of practical applications, ranging from temperature sensors to displays on calculators and other electronic devices.

### 23.3.1 The Structure of Liquid Crystals

Substances that form liquid crystals are usually characterized by molecules with elongated, rod-like shapes. An example is terephthal-bis-(4-*n*-butylaniline), called TBBA, whose molecular structure can be represented as

with hydrocarbon groups at the ends separated by a relatively rigid backbone of benzene rings and  $\text{N}=\text{C}$  bonds. Such rod-like molecules tend to line up even in the liquid phase, as Figure 23.9a shows. Ordering in this phase persists only over small distances, however, and on average a given molecule is equally likely to take any orientation.

The simplest type of liquid-crystal phase is the **nematic phase** (see Fig. 23.9b); TBBA undergoes a transition from liquid to nematic at  $237^\circ\text{C}$ . In a nematic liquid crystal, the molecules display a preferred orientation in a particular direction, but their centers are distributed at random, as they would be in an ordinary liquid. Although liquid-crystal phases are characterized by a net orientation of molecules over large distances, not all the molecules point in exactly the same direction. There are fluctuations in the orientation of each molecule, and only *on average* do the molecules have a greater probability of pointing in a particular direction.

Some liquid crystals form one or more **smectic phases**. These display a variety of microscopic structures that are indicated by the letters A, B, C, and so forth. Figure 23.9c shows one of them, the smectic A structure; the molecules

**FIGURE 23.10** Several cuts through a cholesteric liquid crystal, showing how the molecular orientation changes with position. The pitch  $P$  is the distance over which the orientation repeats itself; here, one half of this distance is shown.

continue to display net orientational ordering, but now, unlike in the nematic phase, the centers of the molecules also tend to lie in layers. Within each layer, however, these centers are distributed at random as in an ordinary liquid. TBBA enters the smectic A phase at  $200^{\circ}\text{C}$ , before undergoing transitions to two other more ordered smectic phases at lower temperatures.

At low enough temperatures (below  $113^{\circ}\text{C}$  for TBBA), a liquid crystal freezes into a crystalline solid (see Fig. 23.9d) in which the molecules' orientations are ordered and their centers lie on a regular three-dimensional lattice. The progression of structures in Figure 23.9 illustrates the meaning of the term *liquid crystal*. Liquid crystals are solid-like in showing orientational ordering but liquid-like in the random distribution of the centers of their molecules.

A third type of liquid crystal is called **cholesteric**. The name stems from the fact that many of these liquid crystals involve derivatives of the cholesterol molecule. The structure of a cholesteric liquid crystal is shown schematically in Figure 23.10. In each plane the molecules show a nematic type of ordering, but the orientation of the molecules changes by a regular amount from plane to plane, leading to a helical structure. The distance between planes with the same orientations is referred to as the *pitch*  $P$ , which can be quite large (on the order of hundreds of nanometers or longer). A cholesteric liquid crystal will strongly diffract light with wavelengths  $\lambda$  comparable to the pitch. As the temperature changes, the pitch changes as well; the color of the diffracted light can therefore be used as a simple temperature sensor.

The particular orientation taken by a liquid crystal is very sensitive to both the nature of the surfaces with which it is in contact and small electric or magnetic fields. This sensitivity is the basis for the use of nematic liquid crystals in electronic display devices such as digital watches and calculators (Fig. 23.11), as well as in large-screen liquid-crystal displays.

### 23.3.2 Micelles and Membranes

The liquid crystals we have discussed so far have all been single-component systems, but an interesting second type can be formed from two-component mixtures. One component of the mixture is frequently water, and a typical second component is sodium stearate, which has the chemical formula

**FIGURE 23.11** The mode of operation of a liquid-crystal display device. (a) The light has a polarization that permits it to pass through the second polarizing filter and strike the mirror, giving a bright display. (b) Imposition of a potential difference across some portion of the display causes the liquid-crystal molecules to rotate, creating a different polarization of light. Because the "rotated" light is blocked by the second filter, it does not reach the mirror, and that part of the display appears black.

**FIGURE 23.12** The structure of a micelle (a) and a reverse micelle (b).

(a)

(b)

$\text{CH}_3(\text{CH}_2)_{16}\text{COO}^-\text{Na}^+$ . Preparation of this soap from animal fat was described in Section 7.6. It is a salt analogous to sodium acetate, and its special properties arise from the different natures of the two ends of the molecules. The long hydrocarbon tail is **hydrophobic** (“water fearing”) because hydrocarbons do not dissolve in water and avoid contact with it. The ionic carboxylate group ( $-\text{COO}^-$ ), on the other hand, is **hydrophilic** and dissolves readily in water both because of its ionic nature and because it can participate in hydrogen bonds. Such molecules are called **amphiphiles**.

If a very small amount of an amphiphile is dissolved in water, it will separate into solvated individual molecules; as soon as a critical concentration is exceeded, however, the molecules organize into a structure called a **micelle**, which contains 40 to 100 molecules (Fig. 23.12a). Micelles are small, nearly spherical clusters of molecules whose hydrocarbon tails are in the nonpolar interior and whose ionic groups are exposed to the water. This organization requires a decrease in entropy but leads to a significant lowering of the energy because the hydrophobic chains are removed from direct contact with water. If, on the other hand, a hydrocarbon solvent is used, *reverse micelles* can form, in which the hydrocarbon tails of the long-chain ions make contact with the solvent and small amounts of water are collected in the polar interior of the micelle (see Fig. 23.12b).

Micelle formation is critical to the action of soaps and detergents. Grease and fat are oily substances that are more soluble in hydrocarbons than in pure water. The function of a soap such as sodium stearate in the cleaning of fabrics is to detach the grease and associated materials (dirt) from the surfaces to which it has adhered and to form a suspension of oil drops surrounded by amphiphile molecules, which can then be rinsed off. The main disadvantage of natural soaps is that their salts with ions such as  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$  (present in dirt or hard water) are not soluble and precipitate, leaving a scum or residue in the objects being washed. To prevent this, a number of analogs to natural soaps have been developed whose calcium and magnesium salts are more soluble in water. Such amphiphilic synthetic agents are called **detergents**.

Micelles are not the only structures that can form when molecules with hydrophilic and hydrophobic sections are dissolved in water. At higher concentrations, flat **bilayer membranes** form (Fig. 23.13) and can stack into a layered or **lamellar phase** that resembles smectic liquid crystals in their macroscopic properties. A bilayer membrane consists of two planar layers of molecules, with the hydrophilic portions in contact with water and with the hydrophobic portions of one layer in contact with the corresponding hydrophobic portions of a second layer. Such membranes can be made artificially with detergent solutions and serve as models for biological membranes that enclose living cells.

**FIGURE 23.13** A bilayer membrane.

Biological membranes contain embedded proteins that control the passage of ions and molecules through the cell wall. In this way they affect the response of the cell to nerve signals and hormones.

## 23.4 Natural Polymers

All the products of human ingenuity in the design of polymers pale beside the products of nature. Plants and animals employ a tremendous variety of long-chain molecules with different functions: some for structural strength, others to act as catalysts, and still others to provide instructions for the synthesis of vital components of the cell. In this section we discuss these three important classes of natural polymers: polysaccharides, proteins, and nucleic acids.

### 23.4.1 Carbohydrates and Polysaccharides

**Carbohydrates** form a class of compounds of carbon with hydrogen and oxygen. The name comes from the chemical formulas of these compounds, which can be written  $C_n(H_2O)_m$ , suggesting a “hydrate” of carbon. Simple **sugars**, or **monosaccharides**, are carbohydrates with the chemical formula  $C_nH_{2n}O_n$ . Sugars with three, four, five, and six carbon atoms are called trioses, tetroses, pentoses, and hexoses, respectively.

Glucose is a hexose sugar that exists in several forms in solution (Fig. 23.14). There is a rapid equilibrium between a straight-chain form (a six-carbon molecule with five  $-OH$  groups and one aldehyde  $-CHO$  group) and a cyclic form, in which the ring is composed of five carbon atoms and one oxygen, with four  $-OH$  side groups and one  $-CH_2OH$  side group. In the straight-chain form, four of the carbon atoms (those numbered 2 through 5) are chiral centers, with four different groups bonded to them. As discussed in Section 7.2 (see Fig. 7.9), each such carbon atom can exist in two configurations, each labeled L- for *levo* or D- for *dextro* (Latin for *left* and *right*, respectively). These configurations give rise to  $2^4 = 16$  distinct hexose sugars. The glucose formed in plant photosynthesis always has the chirality shown in Figure 23.14b. Of the 15 other straight-chain hexose sugars, the only ones found in nature are D-galactose (in the milk sugar lactose) and D-mannose (a plant sugar).

Figure 23.14 shows that glucose actually has two different ring forms, depending on whether the  $-OH$  group created from the aldehyde by the

**FIGURE 23.14** D-Glucose exists in two ring forms in solution (a and c), which interconvert via an open-chain form (b). The two rings differ in the placement of the  $-OH$  and  $-H$  groups on carbon atom 1.

**FIGURE 23.15** In aqueous solutions of the sugar D-fructose, an equilibrium exists among a five-atom ring, an open chain, and a six-atom ring. In addition to the  $\beta$  isomers shown here, both ring forms have  $\alpha$  isomers, in which the  $-\text{CH}_2\text{OH}$  and  $-\text{OH}$  on carbon 2 are exchanged.

closing of the ring lies above or below the plane of the ring. Another way to see this is to note that closing the ring creates a fifth chiral carbon atom. The two ring forms of D-glucose are called  $\alpha$ -D-glucose (Fig. 23.14a) and  $\beta$ -D-glucose (see Fig. 23.14c). In aqueous solution, these two forms interconvert rapidly via the open-chain glucose form and cannot be separated. They can be isolated separately in crystalline form, however. D-fructose, a common sugar found in fruit and honey, has the same molecular formula as D-glucose but is a member of a class of hexose sugars that are ketones rather than aldehydes. In their straight-chain forms, these sugars have the  $\text{C}=\text{O}$  bond at carbon atom 2 rather than carbon atom 1 (Fig. 23.15).

Many plant cells do not stop the synthesis process with simple sugars such as glucose, but rather continue by linking sugars together to form more complex carbohydrates. **Disaccharides** are composed of two simple sugars linked together by a condensation reaction with the elimination of water. Examples shown in Figure 23.16 are the milk sugar lactose and the plant sugar sucrose (ordinary table sugar, extracted from sugarcane and sugar beets). Further linkages of sugar units lead to polymers called **polysaccharides**. The position of the oxygen atom linking the monomer units has a fundamental effect on the properties and functions of the polymers that result. Starch (Fig. 23.17a) is a polymer of  $\alpha$ -D-glucose and is metabolized by humans and animals. Cellulose (see

**FIGURE 23.16** Two disaccharides. Their derivations from monosaccharide building blocks are shown.

**FIGURE 23.17** Both starch (a) and cellulose (b) are polymers of glucose. In starch, all the cyclic glucose units are  $\alpha$ -D-glucose. In cellulose, all the monomer units are  $\beta$ -D-glucose.

Fig. 23.17b), a polymer of  $\beta$ -D-glucose, cannot be digested except by certain bacteria that live in the digestive tracts of goats, cows, and other ruminants and in some insects, such as termites. It forms the structural fiber of trees and plants and is present in linen, cotton, and paper. It is the most abundant organic compound on earth.

### 23.4.2 Amino Acids and Proteins

The monomeric building blocks of the biopolymers, called proteins, are the  $\alpha$ -amino acids. The simplest amino acid is glycine, which has the molecular structure shown in Figure 23.18. An amino acid, as indicated by the name, must contain an amine group ( $-\text{NH}_2$ ) and a carboxylic acid group ( $-\text{COOH}$ ). In  $\alpha$ -amino acids, the two groups are bonded to the same carbon atom. In acidic aqueous solution, the amine group is protonated to form  $-\text{NH}_3^+$ ; in basic solution, the carboxylic acid group loses a proton to form  $-\text{COO}^-$ . At intermediate pH, both reactions occur. The net result is that the simple amino acid form shown in Figure 23.18 is almost never present in aqueous solution.

Two glycine molecules can condense with loss of water to form an amide:

**FIGURE 23.18** The structure of glycine. On the left side is the carboxylic acid group ( $-\text{COOH}$ ), and on the right is the amine group ( $-\text{NH}_2$ ).

The amide functional group connecting two amino acids is referred to as a **peptide linkage**, and the resulting molecule is a *dipeptide*—in this case, diglycine. Because the two ends of the molecule still have carboxylic acid and amine groups, further condensation reactions to form a **polypeptide**, a polymer comprised of many amino acid groups, are possible. If glycine were the only amino

acid available, the result would be polyglycine, a rather uninteresting protein. There is a close similarity between this naturally occurring condensation polymer and the synthetic polyamide nylon. Polyglycine could be called “nylon 2,” a simple polyamide in which each repeating unit contains two carbon atoms.

Nature does not stop with glycine as a monomer unit. Instead, any of 20 different  $\alpha$ -amino acids are found in most natural polypeptides. In each of these, one of the hydrogen atoms on the central carbon atom of glycine is replaced by another side group. Alanine is the next simplest  $\alpha$ -amino acid after glycine; it has a  $-\text{CH}_3$  group in place of an  $-\text{H}$  atom. This substitution has a profound consequence. In alanine, four different groups are attached to a central carbon:  $-\text{COOH}$ ,  $-\text{NH}_2$ ,  $-\text{CH}_3$ , and  $-\text{H}$ . There are two ways in which four different groups can be arranged in a tetrahedral structure about a central atom (see Fig. 7.9). The two optical isomers of alanine are designated by the prefixes L- and D- for *levo* and *dextro* (Latin for “left” and “right,” respectively).

If a mixture of L- and D-alanine were caused to polymerize, nearly all the polymer molecules would have different structures because their sequences of D-alanine and L-alanine monomer units would differ. To create polymers with definite structures for particular roles, there is only one recourse: to build all polypeptides from one of the optical isomers so that the properties will be reproducible from molecule to molecule. Nearly all naturally occurring  $\alpha$ -amino acids are of the L form, and most earthly organisms have no use for D- $\alpha$ -amino acids in making polypeptides. Terrestrial life could presumably have begun equally well using mainly D-amino acids (all biomolecules would be mirror images of their present forms). The mechanism by which the established preference was initially selected is not known.

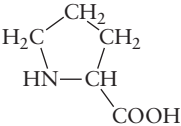

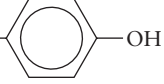

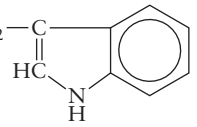

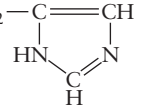

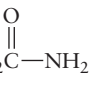

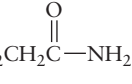

The  $-\text{H}$  group of glycine and  $-\text{CH}_3$  group of alanine give just the first two amino acid building blocks. Table 23.3 shows all 20 important  $\alpha$ -amino acids, arranged by side group. Note the variety in their chemical and physical properties. Some side groups contain basic groups; others are acidic. Some are compact; others are bulky. Some can take part in hydrogen bonds; others can complex readily with metal ions to form coordination complexes.

This variety in properties of the  $\alpha$ -amino acids leads to even more variety in the polymers derived from them, called **proteins**. The term *protein* is usually applied to polymers with more than about 50 amino acid groups; large proteins may contain many thousand such groups. Given the fact that any one of 20  $\alpha$ -amino acids may appear at each point in the chain, the number of possible sequences of amino acids in even small proteins is staggering. Moreover, the amino acid sequence describes only one aspect of the molecular structure of a protein. It contains no information about the three-dimensional conformation adopted by the protein. The carbonyl group and the amine group in each amino acid along the protein chain are potential sites for hydrogen bonds, which may also involve functional groups on the amino acid side chains. Also, the cysteine side groups ( $-\text{CH}_2-\text{SH}$ ) can react with one another, with loss of hydrogen, to form  $-\text{CH}_2-\text{S}-\text{S}-\text{CH}_2-$  disulfide bridges between different cysteine groups in a single chain or between neighboring chains (the same kind of cross-linking by sulfur occurs in the vulcanization of rubber). As a result of these strong intrachain interactions, the molecules of a given protein have a rather well-defined conformation even in solution, as compared with the much more varied range of conformations available to a simple alkane chain (see Fig. 7.3). The three-dimensional structures of many proteins have been determined by X-ray diffraction.

There are two primary categories of proteins: fibrous and globular. A **fibrous protein** is usually a structural material consisting of polymer chains linked in sheets or twisted in long fibers. Silk is a fibrous protein in which the monomer units are primarily glycine and alanine, with smaller amounts of serine and tyrosine. The protein chains are cross-linked by hydrogen bonds to form

TABLE 23.3

 $\alpha$ -Amino Acid Side Groups

<b>Hydrogen "Side Group"</b>		
Glycine	Gly	—H
<b>Alkyl Side Groups</b>		
Alanine	Ala	—CH <sub>3</sub>
Valine	Val	—CH—CH <sub>3</sub>   CH <sub>3</sub>
Leucine	Leu	—CH <sub>2</sub> —CH—CH <sub>3</sub>   CH <sub>3</sub>
Isoleucine	Ile	—CH—CH <sub>2</sub> —CH <sub>3</sub>   CH <sub>3</sub>
Proline	Pro (structure of entire amino acid)	
<b>Aromatic Side Groups</b>		
Phenylalanine	Phe	—CH <sub>2</sub> — 
Tyrosine	Tyr	—CH <sub>2</sub> — 
Tryptophan	Trp	—CH <sub>2</sub> — 
<b>Alcohol-Containing Side Groups</b>		
Serine	Ser	—CH <sub>2</sub> OH
Threonine	Thr	—CH—OH   CH <sub>3</sub>
<b>Basic Side Groups</b>		
Lysine	Lys	—CH <sub>2</sub> CH <sub>2</sub> CH <sub>2</sub> CH <sub>2</sub> NH <sub>2</sub>
Arginine	Arg	—CH <sub>2</sub> CH <sub>2</sub> CH <sub>2</sub> NH—C(=NH)   NH <sub>2</sub>
Histidine	His	—CH <sub>2</sub> — 
<b>Acidic Side Groups</b>		
Aspartic acid	Asp	—CH <sub>2</sub> COOH
Glutamic acid	Glu	—CH <sub>2</sub> CH <sub>2</sub> COOH
<b>Amide-Containing Side Groups</b>		
Asparagine	Asn	—CH <sub>2</sub> — 
Glutamine	Gln	—CH <sub>2</sub> CH <sub>2</sub> — 
<b>Sulfur-Containing Side Groups</b>		
Cysteine	Cys	—CH <sub>2</sub> —SH
Methionine	Met	—CH <sub>2</sub> CH <sub>2</sub> —S—CH <sub>3</sub>

**FIGURE 23.19** (a) View of a  $\beta$ -pleated sheet that emphasizes the interchain hydrogen bonds responsible for the structure. (b) View of two stacked  $\beta$ -pleated sheets that form part of a microcrystalline structure responsible for the great strength of silk.

**FIGURE 23.20**  $\alpha$ -helix protein secondary structure, with interchain hydrogen bonds shown.

sheet-like structures (Fig. 23.19) that are arranged so that the nonhydrogen side groups all lie on one side of the sheet; the sheets then stack in layers. The relatively weak forces between sheets give silk its characteristic smooth feel. The amino acids in wool and hair have side chains that are larger, bulkier, and less regularly distributed than those in silk; therefore, sheet structures do not form. Instead, the protein molecules twist into a right-handed coil called an  $\alpha$ -helix (Fig. 23.20). In this structure, each carbonyl group is hydrogen-bonded to the amine group of the fourth amino acid farther along the chain; the bulky side groups jut out from the helix and do not interfere with one another.

The second type of protein is the **globular protein**. Globular proteins include the carriers of oxygen in the blood (hemoglobin) and in cells (myoglobin). They have irregular folded structures (Fig. 23.21) and typically consist of 100 to 1000 amino acid groups in one or more chains. Globular proteins frequently have parts of their structures in  $\alpha$ -helices and sheets, with other portions in more disordered forms. Hydrocarbon side groups tend to cluster in regions that exclude water, whereas charged and polar side groups tend to remain in close contact with water. The sequences of amino acid units for many such proteins have been worked out by cleaving them into smaller pieces and analyzing the

**FIGURE 23.21** A computer-generated model of the structure of myoglobin. The central heme group (red) is shown in greater detail in Chapter 8—*Connection to Biology: Coordination Complexes in Heme Proteins*; two histidine groups (green) extend toward the central iron atom. Much of the protein (blue tube) is coiled in  $\alpha$ -helices.

structure of the fragments. It took Frederick Sanger 10 years to complete the first such determination of sequence for the 51 amino acids in bovine insulin, an accomplishment that earned him the Nobel Prize in chemistry in 1958. Now, automated procedures enable scientists to rapidly determine amino acid sequences in much longer protein molecules.

**Enzymes** constitute a very important class of globular proteins. They catalyze particular reactions in the cell, such as the synthesis and breakdown of proteins, the transport of substances across cell walls, and the recognition and resistance of foreign bodies. Enzymes act by lowering the activation barrier for a reaction, and they must be selective so as to act only on a restricted group of substrates.

Let's examine the enzyme carboxypeptidase A, whose structure has been determined by X-ray diffraction. It removes amino acids one at a time from the carboxylic acid end of a polypeptide. Figure 23.22 shows the structure of the active site (with a peptide chain in place, ready to be cleaved). A special feature of this enzyme is the role played by the zinc ion, which is coordinated to two histidine residues in the enzyme and to a carboxylate group on a nearby glutamic acid residue. The zinc ion helps remove electrons from the carbonyl group of the peptide linkage, making it more positive and thereby more susceptible to attack by water or by the carboxylate group of a second glutamic acid residue. The side chain on the outer amino acid of the peptide being cleaved is positioned in a hydrophobic cavity, which favors large aromatic or branched side chains (such as that in tyrosine) over smaller hydrophilic side chains (such as that in aspartic acid). Carboxypeptidase A is thus selective about the sites at which it cleaves peptide chains.

The molecular “engineering” that lies behind nature’s design of carboxypeptidase A and other enzymes is truly remarkable. The amino acid residues that form the active site and determine its catalytic properties are *not* adjacent to one another in the protein chain. As indicated by the numbers after the residues in Figure 23.22, the two glutamic acid residues are the 72nd and 270th amino acids along the chain. The enzyme adopts a conformation in which the key residues, distant from one another in terms of chain position, are nonetheless quite close in three-dimensional space, allowing the enzyme to carry out its specialized function.

**FIGURE 23.22** The active site of carboxypeptidase A. Shown in red is a substrate polypeptide that is being cleaved by the enzyme. Green is used to show the role of  $Zn^{2+}$  as a complexing ion, and blue is used to show the hydrogen bonds that maintain the geometry.

### 23.4.3 Nucleotides and Nucleic Acids

We have seen that proteins are copolymers made up typically of 20 types of monomer units. Simply mixing the amino acids and letting them dehydrate to form polymer chains at random would never lead to the particular structures needed by living cells. How does the cell preserve information about the amino acid sequences that make up its proteins, and how does it transmit this information to daughter cells through the reproductive process? These questions lie in the field of molecular genetics, an area in which chemistry plays the central role.

The primary genetic material is deoxyribonucleic acid (DNA). This biopolymer is made up of four types of monomer units called **nucleotides**. Each nucleotide is composed of three parts:

1. One molecule of a pyrimidine or purine base. The four bases are thymine, cytosine, adenine, and guanine (Fig. 23.23a).
2. One molecule of the sugar D-deoxyribose ( $C_5H_{10}O_4$ ). D-Ribose is a pentose sugar with a five-membered ring.
3. One molecule of phosphoric acid ( $H_3PO_4$ ).

**FIGURE 23.23** (a) The structures of the purine and pyrimidine bases. Hydrogen-bonding between pairs of bases is indicated by red dots. (b) The structure of the nucleotide adenosine monophosphate (AMP).

The cyclic sugar molecule links the base to the phosphate group, undergoing two condensation reactions, with loss of water, to form the nucleotide (see Fig. 23.23b). The first key to discovering the structure of DNA was the following observation: Although the proportions of the four bases in DNA from different organisms are quite variable, the chemical amount of cytosine (C) is always approximately equal to that of guanine (G) and the chemical amount of adenine (A) is always approximately equal to that of thymine (T). This suggested some type of base pairing in DNA that could lead to association of C with G and of A with T. The second crucial observation was an X-ray diffraction study by Rosalind Franklin and Maurice Wilkins that suggested the presence of helical structures of more than one chain in DNA.

James Watson and Francis Crick put together these two pieces of information in their famous 1953 proposal of a double-helix structure for DNA. They concluded that DNA consists of two interacting helical strands of nucleic acid polymer (Fig. 23.24), with each cytosine on one strand linked through hydrogen bonds to a guanine on the other and each adenine to a thymine. This accounted for the observed molar ratios of the bases, and it also provided a model for the replication of the molecule, which is crucial for passing on information during

**FIGURE 23.24** The double-helix structure of DNA.

the reproductive process. One DNA strand serves as a template upon which a second DNA strand is synthesized. A DNA molecule reproduces by starting to unwind at one end. As it does so, new nucleotides are guided into position opposite the proper bases on each of the two strands. If the nucleotide does not fit the template, it cannot link to the polymeric strand under construction. The result of the polymer synthesis is two double-helix molecules, each containing one strand from the original and one new strand that is identical to the original in every respect.

Information is encoded in DNA in the sequence of the base pairs. Subsequent research has broken this genetic code and established the connection between the base sequence in a segment of DNA and the amino acid sequence of the protein synthesized according to the directions in that segment. The code in a nucleic acid is read as consecutive, nonoverlapping triplets of bases, with each triplet standing for a particular amino acid. Thus, a nucleic acid strand consisting of pure cytosine gives a polypeptide of pure proline, meaning that the triplet CCC codes for proline. The nucleic acid strand AGAGAGAG . . . is read as the alternating triplets AGA and GAG and gives a polypeptide consisting of alternating arginine (coded by AGA) and glutamic acid (coded by GAG) monomer units. There are 64 ( $4^3$ ) possible triplets, so typically more than one code exists for a particular amino acid. Some triplets serve as signals to terminate a polypeptide chain. Remarkably, the genetic code appears to be universal, independent of the species of plant or animal, a finding that suggests a common origin for all terrestrial life.

A single change in a base pair in DNA causes a change in one amino acid of the protein that is coded for by that DNA. Such a change may seem small, but it may have dramatic (even fatal) effects for the organism in question. For example, the triplets GAA and GAG both code for glutamic acid (an acidic residue), whereas the triplets GTA and GTG code for valine (a nonpolar residue). A single change in the central A to T in the DNA thus changes an amino acid in a protein produced by the organism. This might seem like a small effect, but it can change the structure and mode of action of the protein. This particular change is responsible for the presence of hemoglobin S (instead of hemoglobin A) in the blood of people who have sickle cell anemia. In two of the four hemoglobin S chains a glutamic acid amino acid is changed to a valine, and the result is a decrease in the solubility of S relative to A by a factor of 25. This leads to polymerization of the hemoglobin to form insoluble structures that bend red blood cells into sickle shapes, a change that can lead to early death. One of the challenges of modern genetic engineering is to use chemistry to modify coding molecules in living species to eliminate fatal or disease-causing mutants.

## CHAPTER SUMMARY

---

Mankind has long used naturally occurring polymers, obtained from plants and animals, as useful materials. These are familiar in cotton, wool, and silk fabrics, and in structural applications of wood and rubber. Inspired by these natural products, chemists have invented synthetic routes to these and similar materials, often with modified or improved properties. Curiosity about life processes in living systems has inspired research on natural polymers, such as polysaccharides, proteins, enzymes, and DNA, to discern the relation between their structure and function. The structures of these solid synthetic and natural polymeric materials range from purely amorphous to highly crystalline. The route to controlling their molecular and crystalline structures lies through understanding their local bonding.

## CONCEPTS AND SKILLS

---

### Section 23.1 – Polymerization Reactions for Synthetic Polymers

*Contrast the methods of addition and condensation polymerization (Problems 1–6).*

- Polymer formation requires that many monomers must be attached to a growing polymer molecule. This requires that highly reactive functional groups must be available at each growth step. This is achieved by two main mechanisms.
  - Addition polymerization requires monomers to join the polymer without net loss of atoms. This usually involves free radical reaction of molecules that have C=C double bonds, and proceeds through three steps: initiation, propagation, and termination.
  - Condensation polymerization requires that a small molecule such as water is split off as each monomer is added to the polymer.
- Both addition and condensation polymerization can occur with mixtures of monomers to produce a random copolymer of the two monomers.
- If monomers have three or more reactive sites, cross-linking reactions to form sheets or networks is possible. Cross-linking is often brought about deliberately to obtain stronger materials.

### Section 23.2 – Applications for Synthetic Polymers

*Give several examples of fibers, plastics, and rubbers and describe how they are made and used (Problems 7–10).*

- Synthetic polymers are selected for four major classes of applications based on their physical properties.
  - Fibers for use in fabrics are spun into threads in which their molecules are aligned. They must resist stretching, and usually break after only 10% elongation. The first purely synthetic fiber was nylon, developed by condensation polymerization.
  - Plastics are molded or extruded into desired shapes that harden upon cooling or solvent evaporation. They typically elongate 20% to 100% before breaking. Many of these are formed by addition polymerization of ethene or its derivatives. Examples include polyethylene, polystyrene, and Teflon. By using proper catalysts and manipulating the size of side group substituents, it is possible to overcome the tendency of addition polymerization to form highly branched chains. These tools make it possible to control the degree of crystallinity in polymer materials.
  - Rubbers, or elastomers, stretch readily to elongate by a factor of 10 before breaking. Natural rubber, obtained from the sap of certain trees, can be hardened and toughened by addition of sulfur in the vulcanization process. Synthetic rubber is produced by addition copolymerization of butadiene and styrene.
  - Electrically conducting polymers combine the optical and electronic properties of inorganic semiconductors with the processing ease of conventional polymers. Their structures are continuations of the 1,3-butadiene structure to greater lengths, and the electronic structure for the individual molecule is described by bands. These polymers are made electrically conducting by doping.

### Section 23.3 – Liquid Crystals

*Explain what a liquid crystal is, and state how nematic and smectic phases differ from ordinary liquids and crystalline solids (Problems 11–12).*

- Liquid crystals have properties intermediate between those of true liquids and crystals. Unlike glasses, they are thermodynamically stable.
- Based on microscopic structural details, liquid crystals form three separate ordered phases: nematic, smectic, and cholesteric.
- Orientation of liquid crystals depends sensitively on small electric and magnetic fields. This is the basis of liquid crystal displays for digital information.

*Describe the formation of ordered structures such as micelles and membranes in surfactant solutions (Problems 13–14).*

- Amphiphiles are molecules with a water soluble ionic structure on one end (hydrophilic) and a long hydrocarbon tail on the other end (hydrophobic). When amphiphiles are dissolved in water above a critical concentration, they form ordered clusters called micelles in which the organic tails of the molecules are enclosed in a shell of hydrophilic structures that shield the organic phase from interaction with the water. This structure is stable because it eliminates the repulsive interaction between the organic tails and water. Amphiphiles can form reverse micelles in organic solvents by shielding the hydrophilic structures in a shell of hydrocarbon tails that are dissolved in the organic solvent. At still higher concentrations, amphiphiles can be organized into two-dimensional sheets rather than spherical clusters. The hydrophobic sides of two sheets interact to form a stable bilayer membrane in which the two facing hydrophobic sheets are sandwiched between two hydrophilic layers.

### Section 23.4 – Natural Polymers

*Describe the formation of polysaccharides from sugars, proteins from amino acids, and DNA from nucleotides, and the roles of these biopolymers in living cells (Problems 15–22).*

- Naturally occurring polymers are synthesized by plants and animals to support a variety of life processes.
- Polysaccharides are grown by linkage of simple sugar units (carbohydrates). One example is starch, which is readily metabolized by humans and animals. Another is cellulose, which forms the structural fibers of plants and trees and appears in linen and cotton fabrics and in paper.
- The biological polymers called proteins are built up from the amino acid units, ranging in number from 50 to several thousand per polymer. Since 20 amino acids are available, a very large number of sequences can be realized. Fibrous proteins consist of polymers linked in sheets or twisted in long fibers; they are structural materials. Globular proteins include hemoglobin and enzymes; they generally control chemical reactions in living systems.
- The primary genetic material DNA is a biopolymer made up of four types of monomer units called nucleotides. DNA serves as a template during reproduction to enable a cell to preserve information about the amino acid sequences that make up its proteins, and transfer this information to daughter cells through the genetic code.

## PROBLEMS

Answers to problems whose numbers are red appear in Appendix G. Problems that are more challenging are indicated with asterisks.

### 23.1 Polymerization Reactions for Synthetic Polymers

- Write a balanced chemical equation to represent the addition polymerization of 1,1-dichloroethene. The product of this reaction is Saran, used as a plastic wrap.
- Write a balanced chemical equation to represent the addition polymerization of tetrafluoroethene. The product of this reaction is Teflon.
- A polymer produced by addition polymerization consists of  $(-\text{CH}_2-\text{O}-)$  groups joined in a long chain. What was the starting monomer?
- The polymer polymethyl methacrylate is used to make Plexiglas. It has the formula

Draw the structural formula of the starting monomer.

- The monomer glycine ( $\text{NH}_2-\text{CH}_2-\text{COOH}$ ) can undergo condensation polymerization to form polyglycine, in which the structural units are joined by amide linkages.
  - What molecule is split off in the formation of polyglycine?
  - Draw the structure of the repeat unit in polyglycine.
- The polymer forms  $-(\text{NH}-\text{CH}(\text{CH}_3)-\overset{\text{O}}{\parallel}{\text{C}})_n-$  upon condensation polymerization with loss of water. Draw the structure of the starting monomer.

### 23.2 Applications for Synthetic Polymers

- Determine the mass of adipic acid and the mass of hexamethylenediamine needed to make  $1.00 \times 10^3$  kg of nylon 66 fiber.
- Determine the mass of terephthalic acid and the mass of ethylene glycol needed to make 10.0 kg of polyester fiber.
- In a recent year, 4.37 billion kilograms of low-density polyethylene was produced in the United States. What volume of gaseous ethene at  $0^\circ\text{C}$  and 1.00 atm would give this amount?
- In a recent year, 2.84 billion kilograms of polystyrene was produced in the United States. Polystyrene is the addition polymer formed from the styrene monomer,  $\text{C}_6\text{H}_5\text{CH}=\text{CH}_2$ . How many styrene monomer units were incorporated in that 2.84 billion kilograms of polymer?

### 23.3 Liquid Crystals

- Compare the natures and extents of order in the smectic liquid-crystal and isotropic liquid phases of a substance. Which has the higher entropy? Which has the higher enthalpy?
- Nematic liquid crystals form when a liquid of long rod-like molecules is cooled. What *additional* types of intermolecular interactions would you expect to favor the formation of a *smectic* phase?
- Consider a ternary (three-component) system of amphiphile, hydrocarbon, and water. What structure do you expect to form if small amounts of the first two components are mixed with a large amount of water?
- In addition to spherical micelles and lamellar phases, a binary amphiphile-water mixture can also form extended cylindrical rolls, with the hydrophilic groups pointing out and the hydrophobic chains on the interior. Over what composition range are such cylinders most likely to be found, relative to spherical micelles and planar layers?

### 23.4 Natural Polymers

- By referring to Figure 23.16a, draw the structure of the ring form of  $\beta$ -D-galactose. How many asymmetric carbon atoms (chiral centers) are there in the molecule?
- By referring to Figure 23.23b, draw the structure of the ring form of D-ribose. How many asymmetric carbon atoms (chiral centers) are there in the molecule?
- How many tripeptides can be synthesized using just three different species of  $\alpha$ -amino acids?
- How many different polypeptides, each containing ten amino acids, can be made from the amino acids listed in Table 23.3? How many different polypeptides, each containing 100 amino acids, can be made?
- Draw the structure of the pentapeptide alanine-leucine-phenylalanine-glycine-isoleucine. Assume that the free  $-\text{NH}_2$  group is at the alanine end of the peptide chain. Would this compound be more likely to dissolve in water or in octane? Explain.
- Draw the structure of the pentapeptide aspartic acid-serine-lysine-glutamic acid-tyrosine. Assume that the free  $-\text{NH}_2$  group is at the aspartic acid end of the peptide chain. Would this compound be more likely to dissolve in water or in octane? Explain.
- Suppose a long-chain polypeptide is constructed entirely from phenylalanine monomer units. What is its empirical formula? How many amino acids does it contain if its molar mass is  $17,500 \text{ g mol}^{-1}$ ?
- A typical bacterial DNA has a molar mass of  $4 \times 10^9 \text{ g mol}^{-1}$ . Approximately how many nucleotides does it contain?

## ADDITIONAL PROBLEMS

23. In the addition polymerization of acrylonitrile, a very small amount of butyl lithium causes a reaction that can consume hundreds of pounds of the monomer; however, the butyl lithium is called an initiator, not a catalyst. Explain why.
24. Based on the facts that the free-radical polymerization of ethene is spontaneous and that polymer molecules are less disorganized than the starting monomers, decide whether the polymerization reaction is exothermic or endothermic. Explain.
25. According to a trade journal, approximately 950 million lb of 1,2-dichloroethane was exported from the United States in a recent year. (The common name of this substance is ethylene dichloride.) The article states that “between 500 million and 550 million pounds of PVC could have been made from that ethylene dichloride.” Compute the range of percentage yields of PVC from 1,2-dichloroethane that is implied by these figures.
26. The complete hydrogenation of natural rubber (the addition of  $H_2$  to all double bonds) gives a product that is indistinguishable from the product of the complete hydrogenation of gutta-percha. Explain how this strengthens the conclusion that these two substances are isomers of each other.
27. A reducing solution breaks S—S bonds in proteins, whereas an oxidizing solution allows them to re-form. Discuss how such solutions might be used to carry out the curling of hair.
28. L-Sucrose tastes sweet, but it is not metabolized. It has been suggested as a potential nonnutritive sweetener. Draw the molecular structure of L-sucrose, using Figure 23.16b as a starting point.
29. Polypeptides are synthesized from a 50:50 mixture of L-alanine and D-alanine. How many different isomeric molecules containing 22 monomer units are possible?
30. An osmotic pressure measurement taken on a solution containing hemoglobin shows that the molar mass of that protein is approximately  $65,000 \text{ g mol}^{-1}$ . A chemical analysis shows it to contain 0.344% of iron by mass. How many iron atoms does each hemoglobin molecule contain?
- \*31. At very low pH, alanine is a diprotic acid that can be represented as  $H_3N^+—CH(CH_3)—COOH$ . The  $pK_a$  of the carboxyl group is 2.3, and the  $pK_a$  of the  $—NH_3^+$  group is 9.7.
- (a) At pH 7, what fraction of the amino acid molecules dissolved in an aqueous solution will have the form  $H_3N^+—CH(CH_3)—COO^-$ ?
- (b) What fraction of the molecules at this pH will have the form  $H_2N—CH(CH_3)—COOH$ ?
32. The sequence of bases in one strand of DNA reads ACTTGACCG. Write the sequence of bases in the complementary strand.
33. Nucleic acids are diesters of phosphoric acid. Esters are not usually acidic. Why are nucleic acids acidic, or is this name inappropriate?
34. The codons in the genetic code are sequences of three bases. Explain why sequences of only two bases could not be used to code for the 20 different amino acids commonly found in proteins.
35. The average distance between base pairs measured parallel to the axis of a double-helical DNA molecule is 3.4 angstroms. The average molecular weight of a pair of nucleotides is about  $650 \text{ g mol}^{-1}$ . What is the approximate length in millimeters of a single DNA molecule of molecular weight  $2.8 \times 10^9 \text{ g mol}^{-1}$  (a value typical for the DNA of some bacteria)? About how many base pairs does this DNA contain?

# Scientific Notation and Experimental Error

## A.1 Scientific Notation

Very large and very small numbers are common in chemistry. Repeatedly writing such numbers in the ordinary way (for example, the important number 602,214,100,000,000,000,000,000) would be tedious and would engender errors. *Scientific notation* offers a better way. A number in scientific notation is expressed as a number from 1 to 10 multiplied by 10 raised to some power. Any number can be represented in this way, as the following examples show.

$$\begin{aligned} 643.8 &= 6.438 \times 10^2 \\ -19,000,000 &= -1.9 \times 10^7 \\ 0.0236 &= 2.36 \times 10^{-2} \\ 602,214,100,000,000,000,000,000 &= 6.022141 \times 10^{23} \end{aligned}$$

A simple rule of thumb is that the power to which 10 is raised is  $n$  if the decimal point is moved  $n$  places to the left and is  $-n$  if the decimal is moved  $n$  places to the right.

When two or more numbers written in scientific notation are to be added or subtracted, they should first be expressed as multiples of the *same* power of 10:

$$\begin{array}{r} 6.431 \times 10^4 \longrightarrow 6.431 \times 10^4 \\ +2.1 \times 10^2 \longrightarrow +0.021 \times 10^4 \\ +3.67 \times 10^3 \longrightarrow +0.367 \times 10^4 \\ \hline ? \qquad \qquad \qquad 6.819 \times 10^4 \end{array}$$

When two numbers in scientific notation are multiplied, the coefficients are multiplied and then the powers of 10 are multiplied (by adding the exponents):

$$\begin{aligned} 1.38 \times 10^{-16} \times 8.80 \times 10^3 &= (1.38 \times 8.80) \times 10^{(-16+3)} \\ &= 12.1 \times 10^{-13} = 1.21 \times 10^{-12} \end{aligned}$$

We divide one number by a second by dividing the coefficients and then multiplying by 10 raised to the first exponent minus the second (exponents are subtracted):

$$\begin{aligned} \frac{6.63 \times 10^{-27}}{2.34 \times 10^{-16}} &= \frac{6.63}{2.34} \times \frac{10^{-27}}{10^{-16}} \\ &= 2.83 \times 10^{[-27-(-16)]} = 2.83 \times 10^{-11} \end{aligned}$$

Any calculator or computer equipped to perform scientific and engineering calculations can accept and display numbers in scientific notation. It cannot determine whether the input has an error, however, or whether the answer makes sense. That is your responsibility! Develop the habit of mentally estimating the order of magnitude of the answer as a rough check on your calculator's result.

## A.2 Experimental Error

Chemistry is an experimental science in which every quantitative measurement is subject to some degree of error. We can seek to reduce error by carrying out additional measurements or by changing our experimental apparatus, but we can never eliminate error altogether. It is important, therefore, to be able to assess the results of an experiment quantitatively to establish the limits of the experiment's validity. Errors are of two types: random (lack of precision) and systematic (lack of accuracy).

### A.2.1 Precision and Random Errors

*Precision* refers to the degree of agreement in a collection of experimental results and is estimated by repeating the measurement under conditions as nearly identical as possible. If the conditions are truly identical, then differences among the trials are due to random error. As a specific example, consider some actual results of an early, important experiment by American physicist Robert Millikan in 1909, to measure the magnitude of the charge  $e$  on the electron. The experiment (discussed in greater detail in Chapter 1) involved a study of the motion of charged oil drops suspended in air in an electric field. Millikan made hundreds of measurements on many different oil drops, but we shall consider only a set of results for  $e$  found for one particular drop (Table A.1). The values he found ranged from 4.894 to  $4.941 \times 10^{-10}$  esu. What do we choose to report as the best estimate for  $e$ ? The proper procedure is to first examine the data to see whether any of the results are especially far from the rest (a value above  $5 \times 10^{-10}$  esu would fall into this category). Such values are likely to result from some mistake in carrying out or reporting that particular measurement and therefore are excluded from further consideration (although there have been cases in science where just such exceptional results have led to significant breakthroughs). In Millikan's data, no such points should be excluded. To obtain our best estimate for  $e$ , we calculate the **average value** (or *mean*) by adding up the values found and dividing by the number of measurements. We can write the average value of any property after a series of  $N$  measurements  $x_1, x_2, \dots, x_N$  as

$$\bar{x} = \frac{1}{N} (x_1 + x_2 + \dots + x_N) = \frac{1}{N} \sum_{i=1}^N x_i$$

where a capital Greek sigma ( $\Sigma$ ) is introduced to indicate a summation of  $x_i$  over values of  $i$  from 1 to  $N$ . In the present case, this gives an average for  $e$  of  $4.917 \times 10^{-10}$  esu.

This average by itself does not convey any estimate of uncertainty. If all of the measurements had given results between  $4.91 \times 10^{-10}$  and  $4.92 \times 10^{-10}$  esu, the uncertainty would be less than if the results had ranged from  $4 \times 10^{-10}$  to  $6 \times 10^{-10}$  esu. Furthermore, an average of 100 measurements should have less uncertainty than an average of 5. How are these ideas made quantitative?

**TABLE A.1**

Measurement Number $e$ ( $10^{-10}$ esu)												
1	2	3	4	5	6	7	8	9	10	11	12	13
4.915	4.920	4.937	4.923	4.931	4.936	4.941	4.902	4.927	4.900	4.904	4.897	4.894

From R. A. Millikan, *Phys. Rev.* 32:349, 1911. [1 esu =  $3.3356 \times 10^{-10}$  C]

A statistical measure of the spread of data, called the **standard deviation**  $\sigma$ , is useful in this regard. It is given by the formula

$$\begin{aligned} \sigma &= \sqrt{\frac{(x_1 - \bar{x})^2 + (x_2 - \bar{x})^2 + \cdots + (x_N - \bar{x})^2}{N - 1}} \\ &= \sqrt{\frac{1}{N - 1} \sum_{i=1}^N (x_i - \bar{x})^2} \end{aligned}$$

The standard deviation is found by adding up the squares of the deviations of the individual data points from the average value  $\bar{x}$ , dividing by  $N - 1$ , and taking the square root. Table A.2 shows how  $\sigma$  is used quantitatively. A *confidence limit* is defined as

$$\text{confidence limit} = \pm \frac{t\sigma}{\sqrt{N}}$$

The table gives the factor  $t$  for various numbers of measurements,  $N$ , and for various levels of confidence.

For Millikan’s data,  $N = 13$  and  $\sigma = 0.017 \times 10^{-10}$ . For 95% confidence with 13 measurements, the table shows  $t = 2.18$  and the confidence limit is

$$\text{confidence limit} = \pm \frac{(2.18)(0.017 \times 10^{-10})}{\sqrt{13}} = \pm 0.010 \times 10^{-10} \text{ esu}$$

Thus, a 95% probability exists that the *true* average (obtained by repeating the experiment under the same conditions an infinite number of times) will lie within  $\pm 0.010 \times 10^{-10}$  esu of the average  $4.917 \times 10^{-10}$  esu. Within this 95% confidence level, our best estimate for  $e$  is written as

$$(4.917 \pm 0.010) \times 10^{-10} \text{ esu}$$

For other confidence levels and other numbers of measurements, the factor  $t$  and therefore the confidence limit change.

**TABLE A.2**

$N$ (Number of Observations)	Factor $t$ for Confidence Interval of			
	80%	90%	95%	99%
2	3.08	6.31	12.7	63.7
3	1.89	2.92	4.30	9.92
4	1.64	2.35	3.18	5.84
5	1.53	2.13	2.78	4.60
6	1.48	2.02	2.57	4.03
7	1.44	1.94	2.45	3.71
8	1.42	1.90	2.36	3.50
9	1.40	1.86	2.31	3.36
10	1.38	1.83	2.26	3.25
11	1.37	1.81	2.23	3.17
12	1.36	1.80	2.20	3.11
13	1.36	1.78	2.18	3.06
14	1.35	1.77	2.16	3.01
15	1.34	1.76	2.14	2.98
$\infty$	1.29	1.64	1.96	2.58

## A.2.2 Accuracy and Systematic Errors

The magnitude of the charge  $e$  on the electron has been measured by several different techniques since Millikan's day. The current best estimate for  $e$  is

$$\begin{aligned} e &= (4.80320452 \pm 0.0000011) \times 10^{-10} \text{ esu} \\ &= (1.60217657 \pm 0.00000035) \times 10^{-19} \text{ C} \end{aligned}$$

This value lies outside the range of uncertainty we estimated from Millikan's original data. In fact, it lies well below the smallest of the 13 measurements of  $e$ . Why?

To understand this discrepancy, we need to remember that there is a second source of error in any experiment: *systematic* error that causes a shift in the measured values from the true value and reduces the **accuracy of the result**. By making more measurements, we can reduce the uncertainty due to *random* errors and improve the *precision* of our result; however, if systematic errors are present, the average value will continue to deviate from the true value. Such systematic errors may result from a miscalibration of the experimental apparatus or from a fundamental inadequacy in the technique for measuring a property. In the case of Millikan's experiment, the then-accepted value for the viscosity of air (used in calculating the charge  $e$ ) was subsequently found to be wrong. This caused his results to be systematically too high.

Error thus arises from two sources. Lack of precision (random errors) can be estimated by a statistical analysis of a series of measurements. Lack of accuracy (systematic errors) is much more problematic. If a systematic error is known to be present, we should do our best to correct for it before reporting the result. (For example, if our apparatus has not been calibrated correctly, it should be recalibrated.) The problem is that systematic errors of which we have no knowledge may be present. In this case the experiment should be repeated with different apparatus to eliminate the systematic error caused by a particular piece of equipment; better still, a different and independent way to measure the property might be devised. Only after enough independent experimental data are available can we be convinced of the accuracy of a result—that is, how closely it approximates the true result.

## A.3 Significant Figures

The number of *significant figures* is the number of digits used to express a measured or calculated quantity, excluding zeros that may precede the first nonzero digit. Suppose the mass of a sample of sodium chloride is measured to be 8.241 g and the uncertainty is estimated to be  $\pm 0.001$  g. The mass is said to be given to four significant figures because we are confident of the first three digits (8, 2, 4) and the uncertainty appears in the fourth (1), which nevertheless is still significant. Writing additional digits beyond the 1 would not be justified, however, unless the accuracy of the weighing could be improved. When we record a volume as 22.4 L, we imply that the uncertainty in the measurement is in the last digit written ( $V = 22.4 \pm 0.3$  L, for example). A volume written as 22.43 L, on the other hand, implies that the uncertainty is far less and appears only in the fourth significant figure.

In the same way, writing 20.000 m is quite different from writing 20.0 m. The second measurement (with three significant figures) could easily be made with a common meterstick. The first (with five significant figures) would require a more precise method. We should avoid reporting results such as “700 m,” however, because the two trailing zeros may or may not be significant. The

uncertainty in the measurement could be of order  $\pm 1$  m or  $\pm 10$  m or perhaps  $\pm 100$  m; it is impossible to tell which without further information. To avoid this ambiguity, we can write such measurements using the scientific notation described in Section A.1. The measurement “700 m” translates into any of the following:

$7.00 \times 10^2$ m	Three significant figures
$7.0 \times 10^2$ m	Two significant figures
$7 \times 10^2$ m	One significant figure

Frequently, it is necessary to combine several different experimental measurements to obtain a final result. Some operations involve addition or subtraction, and others entail multiplication or division. These operations affect the number of significant figures that should be retained in the calculated result. Suppose, for example, that a weighed sample of 8.241 g of sodium chloride is dissolved in 160.1 g of water. What will be the mass of the solution that results? It is tempting to simply write  $160.1 + 8.241 = 168.341$  g, but this is *not* correct. In saying that the mass of water is 160.1 g, we imply that there is some uncertainty about the number of tenths of a gram measured. This uncertainty must also apply to the sum of the masses, so the last two digits in the sum are not significant and should be *rounded off*, leaving 168.3 as the final result.

*Following addition or subtraction, round off the result to the leftmost decimal place that contained an uncertain digit in the original numbers.*

Rounding off is a straightforward operation. It consists of first discarding the digits that are not significant and then adjusting the last remaining digit. If the first discarded digit is less than 5, the remaining digits are left as they are (for example, 168.341 is rounded down to 168.3 because the first discarded digit, 4, is less than 5). If the first discarded digit is greater than 5, or if it is equal to 5 and is followed by one or more nonzero digits, then the last digit is increased by 1 (for example, 168.364 and 168.3503 both become 168.4 when rounded off to four digits). Finally, if the first digit discarded is 5 and all subsequent digits are zeros, the last digit remaining is rounded to the nearest even digit (for example, both 168.35 and 168.45 would be rounded to 168.4). This last rule is chosen so that, on the average, as many numbers are rounded up as down. Other conventions are sometimes used.

In multiplication or division it is not the number of decimal places that matters (as in addition or subtraction) but the number of significant figures in the

least precisely known quantity. Suppose, for example, the measured volume of a sample is  $4.34 \text{ cm}^3$  and its mass is  $8.241 \text{ g}$ . The density, found by dividing the mass by the volume on a calculator, for example, is

$$\frac{8.241 \text{ g}}{4.34 \text{ cm}^3} = 1.89884 \dots \text{ g cm}^{-3}$$

How many significant figures should we report? Because the volume is the less precisely known quantity (three significant figures as opposed to four for the mass), it controls the precision that may properly be reported in the answer. Only three significant figures are justified, so the result is rounded to  $1.90 \text{ g cm}^{-3}$ .

*The number of significant figures in the result of a multiplication or division is the smallest of the numbers of significant figures used as input.*

It is best to carry out the arithmetical operations and *then* round the final answer to the correct number of significant figures, rather than round off the input data first. The difference is usually small, but this recommendation is nevertheless worth following. For example, the correct way to add the three distances  $15 \text{ m}$ ,  $6.6 \text{ m}$ , and  $12.6 \text{ m}$  is

$$\begin{array}{r} 15 \text{ m} \\ + 6.6 \text{ m} \\ + \underline{12.6 \text{ m}} \\ \hline 34.2 \text{ m} \longrightarrow 34 \text{ m} \end{array} \quad \text{rather than} \quad \begin{array}{r} 15 \text{ m} \longrightarrow 15 \text{ m} \\ 6.6 \text{ m} \longrightarrow 7 \text{ m} \\ 12.6 \text{ m} \longrightarrow \underline{13 \text{ m}} \\ \hline 35 \text{ m} \end{array}$$

For the same reason, we frequently carry extra digits through the intermediate steps of a worked example and round off only for the final answer. If a calculation is done entirely on a scientific calculator or a computer, several extra digits are usually carried along automatically. Before the final answer is reported, however, it is important to round off to the proper number of significant figures.

Sometimes pure constants appear in expressions. In this case the accuracy of the result is determined by the accuracy of the other factors. The uncertainty in the volume of a sphere,  $\frac{4}{3}\pi r^3$ , depends only on the uncertainty in the radius  $r$ ;  $4$  and  $3$  are pure constants ( $4.000 \dots$  and  $3.000 \dots$ , respectively), and  $\pi$  can be given to as many significant figures ( $3.14159265 \dots$ ) as are warranted by the radius.

## PROBLEMS

Answers to problems whose numbers are red appear in Appendix G.

### A.1 Scientific Notation

- Express the following in scientific notation.
  - 0.0000582
  - 402
  - 7.93
  - 6593.00
  - 0.002530
  - 1.47
- Express the following in scientific notation.
  - 4579
  - 0.05020
  - 2134.560
  - 3.825
  - 0.0000450
  - 9.814
- Convert the following from scientific notation to decimal form.
  - $5.37 \times 10^{-4}$
  - $9.390 \times 10^6$
  - $-2.47 \times 10^{-3}$
  - $6.020 \times 10^{-3}$
  - $2 \times 10^4$
- Convert the following from scientific notation to decimal form.
  - $3.333 \times 10^{-3}$
  - $-1.20 \times 10^7$
  - $2.79 \times 10^{-5}$
  - $3 \times 10^1$
  - $6.700 \times 10^{-2}$

- A certain chemical plant produces  $7.46 \times 10^8$  kg of polyethylene in one year. Express this amount in decimal form.
- A microorganism contains 0.0000046 g of vanadium. Express this amount in scientific notation.

### A.2 Experimental Error

- A group of students took turns using a laboratory balance to weigh the water contained in a beaker. The results they reported were 111.42 g, 111.67 g, 111.21 g, 135.64 g, 111.02 g, 111.29 g, and 111.42 g.
  - Should any of the data be excluded before the average is calculated?
  - From the remaining measurements, calculate the average value of the mass of the water in the beaker.
  - Calculate the standard deviation  $\sigma$  and, from it, the 95% confidence limit.
- By measuring the sides of a small box, a group of students made the following estimates for its volume: 544 cm<sup>3</sup>, 590 cm<sup>3</sup>, 523 cm<sup>3</sup>, 560 cm<sup>3</sup>, 519 cm<sup>3</sup>, 570 cm<sup>3</sup>, and 578 cm<sup>3</sup>.
  - Should any of the data be excluded before the average is calculated?
  - Calculate the average value of the volume of the box from the remaining measurements.
  - Calculate the standard deviation  $\sigma$  and, from it, the 90% confidence limit.
- Of the measurements in problems 7 and 8, which is more precise?
- A more accurate determination of the mass in problem 7 (using a better balance) gives the value 104.67 g, and an accurate determination of the volume in problem 8 gives the value 553 cm<sup>3</sup>. Which of the two measurements in problems 7 and 8 is more accurate, in the sense of having the smaller systematic error relative to the actual value?

**A.3 Significant Figures**

- 11.** State the number of significant figures in each of the following measurements.
- 13.604 L
  - $-0.00345^{\circ}\text{C}$
  - 340 lb
  - $3.40 \times 10^2$  miles
  - $6.248 \times 10^{-27}$  J
- 12.** State the number of significant figures in each of the following measurements.
- $-0.0025$  in
  - 7000 g
  - 143.7902 s
  - $2.670 \times 10^7$  Pa
  - $2.05 \times 10^{-19}$  J
- 13.** Round off each of the measurements in problem 11 to two significant figures.
- 14.** Round off each of the measurements in problem 12 to two significant figures.
- 15.** Round off the measured number 2,997,215.548 to nine significant digits.
- 16.** Round off the measured number in problem 15 to eight, seven, six, five, four, three, two, and one significant digits.
- 17.** Express the results of the following additions and subtractions to the proper number of significant figures. All of the numbers are measured quantities.
- $67.314 + 8.63 - 243.198 =$
  - $4.31 + 64 + 7.19 =$
  - $3.1256 \times 10^{15} - 4.631 \times 10^{13} =$
  - $2.41 \times 10^{-26} - 7.83 \times 10^{-25} =$
- 18.** Express the results of the following additions and subtractions to the proper number of significant figures. All of the numbers are measured quantities.
- $245.876 + 4.65 + 0.3678 =$
  - $798.36 - 1005.7 + 129.652 =$
  - $7.98 \times 10^{17} + 6.472 \times 10^{19} =$
  - $(4.32 \times 10^{-15}) + (6.257 \times 10^{-14}) - (2.136 \times 10^{-13}) =$
- 19.** Express the results of the following multiplications and divisions to the proper number of significant figures. All of the numbers are measured quantities.
- $\frac{-72.415}{8.62} =$
  - $52.814 \times 0.00279 =$
  - $(7.023 \times 10^{14}) \times (4.62 \times 10^{-27}) =$
  - $\frac{4.3 \times 10^{-12}}{9.632 \times 10^{-26}} =$
- 20.** Express the results of the following multiplications and divisions to the proper number of significant figures. All of the numbers are measured quantities.
- $129.587 \times 32.33 =$
  - $\frac{4.7791}{3.21 \times 5.793} =$
  - $\frac{10566.9}{3.584 \times 10^{29}} =$
  - $(5.247 \times 10^{13}) \times (1.3 \times 10^{-17}) =$
- 21.** Compute the area of a triangle (according to the formula  $A = \frac{1}{2}ba$ ) if its base and altitude are measured to equal 42.07 cm and 16.0 cm, respectively. Justify the number of significant figures in the answer.
- 22.** An inch is defined as exactly 2.54 cm. The length of a table is measured as 505.16 cm. Compute the length of the table in inches. Justify the number of significant figures in the answer.

# SI Units, Unit Conversions, and Physics for General Chemistry

This appendix reviews essential concepts of physics, as well as systems of units of measure, essential for work in general chemistry.

## B.1 SI Units and Unit Conversions

Scientific work requires measurement of quantities or properties observed in the laboratory. Results are expressed not as pure numbers but rather as **dimensions** that reflect the nature of the property under study. For example, mass, time, length, area, volume, energy, and temperature are fundamentally distinct quantities, each of which is characterized by its unique dimension. The magnitude of each dimensioned quantity can be expressed in various *units* (for example, feet or centimeters for length). Several systems of units are available for use, and facility at conversion among them is essential for scientific work. Over the course of history, different countries evolved different sets of units to express length, mass, and many other physical dimensions. Gradually, these diverse sets of units are being replaced by international standards that facilitate comparison of measurements made in different localities and that help avoid complications and confusion. The unified system of units recommended by international agreement is called SI, which stands for “Système International d’Unités,” or the International System of Units. In this section we outline the use of SI units and discuss interconversions with other systems of units.

The SI uses seven *base units*, which are listed in Table B.1. All other units can be written as combinations of the base units. In writing the units for a measurement, we abbreviate them (see Table B.1), and we use exponential notation to denote the power to which a unit is raised; a minus sign appears in the exponent when the unit is in the denominator. For example, velocity is a quantity with dimensions of length divided by time, so in SI it is expressed in meters per

**TABLE B.1**

Base Units in the International System of Units

Quantity	Unit	Symbol
Length	meter	m
Mass	kilogram	kg
Time	second	s
Temperature	kelvin	K
Number of moles (of substance)	mole	mol
Electric current	ampere	A
Luminous intensity	candela	cd

TABLE B.2

## Derived Units in SI

Quantity	Unit	Symbol	Definition
Energy	joule	J	$\text{kg m}^2 \text{s}^{-2}$
Force	newton	N	$\text{kg m s}^{-2} = \text{J m}^{-1}$
Power	watt	W	$\text{kg m}^2 \text{s}^{-3} = \text{J s}^{-1}$
Pressure	pascal	Pa	$\text{kg m}^{-1} \text{s}^{-2} = \text{N m}^{-2}$
Electric charge	coulomb	C	A s
Electric potential difference	volt	V	$\text{kg m}^2 \text{s}^{-3} \text{A}^{-1} = \text{J C}^{-1}$

second, or  $\text{m s}^{-1}$ . Some derived units that are used frequently have special names. Energy, for example, is the product of mass and the square of the velocity. Therefore, it is measured in units of kilogram square meters per square seconds ( $\text{kg m}^2 \text{s}^{-2}$ ), and  $1 \text{ kg m}^2 \text{s}^{-2}$  is called a *joule*. Other derived units, such as the pascal for measuring pressure, appear in Table B.2. Although these names provide a useful shorthand, it is important to remember their meanings in terms of the base units.

Because scientists work on scales ranging from the microscopic to the astronomical, there is a tremendous range in the magnitudes of measured quantities. Consequently, a set of **prefixes** has been incorporated into the International System of Units to simplify the description of small and large quantities (Table B.3). The prefixes specify various powers of 10 times the base and derived units. Some of them are quite familiar in everyday use: the kilometer, for example, is  $10^3 \text{ m}$ . Others may sound less familiar—for instance, the femtosecond ( $1 \text{ fs} = 10^{-15} \text{ s}$ ) or the gigapascal ( $1 \text{ GPa} = 10^9 \text{ Pa}$ ).

In addition to base and derived SI units, several units that are not officially sanctioned are used in this book. The first is the liter (abbreviated L), a very convenient size for volume measurements in chemistry; a liter is  $10^{-3} \text{ m}^3$ , or 1 cubic decimeter ( $\text{dm}^3$ ):

$$1 \text{ L} = 1 \text{ dm}^3 = 10^{-3} \text{ m}^3 = 10^3 \text{ cm}^3$$

Second, we use the *angstrom* (abbreviated Å) as a unit of length for atoms and molecules:

$$1 \text{ Å} = 10^{-10} \text{ m} = 100 \text{ pm} = 0.1 \text{ nm}$$

TABLE B.3

## Prefixes in SI

Fraction	Prefix	Symbol	Factor	Prefix	Symbol
$10^{-1}$	<i>deci-</i>	d	10	<i>deca-</i>	da
$10^{-2}$	<i>centi-</i>	c	$10^2$	<i>hecto-</i>	h
$10^{-3}$	<i>milli-</i>	m	$10^3$	<i>kilo-</i>	k
$10^{-6}$	<i>micro-</i>	$\mu$	$10^6$	<i>mega-</i>	M
$10^{-9}$	<i>nano-</i>	n	$10^9$	<i>giga-</i>	G
$10^{-12}$	<i>pico-</i>	p	$10^{12}$	<i>tera-</i>	T
$10^{-15}$	<i>femto-</i>	f			
$10^{-18}$	<i>atto-</i>	a			

This unit is used simply because most atomic sizes and chemical bond lengths fall in the range of one to several angstroms, and the use of either picometers or nanometers is slightly awkward. Next, we use the *atmosphere* (abbreviated atm) as a unit of pressure. It is not a simple power of 10 times the SI unit of the pascal, but rather is defined as follows:

$$1 \text{ atm} = 101,325 \text{ Pa} = 0.101325 \text{ MPa}$$

This unit is used because most chemistry procedures are carried out at pressures near atmospheric pressure, for which the pascal is too small a unit to be convenient. In addition, expressions for equilibrium constants (see Chapter 14) are simplified when pressures are expressed in atmospheres.

The non-SI temperature units require special mention. The two most important temperature scales in the United States are the Fahrenheit scale and the Celsius scale, which employ the Fahrenheit degree ( $^{\circ}\text{F}$ ) and the Celsius degree ( $^{\circ}\text{C}$ ), respectively. The *size* of the Celsius degree is the same as that of the SI temperature unit, the kelvin, but the two scales are shifted relative to each other by  $273.15^{\circ}\text{C}$ :

$$T_{\text{K}} = \frac{1 \text{ K}}{1^{\circ}\text{C}}(t^{\circ}\text{C}) + 273.15 \text{ K}$$

The size of the degree Fahrenheit is  $\frac{5}{9}$  the size of the Celsius degree. The two scales are related by

$$t^{\circ}\text{C} = \frac{5^{\circ}\text{C}}{9^{\circ}\text{F}}(t^{\circ}\text{F} - 32^{\circ}\text{F}) \quad \text{or} \quad t^{\circ}\text{F} = \frac{9^{\circ}\text{F}}{5^{\circ}\text{C}}(t^{\circ}\text{C}) + 32^{\circ}\text{F}$$

The advantage of a unified system of units is that if all the quantities in a calculation are expressed in SI units, the final result must come out in SI units. Nevertheless, it is important to become familiar with the ways in which units are interconverted because units other than SI base units often appear in calculations. The *unit conversion method* provides a systematic approach to this problem.

As a simple example, suppose the mass of a sample is measured to be 64.3 g. If this is to be used in a formula involving SI units, it should be converted to kilograms (the SI base unit of mass). To do this, we use the fact that  $1 \text{ kg} = 1000 \text{ g}$  and write

$$\frac{64.3 \text{ g}}{1000 \text{ g kg}^{-1}} = 0.0643 \text{ kg}$$

Note that this is, in effect, division by 1; because  $1000 \text{ g} = 1 \text{ kg}$ ,  $1000 \text{ g kg}^{-1} = 1$ , and we cancel units between numerator and denominator to obtain the final result. This unit conversion could also be written as

$$64.3 \text{ g} \left( \frac{1 \text{ kg}}{1000 \text{ g}} \right) = 0.0643 \text{ kg}$$

In this book we use the more compact first version of the unit conversion. Instead of *dividing* by  $1000 \text{ g kg}^{-1}$ , we can equally well *multiply* by  $1 = 10^{-3} \text{ kg g}^{-1}$ :

$$(64.3 \text{ g})(10^{-3} \text{ kg g}^{-1}) = 0.0643 \text{ kg}$$

Other unit conversions may involve more than just powers of 10, but they are equally easy to carry out. For example, to express 16.4 inches in meters, we use the fact that  $1 \text{ inch} = 0.0254 \text{ m}$  (or  $1 = 0.0254 \text{ m inch}^{-1}$ ), so

$$(16.4 \text{ inches})(0.0254 \text{ m inch}^{-1}) = 0.417 \text{ m}$$

More complicated combinations are possible. For example, to convert from liter-atmospheres to joules (the SI unit of energy), two separate unit conversions are used:

$$\begin{aligned}(1 \text{ L atm})(10^{-3} \text{ m}^3 \text{ L}^{-1})(101,325 \text{ Pa atm}^{-1}) &= 101.325 \text{ kg m}^2 \text{ s}^{-2} \\ &= 101.325 \text{ Pa m}^3 = 101.325 \text{ J}\end{aligned}$$

When doing chemical calculations, it is very important to write out units explicitly and cancel units in intermediate steps to obtain the correct units for the final result. This practice is a way of checking to make sure that units have not been incorrectly mixed without unit conversions or that an incorrect formula has not been used. If a result that is supposed to be a temperature comes out with units of  $\text{m}^3 \text{ s}^{-2}$ , then a mistake has been made!

## B.2 Background in Physics

Although physics and chemistry are distinct sciences with distinct objectives and methods of investigation, concepts from one can aid investigations in the other. Physical reasoning aids chemical understanding in cases where applied forces move chemical systems to new positions—or change their sizes and shapes—and change their energy. These energy changes can have chemical consequences, as shown in two specific examples. First, the total energy content of a system increases when the system is compressed by externally applied pressure (if the system is thermally isolated). Second, when significant forces exist between molecules, the mutual energy of a pair of molecules changes as the molecules are pushed closer together. Intermolecular forces profoundly influence the organization of matter into solid, liquid, and gaseous states, as well as the effectiveness of molecular collisions in causing chemical reactions. Specific illustrations appear at many places in this book. This section reviews general aspects of motion, forces, and energy as background for these specific applications. For simplicity, we limit the discussion to a *point mass*, which is an object characterized only by its total mass  $m$ . We do not inquire into the internal structure of the object. In various contexts, we represent planets, projectiles, molecules, atoms, nuclei, or electrons by this model to predict their response to applied forces.

### B.2.1 Describing the Motion of an Object: Speed, Velocity, Momentum, and Acceleration

If you are not already familiar with taking the derivative  $df/dx$  of a function  $f(x)$ , read Appendix C.4 before reading on in this section. Likewise, if you are not familiar with a vector  $\vec{v}$  and how to write it in terms of its components  $v_x$  and  $v_y$ , read Appendix C.7 before reading on in this section.

Let's do some examples of the motion of a ball to familiarize you with a bit of physics, and how vectors (Appendix C.7) and derivatives of functions (Appendix C.4) are used to solve simple physical problems. We'll start with motion in a straight line. You are surely familiar with speed = (distance traveled)/(time spent traveling). Imagine standing at  $x = 2$  ft of a Cartesian coordinate system and rolling a ball towards your friend, who is standing at  $x = 17.4$  ft (a positive coordinate, so your friend is in the  $+x$  direction). You could easily calculate the speed you'd have to roll the ball in order for it to reach your friend in 3.5 seconds (if it did not slow down en route). That would be speed =  $(x_f - x_i)/\Delta t = (17.4 \text{ ft} - 2.0 \text{ ft})/(3.5 \text{ s}) = (15.4 \text{ ft})/(3.5 \text{ s}) = 4.4 \text{ ft s}^{-1} = 3 \text{ miles per hour}$ . If

your friend were standing at the position  $x = -13.4$  ft (at a position on the negative side of the  $x$ -axis), you could do the same calculation, but you would not write speed  $= (x_f - x_i)/\Delta t = (-13.4 \text{ ft} - 2 \text{ ft})/(3.5 \text{ s})$  or you would get a negative speed! So the distance traveled is not  $x_f - x_i$ ; that is called the *displacement* of the ball, or its change in position on the  $x$ -axis, and it is negative. The distance traveled is the magnitude of  $(x_f - x_i)$ , or the absolute value of  $x_f - x_i$ ,  $|x_f - x_i|$ . But you have lost some information in this calculation, as you know you have to roll the ball in the  $-x$  direction if you are standing at  $x = 2$  ft and your friend is standing at  $x = -13.4$  ft. In an instance like this, when the quantity you are interested in has both magnitude (the speed of the ball) and direction (you must roll it in the  $-x$  direction), vectors become useful! The next paragraph describes velocity vectors.

To describe the direction of travel, let's write the **velocity** of the ball as  $\vec{v} = (v_x, v_y)$ , where  $v_x$  is called the  $x$ -component of the velocity and  $v_y$  is called the  $y$ -component of the velocity, and show the speed is the length of the velocity vector. If you point the  $y$ -axis of your coordinate system straight upwards, then of course the  $y$ -component of the velocity is 0 since you are rolling the ball on a level field in the  $-x$  direction. The  $x$  component of the velocity  $v_x = (x_f - x_i)/\Delta t = (-13.4 \text{ ft} - 2 \text{ ft})/(3.5 \text{ s}) = -4.4 \text{ ft s}^{-1} = -3$  miles per hour. Instead of writing  $\vec{v} = (v_x, v_y) = (-4.4 \text{ ft s}^{-1}, 0)$ , you could alternatively write  $\vec{v} = v_x \hat{i} + v_y \hat{j} = (-4.4 \text{ ft s}^{-1})\hat{i} + 0\hat{j} = (-4.4 \text{ ft s}^{-1})\hat{i}$ , where  $\hat{i}$  is the unit vector (1,0) in Cartesian coordinate space. Either way of writing the velocity  $\vec{v}$  shows a negative value for  $v_x$ , indicating that it is traveling in the negative direction along the  $x$ -axis, towards your friend at  $x = -13.4$  ft, and the speed is simply  $|\vec{v}| = \text{length of the velocity vector } \vec{v}$ . (Note: In this text we use single bars  $|\vec{v}|$  to indicate the length of a vector, and the absolute value of a scalar.) By the Pythagorean theorem,

$$\text{speed} = \text{length of the velocity vector } \vec{v} = |\vec{v}| = \sqrt{(v_x)^2 + (v_y)^2}$$

Now, if the ball is slowing down en route, you have to distinguish between the instantaneous speed and the **average speed**, and the instantaneous velocity and the **average velocity**. They are equal only if the ball maintains the same speed throughout, and does not change direction. Generalizing the above example to the possibility that either the speed or the direction of travel might change, the *x-component of the velocity* and the *y-component of the velocity* are, more generally,

$$v_x = \frac{dx}{dt} \quad \text{and} \quad v_y = \frac{dy}{dt}$$

If you start your ball at  $x_i = 2$  ft and impart it with an  $x$ -component of the velocity of  $-4.4 \text{ ft s}^{-1}$ , you can calculate the final position of the ball after 3.5 seconds by integrating the above expressions:

$$\int_{x_i}^{x_f} dx = \int_{t=0}^{t=3.5 \text{ s}} v_x dt \quad \text{and} \quad \int_{y_i}^{y_f} dy = \int_{t=0}^{t=3.5 \text{ s}} v_y dt$$

$$x_f - x_i = \int_{t=0}^{t=3.5 \text{ s}} v_x dt \quad \text{and} \quad y_f - y_i = \int_{t=0}^{t=3.5 \text{ s}} v_y dt$$

Using  $v_x = -4.4 \text{ ft s}^{-1}$  and the initial position of the ball at  $x_i = 2$  ft gives  $x_f = 2 \text{ ft} + \int_{t=0}^{t=3.5 \text{ s}} (-4.4 \text{ ft s}^{-1}) dt = 2 \text{ ft} + (-4.4 \text{ ft s}^{-1})(3.5 \text{ s}) = -13.4 \text{ ft}$ , so the ball reaches your friend standing at  $x = -13.4$  in 3.5 seconds. If  $v_x$  were changing en route, you'd have to insert the functional form of  $v_x(t)$  in the integral expression above to get the correct answer.

You are already familiar with accelerating or decelerating your car, that is, changing the speed of your car. But in chemistry and physics problems we have to be a bit more careful and talk about a change in velocity, not just a change in speed. Thus we define the **acceleration**  $\vec{a}$  as a vector, because you can change a velocity vector either by changing its length (the speed) or by changing its direction. Just like the velocity vector, the acceleration vector has components, so you can write  $\vec{a} = (a_x, a_y)$  where

$$a_x = \frac{dv_x}{dt} \quad \text{and} \quad a_y = \frac{dv_y}{dt}$$

Finally, we define the **linear momentum** of an object of mass  $m$  as  $\vec{p} = m\vec{v}$ , so the momentum has components  $p_x = mv_x$  and  $p_y = mv_y$ . You are already familiar with conservation of momentum. Imagine a 100-lb female ice skater (call her particle A) pushing away from a 200-lb male ice skater (call him particle B) from a stationary initial position. If she is imparted an  $x$ -component of velocity  $v_{x,A} = 6$  mph, his speed would be slower, 3 miles per hour, and he would be pushed in the opposite direction, so his  $v_{x,B} = -3$  mph. This reflects the law of *conservation of momentum*. Because initially neither were moving  $p_{x,\text{initial}} = 0$  and at the end, after they have pushed back from one another, the sum of their two momenta is  $p_{x,\text{final}} = p_{x,\text{final},A} + p_{x,\text{final},B} = m_A v_{x,\text{final},A} + m_B v_{x,\text{final},B} = (100 \text{ lb})(6 \text{ mph}) + (200 \text{ lb})(-3 \text{ mph})$ , which sums to 0, so the total momentum is unchanged. As long as there are no external forces (see the next section) on these two ice skaters, the vector sum (adding by components, see Appendix C.7) of their momenta will be conserved.

Generalizing the definition of velocity  $\vec{v}$ , acceleration  $\vec{a}$ , and linear momentum  $\vec{p}$  to three dimensions  $x$ ,  $y$ , and  $z$  is easy. For example, in three dimensions the velocity vector  $\vec{v} = (v_x, v_y, v_z)$ , and its length, the speed, =  $\sqrt{(v_x)^2 + (v_y)^2 + (v_z)^2}$ .

## B.2.2 Forces Change the Motion of an Object

Force is defined as the agent that changes the motion of an object; a force (push or pull on an object) has both magnitude and direction, so is given the vector symbol  $\vec{F}$ . This restatement of our daily experience that pushing or pulling an object causes it to move is the basis of Sir Isaac Newton's first law of motion:

*Every object persists in a state of rest or of uniform motion in a straight line unless compelled to change that state by forces impressed upon it.*

We determine the properties of a force experimentally in the laboratory by measuring the consequences of applying the force. Suppose we have arbitrarily selected a standard test object of known mass  $m_1$ . We apply a force  $\vec{F}_1$  and, by making the distance and time measurements described earlier, determine the acceleration  $\vec{a}_1$  imparted to the object by the force. Experience shows that a different force imparts different acceleration to the test object. Forces can be ranked by the magnitude of the acceleration they impart to the standard test object. Now suppose we choose a second test object of mass  $m_2$ . Applying the original force  $\vec{F}_1$  to this object, so the force on object 2,  $\vec{F}_2$ , is equal to the force you had previously exerted on object 1,  $\vec{F}_1$ , produces an acceleration of object 2,  $\vec{a}_2$ , which is different in magnitude from the acceleration  $\vec{a}_1$  that it gave to the first test object. The less massive object has a larger magnitude acceleration. The results of such experiments are summarized in Newton's second law of motion:

*The acceleration imparted to an object by an applied force has magnitude proportional to the magnitude of the force, is parallel to the direction of the force, and is inversely proportional to the mass of the object.*

In mathematical form this statement becomes

$$\vec{F} = m\vec{a} \quad \text{or} \quad \vec{a} = \vec{F}/m$$

This equation demonstrates that force must have dimensions of  $M L t^{-2}$  (mass  $\times$  distance  $\times$  time $^{-2}$ ). In SI units, force is expressed in newtons (N) where  $1 \text{ N} = 1 \text{ kg m s}^{-2}$ . If you exert the same magnitude and direction of force on a child ice skater, of small mass, and on your heavy spouse, the child will experience a larger magnitude acceleration.

One familiar example is the force caused by gravity at the surface of the earth. Measurements show this force produces a downward acceleration (toward the center of the earth) of constant magnitude  $9.80665 \text{ m s}^{-2}$ , conventionally denoted by  $g$ , the gravitational constant. The magnitude of gravitational force exerted on a body of mass  $m$  is (writing the symbol  $F$  for the magnitude of the force  $\vec{F}$ )

$$F = mg$$

Another familiar example is the restoring force exerted on an object by a spring. In chemistry this is a useful model of the binding forces that keep atoms together in a chemical bond or near their “home” positions in a solid crystal. Imagine an object of mass  $m$  located on a smooth tabletop. The object is connected to one end of a coiled metallic spring; the other end of the spring is anchored to a post in the tabletop. At rest, the object is located at position  $x_0$ . Make your  $x$ -axis have its origin at the post and be directed toward the mass when it is at its rest position, so  $x_0$  is a positive number. When  $x > x_0$ , the spring is stretched. When  $x < x_0$ , the spring is compressed. Now suppose the object is pulled away from the post in a straight line to a new position  $x$  beyond  $x_0$  so the spring is stretched. Measurements show that at the stretched position  $x$  the magnitude of the  $x$ -component of the force exerted on the object by the spring is directly proportional to the magnitude of the displacement from the rest position:

$$|F_x| = k|(x - x_0)|$$

where the vertical bars around  $F_x$  and  $(x - x_0)$  represent the magnitude or absolute value of each. In the preceding equation,  $k$  is a positive constant whose magnitude must be determined empirically in each case studied. Clearly, this force is directed back toward the rest position, and when the object is released, the recoiling spring accelerates the object back toward the rest position. When the object is displaced in the  $+x$  direction from the rest position, so  $x - x_0$  is positive, the restoring force points in the  $-x$  direction; the  $x$ -component of the force is negative. Thus there is a minus sign in the equation for  $F_x$ , the  $x$ -component of the force

$$F_x = -k(x - x_0)$$

You can see that when the position of the mass is closer to the post (at the origin) than the rest position,  $x < x_0$ , the equation above is the product of a negative number,  $-k$ , and another negative number,  $x - x_0$ , so  $F_x$  has a positive value and the mass is pushed in the  $+x$  direction. This is again towards its rest position, as the present position of the mass is closer to the origin than its rest position. When studying the dependence of force on position, we must pay careful attention to the coordinate system. The force and the acceleration at any point are parallel to each other, but the position of the particle (defined relative to some convenient origin of coordinates in each particular case) may point in a different direction. In applications concerned with the height of an object above the earth, the  $y$ -component of gravitational force is usually written as

$$F_y = -mg$$

to emphasize that the vertical displacement  $y$  is positive and pointing away from the surface of the earth, while the gravitational force is clearly directed toward the earth.

Once a force has been determined, the motion of the object under that force can be predicted from Newton's second law. If the  $x$ -component of the force,  $F_x$ , is constant then the  $x$ -component of the acceleration will also be constant. If the object was initially at rest at time  $t = t_1$  (so  $v_x(t_1) = 0$ ) and then is accelerated for a period of time starting at  $t_1$  and ending at  $t_2$ , the  $x$ -component of the velocity at  $t_2$  is given by

$$v_x(t_2) = a_x \Delta t + v_x(t_1) = a_x \Delta t$$

where  $\Delta t = t_2 - t_1$ . The position at  $t_2$  is given by

$$x(t_2) = x(t_1) + \frac{1}{2} a_x (t_2 - t_1)^2$$

if the particle is initially at rest.

If the force depends on position, predicting the motion is slightly more complicated. One must then consider the instantaneous values of each component of the acceleration. For the  $x$ -component of the acceleration,

$$a_x = \frac{dv_x}{dt} \text{ which gives } v_x(t_2) = v_x(t_1) + \int_{t_1}^{t_2} a_x dt$$

You can see that you recover the simpler expressions above if  $a_x$  is a constant (because  $F_x$  is constant) and if  $v_x(t_1) = 0$ . However, when the acceleration is not constant, such as in the case of a mass attached to a spring, this gives a different result. Using  $F_x = -k(x - x_0)$  gives a motion in which the object oscillates about the rest position  $x_0$  with a period  $\tau$  given by

$$\frac{1}{\tau} = \frac{1}{2\pi} \left( \frac{k}{m} \right)^{1/2}$$

The frequency  $\nu$  of the oscillation (the number of cycles per unit time) is given by  $\nu = \tau^{-1}$ . If we represent the motion in terms of the angular frequency  $\omega = 2\pi\nu$ , which has dimensions radians  $s^{-1}$ , the position of the oscillating object is given by

$$x(t) - x_0 = A \cos(\omega t + \delta)$$

where the amplitude  $A$  and the phase factor  $\delta$  are determined by the initial position and velocity of the object.

### B.2.3 Forms of Energy

The concept of **energy** originated in the science of mechanics and was first defined as the capacity to perform work, that is, to move an object from one position to another. It is now understood that energy appears in many different forms, each of which can cause particular kinds of physical and chemical changes. From daily experience, we recognize the kinetic energy due to the speed of an onrushing automobile. To stop the automobile, its *kinetic energy* must be overcome by work performed by its brakes. Otherwise, the automobile will crash into other objects and expend its kinetic energy by deforming these objects, as well as itself. The *potential energy* of a mass of snow on a ski slope becomes the kinetic energy of an avalanche. The *electrical energy* stored in a battery can move objects by driving motors, or warm objects through electric heaters. The chemical energy stored in gasoline can move objects by powering an internal combustion engine. The *thermal energy* of hot steam can move objects by driving a steam engine.

Each of these forms of energy plays a role in chemistry, and each is described at the appropriate point in this textbook. Here we concentrate on the nature of potential and kinetic energy and their interconversion. The understanding we gain here is essential background for understanding these other forms of energy.

The **kinetic energy** of a moving object is defined by

$$\mathcal{T} = \frac{1}{2}mv^2$$

where  $m$  is the mass of the object and  $v$  is its speed. A stationary object has no kinetic energy. In the SI systems of units (see Appendix B.1), energy is expressed in joules (J). Thus, 0.5 joule is the kinetic energy of an object with mass 1 kg moving at a speed of 1 m s<sup>-1</sup>. Experience shows that applying a force to a moving object changes the kinetic energy of the object. If the force is applied in the same direction as the velocity of the object, the kinetic energy is increased; if the force is opposed to the velocity, the kinetic energy is decreased.

**Potential energy** is the energy stored in an object due to its location relative to a specified reference position. Potential energy therefore depends explicitly on the position  $x$  of the object and is expressed as a mathematical function  $V(x)$ . The change in potential energy when an object is moved from position  $x_1$  to position  $x_2$  by a constant force is equal to the work done in moving the object:

$$\text{change in } V(x) = \text{force} \times \text{displacement} = \text{force} \times (x_2 - x_1)$$

To lift an object of mass  $m$  from the surface of the earth to the height  $h$ , some agency must perform work in the amount  $mgh$  against the downward-directed force of gravity, which has constant magnitude acceleration denoted by  $g$ . The change in potential energy is  $mgh$ . Potential energy is expressed in joules in the SI system of units.

## B.2.4 Conservation of Energy

The science of mechanics deals with idealized motions of objects in which friction does not occur. The motions of an object interconvert its potential and kinetic energy subject to the restriction that their sum always remains constant. For example, consider a soccer ball rolling down the side of a steep gully at the edge of the playing field, and assume there is no friction between the ball and the surface on which it rolls. The ball rolls down one side, goes across the bottom, climbs partway up the opposite side, then stops and reverses direction. This pattern is repeated many times as the ball continues to oscillate back and forth across the bottom of the gully. On each downward leg of its journey, the ball loses potential energy and gains kinetic energy, but their sum remains constant. On each upward leg, the ball loses kinetic energy and gains potential energy, but their sum remains constant.

The description in the previous paragraph is clearly an idealization, because eventually the ball comes to rest at the bottom of the gully. In reality, the ball loses some of its kinetic energy through friction with the surface of the gully on each upward leg and on each downward leg of its journey. Both the ball and the gully surface become slightly warmer as a result. The energy lost from the purely mechanical motion is added to the *internal energy* of the ball and the gully surface. The total amount of energy has not changed; we have neither created nor destroyed energy in this process. Rather, we have identified a new mode of energy storage (called internal energy) to interpret the new effects beyond those explained by basic mechanics. Internal energy, heat, and friction are discussed in detail in Chapter 12 as part of the science of thermodynamics.

Similar arguments have extended the law of conservation of energy from the idealized motions of mechanics to include a broad variety of phenomena in which several different forms of energy are involved. This law is one of the

securest building blocks in scientific reasoning. It provides the starting point for interpreting and relating a great variety of superficially different processes. In chemistry this law provides the foundation for studying complex processes in which kinetic, potential, electrical, chemical, and thermal energy are interconverted without net loss or gain.

### B.2.5 Representing Energy Conservation by Potential Energy Curves

Consider again the soccer ball rolling down the walls of the gully. This process is shown schematically in Figure B.1, where the curve  $V(x)$  suggests a “cross-sectional” sketch of the gully. The curve  $V(x)$  actually represents the potential energy of the ball relative to its value at the bottom of the gully. The  $x$  coordinate locates the distance of the ball from the bottom of the gully to a position along its side. Suppose the ball is held in place at the position  $x_1$ . It possesses only potential energy so the total energy  $E$ , normally the sum of the kinetic energy and the potential energy  $E = 1/2 mv^2 + V(x)$  at the point  $x$ , is simply  $E = V(x_1)$ . At the point  $x = x_1$  the speed of the ball is 0 so the kinetic energy is 0. If the ball is released, it falls down the slope and passes across the bottom, where its potential energy is zero and its kinetic energy is  $E$ . It then climbs the opposite side until it rises to position  $-x_1$ , where its kinetic energy is zero. The ball promptly reverses direction and retraces its path back to position  $x_1$ , where its total energy  $E$  is all potential energy.

### B.2.6 Potential Energy Curves, Force, and Stability

One very important application of the potential energy function in this textbook is to provide a way to qualitatively predict the motion of an object without solving Newton’s second law. The method determines the direction of the force applied to an object from knowledge of the potential energy curve as shown in Figure B.1. In preparation for this method, let’s examine the potential energy curves for some familiar forces.

Let’s consider a one-dimensional problem with just one particle here. A more detailed analysis is given in Section 3.3. The value of the potential energy of a particle located at the point  $x$  is always stated relative to its value at a specially selected reference point  $x_0$ . The value  $V(x_0)$  is a constant and is usually assigned the value zero, and the point  $x_0$  is frequently selected as the origin of coordinates for specifying the location of the object.

**FIGURE B.1** Sketch of the potential energy of a soccer ball rolling down the sides of a gully. The ball is released at position  $x_1$  with total energy  $E$ . In idealized motion, it continues to oscillate back and forth across the bottom of the gully. The net force on the ball is always in the direction in which the potential energy is decreasing. In real systems there is sufficient friction between the ball and the gully to bring the ball to rest at the bottom of the gully.

In the presence of a particular  $x$ -component of the force  $F_x$ , the potential energy of the object at  $x$  is defined as the work required to move the object to  $x$  from the reference position  $x_0$ . Since the work done by a constant force in moving an object is defined as (force)  $\times$  (displacement), the definition of potential energy in mathematical terms is

$$V(x) - V(x_0) = (F)(x - x_0)$$

Note carefully that the displacement referred to in the definition of potential energy starts at  $x_0$  and ends at  $x$ . For example, the potential energy of an object of mass  $m$  at height  $h$  above the surface of the earth is the work done by a force  $+mg$  opposing gravity in lifting the object from  $h_0$  to  $h$ :

$$\begin{aligned} V(h) - V(h_0) &= mg(h - h_0) \\ &= mgh - mgh_0 \end{aligned}$$

For a variable force, the definition of potential energy becomes slightly more complicated and requires explicit use of calculus. The potential energy for the linear restoring force  $F_x = -k(x - x_0)$  is

$$V(x) = \frac{1}{2} kx^2$$

where the value  $V(x_0)$  has been set to 0 and  $x_0$  has been selected as the origin of coordinates.

It is instructive to plot these two potential energy functions as graphs (see Appendix C). The gravitational potential energy function is a straight line from the origin with slope  $mg$ , while the potential energy function for the linear restoring force is a parabola. For the parabola the potential energy of the object increases as the distance from the reference point  $x_0$  increases.

Knowledge of the potential energy curve as a function of position lets us predict the direction of the net force on the object at each position. For example in Figure B.1 the  $x$ -component of the force is a function that depends on position,  $F_x(x)$ , and the force is directed toward  $x_0 = 0$  whether  $x$  is negative or positive. From the definition of potential energy stated earlier, but using  $F$  now to represent the gravitational or restoring force, not the opposing force, we get

$$F_x = -dV(x)/dx$$

The net force drives the object toward the position where the potential energy is a minimum and its slope is zero. For both the gravitational force and the linear restoring force, the object experiences forces that attract it back toward the center of force.

The minimum of the potential energy curve shown in Figure B.1 is called a point of **stable equilibrium** because the potential energy of the object increases as it moves away from that point. As the ball tries to climb the wall on either side of the minimum, the restoring force always drives it back toward this position of stable equilibrium. This qualitative interpretation predicts that the ball will oscillate about the equilibrium position, as predicated by the exact solution to Newton's second law quoted earlier.

We use similar potential energy diagrams to represent the interaction between a pair of objects, such as Earth–moon, Earth–Mars, electron–nucleus, electron–electron, nucleus–nucleus, atom–atom, or molecule–molecule. We construct such diagrams at several points in this textbook and use them to interpret the relative motions of the pair of objects. These methods are extremely important in describing the formation of chemical bonds, the states of matter, and the role of molecular collisions in chemical reactions.

## B.2.7 Electrical Forces

The concepts summarized so far in this section also are used to describe the mutual interactions and the motions of electrically charged particles. The only new features are to identify the force that represents electrical interactions and to obtain the corresponding potential energy function. Positive and negative charges and the electrical forces between them were first quantified by Charles Coulomb late in the 18th century. In his honor the unit of charge in SI units is the **coulomb** (C). Electrical charge is fundamentally quantized in units of the magnitude of charge carried by a single electron  $e$ , which is equal to  $1.60218 \times 10^{-19}$  C. The coulomb is thus an inconveniently large unit for chemical reasoning. Nonetheless, for consistency and for quantitative accuracy, physical equations involving charge use SI units.

Suppose a charge of magnitude  $q_1$  is held at the origin of coordinates and another charge of magnitude  $q_2$  is brought near it, at the distance  $r$  from the origin. The magnitude of the acceleration imparted to the charge  $q_2$  by the charge  $q_1$  fixed at the origin can be determined as described earlier for uncharged objects. From such measurements, Coulomb determined that the magnitude of the force was directly proportional to the product of the two charges and inversely proportional to the square of the distance between them:

$$|F| = \frac{|q_1 q_2|}{4\pi\epsilon_0 r^2}$$

The force is expressed in newtons (N) and charge in coulombs (C) and the constant  $\epsilon_0$ , called the permittivity of the vacuum, is  $8.854 \times 10^{-12}$  C<sup>2</sup> J<sup>-1</sup> m<sup>-1</sup>.

Section 3.3 describes the direction of the Coulomb force in detail, so we do not repeat that discussion here. If the two particles are either both positively charged or both negatively charged, the particles feel a **repulsive force**, so the force on particle 2 is directed away from particle 1's location and the force on particle 1 is directed away from particle 2's location. If one particle has a positive charge and the other particle has a negative charge (e.g.,  $q_1 > 0$  and  $q_2 < 0$ ), the particles feel an **attractive force**, so the force on particle 2 is directed towards particle 1's location and the force on particle 1 is directed towards particle 2's location.

The **Coulomb potential energy** corresponding to this force is

$$V(r) = \frac{q_1 q_2}{4\pi\epsilon_0 r}$$

Note that the force varies as  $r^{-2}$  while the potential energy varies as  $r^{-1}$ . Note also that if the charges have the same sign,  $dV/dr$  is negative and the force between the particles is repulsive; if the charges have opposite sign,  $dV/dr$  is positive and the force between the particles is attractive. If we know the potential energy curve between two charged particles, we can predict the forces between them and their resulting motion.

The Coulomb potential energy function holds great importance in chemistry for examining the structure of atoms and molecules. In 1912, Ernest Rutherford proposed that an atom of atomic number  $Z$  comprises a dense, central nucleus of positive charge  $+Ze$  surrounded by a total of  $Z$  individual electrons, each with charge  $-e$ , moving around the nucleus. Thus, each individual electron has a potential energy of interaction with the nucleus given by

$$V(r) = -\frac{Ze^2}{4\pi\epsilon_0 r}$$

and the force between each electron and the nucleus is attractive. Rutherford's model of the atom, firmly based on experimental results, was completely at odds with the physical theories of the day. Attempts to reconcile these results with theory led to the development of the new theory called quantum mechanics.

### B.2.8 Circular Motion and Angular Momentum

An object executing uniform circular motion about a point (for example, a ball on the end of a rope being swung in circular motion) is described by position, velocity, speed, momentum, and force, just as defined earlier for objects in linear motion. It is most convenient to describe this motion in polar coordinates  $r$  and  $\theta$ , which represent, respectively, the distance of the object from the center and its angular displacement from the  $x$ -axis in ordinary Cartesian coordinates. Because  $r$  is constant for circular motion, the motion variables depend directly on  $\theta$ . The magnitude of the angular velocity during the time interval from  $t_1$  to  $t_2$  is given by

$$\omega = \left| \frac{\theta_2 - \theta_1}{t_2 - t_1} \right|$$

for small changes in the angle  $\theta$ . The angular acceleration is given by the rate of change of the angular velocity  $\bar{\omega}$ . In linear motion, we are concerned with the momentum  $p_x = mv_x$  of an object as it heads toward a particular point; the linear momentum measures the impact that the object can transfer in a collision as it arrives at the point. To extend this concept to circular motion, we define the magnitude of the **angular momentum** of an object as it revolves around a point as  $L = mvr$  in the special case of uniform circular motion where the vector  $\vec{r}$ , with length  $r$ , is perpendicular to the velocity vector  $\vec{v}$ , with constant speed  $v$  (see Fig. 3.5 in Chapter 3). The angular momentum of an electron around a nucleus is a crucial feature of atomic structure, which is discussed in Chapter 5.

**PROBLEMS**

Answers to problems whose numbers are red appear in Appendix G.

**B.1 SI Units and Unit Conversions**

- Rewrite the following in scientific notation, using only the base units of Table B.1, without prefixes.
  - 65.2 nanograms
  - 88 picoseconds
  - 5.4 terawatts
  - 17 kilovolts
- Rewrite the following in scientific notation, using only the base units of Table B.1, without prefixes.
  - 66  $\mu\text{K}$
  - 15.9 MJ
  - 0.13 mg
  - 62 GPa
- Express the following temperatures in degrees Celsius.
  - 9001°F
  - 98.6°F (the normal body temperature of human beings)
  - 20°F above the boiling point of water at 1 atm pressure
  - 40°F
- Express the following temperatures in degrees Fahrenheit.
  - 5000°C
  - 40.0°C
  - 212°C
  - 40°C
- Express the temperatures given in problem 3 in kelvins.
- Express the temperatures given in problem 4 in kelvins.
- Express the following in SI units, either base or derived.
  - 55.0 miles per hour (1 mile = 1609.344 m)
  - 1.15  $\text{g cm}^{-3}$
  - $1.6 \times 10^{-19} \text{ C } \text{\AA}$
  - 0.15  $\text{mol L}^{-1}$
  - $5.7 \times 10^3 \text{ L atm day}^{-1}$
- Express the following in SI units, either base or derived.
  - 67.3 atm
  - $1.0 \times 10^4 \text{ V cm}^{-1}$
  - $7.4 \text{ \AA year}^{-1}$
  - 22.4  $\text{L mol}^{-1}$
  - $14.7 \text{ lb inch}^{-2}$  (1 inch = 2.54 cm; 1 lb = 453.59 g)
- The kilowatt-hour (kWh) is a common unit in measurements of the consumption of electricity. What is the conversion factor between the kilowatt-hour and the joule? Express 15.3 kWh in joules.
- A car's rate of fuel consumption is often measured in miles per gallon (mpg). Determine the conversion factor between miles per gallon and the SI unit of meters per cubic decimeter (1 gallon = 3.785  $\text{dm}^3$ , and 1 mile = 1609.344 m). Express 30.0 mpg in SI units.
- A certain V-8 engine has a displacement of 404  $\text{in}^3$ . Express this volume in cubic centimeters ( $\text{cm}^3$ ) and in liters.
- Light travels in a vacuum at a speed of  $3.00 \times 10^8 \text{ m s}^{-1}$ .
  - Convert this speed to miles per second.
  - Express this speed in furlongs per fortnight, a little-used unit of speed. (A furlong, a distance used in horse racing, is 660 ft; a fortnight is exactly 2 weeks.)

**B.2 Background in Physics**

- After being spiked, a volleyball travels with speed near 100 miles per hour. Calculate the kinetic energy of the volleyball. The mass of a volleyball is 0.270 kg.
- The fastball of a famous pitcher in the National League has been clocked in excess of 95 mph. Calculate the work done by the pitcher in accelerating the ball to that speed. The mass of a baseball is 0.145 kg.
- A tennis ball weighs approximately 2 ounces on a postage scale. A student practices his serve against the wall of the chemistry building, and the ball achieves the speed of 98 miles per hour. Calculate the kinetic energy of the ball after the serve.

# Mathematics for General Chemistry

Mathematics is an essential tool in chemistry. This appendix reviews some of the most important mathematical techniques for general chemistry.

## C.1 Using Graphs

In many situations in science, we are interested in how one quantity (measured or predicted) depends on another quantity. The position of a moving car depends on the time, for example, or the pressure of a gas depends on the volume of the gas at a given temperature. A very useful way to show such a relation is through a *graph*, in which one quantity is plotted against another.

The usual convention in drawing graphs is to use the horizontal axis for the variable over which we have control and use the vertical axis for the measured or calculated quantity. After a series of measurements, the points on the graph frequently lie along a recognizable curve, and that curve can be drawn through the points. Because any experimental measurement involves some degree of uncertainty, there will be some scatter in the points, so there is no purpose in drawing a curve that passes precisely through every measured point. If there is a relation between the quantities measured, however, the points will display a systematic trend and a curve can be drawn that represents that trend.

The curves plotted on graphs can have many shapes. The simplest and most important shape is a straight line. A straight line is a graph of a relation such as

$$y = 4x + 7$$

or, more generally,

$$y = mx + b$$

where the variable  $y$  is plotted along the vertical axis and the variable  $x$  along the horizontal axis (Fig. C.1 shows a plot of  $y = 2x - 1$ ). The quantity  $m$  is the *slope* of the line that is plotted, and  $b$  is the *intercept*—the point at which the line crosses the  $y$  axis. This can be demonstrated by setting  $x$  equal to 0 and noting that  $y$  is then equal to  $b$ . The slope is a measure of the steepness of the line; the greater the value of  $m$ , the steeper the line. If the line goes up and to the right, the slope is positive; if it goes down and to the right, the slope is negative.

The slope of a line can be determined from the coordinates of two points on the line. Suppose, for example, that when  $x = 3$ ,  $y = 5$ , and when  $x = 4$ ,  $y = 7$ . These two points can be written in shorthand notation as  $(3, 5)$  and  $(4, 7)$ . The slope of the line is then defined as the “rise over the run”—the change in the  $y$  coordinate divided by the change in the  $x$  coordinate:

$$\text{slope} = m = \frac{\Delta y}{\Delta x} = \frac{7 - 5}{4 - 3} = \frac{2}{1} = 2$$

**FIGURE C.1** A straight-line, or linear, relationship between two experimental quantities is a very desirable result because it is easy to graph and easy to represent mathematically. The equation of this straight line ( $y = 2x - 1$ ) fits the general form  $y = mx + b$ . The line's  $y$  intercept is  $-1$  and its slope is  $2$ .

The symbol  $\Delta$  (capital Greek delta) indicates the change in a quantity—the final value minus the initial value. In chemistry, if the two quantities being graphed have dimensions, the slope has dimensions as well. If a graph of distance traveled (in meters) against time (in seconds) is a straight line, its slope has dimensions of meters per second ( $\text{m s}^{-1}$ ).

## C.2 Solution of Algebraic Equations

In chemistry it is often necessary to solve an algebraic equation for an unknown quantity, such as a concentration or a partial pressure in an equilibrium-constant expression. Let us represent the unknown quantity with the symbol  $x$ . If the equation is linear, the method of solution is straightforward:

$$5x + 9 = 0$$

$$5x = -9$$

$$x = -\frac{9}{5}$$

or, more generally, if  $ax + b = 0$ , then  $x = -b/a$ .

Nonlinear equations are of many kinds. One of the most common in chemistry is the quadratic equation, which can always be rearranged into the form

$$ax^2 + bx + c = 0$$

where each of the constants ( $a$ ,  $b$ , and  $c$ ) may be positive, negative, or 0. The two solutions to a quadratic equation are given by the quadratic formula:

$$x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}$$

As an example, suppose that the equation

$$x = 3 + \frac{7}{x}$$

arises in a chemistry problem. Multiplying by  $x$  and rearranging the terms gives

$$x^2 - 3x - 7 = 0$$

Inserting  $a = 1$ ,  $b = -3$ , and  $c = -7$  into the quadratic formula gives

$$x = \frac{-(-3) \pm \sqrt{(-3)^2 - 4(1)(-7)}}{2} = \frac{3 \pm \sqrt{9 + 28}}{2} = \frac{3 \pm \sqrt{37}}{2}$$

The two roots of the equation are

$$x = 4.5414 \quad \text{and} \quad x = -1.5414$$

In a chemistry problem, the choice of the proper root can frequently be made on physical grounds. If  $x$  corresponds to a concentration, for example, the negative root is unphysical and can be discarded.

The solution of cubic or higher order algebraic equations (or more complicated equations involving sines, cosines, logarithms, or exponentials) becomes more difficult, and approximate or numerical methods must be used. As an illustration, consider the equation

$$x^2 \left( \frac{2.00 + x}{3.00 - x} \right) = 1.00 \times 10^{-6}$$

If  $x$  is assumed to be small relative to both 2.00 and 3.00, we obtain the simpler approximate equation

$$x^2 \left( \frac{2.00}{3.00} \right) \approx 1.00 \times 10^{-6}$$

which leads to the roots  $x = \pm 0.00122$ . We immediately confirm that the solutions obtained in this way *are* small compared with 2.00 (and 3.00) and that our approximation was a good one. When a quantity ( $x$  in this case) is added to or subtracted from a larger quantity in a complicated equation, it is usually worthwhile, in solving the equation, to simply neglect the occurrence of the small quantity. Note that this tactic works only for addition and subtraction, never for multiplication or division.

Suppose now that the equation is changed to

$$x^2 \left( \frac{2.00 + x}{3.00 - x} \right) = 1.00 \times 10^{-2}$$

In this case the equation that comes from neglecting  $x$  compared with 2.00 and 3.00 is

$$x^2 \left( \frac{2.00}{3.00} \right) \approx 1.00 \times 10^{-2}$$

which is solved by  $x \approx \pm 0.122$ . The number 0.122 is smaller than 2.00 and 3.00, but not so small that it can be ignored. In this case more precise results can be obtained by *iteration*. Let us simply add and subtract the approximate positive root  $x \approx +0.122$  as specified inside the parentheses and solve again for  $x$ :

$$x^2 \left( \frac{2.00 + 0.122}{3.00 - 0.122} \right) = 1.00 \times 10^{-2}$$

$$x = 0.116$$

This new value can again be inserted into the original equation and the process repeated:

$$x^2 \left( \frac{2.00 + 0.116}{3.00 - 0.116} \right) = 1.00 \times 10^{-2}$$

$$x = 0.117$$

Once the successive values of  $x$  agree to within the desired accuracy, the iteration can be stopped. Another root of the equation is obtained in a similar fashion if the iterative procedure starts with  $x = -0.122$ .

In some cases iteration fails. Suppose, for example, we have the equation

$$x^2 \left( \frac{2.00 + x}{3.00 - x} \right) = 10.0$$

There is no particular reason to believe that  $x$  should be small compared with 2.00 or 3.00, but if we nevertheless assume that it is, we find  $x = \pm\sqrt{15} = \pm 3.873$ . Putting  $x = +3.873$  back in for an iterative cycle leads to the equation

$$x^2 = -1.49$$

which has no real solutions. Starting with  $x = -3.873$  succeeds no better; it gives

$$x^2 = -36.7$$

One way to overcome these difficulties is to solve the original equation graphically. We plot the left side of the equation against  $x$  and see at which values it becomes equal to 10 (the right side). We might initially calculate

$x$	$x^2 \left( \frac{2.00 + x}{3.00 - x} \right)$
0	0
1	1.5
2	16

We observe that for  $x = 1$  the left side is less than 10, whereas for  $x = 2$  it is greater than 10. Somewhere in between there must be an  $x$  for which the left side is *equal* to 10. We can pinpoint it by selecting values of  $x$  between 1 and 2; if the left side is less than 10,  $x$  should be increased, and if it is greater than 10,  $x$  should be decreased.

$x$	$x^2 \left( \frac{2.00 + x}{3.00 - x} \right)$
1.5	5.25
Increase to 1.8	10.26
Decrease to 1.75	9.19
Increase to 1.79	10.04

Thus, 1.79 is quite close to a solution of the equation. Improved values are easily obtained by further adjustments of this type.

## C.3 Powers and Logarithms

Raising a number to a power and the inverse operation, taking a logarithm, are important in many chemical problems. Although the ready availability of electronic calculators makes the mechanical execution of these operations quite

routine, it remains important to understand what is involved in such “special functions.”

The mathematical expression  $10^4$  implies multiplying 10 by itself 4 times to give 10,000. Ten, or any other number, when raised to the power 0 always gives 1:

$$10^0 = 1$$

Negative powers of 10 give numbers less than 1 and are equivalent to raising 10 to the corresponding *positive* power and then taking the reciprocal:

$$10^{-3} = 1/10^3 = 0.001$$

We can extend the idea of raising to a power to include powers that are not whole numbers. For example, raising to the power  $\frac{1}{2}$  (or 0.5) is the same as taking the square root:

$$10^{0.5} = \sqrt{10} = 3.1623\dots$$

Scientific calculators have a  $10^x$  (or INV LOG) key that can be used for calculating powers of 10 in cases where the power is not a whole number.

Numbers other than 10 can be raised to powers, as well; these numbers are referred to as *bases*. Many calculators have a  $y^x$  key that lets any positive number  $y$  be raised to any power  $x$ . One of the most important bases in scientific problems is the transcendental number called  $e$  (2.7182818 . . .). The  $e^x$  (or INV LN) key on a calculator is used to raise  $e$  to any power  $x$ . The quantity  $e^x$  also denoted as  $\exp(x)$ , is called the *exponential* of  $x$ . A key property of powers is that a base raised to the sum of two powers is equivalent to the product of the base raised separately to these powers. Thus, we can write

$$10^{21+6} = 10^{21} \times 10^6 = 10^{27}$$

The same type of relationship holds for any base, including  $e$ .

Logarithms also occur frequently in chemistry problems. The logarithm of a number is the exponent to which some base has to be raised to obtain the number. The base is almost always either 10 or the transcendental number  $e$ . Thus,

$$B^a = n \quad \text{and} \quad \log_B n = a$$

where  $a$  is the logarithm,  $B$  is the base, and  $n$  is the number.

**Common logarithms** are base-10 logarithms; that is, they are powers to which 10 has to be raised in order to give the number. For example,  $10^3 = 1000$ , so  $\log_{10} 1000 = 3$ . We shall frequently omit the 10 when showing common logarithms and write this equation as  $\log 1000 = 3$ . Only the logarithms of 1, 10, 100, 1000, and so on are whole numbers; the logarithms of other numbers are decimal fractions. The decimal point in a logarithm divides it into two parts. To the left of the decimal point is the *characteristic*; to the right is the *mantissa*. Thus, the logarithm in the equation

$$\log (7.310 \times 10^3) = 3.8639$$

has a characteristic of 3 and a mantissa of 0.8639. As may be verified with a calculator, the base-10 logarithm of the much larger (but closely related) number  $7.310 \times 10^{23}$  is 23.8639. As this case illustrates, the characteristic is determined solely by the location of the decimal point in the number and not by the number's precision, so it is *not* included when counting significant figures. The mantissa should be written with as many significant figures as the original number.

A logarithm is truly an exponent and as such follows the same rules of multiplication and division as other exponents. In multiplication and division we have

$$\log (n \times m) = \log n + \log m$$

$$\log \left( \frac{n}{m} \right) = \log n - \log m$$

Furthermore,

$$\log n^m = m \log n$$

so the logarithm of  $3^5 = 243$  is

$$\log 3^5 = 5 \log 3 = 5 \times 0.47712 = 2.3856$$

There is no such thing as the logarithm of a negative number, because there is no power to which 10 (or any other base) can be raised to give a negative number.

A frequently used base for logarithms is the number  $e$  ( $e = 2.7182818 \dots$ ). The logarithm to the base  $e$  is called the **natural logarithm** and is indicated by  $\log_e$  or  $\ln$ . Base- $e$  logarithms are related to base-10 logarithms by the formula

$$\ln n = 2.3025851 \log n$$

As already stated, calculations of logarithms and powers are inverse operations. Thus, if we want to find the number for which 3.8639 is the common logarithm, we simply calculate

$$10^{3.8639} = 7.310 \times 10^3$$

If we need the number for which the natural logarithm is 2.108, we calculate

$$e^{2.108} = 8.23$$

As before, the number of significant digits in the answer should correspond to the number of digits in the *mantissa* of the logarithm.

## C.4 Slopes of Curves and Derivatives

Very frequently in science, one measured quantity depends on a second one. If the property  $y$  depends on a second property  $x$ , we can write  $y = f(x)$ , where  $f$  is a function that expresses the dependence of  $y$  on  $x$ . Often, we are interested in the effect of a small change  $\Delta x$  on the dependent variable  $y$ . If  $x$  changes to  $x + \Delta x$ , then  $y$  will change to  $y + \Delta y$ . How is  $\Delta y$  related to  $\Delta x$ ? Suppose we have the simple linear relation between  $y$  and  $x$

$$y = mx + b$$

where  $m$  and  $b$  are constants. If we substitute  $y + \Delta y$  and  $x + \Delta x$ , we find

$$y + \Delta y = m(x + \Delta x) + b$$

Subtracting the first equation from the second leaves

$$\Delta y = m\Delta x$$

or

$$\frac{\Delta y}{\Delta x} = m$$

The change in  $y$  is proportional to the change in  $x$ , with a proportionality constant equal to the slope of the line in the graph of  $y$  against  $x$ .

Suppose now we have a slightly more complicated relationship such as

$$y = ax^2$$

where  $a$  is a constant. If we substitute  $y + \Delta y$  and  $x + \Delta x$  here, we find

$$\begin{aligned} y + \Delta y &= a(x + \Delta x)^2 \\ &= ax^2 + 2ax \Delta x + (\Delta x)^2 \end{aligned}$$

**FIGURE C.2** The slope of a curve at a point.

Subtracting as before leaves

$$\Delta y = 2ax \Delta x + (\Delta x)^2$$

Here we have a more complicated, nonlinear relationship between  $\Delta y$  and  $\Delta x$ . If  $\Delta x$  is small enough, however, the term  $(\Delta x)^2$  will be small relative to the term proportional to  $\Delta x$ , and we may write

$$\Delta y \approx 2ax \Delta x \quad (\Delta x \text{ small})$$

$$\frac{\Delta y}{\Delta x} \approx 2ax \quad (\Delta x \text{ small})$$

How do we indicate this graphically? The graph of  $y$  against  $x$  is no longer a straight line, so we need to generalize the concept of slope. We define a **tangent line** at the point  $x_0$  as the line that touches the graph of  $f(x)$  at  $x = x_0$  without crossing it.<sup>1</sup> If  $\Delta y$  and  $\Delta x$  are small (Fig. C.2), the slope of the tangent line is

$$\frac{\Delta y}{\Delta x} = 2ax_0 \quad \text{at} \quad x = x_0$$

for the example just discussed. Clearly, the slope is not constant but changes with  $x_0$ . If we define the slope at each point on the curve by the slope of the corresponding tangent line, we obtain a *new* function that gives the slope of the curve  $f(x)$  at each point  $x$ . We call this new function the *derivative* of  $f(x)$  and represent it with  $df/dx$ . We have already calculated the derivatives of two functions:

$$f(x) = mx + b \Rightarrow \frac{df}{dx} = m$$

$$f(x) = ax^2 \Rightarrow \frac{df}{dx} = 2ax$$

Table C.1 shows derivatives of several other functions that are important in basic chemistry.

TABLE C.1	
Derivatives of Simple Functions	
Function $f(x)$	Derivative $\frac{df}{dx}$
$mx + b$	$m$
$ax^2$	$2ax$
$\frac{a}{x} = ax^{-1}$	$-\frac{a}{x^2} = -ax^{-2}$
$ax^n$	$nax^{n-1}$
$e^{ax}$	$ae^{ax}$
$\ln ax$	$\frac{1}{x}$
$\sin ax$	$a \cos ax$
$\cos ax$	$-a \sin ax$

The constants  $a$ ,  $b$ ,  $m$ , and  $n$  may be positive or negative.

<sup>1</sup>This is an intuitive, rather than a rigorously mathematical, definition of a tangent line.

The derivative gives the slope of the tangent line to  $f(x)$  at each point  $x$  and can be used to approximate the response to a small perturbation  $\Delta x$  in the independent variable  $x$ :

$$\Delta y \approx \frac{df}{dx} \Delta x$$

As an example, consider 1.00 mol of an ideal gas at 0°C that obeys the law

$$P(\text{atm}) = \frac{22.414 \text{ L atm}}{V(\text{L})}$$

Suppose  $V$  is 20.00 L. If the volume  $V$  is changed by a small amount  $\Delta V$  at fixed  $T$  and number of moles, what will be the corresponding change  $\Delta P$  in the pressure? We write

$$\begin{aligned} P &= f(V) = \frac{22.414}{V} = \frac{a}{V} \\ \frac{dP}{dV} &= \frac{df}{dV} = -\frac{a}{V^2} = -\frac{22.414}{V^2} \quad (\text{from Table C.1}) \\ \Delta P &\approx \frac{dP}{dV} \Delta V = -\frac{22.414}{V^2} (\Delta V) \end{aligned}$$

If  $V = 20.00$  L, then

$$\Delta P \approx -\frac{22.414 \text{ L atm}}{(20.00 \text{ L})^2} \Delta V = -(0.0560 \text{ atm L}^{-1}) \Delta V$$

## C.5 Areas under Curves and Integrals

Another mathematical operation that arises frequently in science is the calculation of the area under a curve. Some areas are those of simple geometric shapes and are easy to calculate. If the function  $f(x)$  is a constant,

$$f(x) = a$$

then the area under a graph of  $f(x)$  between the two points  $x_1$  and  $x_2$  is that of a rectangle (Fig. C.3a) and is easily calculated as

$$\text{area} = \text{height} \times \text{base} = a(x_2 - x_1) = [ax_2] - [ax_1]$$

If  $f(x)$  is a straight line that is neither horizontal nor vertical,

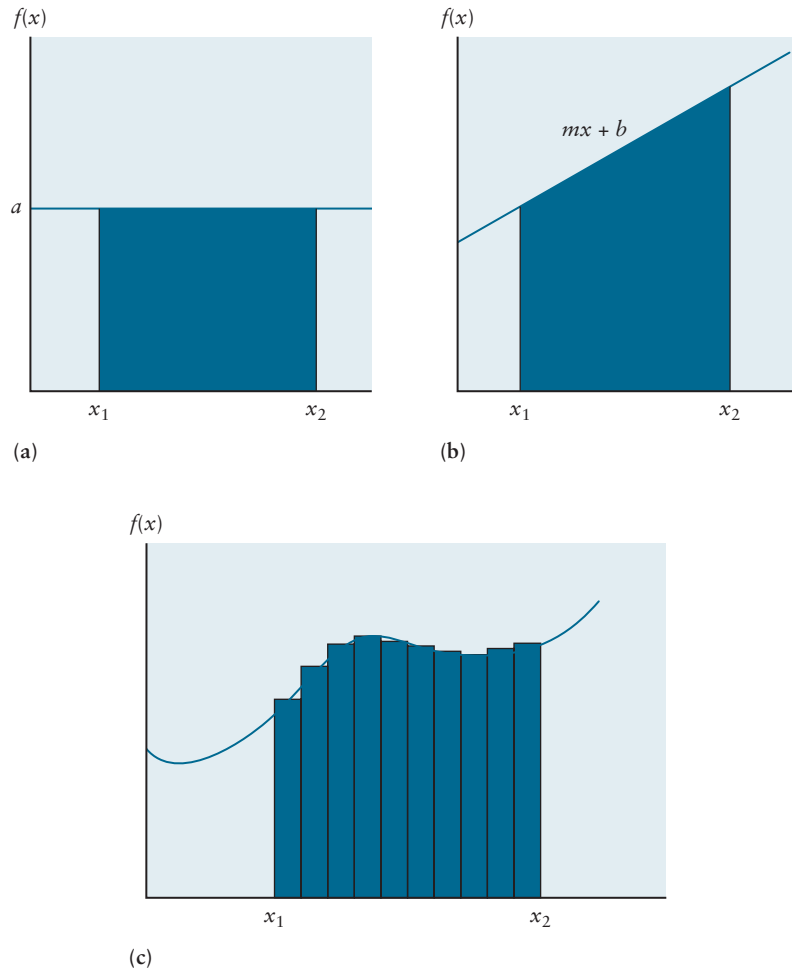

$$f(x) = mx + b$$

then the area is that of a trapezoid (Fig. C.3b) and is equal to

$$\begin{aligned} \text{area} &= \text{average height} \times \text{base} \\ &= \frac{1}{2}(mx_1 + b + mx_2 + b)(x_2 - x_1) \\ &= \left[\frac{1}{2}mx_2^2 + bx_2\right] - \left[\frac{1}{2}mx_1^2 + bx_1\right] \end{aligned}$$

Suppose now that  $f(x)$  is a more complicated function, such as that shown in Figure C.3c. We can estimate the area under this graph by approximating it with a series of small rectangles of width  $\Delta x$  and varying heights. If the height of the  $i$ th rectangle is  $y_i = f(x_i)$ , then we have, approximately,

$$\begin{aligned} \text{area} &\approx f(x_1) \Delta x + f(x_2) \Delta x + \dots \\ &= \sum_i f(x_i) \Delta x \end{aligned}$$

**FIGURE C.3** The integral as the area under a curve.

As the widths of the rectangles  $\Delta x$  become small, this becomes a better approximation. We *define* the area under a curve  $f(x)$  between two points as the limiting value of this sum as  $\Delta x$  approaches 0, called the *definite integral*:

$$\text{area} = \int_{x_1}^{x_2} f(x) dx$$

We have already worked out two examples of such integrals:

$$f(x) = a \Rightarrow \int_{x_1}^{x_2} a dx = [ax_2] - [ax_1]$$

$$f(x) = ax + b \Rightarrow \int_{x_1}^{x_2} (ax + b) dx = \left[\frac{1}{2}ax_2^2 + bx_2\right] - \left[\frac{1}{2}ax_1^2 + bx_1\right]$$

These integrals have an interesting form, which can be generalized to other cases as well: some function  $F$  evaluated at the upper limit ( $x_2$ ) minus that function  $F$  evaluated at the lower limit ( $x_1$ ).

$$\int_{x_1}^{x_2} f(x) dx = F(x_2) - F(x_1)$$

$F$  is called the **antiderivative** of  $f$  because, for reasons we shall not go into here, it is obtained by the inverse of a derivative operation. In other words, if  $F$  is the antiderivative of  $f$ , then  $f$  is the derivative of  $F$ :

$$\frac{dF}{dx} = f(x)$$

TABLE C.2

## Integrals of Simple Functions

Function $f(x)$	Antiderivative $F(x)$	Integral $\int_{x_1}^{x_2} f(x) dx$
$a$	$ax$	$ax_2 - ax_1$
$mx + b$	$\frac{1}{2}mx^2 + bx$	$[\frac{1}{2}mx_2^2 + bx_2] - [\frac{1}{2}mx_1^2 + bx_1]$
$x^n$ ( $n \neq -1$ )	$\frac{1}{n+1}x^{n+1}$	$\frac{1}{n+1}(x_2^{n+1} - x_1^{n+1})$
$\frac{1}{x} = x^{-1}$ ( $x > 0$ )	$\ln x$	$(\ln x_2 - \ln x_1) = \ln \frac{x_2}{x_1}$
$\frac{1}{x^2} = x^{-2}$	$-\frac{1}{x}$	$-\left(\frac{1}{x_2} - \frac{1}{x_1}\right)$
$e^{ax}$	$\frac{e^{ax}}{a}$	$\frac{1}{a}(e^{ax_2} - e^{ax_1})$

The constants  $a$ ,  $b$ ,  $m$ , and  $n$  may be positive or negative.

To calculate integrals, therefore, we invert the results of Table C.1, because we need to find those functions  $F(x)$  whose derivatives are equal to  $f(x)$ . Table C.2 lists several of the most important integrals for basic chemistry.

Several additional mathematical properties of integrals are important at this point. If a function is multiplied by a constant  $c$ , then the integral is multiplied by the same constant:

$$\int_{x_1}^{x_2} cf(x) dx = c \int_{x_1}^{x_2} f(x) dx$$

The reason is self-evident: if a function is multiplied everywhere by a constant factor, then the area under its graph must be increased by the same factor. Second, the integral of the sum of two functions is the sum of the separate integrals:

$$\int_{x_1}^{x_2} [f(x) + g(x)] dx = \int_{x_1}^{x_2} f(x) dx + \int_{x_1}^{x_2} g(x) dx$$

Finally, if the upper and lower limits of integration are reversed, the sign of the integral changes as well. This is easily seen from the antiderivative form:

$$\int_{x_2}^{x_1} f(x) dx = F(x_1) - F(x_2) = -[F(x_2) - F(x_1)] = -\int_{x_1}^{x_2} f(x) dx$$

## C.6 Probability

Many applications in chemistry require us to interpret—and even predict—the results of measurements where we have only limited information about the system and the process involved. In such cases the best we can do is identify the possible outcomes of the experiment and assign a *probability* to each of them. Two examples illustrate the issues we face. In discussions of atomic structure, we would like to know the position of an electron relative to the nucleus. The principles of quantum mechanics tell us we can never know the exact location or trajectory of an electron; the most information we can have is the probability of finding an electron at each point in space around the nucleus. In discussing the behavior of a macroscopic amount of helium gas confined at a particular volume, pressure, and temperature we would like to know the speed with which an atom is moving in the container. We do not have experimental means to “tag” a particular atom, track its motions in the container, and measure its speed. The best we can do is estimate the probability that some typical atom is moving with each possible speed.

Everyone is familiar with the common sense concept of probability as a way to assess the likelihood of a desirable outcome in a game of chance. The purpose of this section is to give a brief introduction to probability in a form suited for scientific work.

### C.6.1 Random Variable

The first step in setting up a probability model of a statistical experiment is to define the *random variable*  $X$ , the measurable quantity whose values *fluctuate*, or change, as we carry out many repetitions of the experiment. While defining the random variable, we also identify the *outcomes* of the statistical experiment, the possible values that  $X$  can take as we carry out many repetitions. If the experiment consists of flipping a coin, then  $X$  is simply the label on the side of the coin facing up, and the only possible outcomes are  $H$  for “heads” and  $T$  for “tails.” If the experiment consists of rolling a die,  $X$  is the number of dots on the side facing up, with integral values from 1 to 6. If the experiment is rolling a pair of dice,  $X$  is the sum of the number of dots on the two sides facing up, with integral values from  $1 + 1 = 2$  to  $6 + 6 = 12$ . If the experiment is to find the position of an electron in an atom,  $X$  is then  $r$ , the distance from the nucleus to the electron, and it can range from 0 to infinity. If the experiment is to find the speed of an atom in a sample of gas,  $X$  is then  $v$ , the speed of the atom, which can range from 0 to some large value.

### C.6.2 Probability and Probability Functions

It is convenient to set up a graphical representation of the probability model. We represent the random variable  $X$  along the horizontal axis of an ordinary Cartesian graph. The possible outcomes of measuring  $X$  are shown as points along the horizontal axis. We see from the earlier examples that these can be either discrete or continuous values, depending on the nature of  $X$ . Along the vertical axis we want to plot  $P(X)$ , the probability of observing the random variable to have the value  $X$ , for each of the possible outcomes.

The **probability function**  $P(X)$  is generated by making multiple measurements of the random variable  $X$  and recording the results in a histogram. The performance of a chemistry class with 50 students on a quiz with maximum score 20 is a good example of a statistical experiment. Here the random variable  $X$  is the score a student achieves, and the possible outcomes are the integers from 0 to 20. The set of graded papers constitute 50 repetitions of the statistical experiment, and the results are summarized in Figure C.4. We define the probability

**FIGURE C.4** Distribution of exam scores in a class of 50 students.

**FIGURE C.5** Probability function for the exam scores in Figure C.4.

that a particular score was achieved on the exam to be the fraction of the papers with that score:

$$P(X_i) = \frac{n_i(X_i)}{N}$$

where  $n_i(X_i)$  is the number of papers with score  $X_i$  and  $N$  is the total number of papers. Figure C.5 shows the probability function generated from the data in Figure C.4. The function has a maximum at  $X = 14$ , which is labeled the *most probable value*  $X_{mp}$ . This is the value that appears most often in the experimental data. Probability is a pure number; it does not have physical dimensions. Probability cannot be determined from a single measurement; many repetitions of the statistical experiment are required for the definition of probability.

The probability function has the interesting property that its sum over all the possible outcomes is 1:

$$P_0 + P_1 + \dots + P_{19} + P_{20} = \frac{1}{50}(n_0 + n_1 + \dots + n_{19} + n_{20}) = \frac{50}{50} = 1$$

We represent this long sum in the following compact way where the uppercase Greek sigma means “add up all the terms,” and the running index  $i$  indicates the term for each possible outcome from 0 to 20:

$$\sum_{i=0}^{20} P_i = \frac{1}{50} \sum_{i=0}^{20} n_i = \frac{50}{50} = 1$$

A probability function with this property is said to be **normalized**. Normalization signifies that we have accounted for all the possible outcomes: the probability that *some* score is achieved is 1. We should always check that a probability function is normalized before using it in further calculations.

### C.6.3 Average Values of the Random Variable

The probability function is used in numerous statistical analyses of the experiment, only one of which we describe here. We calculate  $\bar{X}$ , the *mean*, or average, value of the random variable, by multiplying each possible outcome by its probability and summing over all the possible outcomes. In our compact form this operation for the probability function in Figure C.5 is

$$\bar{X} = \sum_{i=0}^{20} X_i P(X_i) = \frac{1}{50} \sum_{i=0}^{20} X_i n_i = 14.7$$

The mean value is one way to convey the essence of the probability function in a single number: Is the overall class performance on the exam good, fair, or poor? Another way is to state the most probable value  $X_{\text{mp}}$ . In this example the mean value is slightly larger than the most probable value because the distribution slightly favors the high end of the range, courtesy of the student who scored 19 of 20! The mean and most probable values coincide only when the distribution is perfectly symmetrical about the maximum. The complete probability function gives much more insight into the results of the experiment than the mean or most probable values standing alone.

### C.6.4 Probability Density: Continuous Random Variables and Probability Functions

When the random variable is continuous, as in the case of the position of the electron and speed of the helium atom referred to earlier, we must consider every point of the  $X$  axis—not just the integers—as a possible outcome. Therefore, we cannot define the probability of observing a specific value, which we call  $X_0$ . Rather, we define the probability that  $X$  falls within a narrow, infinitesimal interval between  $X_0$  and  $X_0 + dX$ . When the interval  $dX$  is sufficiently small, the probability will be proportional to the width of the interval, and we define the probability as follows:

$$[\text{Probability of } X \text{ falling in the interval between } X_0 \text{ and } X_0 + dX] = \mathcal{P}(X_0)dX$$

Because this analysis is required at each point  $X$ , we drop the subscript 0, and discuss the properties of  $\mathcal{P}(X)$  in general. The function  $\mathcal{P}(X)$ , called the **probability density function** for  $X$ , is plotted as a continuous function above the  $X$ -axis. It is defined for all points in an interval  $(a, b)$  whose end points depend on the nature of  $X$ . In some cases the end points can include  $+\infty, -\infty$ , or both. Note that  $\mathcal{P}(X)$  has physical dimensions of  $X^{-1}$ , since the product  $\mathcal{P}(X)dX$  must be dimensionless.

The probability density plays the same role for continuous variables as does  $P(X)$  for discrete random variables. The normalization condition becomes

$$\int_a^b \mathcal{P}(X) dX = 1$$

and the mean value of  $X$  is calculated as

$$\bar{X} = \int_a^b X \cdot \mathcal{P}(X) dX$$

The symmetry of the probability density function determines whether the most probable and mean values of  $X$  coincide. We use a special symbol here to distinguish probability density from probability. In the main portion of the textbook we do not always make that distinction in symbols. But, it is always clear from context whether we are discussing a probability function or a probability density function.

### C.6.5 Experimental Tests of Theoretical Probability

**Theoretical probability** identifies the possible outcomes of a statistical experiment, and uses theoretical arguments to predict the probability of each. Many applications in chemistry take this form. In atomic and molecular structure problems, the general principles of quantum mechanics predict the probability functions. In other cases the theoretical predictions are based on assumptions about the chemical or physical behavior of a system. In all cases, the validity of these predictions must be tested by comparison with laboratory measurements of the behavior of the same random variable. A full determination of experimental

probability, and the mean values that come from it, must be obtained and compared with the theoretical predictions. A theoretical prediction of probability can never be tested or interpreted with a single measurement. A large number of repeated measurements is necessary to reveal the true statistical behavior.

## C.7 Vectors

In chemistry, many quantities of interest have both magnitude and direction. For example, a strong (large-magnitude) force on a molecule might push it, but you need to know in what direction it is pushed. In the kinetic theory of gases, the distribution of molecular speeds is important, where the speed is the magnitude of the velocity, but when the molecule hits the wall of a container it changes its direction of travel, not its speed. If you wish to understand how an HCl molecule might reorient itself near a cation, you need to know not only how large the dipole moment of HCl is, the magnitude of the dipole moment, but also whether the positive partial charge is near the H or the Cl, as the positively charged side of the diatomic will feel a repulsive force from the cation. If you have already learned a bit about vectors in high school, you may wish to skip to the paragraph below that begins with “A very useful concept is the unit vector. . . .”

A force, velocity, or dipole moment may be represented by a **vector**. We'll restrict our discussion to vectors in a Cartesian coordinate system. In school you learned to label a location in a plane by its  $x$  and  $y$  coordinates. Figure C.6a shows the point  $(x,y) = (-3,4)$ . If you draw an arrow from the origin of the coordinate system to the point  $(-3,4)$ , this is a geometric representation of the vector  $\vec{r}$ . One

**FIGURE C.6** Vectors representing position and velocity. (a) The position vector  $\vec{r} = (r_x, r_y) = (x, y) = (-3, 4)$ . In a physical problem you need to specify units, perhaps miles or angstroms. (b) Velocity vectors for two particles, each with components  $v_x$  and  $v_y$ . Note that the horizontal axis is labeled  $v_x$  now, as it is marked off in increments of  $v_x$  where  $v_x = dx/dt$ , and the vertical axis is labeled  $v_y$  now, where  $v_y = dy/dt$ . The relative velocity vector  $\vec{v}_{rel}$  (of particle #2 with respect to particle #1) is shown in two positions, one to show its components easily and the other to show that  $\vec{v}_1 + \vec{v}_{rel} = \vec{v}_2$ , or  $\vec{v}_{rel} = \vec{v}_2 - \vec{v}_1$ .

can easily determine each *component* of the vector  $\vec{r}$ . The  $x$ -component, typically given the symbol  $r_x$  or simply  $x$ , is  $-3$ , and the  $y$ -component, typically given the symbol  $r_y$  or simply  $y$ , is  $4$ . Thus, the vector  $\vec{r} = (r_x, r_y) = (x, y) = (-3, 4)$ . The length of the vector, also called the *magnitude* of the vector, is, by the Pythagorean theorem,  $\sqrt{(r_x)^2 + (r_y)^2} = \sqrt{(-3)^2 + (4)^2} = 5$ . If the distance units were meters, you would say that the point  $(-3, 4)$  is a distance of 5 m from the origin of the coordinate system.

The two components of the vector  $\vec{r}$  also uniquely determine the direction of the vector  $\vec{r}$  since the angle  $\phi$  in Figure C.6a may be calculated from  $x$  and  $y$ . If you multiply a vector by a number  $c$  like  $c = -2$  or  $c = \pi$  (these numbers are called scalars), the result is simply  $c\vec{r} = c(x, y) = (cx, cy)$ . Thus multiplying a vector by a positive number changes the length of the vector, but not its direction, and multiplying a vector by a negative number reverses its direction.

For instance, if you wished to represent the location of your car with respect to your house, you might imagine the house at the origin of the coordinate system and direct the  $x$ -axis east and the  $y$ -axis north. If the units with which you measure distance are miles, the vector  $\vec{r}$  in Figure C.6a would tell you that your car is located 5 miles from your house (the distance being the magnitude of the vector) in the northwest direction. (Of course, this distance is “as the crow flies” as you typically can’t drive from one point to another by following a single straight line!) In this textbook we typically carry the units along with the numerical values to make it easy for you to keep track of them, so we might write the vector  $\vec{r} = (r_x, r_y) = (x, y) = (-3 \text{ miles}, 4 \text{ miles})$ . Also note that the magnitude of a vector, in this case the distance, is often denoted in mathematics texts as  $\|\vec{r}\|$ , and those texts typically do not put an arrow over the vector  $\vec{r}$ . In this text we will put an arrow over the symbol used for a vector, and to simplify the notation we will indicate the magnitude of the vector  $\vec{r}$  simply by  $r$  without an arrow over it (we will not put “ $\|\ \|$ ” in the notation.)

A very useful concept is the unit vector in the same direction as  $\vec{r}$ . This unit vector is denoted by  $\hat{r}$  where  $\hat{r} = \vec{r}/r$ , so the unit vector  $\hat{r}$  is the vector  $\vec{r}$  divided by its magnitude. Carrying the units with the components of the vector  $\vec{r}$  in Figure C.6a, if the distances are measured in miles, you would calculate

$$\hat{r} = \frac{\vec{r}}{r} = \frac{(-3 \text{ miles}, 4 \text{ miles})}{5 \text{ miles}} = (-0.6, 0.8)$$

Note that even if you carry your units with the values of a vector’s components, a unit vector does not have units of measure associated with it (called “dimensions” in Appendix B.1). If you calculate the magnitude of any unit vector, you will get a value of 1. (e.g., the magnitude of the  $\hat{r}$  above  $= \sqrt{(-0.6)^2 + (0.8)^2} = 1$ ). In Cartesian coordinates it is common to denote the unit vector parallel to the  $x$ -axis as  $\hat{i} = (1, 0)$  and the unit vector parallel to the  $y$ -axis as  $\hat{j} = (0, 1)$ . (Each unit vector points in the direction of increasing  $x$  or  $y$ , respectively.) If you require a third axis, maybe because you are representing the position of a car that is northwest of your house, but also part way up a hill, the unit vectors in the same direction as the Cartesian coordinate axes are  $\hat{i} = (1, 0, 0)$ ,  $\hat{j} = (0, 1, 0)$ , and  $\hat{k} = (0, 0, 1)$ . The magnitude of these unit vectors are, of course, 1. They are particularly useful in any Cartesian coordinate system because you can write any vector as a linear combination of them. For example, the vector  $\vec{r}$  in figure C.6a  $= -3(1, 0) + 4(0, 1) = -3\hat{i} + 4\hat{j}$ .

Thus far, we have been discussing vectors whose magnitudes represent distance. Let’s now consider a problem where we wish to use the length of a vector to represent the speed of an object, and the direction of the vector to indicate the direction of travel. Let  $(x(t), y(t))$  be the position of the object at time  $t$ . To represent a velocity vector, you must label your Cartesian axes not by  $x$  and  $y$ , but rather by  $v_x = dx/dt$  and  $v_y = dy/dt$ , as shown in Figure C.6b (called “velocity

space”). If your unit of measure is miles per hour, then the red vector labeled  $\vec{v}_1 = (v_{1x}, v_{1y}) = (2.5, 6)$  in Figure C.6b has magnitude  $v_1 = \sqrt{(v_{1x})^2 + (v_{1y})^2} = 6.5$  miles per hour. This might be the speed of car #1, and it is traveling in the northeast direction (if again moving to larger values of  $x$  is in the eastward direction and moving to larger values of  $y$  is in the northward direction). The velocity of car #2 is represented by the blue vector labeled  $\vec{v}_2$ , and you would calculate the speed  $v_2$  of car #2 to be  $\sqrt{(v_{2x})^2 + (v_{2y})^2} = 5$  miles per hour. Both cars are travelling eastward, (because both  $v_{1x}$  and  $v_{2x}$  are positive), but the absolute value of  $v_{2x}$  is larger than the absolute value of  $v_{1x}$ , so car #2 is traveling eastward faster than car #1. You may wish to calculate the relative velocity of car #2 with respect to car #1. This is the green vector labeled  $\vec{v}_{\text{rel}}$  in Figure C.6b.

$$\vec{v}_{\text{rel}} = \vec{v}_2 - \vec{v}_1 = (4, 3) - (2.5, 6) = (1.5, -3)$$

From this calculation you see that car #2 is indeed traveling faster eastward than car #1 (the component of the relative velocity vector in the eastward direction is positive), but car #2 is traveling slower in the northward direction than car #1. Try constructing vectors such that car #2 is traveling northeast at 40 miles per hour and car #1 is traveling southwest at 40 miles per hour, so they might be speeding right toward each other. Then calculate  $v_{\text{rel}}$ , the magnitude of  $\vec{v}_{\text{rel}}$ . You will see that the relative speed is a scary 80 miles per hour. Relative velocity is discussed in Chapter 18 in the context of molecular collisions; a large magnitude of the relative velocity helps to surmount the energy barrier to a chemical reaction.

When we discuss attractive and repulsive forces between two molecules or particles, we want to distinguish between the vector that points from particle #1 to particle number #2; let's call it  $\vec{r}_{12}$ , and the vector that points from particle #2 to particle #1,  $\vec{r}_{21}$ . The vector  $\vec{r}_{12} = \vec{r}_2 - \vec{r}_1$  and the vector  $\vec{r}_{21} = \vec{r}_1 - \vec{r}_2$ , so it is easy to show they have the same magnitude,  $r_{12} = r_{21} = r$ , but point in opposite directions  $\vec{r}_{12} = -\vec{r}_{21}$ . The force on particle #2 (exerted by particle #1) is  $\vec{F}_2 = -\frac{dV}{dr} \hat{r}_{12}$  (where  $V(r)$  is the potential energy as a function of the separation  $r$ ) and the force on particle #1 (exerted by particle 2) is  $\vec{F}_1 = -\frac{dV}{dr} \hat{r}_{21}$ , so one immediately recovers Newton's second law, that  $\vec{F}_1 = -\vec{F}_2$  (as long as there are no external forces, only the forces that each of these particles exerts on the other). We use these results in Chapter 3.

## PROBLEMS

Answers to problems whose numbers are red appear in Appendix G.

### C.1 Using Graphs

1. A particular plot of distance traveled against time elapsed is found to be a straight line. After an elapsed time of 1.5 hours, the distance traveled was 75 miles, and after an elapsed time of 3.0 hours, the distance traveled was 150 miles. Calculate the slope of the plot of distance against time, and give its units.
2. The pressure of a gas in a rigid container is measured at several different temperatures, and it is found that a plot of pressure against temperature is a straight line. At 20.0°C the pressure is 4.30 atm, and at 100.0°C the pressure is 5.47 atm. Calculate the slope of the plot of pressure against temperature and give its units.
3. Rewrite each of the following linear equations in the form  $y = mx + b$ , and give the slope and intercept of the corresponding plot. Then draw the graph.
  - (a)  $y = 4x - 7$
  - (b)  $7x - 2y = 5$
  - (c)  $3y + 6x - 4 = 0$

4. Rewrite each of the following linear equations in the form  $y = mx + b$ , and give the slope and intercept of the corresponding plot. Then draw the graph.
- (a)  $y = -2x - 8$   
 (b)  $-3x + 4y = 7$   
 (c)  $7y - 16x + 53 = 0$

5. Graph the relation

$$y = 2x^3 - 3x^2 + 6x - 5$$

from  $y = -2$  to  $y = +2$ . Is the plotted curve a straight line?

6. Graph the relation

$$y = \frac{8 - 10x - 3x^2}{2 - 3x}$$

from  $x = -3$  to  $x = +3$ . Is the plotted curve a straight line?

## C.2 Solution of Algebraic Equations

7. Solve the following linear equations for  $x$ .
- (a)  $7x + 5 = 0$   
 (b)  $-4x + 3 = 0$   
 (c)  $-3x = -2$
8. Solve the following linear equations for  $x$ .
- (a)  $6 - 8x = 0$   
 (b)  $-2x - 5 = 0$   
 (c)  $4x = -8$
9. Solve the following quadratic equations for  $x$ .
- (a)  $4x^2 + 7x - 5 = 0$   
 (b)  $2x^2 = -3 - 6x$   
 (c)  $2x + \frac{3}{x} = 6$
10. Solve the following quadratic equations for  $x$ .
- (a)  $6x^2 + 15x + 2 = 0$   
 (b)  $4x = 5x^2 - 3$   
 (c)  $\frac{1}{2-x} + 3x = 4$
11. Solve each of the following equations for  $x$  using the approximation of small  $x$ , iteration, or graphical solution, as appropriate.
- (a)  $x(2.00 + x)^2 = 2.6 \times 10^{-6}$   
 (b)  $x(3.00 - 7x)(2.00 + 2x) = 0.230$   
 (c)  $2x^3 + 3x^2 + 12x = -16$
12. Solve each of the following equations for  $x$  using the approximation of small  $x$ , iteration, or graphical solution, as appropriate.
- (a)  $x(2.00 + x)(3.00 - x)(5.00 + 2x) = 1.58 \times 10^{-15}$   
 (b)  $x \frac{(3.00 + x)(1.00 - x)}{2.00 - x} = 0.122$   
 (c)  $12x^3 - 4x^2 + 35x = 10$

## C.3 Powers and Logarithms

13. Calculate each of the following expressions, giving your answers the proper numbers of significant figures.
- (a)  $\log(3.56 \times 10^4)$   
 (b)  $e^{-15.69}$   
 (c)  $10^{8.41}$   
 (d)  $\ln(6.893 \times 10^{-22})$
14. Calculate each of the following expressions, giving your answers the proper numbers of significant figures.
- (a)  $10^{-16.528}$   
 (b)  $\ln(4.30 \times 10^{13})$   
 (c)  $e^{14.21}$   
 (d)  $\log(4.983 \times 10^{-11})$
15. What number has a common logarithm of 0.4793?
16. What number has a natural logarithm of  $-15.824$ ?
17. Determine the common logarithm of  $3.00 \times 10^{121}$ . It is quite likely that your calculator will *not* give a correct answer. Explain why.
18. Compute the value of  $10^{-107.8}$ . It is quite likely that your calculator will *not* give the correct answer. Explain why.
19. The common logarithm of 5.64 is 0.751. Without using a calculator, determine the common logarithm of  $5.64 \times 10^7$  and of  $5.64 \times 10^{-3}$ .
20. The common logarithm of 2.68 is 0.428. Without using a calculator, determine the common logarithm of  $2.68 \times 10^{192}$  and of  $2.68 \times 10^{-289}$ .
21. Use the graphical method and a calculator to solve the equation
- $$\log \ln x = -x$$
- for  $x$ . Give  $x$  to four significant figures.
22. Use a calculator to find a number that is equal to the reciprocal of its own natural logarithm. Report the answer to four significant figures.

## C.4 Slopes of Curves and Derivatives

23. Calculate the derivatives of the following functions.
- (a)  $y = 4x^2 + 4$   
 (b)  $y = \sin 3x + 4 \cos 2x$   
 (c)  $y = 3x + 2$   
 (d)  $y = \ln 7x$
24. Calculate the derivatives of the following functions.
- (a)  $y = 6x^{19}$   
 (b)  $y = 7x^2 + 6x + 2$   
 (c)  $y = e^{-6x}$   
 (d)  $y = \cos 2x + \frac{7}{x}$

**C.5 Areas under Curves and Integrals**

25. Calculate the following integrals.

(a)  $\int_2^4 (3x + 1) dx$

(b)  $\int_0^5 x^6 dx$

(c)  $\int_1^4 e^{-2x} dx$

26. Calculate the following integrals.

(a)  $\int_{-1}^3 4 dx$

(b)  $\int_2^{100} \frac{1}{x} dx$

(c)  $\int_2^4 \frac{5}{x^2} dx$

## D

## APPENDIX

# Standard Chemical Thermodynamic Properties

This table lists standard enthalpies of formation  $\Delta H_f^\circ$ , standard third-law entropies  $S^\circ$ , standard free energies of formation  $\Delta G_f^\circ$ , and molar heat capacities at constant pressure,  $c_p$ , for a variety of substances, all at 25°C (298.15 K) and 1 atm. The table proceeds from the left side to the right side of the periodic table. Binary compounds are listed under the element that occurs to the left in the periodic table, except that binary oxides and hydrides are listed with the other element. Thus, KCl is listed with potassium and its compounds, but  $\text{ClO}_2$  is listed with chlorine and its compounds.

Note that the *solution-phase* entropies are not absolute entropies but are measured relative to the arbitrary standard  $S^\circ(\text{H}^+(\text{aq})) = 0$ . Consequently, some of them (as well as some of the heat capacities) are negative.

Most of the thermodynamic data in these tables were taken from the *NBS Tables of Chemical Thermodynamic Properties* (1982) and changed, where necessary, from a standard pressure of 0.1 MPa to 1 atm. The data for organic compounds  $\text{C}_n\text{H}_m$  ( $n > 2$ ) were taken from the *Handbook of Chemistry and Physics* (1981).

## APPENDIX

# Standard Reduction Potentials at 25°C

Half-Reaction	$E^\circ$ (volts)
$F_2(g) + 2 e^- \rightarrow 2 F^-$	2.87
$H_2O_2 + 2 H_3O^+ + 2 e^- \rightarrow 4 H_2O$	1.776
$PbO_2(s) + SO_4^{2-} + 4 H_3O^+ + 2 e^- \rightarrow PbSO_4(s) + 6 H_2O$	1.685
$Au^+ + e^- \rightarrow Au(s)$	1.68
$MnO_4^- + 4 H_3O^+ + 3 e^- \rightarrow MnO_2(s) + 6 H_2O$	1.679
$HClO_2 + 2 H_3O^+ + 2 e^- \rightarrow HClO + 3 H_2O$	1.64
$HClO + H_3O^+ + e^- \rightarrow Cl_2(g) + 2 H_2O$	1.63
$Ce^{4+} + e^- \rightarrow Ce^{3+}$ (1 M $HNO_3$ solution)	1.61
$2 NO(g) + 2 H_3O^+ + 2 e^- \rightarrow N_2O(g) + 3 H_2O$	1.59
$BrO_3^- + 6 H_3O^+ + 5 e^- \rightarrow Br_2(\ell) + 9 H_2O$	1.52
$Mn^{3+} + e^- \rightarrow Mn^{2+}$	1.51
$MnO_4^- + 8 H_3O^+ + 5 e^- \rightarrow Mn^{2+} + 12 H_2O$	1.491
$ClO_3^- + 6 H_3O^+ + 5 e^- \rightarrow Cl_2(g) + 9 H_2O$	1.47
$PbO_2(s) + 4 H_3O^+ + 2 e^- \rightarrow Pb^{2+} + 6 H_2O$	1.46
$Au^{3+} + 3 e^- \rightarrow Au(s)$	1.42
$Cl_2(g) + 2 e^- \rightarrow 2 Cl^-$	1.3583
$Cr_2O_7^{2-} + 14 H_3O^+ + 6 e^- \rightarrow 2 Cr^{3+} + 21 H_2O$	1.33
$O_3(g) + H_2O + 2 e^- \rightarrow O_2 + 2 OH^-$	1.24
$O_2(g) + 4 H_3O^+ + 4 e^- \rightarrow 6 H_2O$	1.229
$MnO_2(s) + 4 H_3O^+ + 2 e^- \rightarrow Mn^{2+} + 6 H_2O$	1.208
$ClO_4^- + 2 H_3O^+ + 2 e^- \rightarrow ClO_3 + 3 H_2O$	1.19
$Br_2(\ell) + 2 e^- \rightarrow 2 Br^-$	1.065
$NO_3^- + 4 H_3O^+ + 3 e^- \rightarrow NO(g) + 6 H_2O$	0.96
$2 Hg^{2+} + 2 e^- \rightarrow Hg_2^{2+}$	0.905
$Ag^+ + e^- \rightarrow Ag(s)$	0.7996
$Hg_2^{2+} + 2 e^- \rightarrow 2 Hg(\ell)$	0.7961
$Fe^{3+} + e^- \rightarrow Fe^{2+}$	0.770
$O_2(g) + 2 H_3O^+ + 2 e^- \rightarrow H_2O_2 + 2 H_2O$	0.682

## APPENDIX

## Answers to Odd-Numbered Problems

## CHAPTER 1

- Mercury is an element; water and sodium chloride are compounds. The other materials are mixtures: seawater and air are homogeneous; table salt and wood are heterogeneous. Mayonnaise appears homogeneous to the naked eye, but under magnification shows itself as water droplets suspended in oil.
- Substances
- 16.9 g
- (a) 2.005 and 1.504 g  
(b)  $2.005/1.504 = 1.333 = 4/3$ ; SiN (or a multiple)
- 2, 3, 4, 5
- (a) HO (or any multiple, such as  $\text{H}_2\text{O}_2$ )  
(b) All would give  $\text{H}_2$  and  $\text{O}_2$  in 1:1 ratio.
- 2.0 L  $\text{N}_2\text{O}$ , 3.0 L  $\text{O}_2$
- 0.052 m
- 28.086
- 11.01
- (a)  $145/94 = 1.54$   
(b) 94 electrons
- 95 protons, 146 neutrons, 95 electrons
- $2.107298 \times 10^{-22}$  g
- (a) 283.89    (b) 115.36    (c) 164.09    (d) 158.03  
(e) 132.13
- The total count of  $2.52 \times 10^9$  atoms of gold has a mass of only  $8.3 \times 10^{-13}$  g, which is far too small to detect with a balance.
- 1.041 mol
- $2540 \text{ cm}^3 = 2.54 \text{ L}$
- $7.03 \times 10^{23}$  atoms

## CHAPTER 2

- Pt: 47.06%; F: 36.67%; Cl: 8.553%; O: 7.720%
- $\text{N}_4\text{H}_6$ ,  $\text{H}_2\text{O}$ , LiH,  $\text{C}_{12}\text{H}_{26}$
- 0.225%
- $\text{Zn}_3\text{P}_2\text{O}_8$
- $\text{Fe}_3\text{Si}_7$

- $\text{BaN}$ ,  $\text{Ba}_3\text{N}_2$
- (a) 0.923 g C, 0.077 g H  
(b) No  
(c) 92.3% C, 7.7% H  
(d) CH
- $\text{C}_4\text{F}_8$
- (a) 62.1  
(b) 6  
(c) 56  
(d) Si (atomic mass 28.1), N (atomic mass 14.0)  
(e)  $\text{Si}_2\text{H}_6$
- (a)  $3 \text{ H}_2 + \text{N}_2 \longrightarrow 2 \text{ NH}_3$   
(b)  $2 \text{ K} + \text{O}_2 \longrightarrow \text{K}_2\text{O}_2$   
(c)  $\text{PbO}_2 + \text{Pb} + 2 \text{ H}_2\text{SO}_4 \longrightarrow 2 \text{ PbSO}_4 + 2 \text{ H}_2\text{O}$   
(d)  $2 \text{ BF}_3 + 3 \text{ H}_2\text{O} \longrightarrow \text{B}_2\text{O}_3 + 6 \text{ HF}$   
(e)  $2 \text{ KClO}_3 \longrightarrow 2 \text{ KCl} + 3 \text{ O}_2$   
(f)  $\text{CH}_3\text{COOH} + 2 \text{ O}_2 \longrightarrow 2 \text{ CO}_2 + 2 \text{ H}_2\text{O}$   
(g)  $2 \text{ K}_2\text{O}_2 + 2 \text{ H}_2\text{O} \longrightarrow 4 \text{ KOH} + \text{O}_2$   
(h)  $3 \text{ PCl}_5 + 5 \text{ AsF}_3 \longrightarrow 3 \text{ PF}_5 + 5 \text{ AsCl}_3$
- (a) 12.06 g    (b) 1.258 g    (c) 4.692 g
- 7.83 g  $\text{K}_2\text{Zn}_3[\text{Fe}(\text{CN})_6]_2$
- 0.134 g  $\text{SiO}_2$
- $1.18 \times 10^3$  g
- 418 g KCl; 199 g  $\text{Cl}_2$
- (a) 58.8    (b) Probably nickel (Ni)
- 42.49% NaCl, 57.51% KCl
- 14.7 g  $\text{NH}_4\text{Cl}$ , 5.3 g  $\text{NH}_3$
- 303.0 g Fe; 83.93%

## CHAPTER 3

- Melting point  $1250^\circ\text{C}$  (obs.  $1541^\circ\text{C}$ ), boiling point  $2386^\circ\text{C}$  (obs.  $2831^\circ\text{C}$ ), density  $3.02 \text{ g cm}^{-3}$  (obs. 2.99)
- $\text{SbH}_3$ , HBr,  $\text{SnH}_4$ ,  $\text{H}_2\text{Se}$
- (a)  $F_x = 0$ ,  $F_y = -5.77 \times 10^{-9}$  N  
(b)  $V = 1.15 \times 10^{-18}$  J = 7.20 eV
- (a) At 2.12 Å separation, the magnitude of the force is  $5.13 \times 10^{-9}$  N. At 0.529 Å separation, the magnitude of the force is  $8.24 \times 10^{-8}$  N.  
(b) -20.4 eV  
(c)  $2.68 \times 10^6 \text{ m s}^{-1}$

9. (a) Sr (b) Rn (c) Xe (d) Sr
11. Using data for Be from Table 3.1, calculate  $\log(IE_n)$  for  $n = 1, 2, 3,$  and  $4$ . The graph of  $\log(IE_n)$  versus  $n$  shows a dramatic increase between  $n = 2$  and  $n = 3$ , suggesting two easily removed electrons outside a stable helium-like inner shell containing two electrons.
13. (a) Cs (b) F (c) K (d) At
15.  $K < Si < S < O < F$
- 17.

21. (a)  $86 e^-$  (8 valence, 78 core)  
 (b)  $37 e^-$  (1 valence, 36 core)  
 (c)  $36 e^-$  (8 valence, 28 core)  
 (d)  $52 e^-$  (6 valence, 46 core)
23.  $K(g) + Cl(g) \longrightarrow K^+(g) + Cl^-(g) \Delta E = 70 \text{ kJ mol}^{-1}$   
 $K(g) + Cl(g) \longrightarrow K^2(g) + Cl^1(g) \Delta E = 1203 \text{ kJ mol}^{-1}$
25.  $450 \text{ kJ mol}^{-1}$
27. The As–H bond length will lie between 1.42 and 1.71 Å (observed: 1.52 Å).  $SbH_3$  will have the weakest bond.
29. Bond lengths are often shorter than the sum of atomic radii in polar molecules because of the electrostatic attraction between the oppositely charged ends of the dipole. Such shortening is slight in HI, indicating that it is not very polar.

31. Most polar:  $N-P > C-N > N-O > N-N$ ; least polar
33. (a)  $Cl_4$  (b)  $OF_2$  (c)  $SiH_4$
35. ClO, 16%; KI, 74%;  $TlCl$ , 38%;  $InCl$ , 33%
37. HF, 40%; HCl, 19%; HBr, 14%; HI, 8%; CsF, 87%

41. The first is favored.

43. (a) Group IV,  $CO_2$  (b) Group VII,  $Cl_2O_7$   
 (c) Group V, V,  $NO_2^-$  (d) Group VI, VI,  $HSO_4^-$

47.   
 Bond lengths: N–H  $1.01 \times 10^{-10} \text{ m}$ ,  
 N–C  $1.47 \times 10^{-10} \text{ m}$ , C=O  $1.20 \times 10^{-10} \text{ m}$

Between  $1.18 \times 10^{-10} \text{ m}$  and  $1.43 \times 10^{-10} \text{ m}$ .

59. (a) SN = 4, tetrahedral (b) SN = 3, trigonal planar  
 (c) SN = 6, octahedral (d) SN = 4, pyramidal  
 (e) SN = 5, distorted T-shape

61. (a) SN = 6, square planar  
 (b) SN = 4, bent, angle < 109.5°  
 (c) SN = 4, pyramidal, angle < 109.5°  
 (d) SN = 2, linear

63. (a) SO<sub>3</sub> (b) NF<sub>3</sub> (c) NO<sub>2</sub><sup>-</sup> (d) CO<sub>3</sub><sup>2-</sup>

65. Only (d) and (e) are polar.

67. No, because VSEPR theory predicts a steric number of 3 and a bent molecule in both cases.

69. (a) Linear (b) The N end

73. (a) CsCl, cesium chloride  $\text{Cs}\cdot + \cdot\ddot{\text{Cl}}\cdot \rightarrow (\text{Cs}^+)(:\ddot{\text{Cl}}:^-)$   
 (b) CaAt<sub>2</sub>, calcium astatide  $\text{Ca}\cdot + 2\cdot\ddot{\text{At}}\cdot \rightarrow (\text{Ca}^{2+})(:\ddot{\text{At}}:^-)_2$   
 (c) Al<sub>2</sub>S<sub>3</sub>, aluminum sulfide  
 $2\cdot\ddot{\text{Al}}\cdot + 3\cdot\ddot{\text{S}}\cdot \rightarrow (\text{Al}^{3+})_2(:\ddot{\text{S}}:^{2-})_3$   
 (d) K<sub>2</sub>Te, potassium telluride  $2\text{K}\cdot + \cdot\ddot{\text{Te}}\cdot \rightarrow (\text{K}^+)_2(:\ddot{\text{Te}}:^{2-})$

75. (a) Aluminum oxide (b) Rubidium selenide  
 (c) Ammonium sulfide (d) Calcium nitrate  
 (e) Cesium sulfate  
 (f) Potassium hydrogen carbonate

77. (a) AgCN (b) Ca(OCl)<sub>2</sub> (c) K<sub>2</sub>CrO<sub>4</sub>  
 (d) Ga<sub>2</sub>O<sub>3</sub> (e) KO<sub>2</sub> (f) Ba(HCO<sub>3</sub>)<sub>2</sub>

79. Na<sub>3</sub>PO<sub>4</sub>, sodium phosphate

81. (a) SiO<sub>2</sub> (b) (NH<sub>4</sub>)<sub>2</sub>CO<sub>3</sub> (c) PbO<sub>2</sub>  
 (d) P<sub>2</sub>O<sub>5</sub> (e) CaI<sub>2</sub> (f) Fe(NO<sub>3</sub>)<sub>3</sub>

83. (a) Copper(I) sulfide and copper(II) sulfide  
 (b) Sodium sulfate  
 (c) Tetraarsenic hexaoxide  
 (d) Zirconium(IV) chloride  
 (e) Dichlorine heptaoxide  
 (f) Gallium(I) oxide

## CHAPTER 4

1. 0.66 m s<sup>-1</sup>  
 3. 3.04 m  
 5. (a) 5.00 × 10<sup>5</sup> s<sup>-1</sup> (b) 4.4 min  
 7. λ = 1.313 m; time = 0.0873 s  
 9. 2.7 K  
 11. Red  
 13. 550 nm, green  
 15. (a) 3.371 × 10<sup>-19</sup> J (b) 203.0 kJ mol<sup>-1</sup>  
 (c) 4.926 × 10<sup>-3</sup> mol s<sup>-1</sup>  
 17. 5.895 × 10<sup>-7</sup> m  
 19. r<sub>3</sub> = 0.0952 nm, E<sub>3</sub> = 26.06 × 10<sup>-18</sup> J,  
 energy per mole = 3.65 × 10<sup>3</sup> kJ mol<sup>-1</sup>,  
 ν = 1.14 × 10<sup>16</sup> s<sup>-1</sup>, λ = 2.63 × 10<sup>-8</sup> m = 26.3 nm  
 21. 72.90 nm, ultraviolet  
 23. Blue  
 25. Part of the yellow light, together with green and blue light, will eject electrons from cesium. No visible light will eject electrons from selenium; ultraviolet light is required.

27. (a) 7.4 × 10<sup>-20</sup> J (b) 4.0 × 10<sup>5</sup> m s<sup>-1</sup>

29. (a) 100 cm, 33 cm (b) two nodes

31. (a) 7.27 × 10<sup>-7</sup> m (b) 3.96 × 10<sup>10</sup> m  
 (c) 2.2 × 10<sup>-34</sup> m

35. (a) 5.8 × 10<sup>4</sup> m s<sup>-1</sup> (b) 7.9 m s<sup>-1</sup>

37. (a)

The probability of finding this particle between  $x_1 = 3 \text{ \AA}$  and  $x_2 = 4 \text{ \AA}$  is

$$\int_{3 \text{ \AA}}^{4 \text{ \AA}} \frac{2}{7 \text{ \AA}} \sin^2 \left( \frac{3\pi x}{7 \text{ \AA}} \right) dx = 0.25 = 25\%$$

If you are not yet comfortable with integrals, you can estimate the shaded area under the curve as 120 rectangles multiplied by the area per rectangle in the graph of  $|\psi|^2$  above,  $(0.01 \text{ \AA}^{-1})(0.2 \text{ \AA}) = 0.002$ . This gives a probability of  $0.24 = 24\%$ , so the estimated count of rectangles was close to correct.

$$\begin{aligned} \text{(b)} \quad \mathcal{H}\psi(x) &= -\frac{\hbar^2}{8\pi^2 m} \frac{d^2}{dx^2} \sqrt{\frac{2}{7 \text{ \AA}}} \sin \left( \frac{3\pi x}{7 \text{ \AA}} \right) \\ &= -\frac{\hbar^2}{8\pi^2 m} \left( \frac{3\pi}{7 \text{ \AA}} \right) \sqrt{\frac{2}{7 \text{ \AA}}} \frac{d}{dx} \cos \left( \frac{3\pi x}{7 \text{ \AA}} \right) \\ &= \frac{\hbar^2}{8\pi^2 m} \left( \frac{3\pi}{7 \text{ \AA}} \right)^2 \sqrt{\frac{2}{7 \text{ \AA}}} \sin \left( \frac{3\pi x}{7 \text{ \AA}} \right) \end{aligned}$$

This is indeed a constant,  $E$ , multiplied by the original

$$\psi = \sqrt{\frac{2}{7 \text{ \AA}}} \sin \left( \frac{3\pi x}{7 \text{ \AA}} \right)$$

$$\text{So } E = \frac{\hbar^2}{8\pi^2 m} \left( \frac{3\pi}{7 \text{ \AA}} \right)^2 = \frac{3^3 \hbar^2}{8m(7 \text{ \AA})^2}, \text{ in agreement}$$

with Equation 4.37

39.  $E_1 = 3.36 \times 10^{-18} \text{ J}$ ;  $E_2 = 1.34 \times 10^{-17} \text{ J}$ ;  
 $E_3 = 3.02 \times 10^{-17} \text{ J}$ ;  $\lambda = 1.97 \times 10^8 \text{ m}$
41. (a)  $\tilde{\Psi}_{21} = \tilde{\Psi}_{12}$  because the  $x$ - and  $y$ -axes are equivalent in a square box.  
 (b) Exchanging  $x$  and  $y$  corresponds to a 90-degree rotation.  
 (c) Exchanging labels cannot change the energy of the particle, a physically observable quantity.

## CHAPTER 5

- Only (b) is allowed.
- (a)  $4p$  (b)  $2s$  (c)  $6f$
- $2.0 \times 10^{-7}$  and 0
- (a) 2 radial, 1 angular (b) 1 radial, 0 angular (c) 2 radial, 3 angular
- $\psi_{p_z}^2 \propto \cos^2 \theta = 0$  for  $\theta = \pi/2$ ;  $d_{xz}$  nodal planes are the  $y$ - $z$  and  $x$ - $y$  planes;  $d_{x^2-y^2}$  nodal planes are two planes containing the  $z$ -axis at  $45^\circ$  from the  $x$ - and  $y$ -axes.
- 3.17  $\text{\AA}$ , 2.64  $\text{\AA}$
- $\epsilon_{2s} = -0.41 \text{ Ry} = -538 \text{ kJ mol}^{-1}$  and  $\bar{r} = 3.9a_0$ .
- 1 Ry exactly, -0.397 Ry, -0.376 Ry
- (a)  $1s^2 2s^2 2p^2$  (b)  $[\text{Ar}]3d^{10} 4s^2 4p^4$  (c)  $[\text{Ar}]3d^6 4s^2$
- $\text{Be}^+$ :  $1s^2 2s^1$ ;  $\text{C}^-$ :  $1s^2 2s^2 2p^3$ ;  $\text{Ne}^{2+}$ :  $1s^2 2s^2 2p^4$ ;  $\text{Mg}^+$ :  $[\text{Ne}]3s^1$ ;  $\text{P}^{2+}$ :  $[\text{Ne}]3s^2 3p^1$ ;  $\text{Cl}^-$ :  $[\text{Ne}]3s^2 3p^6$ ;  $\text{As}^+$ :  $[\text{Ar}]3d^{10} 4s^2 4p^2$ ;  $\text{I}^-$ :  $[\text{Kr}]4d^{10} 5s^2 5p^6$ . All except  $\text{Cl}^-$  and  $\text{I}^-$  are paramagnetic.
- (a) In (b)  $\text{S}^{2-}$  (c)  $\text{Mn}^{4+}$
- 117
- First "noble gases" at  $Z = 1, 5, 9$
- 9.52 eV or  $1.52 \times 10^{-18} \text{ J}$
- (a)  $Z_{\text{eff},1s} = 7.12$  (b)  $Z_{\text{eff},2s}$  approx equal 3.2 (c)  $Z_{\text{eff},2p}$  approx equal 1.9
- (a) K (b) Cs (c) Kr (d) K (e)  $\text{Cl}^-$
- (a)  $\text{S}^{2-}$  (b)  $\text{Ti}^{2+}$  (c)  $\text{Mn}^{2+}$  (d)  $\text{Sr}^{2+}$
- (a) For definition see Section 3.4. Helium has two electrons in the  $1s$  orbital, which has the smallest radius. Moreover, each electron only partially screens the other from the nucleus, which has charge +2. Therefore, removal of the first electron requires considerable energy.  
 (b) Li, because  $\text{Li}^+$  is essentially like He and explanation in (a) applies.  
 (c) 50.4 nm
- (a) Start with  $\text{Ca}^{2+}$  and Ar, which are isoelectronic; that is, they have the same number of electrons.  $\text{Ca}^{2+}$  has the higher nuclear charge and is therefore smaller. Mg is above Ca in Group 2, so its  $2+$  ion is smaller than that of Ca.  $\text{Br}^-$  is larger than  $\text{Cl}^-$  in Group 7, which is, in turn, larger than Ar. Therefore,  $\text{Mg}^{2+} < \text{Ca}^{2+} < \text{Ar} < \text{Br}^-$ .  
 (b) Na has one  $s$  electron, well shielded from the nucleus; Ne and  $\text{Na}^+$  are isoelectronic, but  $\text{Na}^+$  has a net positive charge; O has an unfilled shell, but no special stability relative to Ne. Therefore,  $\text{Na} < \text{O} < \text{Ne} < \text{Na}^+$ .  
 (c) Al is metallic, and thus electropositive; electronegativity sequence of others follows their relative horizontal positions in the periodic table. Therefore,  $\text{Al} < \text{H} < \text{O} < \text{F}$ .
- 318.4 nm, near ultraviolet

## CHAPTER 6

1. 0, 1, 2, 3, 2, 3 (6  $\sigma$  orbitals in order of increasing energy)
3. All circles.
5. The  $1\sigma_g$  MO
7. State (b) has higher energy because it has two electrons in the anti-bonding MO.
9.  $H_2$
11.  $He_2^+$
15. Smaller bond energy; larger bond length
17. (a)  $F_2: (\sigma_{g2s})^2(\sigma_{u2s}^*)^2(\sigma_{g2p})^2(\pi_{u2p})^4(\pi_{g2p}^*)^4$ ;  
 $F_2^+: (\sigma_{g2s})^2(\sigma_{u2s}^*)^2(\sigma_{g2p})^2(\pi_{u2p})^4(\pi_{g2p}^*)^3$   
 (b)  $F_2: 1, F_2^+ : \frac{3}{2}$   
 (c)  $F_2^+$  should be paramagnetic.  
 (d)  $F_2 < F_2^+$
19.  $(\sigma_{g3s})^2(\sigma_{u3s}^*)^2(\sigma_{g3p_z})^2(\pi_{u3p})^4(\pi_{g3p}^*)^2$  bond order = 2; paramagnetic
21. (a) F, 1 (b) N,  $2\frac{1}{2}$  (c) O,  $1\frac{1}{2}$
23. (a) is diamagnetic; (b) and (c) are paramagnetic.
25. Bond order  $2\frac{1}{2}$ , paramagnetic
27. The outermost electron in CF is in a  $\pi_{2p}^*$  molecular orbital. Removing it gives a stronger bond.
29.  $(\sigma_{1s})^2(\sigma_{1s}^*)^2$  bond order = 0. It should be unstable.
31. Ground-state electronic configurations  
 CF:  $(\sigma_{2s})^2(\sigma_{2s}^*)^2(\pi_{2p_x}, \pi_{2p_y})^4(\sigma_{2p_z})^2(\pi_{2p_x}^*, \pi_{2p_y}^*)^1$   
 CH:  $(\sigma^{nb})^2\sigma^1(\pi_x^{nb}, \pi_y^{nb})^2$   
 CH<sup>+</sup>:  $(\sigma^{nb})^2\sigma^1(\pi_x^{nb}, \pi_y^{nb})^1$   
 CN<sup>-</sup>:  $(\sigma_{2s})^2(\sigma_{2s}^*)^2(\pi_{2p_x}, \pi_{2p_y})^4(\sigma_{2p_z})^2$   
 CF, CH, and CH<sup>+</sup> have unpaired electrons.
33. Ground-state electronic configurations and bond orders:  
 CF<sup>+</sup>:  $(\sigma_{2s})^2(\sigma_{2s}^*)^2(\pi_{2p_x}, \pi_{2p_y})^4(\sigma_{2p_z})^2$   
 BO =  $(0.5)(8 - 2) = 3$   
 CF<sup>-</sup>:  $(\sigma_{2s})^2(\sigma_{2s}^*)^2(\pi_{2p_x}, \pi_{2p_y})^4(\sigma_{2p_z})^2(\pi_{2p_x}^*, \pi_{2p_y}^*)^2$   
 BO =  $(0.5)(8 - 4) = 2$   
 NO:  $(\sigma_{2s})^2(\sigma_{2s}^*)^2(\pi_{2p_x}, \pi_{2p_y})^4(\sigma_{2p_z})^2(\pi_{2p_x}^*, \pi_{2p_y}^*)^1$   
 BO =  $(0.5)(8 - 3) = 2.5$   
 Bond dissociation energies are ranked  $CF^+ > NO > CF^-$  because bond dissociation energy correlates with bond order.
35. (a) IE = 15.6 eV, from  $\sigma_{g2p_z}$ , which is highest occupied level.  
 (b) IE = 16.7 eV, from  $\pi_{u2p_{xy}}$ , which is second-highest occupied level.

37.

39. 11.88 eV: the  $4p_x$  or the  $4p_y$  orbital; 15.2 eV: the  $\sigma$  orbital
41.  $Li_2: \psi_{\sigma}^{\text{bond}}(1, 2; R_{AB}) = c_1[2s^A(1)2s^B(2) + 2s^A(2)2s^B(1)]$   
 $C_2: \psi_{\pi}^{\text{bond}}(1, 2, 3, 4; R_{AB}) = c_1R_{AB}[2p_y^A(1)2p_y^B(2)][2p_x^A(3)2p_x^B(4)] + c_1R_A[2p_y^A(2)2p_y^B(1)][2p_x^A(4)2p_x^B(3)]$
43. Because the ground state of Be has no unpaired electrons, the simple VB model predicts that a bond will not form between two Be atoms. The same result is predicted by the LCAO approach. Two of the valence electrons in  $Be_2$  occupy a bonding molecular orbital, but the other two must occupy an antibonding molecular orbital, leading to bond order zero.
45.  $\psi_{\sigma}^{\text{bond}}(1, 2; R_{BH}) = C_1[1s^H(1)2p_z^B(2)] + C_2[1s^H(2)2p_z^B(1)]$   
 The simple VB model predicts a diatomic molecule BH. This is incorrect. The correct prediction is  $BH_3$ .
47. N has one unpaired electron in each of its  $2p$  orbitals. Each of these can overlap with H  $1s$  to form an  $s$  bond whose wave function has the form  $\psi_{\sigma} = C_1[2p_a^N(1)1s^H(2)] + C_2[2p_a^N(2)1s^H(1)]$  where  $a$  is  $x, y$ , or  $z$ .  
 Because the  $2p$  orbitals are mutually perpendicular, the simple VB model predicts a trigonal pyramid with angles of 90 degrees.
49.  $sp^3$  hybridization of central N<sup>-</sup> bent molecular ion
51. (a)  $sp^3$  on C, tetrahedral  
 (b)  $sp$  on C, linear  
 (c)  $sp^3$  on O, bent  
 (d)  $sp^3$  on C, pyramidal  
 (e)  $sp$  on Be, linear
53.  $sp^2$  hybrid orbitals.  $ClO_3^+$  is trigonal planar,  $ClO_2^+$  is bent.
55.  $sp^3$  hybrid orbitals, tetrahedral
59. Sixteen electrons, so molecule is linear;  $sp$  hybridization of central N gives two  $\sigma$  bonds, with  $2p_z$  orbitals on outer nitrogen atoms (four electrons). Lone pairs on both  $2s$  orbitals on outer nitrogen atoms (four atoms).  $\pi$  system as in Figure 6.22:  $(\pi)^4(\pi^{nb})^4$  with eight electrons. Total bond order = 4; bond order 2 per N<sup>-</sup> bond.  $N_3$  and  $N_3^+$  should be bound.  $N_3$  and  $N_3^+$  are paramagnetic.

$SN = 3$ ,  $sp^2$  hybridization, bent molecule. The  $2p_z$  orbitals perpendicular to the plane of the molecule can be combined into a  $\pi$  molecular orbital containing one pair of electrons. This orbital adds bond order 1/2 to each N—O bond, for a total bond order of 3/2 per bond. There is also a  $\pi_z^{\text{nb}}$  (non-bonding) MO occupied by two electrons, but that does not affect the bond order.

63. They are similar to the MOs of benzene, Figure 6.54, with a few important differences. N is more electronegative than C, so the lowest  $\pi$  MO has increased electron density near the N atom, as shown at <http://csi.chemie.tu-darmstadt.de/ak/fimmel/tutorials/orbitals/molecular/pyridine.html>.

The coefficient multiplying the N  $2p_z$  orbital is larger for the linear combination of AOs that is used to construct the lowest  $\pi$  MO. Because the square of the coefficient of this atomic orbital summed over all the  $\pi$  MOs must equal 1, it contributes less to the highest  $\pi^*$  MO.

Finally, the presence of the N atom breaks the degeneracy in the middle two sets of  $\pi$  MOs, with the orbitals that have contributions from a  $2p_z$  orbital on the N atom lowering with respect to the other in each set. Thus the  $\pi$  orbitals of pyridine have six different energies, and the lowest three in energy are filled.

## CHAPTER 7

1. Yes, if the amount of knocking is less than that of iso-octane. Examples are the BTX compounds.

5. (a)  $\text{C}_{10}\text{H}_{22} \longrightarrow \text{C}_5\text{H}_{10} + \text{C}_5\text{H}_{12}$   
 (b) Two: 1-pentene and 2-pentene

11. (a) 1,2-Hexadiene  
 (b) 1,3,5-Hexatriene  
 (c) 2-Methyl-1-hexene  
 (d) 3-Hexyne

13. (a)  $sp^2, sp, sp^2, sp^3, sp^3, sp^3$   
 (b) All  $sp^2$   
 (c)  $sp^2, sp^2$ ; all others  $sp^3$   
 (d)  $sp^3, sp^3, sp, sp, sp^3, sp^3$

15. 30 double bonds; on the bonds shared by two hexagonal faces

17. 11.2%;  $4.49 \times 10^9$  kg

25. 79.9 L

27.  $-\text{CH}_3$  carbon  $sp^3$ , other carbon  $sp^2$ . A  $\pi$  orbital with two electrons bonds the second carbon atom with the oxygen atom. The three groups around the second carbon form an approximately trigonal planar structure, with bond angles near 120 degrees. The geometry about the first carbon atom is approximately tetrahedral, with angles near 109.5 degrees.

29. The Lewis diagrams for HCOOH and HCOO
- <sup>-</sup>
- are

One resonance form is given for HCOOH, but two are given for the formate anion HCOO<sup>-</sup>. In formic acid, one oxygen atom is doubly bonded to the carbon atom, and the other is singly bonded. In the anion, there is some double-bond character in both C—O bonds. The carbon atom in HCOOH is *sp*<sup>2</sup> hybridized (SN 3), and the OH oxygen atom is *sp*<sup>3</sup> hybridized (SN 4). The immediate surroundings of the carbon atom have trigonal planar geometry, and the C—O—H group is bent. In the HCOO<sup>-</sup>, the carbon atom is *sp*<sup>2</sup> hybridized (SN 3) and both O atoms have a *p* orbital perpendicular to the OCO plane that can participate in  $\pi$  bonding. These two O atom *p* orbitals and the remaining *p* orbital on the C atom result in a three-center four-electron  $\pi$  system. In HCOOH,  $\pi$  overlap occurs between out-of-plane *p* orbitals on the carbon atom and only one oxygen atom. Both the C— to —O bond lengths in the formate ion should lie somewhere between the value for the single bond (1.36 Å) and the value for the double bond (1.23 Å).

31. (a) Alcohol: CH<sub>3</sub>CH(OH)CH<sub>3</sub>, isopropyl alcohol;  
 carboxylic acid: CH<sub>3</sub>C(CH<sub>3</sub>)(OCH<sub>3</sub>)(CH<sub>2</sub>)<sub>3</sub>CH(CH<sub>3</sub>) =  
 CH<sub>2</sub>CH = CHC(CH<sub>3</sub>) = CHCOOH  
 (b) 3,7,11-Trimethyl-2,4-dodecadiene
33. (a) C<sub>9</sub>H<sub>8</sub>O<sub>4</sub> (b) 1.80 × 10<sup>-3</sup> mol
35. Dehydrogenate to make C—O bond from C—OH bond on first ring; move C—C bond from first to second ring; insert C=O group on third ring; remove hydrocarbon side chain on fourth ring together with hydrogen atom and replace it with an —OH group and a —COCH<sub>2</sub>OH group.

## CHAPTER 8

1. (a) PtF<sub>4</sub> (b) PtF<sub>6</sub>
3. V<sub>10</sub>O<sub>28</sub><sup>6-</sup> + 16 H<sub>3</sub>O<sup>+</sup> → 10 VO<sub>2</sub><sup>+</sup> + 24 H<sub>2</sub>O + 5 state, V<sub>2</sub>O<sub>5</sub>
5. 2 TiO<sub>2</sub> + H<sub>2</sub> → Ti<sub>2</sub>O<sub>3</sub> + H<sub>2</sub>O titanium(III) oxide
7. +2, +4, +3, +7, mixed +2 and +3, +7
9. Small ligands with large charge densities, such as F<sup>-</sup>, can stabilize the higher oxidation states of a given transition metal.
11. Al<sup>3+</sup> is a hard acid that prefers to pair with the hard base O<sup>2-</sup>, whereas Ni<sup>2+</sup> and Cu<sup>2+</sup> are borderline acids that prefer to pair with the soft base S<sup>2-</sup>.
13. Melting and boiling points. TiCl<sub>4</sub> is predicted to be a covalent compound because Ti<sup>4+</sup> is a high oxidation state cation that can accept electrons from Cl<sup>-</sup> ions to form covalent (dative) bonds.
15. Monodentate, at the N-atom lone pair
17. +2, +2, +2, 0
19. (a) Na<sub>2</sub>[Zn(OH)<sub>4</sub>] (b) [Co(en)<sub>2</sub>Cl<sub>2</sub>]NO<sub>3</sub>  
 (c) [Pt(H<sub>2</sub>O)<sub>3</sub>Br]Cl (d) [Pt(NH<sub>3</sub>)<sub>4</sub>(NO<sub>2</sub>)<sub>2</sub>]Br<sub>2</sub>

21. (a) Ammonium diamminetetraisothiocyanatochromate(III)  
 (b) Pentacarbonyltechnetium(I) iodide  
 (c) Potassium pentacyanomanganate(IV)  
 (d) Tetra-ammineaquachlorocobalt(III) bromide
23. [Cu(NH<sub>3</sub>)<sub>2</sub>Cl<sub>2</sub>] < KNO<sub>3</sub> < Na<sub>2</sub>[PtCl<sub>6</sub>] < [Co(NH<sub>3</sub>)<sub>6</sub>]Cl<sub>3</sub>
25. (a) [Pt(NH<sub>3</sub>)<sub>2</sub>BrCl] has two isomers (*cis* and *trans*). Neither is optically active.  
 (b) [Co(CN)<sub>3</sub>(H<sub>2</sub>O)<sub>2</sub>Cl]<sup>-</sup> has three possible isomers. None of the three isomers is optically active.  
 (c) [V(C<sub>2</sub>O<sub>4</sub>)<sub>3</sub>]<sup>3-</sup> is enantiomeric with two possible optical isomers.
27. Three isomeric [Fe(en)<sub>2</sub>Cl<sub>2</sub>]<sup>+</sup> complexes exist.
29. (a) Strong: 1, weak: 5 (b) Strong or weak: 0  
 (c) Strong or weak: 3 (d) Strong: 2, weak: 4  
 (e) Strong: 0, weak: 4
31. [Fe(CN)<sub>6</sub>]<sup>3-</sup>: 1 unpaired, CFSE = -2 Δ<sub>o</sub>; [Fe(H<sub>2</sub>O)<sub>6</sub>]<sup>3+</sup>: = unpaired, CFSE = 0
33. *d*<sup>3</sup> gives half-filled and *d*<sup>8</sup> filled and half-filled shells for metal ions in an octahedral field. *d*<sup>5</sup> will be half-filled and stable for high spin (small Δ<sub>o</sub>), and *d*<sup>6</sup> will be a filled subshell and stable for low spin (large Δ<sub>o</sub>).
35. This ion does not absorb any significant amount of light in the visible range.
37. λ ≈ 480 nm; Δ<sub>o</sub> ≈ 250 kJ mol<sup>-1</sup>
39. -500 kJ mol<sup>-1</sup>
41. (a) Orange–yellow  
 (b) Approximately 600 nm (actual: 575 nm)  
 (c) Decrease, because CN<sup>-</sup> is a strong-field ligand and will increase Δ<sub>o</sub>.
43. (a) Pale, because F<sup>-</sup> is an even weaker field ligand than H<sub>2</sub>O, so it should be high-spin *d*<sup>5</sup>. This is a half-filled shell and the complex will absorb only weakly.  
 (b) Colorless, because Hg(II) is a *d*<sup>10</sup> filled-subshell species.
45. [AuBr<sub>4</sub>]<sup>-</sup> is a low-spin, *d*<sup>8</sup> square planar complex, the square planar geometry being favored for larger cations. [NiBr<sub>4</sub>]<sup>2-</sup> is high-spin, *d*<sup>8</sup> tetrahedral complex, the tetrahedral geometry being favored for smaller cations.

## CHAPTER 9

1. NH<sub>4</sub>HS(s) → NH<sub>3</sub>(g) + H<sub>2</sub>S(g)
3. NH<sub>4</sub>Br(s) + NaOH(aq) → NH<sub>3</sub>(g) + H<sub>2</sub>O(l) + NaBr(aq)
5. 10.3 m
7. 1.40 × 10<sup>4</sup> ft
9. 1697.5 atm, 1.7200 × 10<sup>3</sup> bar
11. 0.857 atm
13. 8.00 L
15. 14.3 gill
17. 134 L
19. 35.2 psi
21. (a) 19.8 atm (b) 23.0 atm

23. The mass of a gas in a given volume changes proportionately to the absolute temperature. This statement will be true only at  $-19.8^{\circ}\text{C}$ .
25. (a)  $2\text{Na}(s) + 2\text{HCl}(g) \longrightarrow 2\text{NaCl}(s) + \text{H}_2(g)$   
(b) 4.23 L
27.  $3.0 \times 10^6$  L
29. 24.2 L
31. (a) 932 L  $\text{H}_2\text{S}$  (b) 1.33 kg, 466 L  $\text{SO}_2$
33.  $X_{\text{SO}_3} = 0.135$ ;  $P_{\text{SO}_3} = 0.128$  atm
35.  $X_{\text{N}_2} = 0.027$ ;  $P_{\text{N}_2} = 1.6 \times 10^{-4}$  atm
37. (a)  $X_{\text{CO}} = 0.444$  (b)  $X_{\text{CO}} = 0.33$
39. (a)  $5.8 \times 10^{17}$  (b) 520 L
41. (a)  $1.93 \times 10^3 \text{ m s}^{-1} = 1.93 \text{ km s}^{-1}$  (b)  $226 \text{ m s}^{-1}$
43.  $6100 \text{ m s}^{-1}$  (6000 K),  $790 \text{ m s}^{-1}$  (100 K)
45. 1.82%
47. Greater. As  $T$  increases, the Maxwell–Boltzmann distribution shifts to higher speeds.
49. 162 atm =  $2.38 \times 10^3$  psi
51. (a) 27.8 atm (b) 24.6 atm; attractive forces dominate.
53.  $6.1 \times 10^{-9}$  m
55.  $92.6 \text{ g mol}^{-1}$
57. 1830 stages
59.  $7.4 \times 10^{-7}$  atm;  $20 \text{ m}^2 \text{ s}^{-1}$

**CHAPTER 10**

1. Gas
3. (a) Condensed (b)  $10.3 \text{ cm}^3 \text{ mol}^{-1}$
5. Condensed
7. The liquid water has vaporized to steam.
9. Harder, because forces binding the particles in NaCl are stronger and resist deformation better.
11. In all three phases, the diffusion constant should decrease as its density is increased. At higher densities, molecules are closer to each other. In gases, they will collide more often and travel shorter distances between collisions. In liquids and solids, there will be less space for molecules to move around each other.
13. Both involve the interaction of an ion with a dipole. In the first case, the dipole is permanent (preexisting), whereas in the second, it is induced by the approach of the ion. Induced dipole forces are weaker than ion–dipole forces. Examples:  $\text{Na}^+$  with HCl (ion–dipole);  $\text{Na}^+$  with  $\text{Cl}_2$  (induced dipole).
15. (a) *Ion–ion*, dispersion (b) *Dipole–dipole*, dispersion  
(c) Dispersion (d) Dispersion
17. Bromide ion
19. (a)  $2.0 \times 10^{-10}$  m;  $2.5 \times 10^{-10}$  m  
(b) KCl has a longer bond yet lower potential energy (greater bond strength).

21. Heavier gases have stronger attractive forces, favoring the liquid and solid states.
23.  $\text{Ne} < \text{NO} < \text{NH}_3 < \text{RbCl}$ ; nonpolar < polar < hydrogen-bonded < ionic
25. An eight-membered ring of alternating H and O atoms is reasonable. The ring is probably not planar.
27. The two have comparable molar masses, but the hydrogen-bonding in hydrazine should give it a higher boiling point.
29.  $6.7 \times 10^{25}$
31. 6.16 L; several times smaller than the volume of 1 mol at standard temperature and pressure ( $22.4 \text{ L mol}^{-1}$ )
33.  $7.02 \times 10^{13} \text{ atoms cm}^{-3}$
35.  $0.9345 \text{ g L}^{-1}$
37. 2.92 g  $\text{CaCO}_3$
39. 0.69 atm; 31% lies below
41. Iridium. Its higher melting and boiling points indicate that the intermolecular forces in iridium are stronger than those in sodium.
43. No phase change will occur.
47. (a) Liquid (b) Gas (c) Solid (d) Gas
49. (a) Above. If gas and solid coexist at  $-84.0^{\circ}\text{C}$ , their coexistence must extend upward in temperature to the triple point.  
(b) The solid will sublime at some temperature below  $-84.0^{\circ}\text{C}$ .
51. The meniscus between gas and liquid phases will disappear at the critical temperature, 126.19 K.

**CHAPTER 11**

1. (a)  $5.53 \times 10^{-3} \text{ M}$  (b)  $5.5 \times 10^{-3}$  molal  
(c) 3.79 L
3. Molarity = 12.39 M in HCl; mole fraction of HCl = 0.2324; molality = 16.81 molal in HCl
5. 8.9665 molal
7. 0.00643 g  $\text{H}_2\text{O}$
9. (a)  $1.33 \text{ g mL}^{-1}$  (b) 164 mL
11. 1.06 M in NaOH
13. (a)  $\text{Ag}^+(aq) + \text{Cl}^-(aq) \longrightarrow \text{AgCl}(s)$   
(b)  $\text{K}_2\text{CO}_3(s) + 2\text{H}^+(aq) \longrightarrow$   
 $2\text{K}^+(aq) + \text{CO}_2(g) + \text{H}_2\text{O}(\ell)$   
(c)  $2\text{Cs}(s) + 2\text{H}_2\text{O}(\ell) \longrightarrow$   
 $2\text{Cs}^+(aq) + 2\text{OH}^-(aq) + \text{H}_2(g)$   
(d)  $2\text{MnO}_4^-(aq) + 16\text{H}^+(aq) + 10\text{Cl}^-(aq) \longrightarrow$   
 $5\text{Cl}_2(g) + 2\text{Mn}^{2+}(aq) + 8\text{H}_2\text{O}(\ell)$
15. 16.8 mL of 7.91 M  $\text{HNO}_3$
17.  $6.74 \times 10^3$  L  $\text{CO}_2(g)$
19. (a)  $\text{Ca}(\text{OH})_2(aq) + 2\text{HF}(aq) \longrightarrow \text{CaF}_2(aq) + 2\text{H}_2\text{O}(\ell)$   
Hydrofluoric acid, calcium hydroxide, calcium fluoride

- (b)  $2 \text{RbOH}(aq) + \text{H}_2\text{SO}_4(aq) \longrightarrow \text{Rb}_2\text{SO}_4(aq) + 2 \text{H}_2\text{O}(\ell)$   
Sulfuric acid, rubidium hydroxide, rubidium sulfate
- (c)  $\text{Zn}(\text{OH})_2(s) + 2 \text{HNO}_3(aq) \longrightarrow \text{Zn}(\text{NO}_3)_2(aq) + 2 \text{H}_2\text{O}(\ell)$   
Nitric acid, zinc hydroxide, zinc nitrate
- (d)  $\text{KOH}(aq) + \text{CH}_3\text{COOH}(aq) \longrightarrow \text{KCH}_3\text{COO}(aq) + \text{H}_2\text{O}(\ell)$   
Acetic acid, potassium hydroxide, potassium acetate
21. Sodium sulfide
23. (a)  $\text{PF}_3 + 3 \text{H}_2\text{O} \longrightarrow \text{H}_3\text{PO}_3 + 3 \text{HF}$   
(b)  $[\text{H}_3\text{PO}_3] = 0.0882 \text{ M}; [\text{HF}] = 0.265 \text{ M}$
25.  $0.04841 \text{ M HNO}_3$
27. (a)  $2 \text{PF}_2\text{I}(\ell) + 2 \text{Hg}(\ell) \longrightarrow \text{P}_2\text{F}_4(\text{g}) + \text{Hg}_2\text{I}_2(\text{s})$   
(b)  $2 \text{KClO}_3(\text{s}) \longrightarrow 2 \text{KCl}(\text{s}) + 3 \text{O}_2(\text{g})$   
(c)  $4 \text{NH}_3(\text{g}) + 5 \text{O}_2(\text{g}) \longrightarrow 4 \text{N}(\text{g}) + 6 \text{H}_2\text{O}(\text{g})$   
(d)  $2 \text{As}(\text{s}) + 6 \text{NaOH}(\ell) \longrightarrow 2 \text{Na}_3\text{AsO}_3(\text{s}) + 3 \text{H}_2(\text{g})$
29.  $2 \text{Au}(\text{s}) + 6 \text{H}_2\text{SeO}_4 \longrightarrow \text{Au}_2(\text{SeO}_4)_3(aq) + 3 \text{H}_2\text{SeO}_3(aq) + 3 \text{H}_2\text{O}_6(\ell)$   
Au is oxidized  
 $\text{H}_2\text{SeO}_4$  is reduced (half of it)
31. (a)  $2 \text{VO}_2^+(aq) + \text{SO}_2(\text{g}) \longrightarrow 2 \text{VO}^2+(aq) + \text{SO}_4^{2-}(aq)$   
(b)  $\text{Br}_2(\ell) + \text{SO}_2(\text{g}) + 6 \text{H}_2\text{O}(\ell) \longrightarrow 2 \text{Br}^-(aq) + \text{SO}_4^{2-}(aq) + 4 \text{H}_3\text{O}^+(aq)$   
(c)  $\text{Cr}_2\text{O}_7^{2-}(aq) + 3 \text{Np}^{4+}(aq) + 2 \text{H}_3\text{O}^+(aq) \longrightarrow 2 \text{Cr}^{3+}(aq) + 3 \text{NpO}_2^{2+}(aq) + 3 \text{H}_2\text{O}(\ell)$   
(d)  $5 \text{HCOOH}(aq) + 2 \text{MnO}_4^-(aq) + 6 \text{H}_3\text{O}^+(aq) \longrightarrow 5 \text{CO}_2(\text{g}) + 2 \text{Mn}^{2+}(aq) + 14 \text{H}_2\text{O}(\ell)$   
(e)  $3 \text{Hg}_2\text{HPO}_4(\text{s}) + 2 \text{Au}(\text{s}) + 8 \text{Cl}^-(aq) + 3 \text{H}_3\text{O}^+(aq) \longrightarrow 6 \text{Hg}(\ell) + 3 \text{H}_2\text{PO}_4^-(aq) + 2 \text{AuCl}_4^-(aq) + 3 \text{H}_2\text{O}(\ell)$
33. (a)  $2 \text{Cr}(\text{OH})_3(\text{s}) + 3 \text{Br}_2(aq) + 10 \text{OH}^-(aq) \longrightarrow 2 \text{CrO}_4^{2-}(aq) + 6 \text{Br}^-(aq) + 8 \text{H}_2\text{O}(\ell)$   
(b)  $\text{ZrO}(\text{OH})_2(\text{s}) + 2 \text{SO}_3^{2-}(aq) \longrightarrow \text{Zr}(\text{s}) + 2 \text{SO}_4^{2-}(aq) + \text{H}_2\text{O}(\ell)$   
(c)  $7 \text{HPbO}_2^-(aq) + 2 \text{Re}(\text{s}) \longrightarrow 7 \text{Pb}(\text{s}) + 2 \text{ReO}_4^-(aq) + \text{H}_2\text{O}(\ell) + 5 \text{OH}^-(aq)$   
(d)  $4 \text{HXeO}_4^-(aq) + 8 \text{OH}^-(aq) \longrightarrow 3 \text{XeO}_6^{4-}(aq) + \text{Xe}(\text{g}) + 6 \text{H}_2\text{O}(\ell)$   
(e)  $\text{N}_2\text{H}_4(aq) + 2 \text{CO}_3^{2-}(aq) \longrightarrow \text{N}_2(\text{g}) + 2 \text{CO}(\text{g}) + 4 \text{OH}^-(aq)$
35. (a)  $\text{Fe}^{2+}(aq) \longrightarrow \text{Fe}^{3+}(aq) + e^-$  oxidation  
 $\text{H}_2\text{O}_2(aq) + 2 \text{H}_3\text{O}^+(aq) + 2 e^- \longrightarrow 4 \text{H}_2\text{O}(\ell)$  reduction  
(b)  $5 \text{H}_2\text{O}(\ell) + \text{SO}_2(aq) \longrightarrow \text{HSO}_4^-(aq) + 3 \text{H}_3\text{O}^+(aq) + 2 e^-$  oxidation  
 $\text{Mn}^{4+}(aq) + 8 \text{H}_3\text{O}^+(aq) + 5 e^- \longrightarrow \text{Mn}^{2+}(aq) + 12 \text{H}_2\text{O}(\ell)$  reduction  
(c)  $\text{ClO}_2^-(aq) \longrightarrow \text{ClO}_2(\text{g}) + e^-$  oxidation  
 $\text{ClO}_2^-(aq) + 4 \text{H}_3\text{O}^+(aq) + 4 e^- \longrightarrow \text{Cl}^-(aq) + 6 \text{H}_2\text{O}(\ell)$  reduction
37.  $3 \text{HNO}_2(aq) \longrightarrow \text{NO}_3^-(aq) + 2 \text{NO}(\text{g}) + \text{H}_3\text{O}^+(aq)$
39.  $7.175 \times 10^{-3} \text{ M Fe}^{2+}(aq)$

41.  $0.2985 \text{ atm}$
43.  $3.34 \text{ K kg mol}^{-1}$
45.  $340 \text{ g mol}^{-1}$
47.  $1.7 \times 10^2 \text{ g mol}^{-1}$
49.  $-2.8^\circ\text{C}$ . As the solution becomes more concentrated, its freezing point decreases further.
51. 2.70 particles (complete dissociation of  $\text{Na}_2\text{SO}_4$  gives 3 particles)
53.  $1.88 \times 10^4 \text{ g mol}^{-1}$
55.  $7.46 \times 10^3 \text{ g mol}^{-1}$
57. (a)  $0.17 \text{ mol CO}_2$   
(b) Because the partial pressure of  $\text{CO}_2$  in the atmosphere is much less than 1 atm, the excess  $\text{CO}_2$  will bubble out from the solution and escape when the cap is removed.
59.  $4.13 \times 10^2 \text{ atm}$
61. 0.774
63. (a) 0.491 (b) 0.250 atm (c) 0.575

## CHAPTER 12

1.  $-2.16 \times 10^4 \text{ L atm} = -2.19 \times 10^6 \text{ J}$
3. 86.6 m
5. 24.8, 28.3, 29.6, 31.0, and  $32.2 \text{ J K}^{-1} \text{ mol}^{-1}$ , respectively; extrapolating gives about  $33.5 \text{ J K}^{-1} \text{ mol}^{-1}$  for Fr.
7. 26.1, 25.4, 25.0, 24.3, 25.4, and  $27.6 \text{ J K}^{-1} \text{ mol}^{-1}$
9. (a)  $w$  is zero,  $q$  is positive, and  $\Delta U$  is positive.  
(b)  $w$  is zero,  $q$  is negative, and  $\Delta U$  is negative.  
(c)  $(w_1 + w_2)$  is zero.  $(\Delta U_1 + \Delta U_2) = (q_1 + q_2)$ . The latter two sums could be any of three possibilities: both positive, both negative, or both zero.
11.  $0.468 \text{ J K}^{-1} \text{ g}^{-1}$
13.  $q_1 = Mc_{s1}\Delta T_1 = -q_2 = -Mc_{s2}\Delta T_2$   $\frac{C_{s1}}{C_{s2}} = -\frac{\Delta T_2}{\Delta T_1}$
15.  $314 \text{ J g}^{-1}$  (modern value is  $333 \text{ J g}^{-1}$ )
17.  $w = -323 \text{ J}; \Delta U = -393 \text{ J}; q = -70 \text{ J}$
19. (a) 38.3 L  
(b)  $w = -1.94 \times 10^3 \text{ J}; q = 0; \Delta U = -1.94 \times 10^3 \text{ J}$   
(c) 272 K
21.  $\Delta U = +11.2 \text{ kJ}; q = 0; w = +11.2 \text{ kJ}$
23. For HI:  
The measured value is  $c_p = 29.16 \text{ J mol}^{-1} \text{ K}^{-1}$ . (Appendix D)  
The vibrational contribution =  $29.16 - 29.10 = 0.06 \text{ J mol}^{-1} \text{ K}^{-1}$ .  
Percent of  $c_p$  for HI due to vibration =  $(0.06/29.16) \times 100 = 0.2\%$   
For  $\text{I}_2$ :  
The measured value is  $c_p = 36.90 \text{ J mol}^{-1} \text{ K}^{-1}$ . (Appendix D)  
The vibrational contribution =  $36.02 - 29.10 = 7.80 \text{ J mol}^{-1} \text{ K}^{-1}$ .

Percent of  $c_p$  for  $I_2$  due to vibration =  $(7.80/36.90) \times 100 = 21.1\%$

25. (a) for Argon  $\Delta H = 11.4$  kJ  
(b) for  $C_2H_4$   $\Delta H = 73.2$  kJ
27. (a)  $-6.68$  kJ (b)  $+7.49$  kJ (c)  $+0.594$  kJ
29.  $41.3$  kJ
31.  $+513$  J
33.  $10.4^\circ C$
35.  $-623.5$  kJ
37. A pound of diamonds. (This is recommended as a source of heat only as a last resort, however!)
39.  $-555.93$  kJ
41. (a)  $-878.26$  kJ (b)  $-1.35 \times 10^7$  kJ of heat absorbed
43. (a)  $-81.4$  kJ (b)  $55.1^\circ C$
45.  $\Delta H_f^\circ = -152.3$  kJ mol $^{-1}$
47. (a)  $C_{10}H_8(s) + 12 O_2(g) \longrightarrow 10 CO_2(g) + 4 H_2O(\ell)$   
(b)  $-5157$  kJ (c)  $-5162$  kJ (d)  $+84$  kJ mol $^{-1}$
49.  $-264$  kJ mol $^{-1}$
51.  $-1.58 \times 10^3$  kJ
53. Each side of the equation has three B–Br and three B–Cl bonds.
55.  $w = -6.87$  kJ;  $q = +6.87$  kJ;  $\Delta U = \Delta H = 0$
57.  $T_f = 144$  K;  $w = \Delta U = 23.89$  kJ;  $\Delta H = 26.48$  kJ
59.  $N_{high}/N_{low} = 0.91$
61.  $5.3 \times 10^{-4}$
63.  $2.42 \times 10^{-9}$

### CHAPTER 13

1. (a) The system is all the matter participating in the reaction  $NH_4NO_3(s) \longrightarrow NH_4^+(aq) + NO_3^-(aq)$ . This includes solid ammonium nitrate, the water in which it dissolves, and the aquated ions that are the products of the dissolution process. The surroundings include the flask or beaker in which the system is held, the air above the system, and other neighboring materials. The dissolution of ammonium nitrate is spontaneous after any physical separation (such as a glass wall or a space of air) between the water and the ammonium nitrate has been removed.
- (b) The system is all the matter participating in the reaction  $H_2(g) + O_2(g) \longrightarrow$  products. The surroundings are the walls of the bomb and other portions of its environment that might deliver heat or work or absorb heat or work. The reaction of hydrogen with oxygen is spontaneous. Once hydrogen and oxygen are mixed in a closed bomb, no constraint exists to prevent their reaction. It is found experimentally that this system gives products quite slowly at room temperature (no immediate explosion). It explodes instantly at higher temperatures.
- (c) The system is the rubber band. The surroundings consist of the weight (visualized as attached to the lower

end of the rubber band), a hanger at the top of the rubber band, and the air in contact with the rubber band. The change is spontaneous once a constraint such as a stand or support underneath the weight is removed.

- (d) The system is the gas contained in the chamber. The surroundings are the walls of the chamber and the moveable piston head. The process is spontaneous if the force exerted by the weight on the piston exceeds the force exerted by the collisions of the molecules of the gas on the bottom of the piston. (The forces due to the mass of the piston itself and friction between the piston and the walls within which it moves are neglected.)
- (e) The system is the drinking glass in the process glass  $\longrightarrow$  fragments. The surroundings are the floor, the air, and the other materials in the room. The change is spontaneous. It occurs when the constraint, which is whatever portion of the surroundings holds the glass above the floor, is removed.
3. (a)  $6 \times 6 = 36$  (b) 1 in 36
5. The tendency for entropy to increase
7.  $10^{-3.62 \times 10^{23}}$  (that is, 1 part in  $10^{+3.62 \times 10^{23}}$ )
9. (a)  $\Delta S > 0$  (b)  $\Delta S > 0$  (c)  $\Delta S < 0$
11.  $9.61$  J K $^{-1}$  mol $^{-1}$
13.  $29$  kJ mol $^{-1}$
15.  $\Delta U = \Delta H = 0$ ;  $w = -1.22 \times 10^4$  J;  $q = +1.22 \times 10^4$  J;  $\Delta S = +30.5$  J K $^{-1}$
17.  $\Delta S_{sys} = +30.2$  J K $^{-1}$ ;  $\Delta S_{surr} = -30.2$  J K $^{-1}$ ;  $\Delta S_{univ} = 0$
19.  $\Delta S_{Fe} = -8.24$  J K $^{-1}$ ;  $\Delta S_{H_2O} = +9.49$  J K $^{-1}$ ;  $\Delta S_{tot} = +1.25$  J K $^{-1}$
21. (a)  $-116.58$  J K $^{-1}$  (b) Lower (more negative)
23.  $\Delta S^\circ = -162.54, -181.12, -186.14, -184.72, -191.08$  J K $^{-1}$ . The entropy changes in these reactions become increasingly negative with increasing atomic mass, except that the rubidium reaction is out of line.
25.  $\Delta S_{surr}$  must be positive and greater in magnitude than  $44.7$  J K $^{-1}$ .
27.  $\Delta S_{sys} > 0$  because the gas produced (oxygen) has many possible microstates.
29. (a)  $+740$  J (b)  $2.65$  kJ (c) No (d)  $196$  K
31.  $q = +38.7$  kJ;  $w = -2.92$  kJ;  $\Delta U = +35.8$  kJ;  $\Delta S_{sys} = +110$  J K $^{-1}$ ;  $\Delta G = 0$
33. Overall reaction:  $2 Fe_2O_3(s) + 3 C(s) \longrightarrow 4 Fe(s) + 3 CO_2(g)$   $\Delta G = +840$  J +  $3(-400)$  J =  $-360$  J < 0
35. (a)  $0 < T < 3000$  K  
(b)  $0 < T < 1050$  K  
(c) Spontaneous at all temperatures
37.  $WO_3(s) + 3 H_2(g) \longrightarrow W(s) + 3 H_2O(g)$   
 $\Delta H^\circ = 117.41$  kJ;  $\Delta S^\circ = 131.19$  J K $^{-1}$ ;  $\Delta G < 0$  for  $T > \Delta H^\circ/\Delta S^\circ = 895$  K
39. (a)  $0.333$  (b)  $q = -1000$  J (c)  $w = -500$  J

## CHAPTER 14

1. (a)  $\left[ \frac{P_{\text{H}_2\text{O}}^2}{P_{\text{H}_2}^2 P_{\text{O}_2}} \right]_{\text{eq}} = K$  (b)  $\left[ \frac{P_{\text{XeF}_6}}{P_{\text{Xe}} P_{\text{F}_2}^3} \right]_{\text{eq}} = K$
- (c)  $\left[ \frac{P_{\text{CO}_2}^{12} P_{\text{H}_2\text{O}}^6}{P_{\text{C}_6\text{H}_6}^2 P_{\text{O}_2}^{15}} \right]_{\text{eq}} = K$
3.  $\text{P}_4(\text{g}) + 6 \text{Cl}_2(\text{g}) + 2 \text{O}_2(\text{g}) \rightleftharpoons 4 \text{POCl}_3(\text{g})$   
 $\left[ \frac{P_{\text{POCl}_3}^4}{P_{\text{P}_4} P_{\text{Cl}_2}^6 P_{\text{O}_2}^2} \right]_{\text{eq}} = K$
5. (a)  $\left[ \frac{P_{\text{CO}_2} P_{\text{H}_2}}{P_{\text{CO}} P_{\text{H}_2\text{O}}} \right]_{\text{eq}} = K$  (b) 0.056 atm
7. (a) The graph is a straight line passing through the origin.  
 (b) The experimental  $K$ 's range from  $3.42 \times 10^{-2}$  to  $4.24 \times 10^{-2}$ , with a mean of  $3.84 \times 10^{-2}$ .
9. (a)  $\left[ \frac{(P_{\text{H}_2\text{S}})^8}{(P_{\text{H}_2})^8} \right]_{\text{eq}} = K$  (b)  $\left[ \frac{(P_{\text{COCl}_2})(P_{\text{H}_2})}{(P_{\text{Cl}_2})} \right]_{\text{eq}} = K$
- (c)  $[P_{\text{CO}_2}]_{\text{eq}} = K$  (d)  $\left[ \frac{1}{(P_{\text{C}_2\text{H}_2})^3} \right]_{\text{eq}} = K$
11. (a)  $\left[ \frac{[\text{Zn}^{2+}]}{[\text{Ag}^+]^2} \right]_{\text{eq}} = K$
- (b)  $\left[ \frac{[\text{VO}_3(\text{OH})^{2-}][\text{OH}^-]}{[\text{VO}_4^{3-}]} \right]_{\text{eq}} = K$
- (c)  $\left[ \frac{[\text{HCO}_3^-]^6}{[\text{As}(\text{OH})_6^{3-}]^2 P_{\text{CO}_2}^6} \right]_{\text{eq}} = K$
13.  $\Delta G^\circ = -550.23 \text{ kJ}$ ;  $K = 2.5 \times 10^{96}$
15. (a)  $2.6 \times 10^{12}$   $\left[ \frac{P_{\text{SO}_3}}{(P_{\text{SO}_2})(P_{\text{O}_2})^{1/2}} \right]_{\text{eq}} = K$   
 (b)  $5.4 \times 10^{-35}$   $[(P_{\text{O}_2})^{1/2}]_{\text{eq}} = K$   
 (c)  $5.3 \times 10^3$   $[[\text{Cu}^{2+}][\text{Cl}^-]^2]_{\text{eq}} = K$
17.  $K_1 = (K_2)^3$
19.  $K_2/K_1$
21.  $1.04 \times 10^{-4}$
23. 14.6
25. (a)  $P_{\text{SO}_2} = P_{\text{Cl}_2} = 0.58 \text{ atm}$ ;  $P_{\text{SO}_2\text{Cl}_2} = 0.14 \text{ atm}$  (b) 2.4
27. (a) 0.180 atm (b) 0.756
29.  $P_{\text{PCl}_5} = 0.078 \text{ atm}$ ;  $P_{\text{PCl}_3} = P_{\text{Cl}_2} = 0.409 \text{ atm}$
31.  $P_{\text{Br}_2} = 0.0116 \text{ atm}$ ;  $P_{\text{I}_2} = 0.0016 \text{ atm}$ ;  $P_{\text{IBr}} = 0.0768 \text{ atm}$
33.  $P_{\text{N}_2} = 0.52 \text{ atm}$ ;  $P_{\text{O}_2} = 0.70 \text{ atm}$ ;  $P_{\text{NO}} = 3.9 \times 10^{-16} \text{ atm}$
35.  $P_{\text{N}_2} = 0.0148 \text{ atm}$ ;  $P_{\text{H}_2} = 0.0445 \text{ atm}$ ;  $P_{\text{NH}_3} = 0.941 \text{ atm}$
37.  $5.6 \times 10^{-5} \text{ mol L}^{-1}$
39.  $2.0 \times 10^{-2}$
41. (a) 0.31 atm (b) 1.65 atm, 0.15 atm
43. (a)  $8.46 \times 10^{-5}$  (b) 0.00336 atm

45. (a)  $9.83 \times 10^{-4}$  (b) Net consumption
47.  $K > 5.1$
49. (a)  $Q = 2.05$ ; reaction shifts to right  
 (b)  $Q = 3.27$ ; reaction shifts to left
51. (a) 0.800, left  
 (b)  $P_{\text{P}_4} = 5.12 \text{ atm}$ ,  $P_{\text{P}_2} = 1.77 \text{ atm}$   
 (c) Dissociation
53. (a) Shifts left  
 (b) Shifts right  
 (c) Shifts right  
 (d) The volume must have been increased to keep the total pressure constant; shift is to left.  
 (e) No effect
55. (a) Exothermic (b) Decrease
57. Run the first step at low temperature and high pressure, and the second step at high temperature and low pressure.
59. Low temperature and high pressure
61.  $-58 \text{ kJ}$
63. (a)  $-56.9 \text{ kJ}$   
 (b)  $\Delta H^\circ = 255.6 \text{ kJ}$ ,  $\Delta S^\circ = +4.2 \text{ J K}^{-1}$
65.  $4.3 \times 10^{-3}$
67. (a)  $23.8 \text{ kJ mol}^{-1}$   
 (b)  $T_b = 240 \text{ K}$

69. (a)

 (b)  $-16.9 \times 10^3 \text{ J mol}^{-1}$ 

71. 76

 73. (a)  $K_1 = 1.64 \times 10^{-2}$ ;  $K_2 = 5.4$  (b) 330

## CHAPTER 15

1. (a)  $\text{Cl}^-$  cannot act as a Brønsted–Lowry acid.  
 (b)  $\text{SO}_4^{2-}$   
 (c)  $\text{NH}_3$   
 (d)  $\text{NH}_2^-$  (but  $\text{NH}_3$  put in water acts as a base, not an acid)  
 (e)  $\text{OH}^-$
3.  $\text{HCO}_3^-$  serves as the base.
5. (a)  $\text{CaO}(\text{s}) + \text{H}_2\text{O}(\ell) \longrightarrow \text{Ca}(\text{OH})_2(\text{s})$   
 (b) The CaO acts as a Lewis base, donating a pair of electrons (located on the oxide ion) to one of the hydrogen ions (the Lewis acid) of the water molecule.

7. (a) Fluoride acceptor  
(b) Acids:  $\text{BF}_3$ ,  $\text{TiF}_4$ ; bases:  $\text{ClF}_3\text{O}_2$ ,  $\text{KF}$
9. (a) Base,  $\text{Mg}(\text{OH})_2$  (b) Acid,  $\text{HOCl}$   
(c) Acid,  $\text{H}_2\text{SO}_4$  (d) Base,  $\text{CsOH}$
11.  $\text{SnO}(\text{s}) + 2 \text{HCl}(\text{aq}) \longrightarrow \text{Sn}^{2+}(\text{aq}) + 2 \text{Cl}^{-}(\text{aq}) + \text{H}_2\text{O}(\ell)$ ;  
 $\text{SnO}(\text{s}) + \text{NaOH}(\text{aq}) + \text{H}_2\text{O}(\ell) \longrightarrow$   
 $\text{Sn}(\text{OH})_3^{-}(\text{aq}) + \text{Na}^{+}(\text{aq})$
13. 3.70
15.  $3 \times 10^{-7} \text{ M} < [\text{H}_3\text{O}^{+}] < 3 \times 10^{-6} \text{ M}$ ;  
 $3 \times 10^{-9} \text{ M} < [\text{OH}^{-}] < 3 \times 10^{-8} \text{ M}$
17.  $[\text{H}_3\text{O}^{+}] = 1.0 \times 10^{-8} \text{ M}$ ;  $[\text{OH}^{-}] = 1.7 \times 10^{-6} \text{ M}$
19. The first reaction is more likely to be correct. In the second case, the reactant  $\text{H}_3\text{O}^{+}$  would be present at very low concentration ( $10^{-7} \text{ M}$ ) and would give neither a fast nor a vigorous reaction.
21. (a)  $\text{C}_{10}\text{H}_{15}\text{ON}(\text{aq}) + \text{H}_2\text{O}(\ell) \rightleftharpoons$   
 $\text{C}_{10}\text{H}_{15}\text{ONH}^{+}(\text{aq}) + \text{OH}^{-}(\text{aq})$   
(b)  $7.1 \times 10^{-11}$   
(c) Stronger
23.  $K = 24$ ;  $\text{HClO}_2$  is the stronger acid and  $\text{NO}_2^{-}$  the stronger base.
25. (a) Methyl orange (b) 3.8 to 4.4
27. 2.35
29. (a) 2.45 (b) 0.72 mol
31. 1.2
33.  $1.2 \times 10^{-6}$
35. 10.4
37. 0.083 M
39. The reaction gives a base of moderate strength, the acetate ion, in solution, so the  $\text{pH} > 7$ .
41.  $\text{HCl} < \text{NH}_4\text{Br} < \text{KI} < \text{NaCH}_3\text{COO} < \text{NaOH}$
43. 8.08
45. (a) 4.36 (b) 4.63
47. *m*-Chlorobenzoic acid
49. 639 mL
51. 13.88, 11.24, 7.00, 2.77
53. 2.86, 4.72, 8.71, 11.00
55. 11.89, 11.52, 10.79, 8.20, 6.05, 3.90, 1.95
57. 0.97 g
59. 0.0872 g,  $\text{pH} = 6.23$  if no approximations are made, bromothymol blue
61.  $4 \times 10^{-7}$
63.  $[\text{H}_3\text{AsO}_4] = 8.0 \times 10^{-2} \text{ M}$ ;  
 $[\text{H}_2\text{AsO}_4^{-}] = [\text{H}_3\text{O}^{+}] = 2.0 \times 10^{-2} \text{ M}$ ;  
 $[\text{HAsO}_4^{2-}] = 9.3 \times 10^{-8} \text{ M}$ ;  $[\text{AsO}_4^{3-}] = 1.4 \times 10^{-17} \text{ M}$
65.  $[\text{PO}_4^{3-}] = 0.020 \text{ M}$ ;  $[\text{HPO}_4^{2-}] = [\text{OH}^{-}] = 0.030 \text{ M}$ ;  
 $[\text{H}_2\text{PO}_4^{-}] = 1.61 \times 10^{-7} \text{ M}$ ;  $[\text{H}_3\text{PO}_4] = 7.1 \times 10^{-18} \text{ M}$
67.  $[\text{H}_2\text{CO}_3] = 8.5 \times 10^{-6} \text{ M}$ ;  $[\text{HCO}_3^{-}] = 1.5 \times 10^{-6} \text{ M}$ ;  
 $[\text{CO}_3^{2-}] = 2.8 \times 10^{-11} \text{ M}$
69. Propene
71.  $46 \text{ kJ mol}^{-1}$
73.  $\text{p}K_{\text{a}1}$  should be smaller than 4.9;  $\text{p}K_{\text{a}2}$  should be larger.

**CHAPTER 16**

1. 4.65 L
3. About  $48^\circ\text{C}$
5.  $\text{Fe}_2(\text{SO}_4)_3(\text{s}) \rightleftharpoons 2 \text{Fe}^{3+}(\text{aq}) + 3 \text{SO}_4^{2-}(\text{aq})$   
 $[\text{Fe}^{3+}]^2[\text{SO}_4^{2-}]^3 = K_{\text{sp}}$
7. 0.0665 g per 100 mL water
9.  $14.3 \text{ g L}^{-1}$
11.  $[\text{I}^{-}] = 6.2 \times 10^{-10} \text{ M}$ ,  $[\text{Hg}_2^{2+}] = 3.1 \times 10^{-10} \text{ M}$
13.  $1.9 \times 10^{-12}$
15.  $1.6 \times 10^{-8}$
17. Yes. The initial reaction quotient is  $6.2 \times 10^{-10} > K_{\text{sp}}$ .
19. Yes
21.  $[\text{Pb}^{2+}] = 2.3 \times 10^{-10} \text{ M}$ ;  $[\text{IO}_3^{-}] = 0.033 \text{ M}$
23.  $[\text{Ag}^{+}] = 1.8 \times 10^{-2} \text{ M}$ ;  $[\text{CrO}_4^{2-}] = 6.2 \times 10^{-9} \text{ M}$
25.  $2.4 \times 10^{-8} \text{ mol L}^{-1}$
27. (a)  $3.4 \times 10^{-6} \text{ M}$  (b)  $1.6 \times 10^{-14} \text{ M}$
29.  $9.1 \times 10^{-3} \text{ M}$
31. In pure water:  $1.2 \times 10^{-4} \text{ M}$ ; at  $\text{pH} 7$ :  $0.15 \text{ M}$
33. (a) Unchanged (b) Increase (c) Increase
35.  $[\text{Cu}(\text{NH}_3)_4^{2+}] = 0.10 \text{ M}$ ;  $[\text{Cu}^{2+}] = 7 \times 10^{-14} \text{ M}$
37.  $[\text{K}^{+}] = 0.0051 \text{ M}$  and  $[\text{Na}^{+}] = 0.0076 \text{ M}$
39. More will dissolve in 1 M  $\text{NaCl}$  ( $3 \times 10^{-5}$  versus  $1.3 \times 10^{-5} \text{ mol L}^{-1}$ ). Less will dissolve in 0.100 M  $\text{NaCl}$  ( $3 \times 10^{-6}$  versus  $1.3 \times 10^{-5} \text{ mol L}^{-1}$ ).
41.  $\text{Cu}^{2+}(\text{aq}) + 2 \text{H}_2\text{O}(\ell) \rightleftharpoons \text{CuOH}^{+}(\text{aq}) + \text{H}_3\text{O}^{+}(\text{aq})$  or  
 $\text{Cu}(\text{H}_2\text{O})_4^{2+}(\text{aq}) + \text{H}_2\text{O}(\ell) \rightleftharpoons$   
 $\text{Cu}(\text{H}_2\text{O})_3\text{OH}^{+}(\text{aq}) + \text{H}_3\text{O}^{+}(\text{aq})$
43. 5.3
45.  $K_{\text{a}} = 9.6 \times 10^{-10}$
47. In the first case, solid  $\text{Pb}(\text{OH})_2$  will precipitate;  $[\text{Pb}^{2+}] = 4.2 \times 10^{-13} \text{ M}$ ,  $[\text{Pb}(\text{OH})_2] = 0.17 \text{ M}$ . In the second case, solid  $\text{Pb}(\text{OH})_2$  will not precipitate;  $[\text{Pb}^{2+}] = 1 \times 10^{-13} \text{ M}$ ,  $[\text{Pb}(\text{OH})_2] = 0.050 \text{ M}$ .
49. (a)  $8.6 \times 10^{-4} \text{ M}$ ,  $\text{Pb}^{2+}$  in solid (b)  $3.1 \times 10^{-7}$
51.  $[\text{I}^{-}] = 4.1 \times 10^{-4} \text{ M}$
53.  $2 \times 10^{-13} \text{ M}$
55.  $\text{pH} = 2.4$ ;  $[\text{Pb}^{2+}] = 6 \times 10^{-11} \text{ M}$

**CHAPTER 17**

1. Electrons flow from the left electrode to the right as  $\text{Cr}(\text{II})$  is oxidized to  $\text{Cr}(\text{III})$ . In the salt bridge, negative ions flow from right to left and positive ions from left to right. The overall reaction is represented as follows:  
 $2 \text{Cr}^{2+}(\text{aq}) + \text{Cu}^{2+}(\text{s}) \longrightarrow 2 \text{Cr}^{3+}(\text{aq}) + \text{Cu}(\text{s})$

3. 0.180 mol
5. (a)  $\text{Zn}(s) + \text{Cl}_2(g) \longrightarrow \text{Zn}^{2+}(aq) + 2 \text{Cl}^-(aq)$   
 (b)  $1.20 \times 10^3 \text{ C}$ ;  $1.24 \times 10^{-2} \text{ mol } e^-$   
 (c) Decreases by 0.407 g (d) 0.152 L  $\text{Cl}_2$  consumed
7. +2
9. (a) Anode:  $\text{Cl}^- \longrightarrow \frac{1}{2} \text{Cl}_2(g) + e^-$ ;  
 cathode:  $\text{K}^+ + e^- \longrightarrow \text{K}(\ell)$   
 total:  $\text{Cl}^- + \text{K}^+ \longrightarrow \text{K}(\ell) + \frac{1}{2} \text{Cl}_2(g)$   
 (b) Mass K = 14.6 g; mass  $\text{Cl}_2$  = 13.2 g
11.  $\Delta G^\circ = -921 \text{ J}$ ; max work done by cell = +921 J
13. (a) Anode:  $\text{Co} \longrightarrow \text{Co}^{2+} + 2 e^-$ ;  
 cathode:  $\text{Br}_2 + 2 e^- \longrightarrow 2 \text{Br}^-$ ;  
 total:  $\text{Co} + \text{Br}_2 \longrightarrow \text{Co}^{2+} + 2 \text{Br}^-$   
 (b) 1.34 V
15. (a) Anode:  $\text{Zn} \longrightarrow \text{Zn}^{2+} + 2 e^-$ ;  
 cathode:  $\text{In}^{3+} + 3 e^- \longrightarrow \text{In}$   
 (b) -0.338 V
17. Reducing agent
19.  $\text{Br}_2$  less effective than  $\text{Cl}_2$
21. (a)  $\text{BrO}_3^-$  (b) Cr (c) Co
23. (a)  $E^\circ = -0.183 \text{ V}$  (b) It will not disproportionate.
25. (a) No (b)  $\text{Br}^-$
27. 0.381 V
29. -0.31 V
31. 5.17
33. (a) 0.31 V (b)  $1 \times 10^{-8} \text{ M}$
35.  $K = 3 \times 10^{31}$ , orange
37.  $3 \times 10^6$
39. pH = 2.53;  $K_a = 0.0029$
41. (a) 1.065 V (b)  $1.3 \times 10^{-11} \text{ M}$  (c)  $7.6 \times 10^{-13}$
43. The midpoint between the waves appears at -0.195 V, reflecting the difference between the reduction potentials of the SCE and Ag/AgCl reference electrodes.
45.  $E = E_{\text{HOMO}} - E_{\text{LUMO}} = 2.4 \text{ eV}$ ,  $\lambda = 517 \text{ nm}$ , green
47. Yes, the valence band potential is sufficiently positive to oxidize water and the conduction band potential is sufficiently negative to reduce  $\text{H}^+$ .
49. The redox potential of the HOMO must be more negative than the conduction band of strontium titanate (-0.2 V) in order to inject electrons and that of the LUMO must be more positive than the water oxidation potential (1.229 V) so the minimum HOMO - LUMO gap must be around 1.5 eV.
51. 2.041 V; 12.25 V
53. (a)  $9.3 \times 10^6 \text{ C}$  (b)  $1.1 \times 10^8 \text{ J}$
55. No, because  $\text{H}_2\text{SO}_4(aq)$  is not the only substance whose amount changes during discharge. The accumulated  $\text{PbSO}_4$  must also be removed and replaced by Pb and  $\text{PbO}_2$ .
57.  $7900 \text{ J g}^{-1}$

59.  $\Delta E = -0.419 \text{ V}$ , not spontaneous under standard conditions (pH = 14). If  $[\text{OH}^-]$  is small enough, the equilibrium will shift to the right and the reaction will become spontaneous.
61. According to its reduction potential, yes. In practice, however, the sodium would react instantly and explosively with the water and would therefore be useless for this purpose.
63.  $2 \text{Cl}^- \longrightarrow \text{Cl}_2(g) + 2 e^-$  anode  
 $\text{Na}^+ + e^- \longrightarrow \text{Na}(\ell)$  cathode
65.  $4.4 \times 10^4 \text{ kg}$
67.  $2 \text{Mg} + \text{TiCl}_4 \longrightarrow \text{Ti} + 2 \text{MgCl}_2$ ; 102 kg
69. 42.4 min
71. (a) Ni  
 (b) 21.9 g (provided the electrolyte volume is very large)  
 (c)  $\text{H}_2$

## CHAPTER 18

1.  $5.3 \times 10^{-5} \text{ mol L}^{-1} \text{ s}^{-1}$
3.  $\text{rate} = -\frac{\Delta[\text{N}_2]}{\Delta t} = -\frac{1}{3} \frac{\Delta[\text{H}_2]}{\Delta t} = \frac{1}{2} \frac{\Delta[\text{NH}_3]}{\Delta t}$
5. (a)  $\text{Rate} = k[\text{NO}]^2[\text{H}_2]$ ;  $k$  has the units  $\text{L}^2 \text{ mol}^{-2} \text{ s}^{-1}$ .  
 (b) An increase by a factor of 18
7. (a)  $\text{Rate} = k[\text{C}_5\text{H}_5\text{N}][\text{CH}_3\text{I}]$  (b)  $k = 75 \text{ L mol}^{-1} \text{ s}^{-1}$   
 (c)  $7.5 \times 10^{-8} \text{ mol L}^{-1} \text{ s}^{-1}$
9.  $3.2 \times 10^4 \text{ s}$
11. 0.0019 atm
13.  $5.3 \times 10^{-3} \text{ s}^{-1}$
15.  $2.3 \times 10^{-5} \text{ M}$
17.  $2.9 \times 10^{-6} \text{ s}$
19. (a) Bimolecular,  $\text{rate} = k[\text{HCO}][\text{O}_2]$   
 (b) Termolecular,  $\text{rate} = k[\text{CH}_3][\text{O}_2][\text{N}_2]$   
 (c) Unimolecular,  $\text{rate} = k[\text{HO}_2\text{NO}_2]$
21. (a) The first step is unimolecular; the others are bimolecular.  
 (b)  $\text{H}_2\text{O}_2 + \text{O}_3 \longrightarrow \text{H}_2\text{O} + 2 \text{O}_2$   
 (c) O, ClO,  $\text{CF}_2\text{Cl}$ , Cl
23.  $0.26 \text{ L mol}^{-1} \text{ s}^{-1}$
25. (a)  $\text{A} + \text{B} + \text{E} \longrightarrow \text{D} + \text{F}$   $\text{rate} = \frac{k_1 k_2 [\text{A}][\text{B}][\text{E}]}{k_{-1} [\text{D}]}$   
 (b)  $\text{A} + \text{D} \longrightarrow \text{B} + \text{F}$   $\text{rate} = \frac{k_1 k_2 k_3}{k_{-1} k_{-2}} \frac{[\text{A}][\text{D}]}{[\text{B}]}$
27. Only mechanism (b)
29. Only mechanism (a)
31.  $\text{rate} = \frac{k_2 k_1 [\text{A}][\text{B}][\text{E}]}{k_2 [\text{E}] + k_{-1} [\text{D}]}$  When  $k_2 [\text{E}] \ll k_{-1} [\text{D}]$
33.  $\frac{d[\text{Cl}_2]}{dt} = \frac{k_1 k_2 [\text{NO}_2\text{Cl}]^2}{k_{-1} [\text{NO}_2] + k_2 [\text{NO}_2\text{Cl}]}$
35. (a)  $4.25 \times 10^5 \text{ J}$  (b)  $1.54 \times 10^{11} \text{ L mol}^{-1} \text{ s}^{-1}$

37. (a)  $1.49 \times 10^{-3} \text{ L mol}^{-1} \text{ s}^{-1}$  (b)  $1.30 \times 10^3 \text{ s}$   
 39. (a)  $4.3 \times 10^{-3} \text{ s}^{-1}$  (b)  $1.7 \times 10^5 \text{ s}^{-1}$   
 41.  $70.3 \text{ kJ mol}^{-1}$   
 43. For OH + ethane,  $\varepsilon_B \approx 21.1 \text{ kJ mol}^{-1}$ . For OH + ethene,  $\varepsilon_B \approx 0 \text{ kJ mol}^{-1}$ .  $E_{\text{rel}} = 83 \text{ kJ mol}^{-1} > 21 \text{ kJ mol}^{-1}$  so yes, if not a glancing collision.  
 45.  $6.0 \times 10^9 \text{ L mol}^{-1} \text{ s}^{-1}$   
 47. The rate constant is much smaller than that expected for a diffusion-controlled reaction so it is limited by a large activation energy.  
 49. (a)  $1 \times 10^{-3} \text{ mol L}^{-1} \text{ s}^{-1}$  (b)  $5 \times 10^{-5} \text{ M}$

**CHAPTER 19**

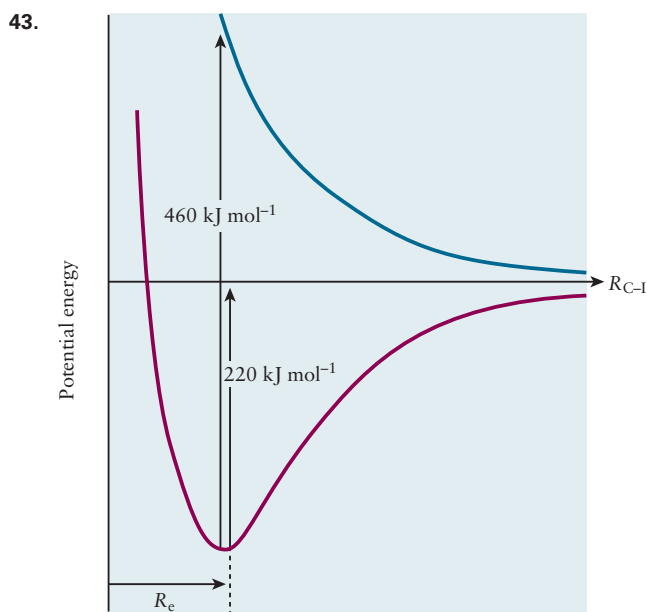

1. (a)  $2 \text{ }^{12}_6\text{C} \longrightarrow \text{}^{23}_{12}\text{Mg} + \text{}^1_0n$   
 (b)  $^{15}_7\text{N} + \text{}^1_1\text{H} \longrightarrow \text{}^{12}_6\text{C} + \text{}^4_2\text{He}$   
 (c)  $2 \text{ }^3_2\text{He} \longrightarrow \text{}^4_2\text{He} + 2 \text{}^1_1\text{H}$   
 3. (a)  $3.300 \times 10^{10} \text{ kJ mol}^{-1} = 342.1 \text{ MeV total}$ ;  
 $8.551 \text{ MeV per nucleon}$   
 (b)  $7.312 \times 10^{10} \text{ kJ mol}^{-1} = 757.9 \text{ MeV total}$ ;  
 $8.711 \text{ MeV per nucleon}$   
 (c)  $1.738 \times 10^{11} \text{ kJ mol}^{-1} = 1801.7 \text{ MeV total}$ ;  
 $7.570 \text{ MeV per nucleon}$   
 5. The two  $^4\text{He}$  atoms are more stable, with a mass lower than that of one  $^8\text{Be}$  atom by  $9.85 \times 10^{-5} \text{ u}$ .  
 7.  $16.96 \text{ MeV}$   
 9. (a)  $^{39}_{17}\text{Cl} \longrightarrow \text{}^{39}_{18}\text{Ar} + \text{}^0_{-1}e^- + \bar{\nu}$   
 (b)  $^{22}_{11}\text{Na} \longrightarrow \text{}^{22}_{10}\text{Ne} + \text{}^0_{-1}e^- + \bar{\nu}$   
 (c)  $^{224}_{88}\text{Ra} \longrightarrow \text{}^{220}_{86}\text{Rn} + \text{}^4_2\text{He}$   
 (d)  $^{82}_{38}\text{Sr} + \text{}^0_{-1}e^- \longrightarrow \text{}^{82}_{37}\text{Rb} + \bar{\nu}$   
 11.  $^{19}\text{Ne}$  decays to  $^{19}\text{F}$  by positron emission;  $^{23}\text{Ne}$  decays to  $^{23}\text{Na}$  by  $\beta^-$  decay (electron emission).  
 13. An electron,  $0.78 \text{ MeV}$   
 15.  $^{30}_{14}\text{Si} + \text{}^1_0n \longrightarrow \text{}^{31}_{14}\text{Si} \longrightarrow \text{}^{31}_{15}\text{P} + \text{}^0_{-1}e^- + \bar{\nu}$   
 17.  $^{210}_{84}\text{Po} \longrightarrow \text{}^{206}_{82}\text{Pb} + \text{}^4_2\text{He}$      $\text{}^4_2\text{He} + \text{}^9_4\text{Be} \longrightarrow \text{}^{12}_6\text{C} + \text{}^1_0n$   
 19.  $3.7 \times 10^{10} \text{ min}^{-1}$   
 21. (a)  $1.0 \times 10^6$  (b)  $5.9 \times 10^4$   
 23.  $1.6 \times 10^{18} \text{ disintegrations s}^{-1}$   
 25. 4200 years  
 27.  $3.0 \times 10^9 \text{ years}$   
 29.  $5.9 \times 10^9 \text{ years}$   
 31.  $^{11}_6\text{C} \longrightarrow \text{}^{11}_5\text{B} + \text{}^0_1e^+ + \nu$ ;  $^{15}_8\text{O} \longrightarrow \text{}^{15}_7\text{N} + \text{}^0_1e^+ + \nu$   
 33. Exposure from  $^{15}\text{O}$  is greater by a factor of  $1.72/0.99 = 1.74$ .  
 35. (a)  $2.3 \times 10^{10} \text{ Bq}$   
 (b)  $0.025 \text{ mGy}$   
 (c) Yes. A dose of  $5 \text{ Gy}$  has a 50% chance of being lethal; this dose is greater than  $8.5 \text{ Gy}$  in the first 8 days.  
 37. (a)  $^{90}_{38}\text{Sr} \longrightarrow \text{}^{90}_{40}\text{Zr} + 2 \text{}^0_{-1}e^- + 2 \bar{\nu}$   
 (b)  $2.8 \text{ MeV}$   
 (c)  $5.23 \times 10^{12} \text{ disintegrations s}^{-1}$   
 (d)  $4.44 \times 10^{11} \text{ disintegrations s}^{-1}$

39. Increase (assuming no light isotopes of U are products of the decay)  
 41.  $7.59 \times 10^7 \text{ kJ g}^{-1}$

**CHAPTER 20**

1. (a)  $A = 0.699$  (b)  $\varepsilon = 1 \times 10^3 \text{ L mol}^{-1} \text{ cm}^{-1}$   
 3.  $c_A = 0.000368 \text{ mol L}^{-1}$   
 $c_B = 0.00157 \text{ mol L}^{-1}$   
 5. Use the Beer-Lambert law in the form  $I_t = I_0 \exp[-(N/V)\sigma\ell]$  and rearrange it to solve for  $\ell$  to get  
 $\ell = -\sigma^{-1}(N/V)^{-1} \ln(I_t/I_0)$   
 $= -(5 \times 10^{-20} \text{ cm}^2 \text{ molecule}^{-1})^{-1} \times$   
 $(5 \times 10^{12} \text{ molecules cm}^{-3})^{-1} \ln(0.4)$   
 $= 3.7 \times 10^6 \text{ cm} = 37 \text{ km}$   
 7.  $35583.5 \text{ cm}^{-1}$   
 9.  $N_{\nu=1}/N_{\nu=0} = \exp(-\Delta\varepsilon/k_B T) = 0.17$ ;  
 $N_{J=1}/N_{J=0} = 3 \exp(-\Delta\varepsilon/k_B T) = 2.86$   
 11.  $6.736 \times 10^{-23} \text{ J} = 40.56 \text{ J mol}^{-1}$   
 13. (a)  $1.45 \times 10^{-46} \text{ kg m}^2$   
 (b)  $E_1 = 7.65 \times 10^{-23} \text{ J}$ ;  $E_2 = 2.30 \times 10^{-22} \text{ J}$ ;  
 $E_3 = 4.59 \times 10^{-22} \text{ J}$   
 (c)  $1.13 \text{ \AA}$   
 15.  $I = h/(8\pi^2 c \tilde{\nu}) = 1.929 \times 10^{-46} \text{ kg m}^2$   
 17.  $25.4 \text{ kg s}^{-2}$   
 19.  $5.1 \times 10^2 \text{ kg s}^{-2}$   
 21.  $(\nu_i, J_i) = (1, 3)$  and  $(1, 1)$ . The transition from  $(0, 2)$  to  $(1, 1)$  requires  $2950 \text{ cm}^{-1}$ . The transition from  $(0, 2)$  to  $(1, 3)$  requires a  $3050 \text{ cm}^{-1}$  photon. It also can undergo a pure rotational transition from  $J_i = 2$  to  $J_f = 3$ , by absorbing a  $60 \text{ cm}^{-1}$  photon.  
 23.  $5.3 \times 10^{-4}$   
 25. Rearranging Equation 20.10 to solve for  $k$ , with vibrational frequencies given in  $\text{cm}^{-1}$ , and substituting the values given for each molecule we find that  $k = 966.0 \text{ N m}^{-1}$  ( $^1\text{H}^{19}\text{F}$ ),  $516.3 \text{ N m}^{-1}$  ( $^1\text{H}^{35}\text{Cl}$ ),  $351.7 \text{ N m}^{-1}$  ( $^1\text{H}^{81}\text{Br}$ ),  $313.7 \text{ N m}^{-1}$  ( $^1\text{H}^{127}\text{I}$ ).  $\mu \approx 1$  for all of these molecules so the vibrational frequency is most sensitive to differences in the force constants.  
 27.  $(\nu_{\text{CD}})/(\nu_{\text{CH}}) \approx \sqrt{\mu_{\text{CH}}/\mu_{\text{CD}}}$  so  $\nu_{\text{CD}} \approx 2165 \text{ cm}^{-1}$   
 29.  $\text{NH}_3$  (6);  $\text{C}_2\text{H}_4$  (12);  $\text{CCl}_2\text{F}_2$  (9);  $\text{CH}_3\text{CH}_2\text{OH}$  (21)  
 31. The top spectrum is that of nonane and the bottom spectrum is that of 1-hexanol. Prominent bands in the nonane spectrum include those due to aliphatic C—H stretching modes around  $2,900 \text{ cm}^{-1}$ ,  $-\text{CH}_2$  and  $-\text{CH}_3$  bending modes near  $1,450$  and  $1,375 \text{ cm}^{-1}$ , respectively. Prominent bands in the 1-hexanol spectrum include the broad O—H stretch around  $3,400 \text{ cm}^{-1}$  characteristic of hydrogen-bonded alcohols,  $-\text{CH}_2$  and  $-\text{CH}_3$  bending modes near  $1,450$  and  $1,375 \text{ cm}^{-1}$  similar to those in nonane, and the C—O stretch around  $1,075 \text{ cm}^{-1}$ , also characteristic of alcohols.  
 33. 2, 3:2; 1; 2, 6:1

35. Decrease, because the electron will enter a  $\pi^*$  antibonding orbital
37. In the blue range, around 450 nm
39. Shorter; the  $\pi$  bonding is localized in cyclohexene.
41. 474 nm

45.  $2.72 \times 10^{-7} \text{ m}$

SN = 3,  $sp^2$  hybridization, bent molecule

Two electrons in a  $\pi$  orbital formed from the three  $2p_z$  orbitals perpendicular to the molecular plane, total bond order of  $\frac{3}{2}$  for each O—O bond.

49. 8 molecules

## CHAPTER 21

- (b), (c), and (d)
- Two mirror planes, one 2-fold rotation axis
- 3.613 Å
- 102.9°
- $\pm 49.87^\circ$  and  $\pm 115.0^\circ$
- (a)  $5.675 \times 10^6 \text{ Å}^3$  (b)  $5 \times 10^{14}$
- 4.059 g  $\text{cm}^{-3}$
- (a)  $1.602 \times 10^{-22} \text{ cm}^3$   
(b)  $3.729 \times 10^{-22} \text{ g}$   
(c)  $4.662 \times 10^{-23} \text{ g}$   
(d)  $6.025 \times 10^{23}$  (in error by 0.05%)
- 8
- ReO<sub>3</sub>
- (a) 2.48 Å (b) 2.87 Å (c) 1.24 Å
- (a) 2 (b) 0.680

- 0.732
- (a) Ionic (b) Covalent  
(c) Molecular (d) Metallic
- CO < BaCl<sub>2</sub> < Co < SiC
- 8, 6, 12
- Not by a significant amount because each vacancy is accompanied by an interstitial. In large numbers, such defects could cause a small bulging of the crystal and a decrease in its density.
- (a) Fe<sub>0.9352</sub>O (b) 13.86% of the iron
- 664 kJ mol<sup>-1</sup>
- (a) 1041 kJ mol<sup>-1</sup> (b) 1205 kJ mol<sup>-1</sup>

## CHAPTER 22

- The structures of P<sub>2</sub>O<sub>7</sub><sup>4-</sup> and S<sub>2</sub>O<sub>7</sub><sup>2-</sup> have the same number of electrons and are found by writing “P” or “S” in place of “Si” and adjusting the formal charges. The chlorine compound is Cl<sub>2</sub>O<sub>7</sub>, dichlorine heptaoxide.
- (a) Tetrahedra; Ca: +2, Fe: +3, Si: +4, O: -2  
(b) Infinite sheets; Na: +1, Zr: +2, Si: +4, O: -2  
(c) Pairs of tetrahedra; Ca: -2, Zn: +2, Si: +4, O: -2  
(d) Infinite sheets; Mg: +2, Si: +4, O: -2, H: +1
- (a) Infinite network; Li: +1, Al: +3, Si: +4, O: -2  
(b) Infinite sheets; K: +1, Al: +3, Si: +4, O: -2, H: +1  
(c) Closed rings or infinite single chains; Al: +3, Mg: +2, Si: +4, O: -2
- Mg<sub>3</sub>Si<sub>4</sub>O<sub>10</sub>(OH)<sub>2</sub>(s) → 3 MgSiO<sub>3</sub>(s) + SiO<sub>2</sub>(s) + H<sub>2</sub>O(g)
- 234 L
- 0.418 mol Si, 0.203 mol Na, 0.050 mol Ca, 0.0068 mol Al, 0.002 mol Mg, 0.0005 mol Ba
- 113.0 kJ
- $\frac{7}{5}$
- (a) SiO<sub>2</sub>(s) + 3 C(s) → SiC(s) + 2 CO(g)  
(b) +624.6 kJ mol<sup>-1</sup>  
(c) Low conductivity, high melting point, very hard
- 1188.2 kJ, unstable
- 24 (Ω m)<sup>-1</sup> or 24 S m<sup>-1</sup>
- 1.26 C V<sup>-1</sup> s<sup>-1</sup> m<sup>-1</sup> or 1.26 (Ω m)<sup>-1</sup> or 1.26 S m<sup>-1</sup>
- 1.5 electrons per Cu atom
- $2.16 \times 10^{-19} \text{ J}$
- $6.1 \times 10^{-27}$  electrons in a cm<sup>3</sup>, a negligible number density
- (a) Electron movement (*n*-type)  
(b) Hole movement (*p*-type)
- 680 nm, red
- Decrease

## CHAPTER 23

- $n \text{ CCl}_2 = \text{CH}_2 \longrightarrow -(\text{CCl}_2 - \text{CH}_2 -)_n$
- Formaldehyde, H<sub>2</sub>C=O
- (a) H<sub>2</sub>O (b) -(NH-CH<sub>2</sub>-CO-)

7. 646 kg adipic acid and 513 kg hexamethylenediamine  
 9.  $3.49 \times 10^{12} \text{ L} = 3.49 \times 10^9 \text{ m}^3 = 3.49 \text{ km}^3$   
 11. The isotropic phase has higher entropy and higher enthalpy.  
 13. A micelle (containing hydrocarbon in the interior and water on the outside)  
 15. 5 chiral centers  
 17. 27  
 19. In octane, because the side groups are all hydrocarbon  
 21.  $\text{C}_9\text{H}_9\text{NO}$ ; 119 units

**APPENDIX A**

1. (a)  $5.82 \times 10^{25}$  (b)  $1.402 \times 10^3$  (c) 7.93  
 (d)  $-6.59300 \times 10^3$  (e)  $2.530 \times 10^{-3}$  (f) 1.47  
 3. (a) 0.000537 (b) 9,390,000 (c)  $-0.00247$   
 (d) 0.00620 (e) 20,000  
 5. 746,000,000 kg  
 7. (a) The value is 135.6 (b) 111.34 g  
 (c) 0.22 g, 0.23 g  
 9. That of the mass in problem 7  
 11. (a) 5 (b) 3 (c) Either two or three  
 (d) 3 (e) 4  
 13. (a) 14 L (b)  $-0.0034^\circ\text{C}$   
 (c)  $340 \text{ lb} = 3.4 \times 10^2 \text{ lb}$  (d)  $3.4 \times 10^2 \text{ miles}$   
 (e)  $6.2 \times 10^{-27} \text{ J}$   
 15. 2,997,215.55  
 17. (a)  $-167.25$  (b) 76  
 (c)  $3.1693 \times 10^{15}$  (d)  $-7.59 \times 10^{-25}$   
 19. (a)  $-8.40$  (b) 0.147  
 (c)  $3.24 \times 10^{-12}$  (d)  $4.5 \times 10^{13}$   
 21.  $A = 337 \text{ cm}^2$

**APPENDIX B**

1. (a)  $6.52 \times 10^{-11} \text{ kg}$  (b)  $8.8 \times 10^{-11} \text{ s}$   
 (c)  $5.4 \times 10^{12} \text{ kg m}^2 \text{ s}^{-3}$   
 (d)  $1.7 \times 10^4 \text{ kg m}^2 \text{ s}^{-3} \text{ A}^{-1}$   
 3. (a)  $4983^\circ\text{C}$  (b)  $37.0^\circ\text{C}$  (c)  $111^\circ\text{C}$  (d)  $-40^\circ\text{C}$

5. (a) 5256 K (b) 310.2 K (c) 384 K (d) 233 K  
 7. (a)  $24.6 \text{ m s}^{-1}$  (b)  $1.51 \times 10^3 \text{ kg m}^{-3}$   
 (c)  $1.6 \times 10^{-29} \text{ A s m}$  (d)  $1.5 \times 10^2 \text{ mol m}^{-3}$   
 (e)  $6.7 \text{ kg m}^2 \text{ s}^{-3} = 6.7 \text{ W}$   
 9.  $1 \text{ kW}\cdot\text{hr} = 3.6 \times 10^6 \text{ J}$ ;  $15.3 \text{ kW}\cdot\text{hr} = 5.51 \times 10^7 \text{ J}$   
 11.  $6620 \text{ cm}^3$  or 6.62 L  
 13.  $3 \times 10^2 \text{ J}$   
 15. 55 J

**APPENDIX C**

1. 50 miles per hour  
 3. (a) Slope = 4, intercept =  $-7$   
 (b) Slope  $\frac{7}{2} = 3.5$ , intercept =  $-\frac{5}{2} = -2.5$   
 (c) Slope =  $-2$ , intercept =  $\frac{4}{3} = 1.3333 \dots$   
 5. The graph is not a straight line.  
 7. (a)  $-\frac{5}{7} = -0.7142857 \dots$  (b)  $\frac{3}{4} = 0.75$   
 (c)  $\frac{2}{3} = 0.6666 \dots$   
 9. (a) 0.5447 and  $-2.295$  (b)  $-0.6340$  and  $-2.366$   
 (c) 2.366 and 0.6340  
 11. (a)  $6.5 \times 10^{-7}$  (also two complex roots)  
 (b)  $4.07 \times 10^{-2}$  (also 0.399 and 21.011)  
 (c)  $-1.3732$  (also two complex roots)  
 13. (a) 4.551 (b)  $1.53 \times 10^{-7}$   
 (c)  $2.6 \times 10^8$  (d)  $-48.7264$   
 15. 3.015  
 17. 121.477  
 19. 7.751 and  $-2.249$   
 21.  $x = 1.086$   
 23. (a)  $8x$  (b)  $3 \cos 3x - 8 \sin 2x$  (c) 3 (d)  $\frac{1}{x}$   
 25. (a) 20 (b)  $\frac{78125}{7}$  (c) 0.0675

Page numbers followed by “f” denote figures; those followed by “t” denote tables. Page numbers preceded by “A” indicate Appendix page numbers.

- Absolute zero** The theoretical minimum of temperature, at which the entropy of a crystalline pure substance becomes equal to zero, 379–380, 545
- Absorbance** Natural logarithm of the ratio of light intensity passing through a reference cell to the light intensity passing through a sample cell in a spectrophotometer, 846
- Absorption spectrum**, 135, 136f, 142
- Acceleration** The rate at which the velocity of an object changes in response to an applied force, A.13
- Accuracy of the result** The extent to which a measurement gives the true value of a quantity by reducing systematic errors, A.5
- Acid** A substance capable of donating hydrogen ions, 451, 612  
 classification of, 612–618  
   Arrhenius, 612–613, 618  
   Brønsted–Lowry, 613–615, 618  
   comparison of definitions, 618  
   Lewis, 616–618  
 hard and soft, 331–333, 332t  
 molecular structure and acid strength, 626–628  
 monoprotic, 645  
 names of common acids, 451t  
 organic, 649, 652–655, 652t  
 oxoacids, 627–628, 627f, 628t  
 polyprotic, 645–649, 659–660, 660f  
 properties in aqueous solutions, 619–622  
 strength of acids and bases, 622–630, 624f  
 strong, 620–621, 624f  
   titration with strong base, 640–642, 641f  
 weak, 622, 624f, 630–632  
   polyprotic acids, 645–649  
   titration with strong base, 642–645, 643f
- Acid anhydride** A compound that forms an acid upon addition of water, 617
- Acid ionization constant** The equilibrium constant that relates the concentration of an acid to the concentrations of the products of its ionization, 622–626  
 acid strength and, 624f  
 of acids in water at 25°C, 623t  
 for oxoacids of nonmetals, 628t
- Acid rain** Rain having a concentration of dissolved acids such that its pH is less than about 5.6, 665–666, 884
- Acid–base equilibria**, 611–661  
 acid and base strength, 622–630, 624f  
 amphoteric equilibria, 658–659  
 buffer solutions, 635–640, 640f  
 exact treatment of, 655–660  
 hydrolysis, 633–635  
 indicators, 628–630, 628f–630f  
 molecular structure and acid strength, 626–628  
 pH, 621–622, 621f  
 titration curves, 640–645, 641f, 643f  
   polyprotic acid, 659–660, 660f  
   strong acid with strong base, 640–642, 641f  
   weak acid with strong base, 642–645, 643f  
 weak acids and, 630–632  
 weak bases and, 633
- Acid–base indicator**, 628–630, 628f–630f
- Acid–base titration curves**, 640–645, 641f, 643f
- Acid–base titrations**, 448–452, 640–645
- Acidity of complex ions**, 684–685, 684t
- Actinide elements** Elements from Ac to Lr in the periodic table of the elements, 59, 60f, A.55
- Activated complex** A transient species, formed by the collision of reacting molecules, that can break apart to form products; the activated complex lies at the maximum in a plot of energy *versus* progress along the reaction path, 778–779, 779f, 788–789. *See also* **Transition state**
- Activation energy ( $E_a$ )** The energy term in the Arrhenius equation that gives the temperature dependence of the rate constant;  $E_a$  is obtained from the slope of a plot of  $\ln k$  against  $1/T$ ; interpreted as the minimum collision energy in an encounter between molecules for reaction to ensue, 777
- Activation-energy controlled reaction**, 793
- Active site**, enzyme, 797, 797f
- Activity** [1] ( $a_i$ ) For a dilute gas, the ratio of the partial pressure to a reference pressure of 1 atm; for a dilute solute species, the ratio of the concentration to a reference concentration of 1 M, 579–580
- Activity** [2] ( $A$ ) The disintegration rate of a collection of unstable nuclei, 818–819
- Activity coefficient ( $\gamma_i$ )** A correction factor that relates the activity of a nonideal gaseous species to its partial pressure, or the activity of a species in a nonideal solution to its concentration, 579
- Actual yield** The amount of a product of a chemical reaction that is found to form experimentally, 46–47
- Addition polymerization** A reaction in which monomers react to form polymers without net loss of atoms, 968–970, 969f
- Adiabatic process** A process occurring in a system that is thermally insulated from its surroundings, so  $q = 0$ , 515–517, 517f, 531, 539

- Adiabatic walls** Boundaries that separate thermodynamic systems from their surroundings or from other systems and block the flow of thermal energy, 482
- Affinity, 14
- Air, composition of, 371t
- Alchemists, 3
- Alcohol** An organic compound characterized by the functional group  $\text{—OH}$ , 306–307, 306f
- Aldehyde** An organic compound characterized by the  $\begin{array}{c} \text{O} \\ || \\ \text{—C—H} \end{array}$  functional group, 310, 310f
- Algebraic equations, solving, A.22–A.24
- Alkali halide** A compound formed by reaction of an element from Group I of the periodic table with an element from Group VII, 61
- Alkali metals** Elements of Group I of the periodic table, 61, A.47
- Alkaline dry cell** A primary cell having an alkaline electrolyte and using the reaction  $\text{Zn(s)} + 2 \text{MnO}_2\text{(s)} + \text{H}_2\text{O(l)} \rightarrow \text{Zn(OH)}_2\text{(s)} + \text{Mn}_2\text{O}_3\text{(s)}$  to generate a voltage, 729
- Alkaline-earth metals** Elements of Group II of the periodic table, 61, A.48
- Alkanes, 291–297  
branched-chain, 294–297  
cyclic, 293–294, 294f  
normal (straight-chain), 291–293, 291f–292f, 291t  
petroleum distillation, 292–293, 293f
- Alkene** A hydrocarbon with one or more double bonds between carbon atoms, 265
- Alkyl halide** An organic compound the molecules of which have a halogen atom bonded to an alkyl group, 305–306
- Alkyl side groups, 295t
- Alkyne** A hydrocarbon containing one or more triple bonds, 265
- Allotropes, 61
- Alloy** A macroscopically homogeneous mixture of two or more metals, 926  
of bismuth, 439–440  
interstitial alloy, 926  
sialons, 952  
substitutional alloy, 926
- Alloy steels, 926
- Alpha decay** ( $\alpha$ -decay) A mode of radioactive decay in which a nuclide emits an alpha particle, 816
- Alpha helix ( $\alpha$ -helix), 987, 987f
- Alpha particles, 22, 22f, 67
- Alumina** The compound  $\text{Al}_2\text{O}_3$ , which appears in several different crystalline forms, 948–949, 949f
- Aluminosilicates** Any mineral containing aluminum, silicon, and oxygen, 938–939
- Aluminum and electrometallurgy, 739–741, 740f
- Amides, 315
- Amines, 315
- Amino acids, 984–988, 984f, 986t
- Ammeter** An instrument used to measure the direction and magnitude of flow of an electric current, 695, 695f
- Ammonium perchlorate, as rocket fuel, 412
- Amorphous solid** A solid that lacks long-range order in the arrangement of its atoms, 923, 926–927
- Amphiphiles** Molecules that are both hydrophilic and hydrophobic, 981
- Amphoteric** Exhibiting the properties of either an acid or a base, depending on reaction conditions, 330, 614
- Amphoteric equilibria, 658–659
- Amphoterism of complex ions, 684–685
- Amplitude** The distance from center to crest or center to trough of a standing or traveling wave, 126
- Analgesics, 318–320, 319f–320f
- Angle strain** Additional contribution to the total potential energy of a molecule arising from distortion of bond angles away from their equilibrium values, 294
- Ångström, Anders, 30  
unit,  $1 \times 10^{-10}$  m, 30
- Angular momentum** In circular motion, the product of the radius of the circle described by the moving particle, its mass, and its speed;  $L = mvr$ , 140, A.20  
circular motion and, A.20  
photon, 852–853, 852f
- Angular momentum quantum number** A quantum number for a one-electron atom that governs the shape of the orbital; takes integer values from  $\ell = 0$  to  $\ell = n - 1$ , where  $n$  is the principal quantum number, 179
- Angular node** A surface in a wave function at which the electron density equals zero and across which the wave function changes sign, 190
- Anion** A negatively charged ion, 70  
formulas and names of common anions, 113t
- Annealing** The slow cooling of a piece of material to allow the release of internal stresses by shortrange diffusion of atoms, 945
- Annihilation radiation** The radiation given off when a particle and its antiparticle encounter and annihilate each other, 812, 825, 825f
- Anode** The site at which oxidation occurs in an electrochemical cell, 16, 17, 20f, 695, 695f  
sacrificial, 738
- Antibacterial agents, 320–321, 321f
- Antibonding molecular orbital** (e.g.  $\sigma^*$  or  $\pi^*$ ) A molecular orbital in which the occupation by electrons results in a reduction of bond strength, 230, 236
- Antiderivative** A new function obtained from another function by the operation of integration, which is the inverse of the derivative operation, A.29, A.30t
- Antiparticles** Any body that annihilates its conjugate particle to give high energy photons, 812
- Antiproton** ( $p^-$ ) The (negatively charged) antiparticle of the proton, 812
- Aquated, 671
- Aqueous solution** Containing water, as in “aqueous solution,” or dissolved in water as in “aqueous ions,” 446  
balancing oxidation-reduction equations in, 453–456  
electrolysis, 744–746  
of ionic species, 446–448, 447f  
of molecular species, 446, 446f
- Areas under curves and integrals, A.28–A.30, A.29
- Aromatic hydrocarbon** A compound of hydrogen and carbon, the molecules of which contain one or more rings with conjugated  $\pi$  electron systems, 300–302, 302f
- Arrhenius, Svante, 450, 776–777

- Arrhenius acids and bases, 612–613, 618
- Arrhenius law, 777–778
- Artificial photosynthesis, 726
- Asbestos** A fibrous material, formerly used for thermal insulation, that is composed of double-chain and rolled-up layered silicates, 938
- Aspsin, Joseph, 946
- Atactic form** Polymer structure in which side groups are randomly positioned along the backbone chain, 976, 976f
- Atmosphere, 880–882
- Atmospheric chemistry, 880–889  
stratospheric chemistry, 885–889  
tropospheric chemistry, 882–885
- Atom(s)
- aufbau principle, 201–206
    - helium to argon, 202–204, 203f
    - transition-metal elements and beyond, 205–206, 206f
  - electronegativity of, 53, 79–82
  - electrons of. *See* **Electrons** ( $e^-$ )
  - energy quantization in. *See* Energy quantization in atoms
  - forces and potential energy in, 62–69
  - hydrogen atom. *See* Hydrogen atoms
  - in interstellar space, 217–218
  - laws of chemical combination, 8–15
  - Lennard-Jones parameters for, 398t
  - neutrons, 26
  - nucleus, 20–22, 25–26
  - oxidation number of, 112–114
  - periodic properties, 209–214
    - electron affinity, 213–214, 213f
    - sizes of atoms and ions, 209–212, 211f
    - trends in ionization energies, 212–213, 212f
  - planetary model of, 22–23
  - protons, 26
  - quantum mechanics and structure of, 177–215
  - relative mass, 23–25, 24f
  - shell model of, 73–75, 75f
    - many-electron atoms, 196–201
    - periodic table and, 206–209
  - structure of, 15–23
- Atomic force microscopy** A form of scanning probe microscopy that images the surfaces of samples by measuring the strength of the force between the sample and the tip of the microscope at each location as the tip is scanned systematically across the sample surface, 33
- Atomic mass unit** (u) A unit of mass defined as exactly 1/12 of the mass of a single atom of  $^{12}\text{C}$ , 808
- Atomic number** ( $Z$ ) The number of electrons in the neutral atom; also, the number of protons in the nucleus of the atom, 26, 59. *See also* **Relative atomic mass**
- Atomic orbitals** (AOs) The wave functions that, when squared, give the probability density for the locations of electrons in atoms, 170, 220
- hybridization, 258
    - molecular geometry and, 262–263, 262f
    - polyatomic molecules, 259–266
    - $sp$  hybridization, 259–260, 259f
    - $sp^2$  hybridization, 260–262, 261f
    - $sp^3$  hybridization, 262–263, 262t
  - lone pairs and, 263–264
  - minimum basis set, 236
  - nonbonding, 249
- Atomic radius, 209–210, 211f  
transition metals, 326–327, 326t, 327f
- Atomic spectra, 135–137, 136f, 142
- Atomic theory of matter** The postulate that matter is composed of indestructible atoms that combine in whole-number ratios to form compounds, 11. *See also* Matter, atomic theory
- Attractive force** A force that accelerates two objects to move toward each other, (so decreasing their separation  $r$  decreases their potential energy  $V$ ,  $dV/dr$  is positive), A.19
- Aufbau principle, 201–206  
helium to argon, 202–204, 203f  
transition-metal elements and beyond, 205–206, 206f
- Autoionization of water** The spontaneous reaction of molecules of a substance to give pairs of ions; the autoionization of water to give  $\text{H}_3\text{O}^+$  plus  $\text{OH}^-$  ions, although slight in extent, is great in importance, 619
- Average reaction rate** The change in the concentration of a product of a reaction divided by the time interval over which the change occurs and also divided by the coefficient of the product in the chemical equation for the reaction, 756–757, 757f
- Average speed** For a single object, the value of the instantaneous speed averaged over a period of time. For a collection of objects, such as the molecules in a gas, the average value of the instantaneous speed of all the molecules, 392, A.12
- Average value** In a series of measurements, the sum of all the values observed divided by the number of measurements, A.3
- Average velocity** The rate of change of the location of an object defined over a time interval as opposed to the instantaneous value, A.12
- Avogadro, Amedeo, 13
- Avogadro's hypothesis, 13–15, 39, 380–381
- Avogadro's number** ( $N_A$ ) The number of atoms in exactly 12 grams of  $^{12}\text{C}$ ; equal to  $6.022141 \times 10^{23} \text{ mol}^{-1}$ , 27
- Axial sites** Lying along the axis of symmetry perpendicular to the plane that contains the equator; used to describe a type of site for atom or group substitution in a molecule, 109
- Azeotrope, 470–472, 471f
- Backbonding** A bonding mechanism in which un-occupied  $\pi^*$  orbitals in CO and related molecules accept and de-localize electron density from  $d$  orbitals in a metal, strengthening the bond between the molecule and the metal, 360
- Balance, 35f
- Balanced chemical equations, writing, 39–43
- Balanced nuclear equation** A nuclear equation in which the sums of the atomic number or particle charge on both sides of the equation are equal and the sums of the mass number on both sides of the equation are equal, 809
- Balancing oxidation-reduction equations in aqueous solutions, 453–456
- Ball-and-stick models, 55–56, 55f, 59f
- Balmer, J. J., 135

- Band gap** The energy difference between the top of one band and the bottom of the next higher band, 958
- Band of levels, 722. *See also* **Energy band**
- Band theory of conduction, 957–959
- Barometer** A device to measure the pressure of the atmosphere, 373f, 374
- Base (mathematical), A.25
- Base** A substance that, when dissolved in water, increases the amount of hydroxide ion relative to that present in pure water, 451, 612
- classification of, 612–618
- Arrhenius, 612–613
- Brønsted–Lowry, 613–615
- comparison of definitions, 618
- Lewis, 616–618
- hard and soft, 331–333, 332t
- organic, 649, 652–654
- properties in aqueous solutions, 619–622
- solubility of salts of bases, 679–680
- strength of acids and bases, 622–630, 624f
- strong, 620–621, 624f
- titration of strong acid with, 640–642, 641f
- titration of weak acid with, 642–645, 643f
- weak, 624f, 633
- Base anhydride** A compound that reacts with water to form bases, 617
- Base units, A.8, A.8t
- Battery** A galvanic cell or group of cells used to generate electrical work, 728–733
- alkaline dry cell, 729
- lead–acid, 730–731, 731f
- Leclanché cell, 728–7298, 728f
- lithium, 730
- lithium-ion, 731–732, 732f
- nickel metal hydride, 732
- rechargeable, 730–733
- sodium–sulfur, 733, 733f
- zinc–mercuric oxide cell, 729–730, 729f
- Bayer process** An industrial process for the purification of aluminum(III) oxide through its selective dissolution in a strongly basic solution, 739–740
- Becquerel, Henri, 21, 817
- Becquerel (unit of activity), 819
- Bednorz, J. Georg, 950
- Beer–Lambert law, 845–846
- Beer's law** Relates the amount of light absorbed by a sample to its concentration, the path length, and its molar extinction coefficient, 846
- Berthollet, Claude, 10
- Berthollides** Solids that exist over a small range of compositions, without the definite stoichiometry implied by a single molecular formula, 10
- Beryllia ceramic, 948
- Beryllium, electron configuration of, 202, 203f
- Beta decay, 813–814
- Beta particle** A high energy electron ( $\beta^-$ ) or positron ( $\beta^+$ ) emitted from an unstable nucleus in a nuclear decay process, 813–814, 814f
- Bilayer membranes** Structure formed when high concentrations of molecules having both hydrophilic and hydrophobic sections are dissolved in water, 981
- Bimolecular reaction** An elementary reaction that occurs through collision of two molecules, 766
- Binary compounds, 8
- naming, 116–117, 117t
- Binding energy** ( $E_B$ ) The energy required to separate a nucleus into its component protons and neutrons; also, the energy required to remove an electron from a specific orbital in an atom, 811–812
- Biological materials, conjugated molecules in, 176
- Biology, radiation in, 822–827
- Birge–Spencer plot, 862, 863f
- Bismuth, alloys of, 439–440
- Blackbody radiation** Electromagnetic radiation emitted from an idealized dark-colored solid which is in thermal equilibrium with the radiation, 131–134, 131f, 134f
- Blood plasma, buffered, 650–651
- Boat conformation** Conformation of cyclohexane in which four carbon atoms lie in a plane with two carbon atoms above the plane, 294, 294f
- Body-centered** An adjective describing a solid lattice that has a lattice point at the center of each unit cell (in addition to the ones at the corners), 909, 909f
- Body-centered cubic (bcc) structure** A crystalline structure that has one atom located at each point of the bcc lattice. The points at each corner are shared among the 8 unit cells meeting at that corner and together contribute one atom to the unit cell. The total number of atoms in the unit cell is 2, 912, 912f, 914t
- Bohr, Niels, 136, 139
- Bohr model, 139–142
- Bohr radius** ( $a_0$ ) The radius of the first electron orbit in the Bohr model for the hydrogen atom; equal to  $5.29 \times 10^{-11}$  m, 140
- Boiling point** ( $T_b$ ) The temperature at which the equilibrium vapor pressure of a liquid equals the external pressure, 427, 427f, 432–433
- normal, 433
- Boiling-point elevation** The colligative property in which the boiling point of a solvent is raised by the presence of a nonvolatile solute, 460–463, 461f, 461t
- Boltzmann, Ludwig, 385, 390, 518
- Boltzmann energy distribution** (also simply Boltzmann distribution) An exponential distribution which, when corrected for the degeneracy of each energy level, gives the population of the energy levels of a molecule as a function of temperature, 518, 849–850, 854
- Boltzmann's constant** ( $k_B$ ) The universal gas constant divided by Avogadro's number,  $R/N_A = 1.38065 \times 10^{-23}$  J K $^{-1}$ , 132, 388, 533, 849
- Bomb calorimeters, 493, 494f
- Bond(s)
- backbonding, 360
- coordination chemistry. *See* **Coordination chemistry/complexes**
- covalent, 53, 90–98
- coordinate, 616
- polar, 53, 96

- crystal field theory. *See* **Crystal field theory**
- dative, 330, 616
- de-localized bonds. *See* **Linear combination of atomic orbitals (LCAO)**
- dipole moment, 97, 98t, 111
- double, 100
- excess bond energy, 81
- formation of, 83–85
- hydrogen molecular ion, 229–230
- ionic, 53, 85–90
- LCAO approximation. *See* **Linear combination of atomic orbitals (LCAO)**
- ligand-to-metal, 359–362, 361f
- localized bonds. *See* **Valence bond (VB) method**
- metal-to-ligand, 361f, 362
- organic molecule bonding. *See* **Organic molecule bonding**
- percent ionic character, 97–98, 98f, 98t
- periodic behavior in chemical bonding, 75–77
- pi ( $\pi$ ) bonds, 256
- polar, 53, 96
- quantum mechanics and, 221–224
- sigma ( $\sigma$ ) bonds, 256
- transition-metal elements. *See* **Transition-metal elements**
- triple, 100
- valence bond model. *See* **Valence bond (VB) method**
- Bond dissociation energy** The amount of energy that must be transferred to a molecule in order to break a particular chemical bond, 221
- Bond energy** Also called bond dissociation energy; the amount of energy that must be transferred to a molecule in order to break a particular chemical bond, 92, 92t, 95t, 246t
- Bond enthalpy** The enthalpy change  $\Delta H$  in a reaction in which a chemical bond is broken in the gas phase, 511–512, 511t, 950t
- Bond force constant ( $k$ )** A measure of the stiffness of a chemical bond, it correlates with theoretical models of bond order and is measured experimentally using vibrational spectroscopy, 96, 246f
- Bond length, 91–92, 92t, 95t, 96t, 245t, 246f
- Bond order** A measure of the strength of a chemical bond; in the Lewis model, defined as the number of shared electron pairs; in the molecular orbital description, defined as one-half the number of electrons in bonding molecular orbitals minus one-half the number of electrons in antibonding ones, 95–96, 236
- first-row homonuclear diatomic molecules, 237t, 246t
- second-row homonuclear diatomic molecules, 237t, 246t, 247f
- Bonding molecular orbital** A molecular orbital, the occupation of which by one or two electrons results in an increase in bond strength, 229, 236
- Boranes, 261
- Born, Max, 157, 223, 930
- Born–Haber cycle** A thermodynamic cycle that allows the experimental determination of lattice energies in ionic crystals, 930
- Born–Oppenheimer approximation, 223–224, 224f, 840, 851
- Boron, electron configuration of, 202, 203f
- Boron nitride, 952
- Bound motion, 68, 69f
- Boundary conditions** Restrictions that must be placed on the solutions to differential equations to reflect certain conditions known in advance about the system, 147, 158
- Boyle, Robert, 3, 375–376, 375f
- Boyle's law** At constant temperature, the product of pressure and volume is a constant for a fixed amount of a gas;  $PV = C$  or  $P_1V_1 = P_2V_2$ , 376–377, 376f, 380
- Bragg, W. H. and W. L., 909
- Bragg angles, 911
- Bragg law** The relationship giving the angle  $\theta$  for Bragg diffraction of X-rays of wavelength  $\lambda$  from parallel planes in a crystal separated by the distance  $d$ :  $n\lambda = 2d \sin \theta$ ;  $n$ , an integer, is the *order* of the Bragg reflection, 910f, 911
- Bragg reflection, 910f, 911
- Branched-chain alkane** A saturated hydrocarbon in which one or more carbon atoms are bonded to three or four other carbon atoms, 294–297
- Branching chain reaction** A chain reaction in which the number of reactive intermediates increases during the propagation steps, 775
- Breeder reactor, 831
- Brønsted–Lowry acid** A substance that can donate a hydrogen ion to a Brønsted–Lowry base, 613–615, 618, 619
- Brønsted–Lowry base** A substance that can accept a hydrogen ion from a Brønsted–Lowry acid, 613–615, 618, 619
- Brown, Robert, 473
- Brownian motion** The continual random motion of colloidal particles as they undergo collisions with surrounding solvent molecules, 473
- Buckminsterfullerene, 303, 303f
- Buffer solution** A solution that maintains approximately constant pH upon small additions of acid or base, 635–640, 640f
- calculation of buffer action, 635–638
- designing buffers, 638–640
- Buffered blood plasma, 650–651
- Calorimeter
- bomb, 493, 494f
- ice, 488–489, 489f
- Calorimetry** Methods for measuring quantitatively the amount of heat transferred into or out of a thermodynamic system in a process, 488–489, 489f
- Canal rays** Positively charged particles (ions) in cathode ray tubes, 20–21
- Cannizzaro, Stanislao, 15
- Carbohydrates** Any compound of general formula  $C_n(H_2O)_m$ , 982–984, 982f–984f
- Carbon
- covalent crystals, 920, 921f
- electron configuration of, 202, 203f
- hybridization and multiple bonds in organic carbon compounds, 264–266, 264f–266f
- nanotubes, 304, 304f
- radioactive dating, 821–822

- Carbon and organic molecule bonding. *See* **Organic molecule bonding**
- Carbonate minerals in fresh water and seawater, 691–692, 691f
- Carbonylation** A reaction in which the C=O group is inserted into a previously existing bond, 311
- Carboxylic acid** An organic compound the molecules of which contain the –COOH functional group, 311, 311f
- Carnot, Sadi, 536
- Carnot cycle, 536, 552–554, 553f, 556–557, 557f
- Carnot engines, efficiency of, 555–556
- Carothers, Wallace, 973
- Catalysis, 794–797
- Catalyst** A substance that takes part in a chemical reaction, speeds it up, but itself undergoes no permanent chemical change, 300, 794  
action of, 794–797, 795f–796f  
enzymes as, 797  
in sulfuric acid manufacturing, 41–42
- Catalytic converter** An assembly of catalysts used in automobiles to oxidize hydrocarbons and CO to carbon dioxide and water and to reduce oxides of nitrogen to the elements, 796–797, 796f
- Catalytic cracking** The breaking down of long-chain hydrocarbon molecules in petroleum using catalysts, 300
- Cathode** The site at which reduction occurs in an electrochemical cell; source of electrons in a cathode ray tube, 16, 17, 20, 20f, 695, 695f
- Cathode ray tube, 17, 17f, 21
- Cathode rays** Beams of electrons ( $e^-$ ) observed in vacuum tubes. They emanate from the negatively charged electrode and carry electrical charge, 16
- Cation** A positively charged ion, 70
- Cell constants** The three edges and three angles that describe the size and shape of the unit cell of a crystalline solid, 907
- Cell potential** The electrical potential difference between two half-cells, 697  
Gibbs free energy and, 700–708  
standard, 703  
standard reduction potentials, 703–706
- Cements, 946–948, 947t
- Ceramic** A synthetic material that has as its essential components inorganic, nonmetallic materials, 941  
cements, 946–948, 947t  
composite, 952, 952f  
composition and structure, 942–943, 942f  
glass, 944–946, 945f–946f, 945t  
making, 943  
mixed oxide, 949  
nonoxide, 942, 950–952, 950t  
nonsilicate, 948–952  
oxide, 942, 948–949  
pottery, 943–944  
properties of, 941–943  
silicate, 942, 943–948  
superconducting, 949–950, 950f
- Ceramic phase** Any portion of the whole body that is physically homogeneous and bounded by a surface that separates it from other parts, 942
- Cesium chloride structure of ionic crystals** An ionic crystal structure that consists of two interpenetrating simple cubic lattices: one of cations, and the other of anions, 917, 917f
- Chadwick, James, 827
- Chain reaction** A reaction that proceeds through a series of linked elementary reactions; the general steps are initiation, propagation, and termination, 774–775
- Chair conformation** Conformation of cyclohexane in which four carbon atoms line in a plane with one carbon atom above the plane and one below, 294, 294f
- Chalcogen elements** An element of Group VI of the periodic table, 61, A.50
- Chapman, Sydney, 886
- Chapman cycle, 886, 886f
- Charge, oxidation number and, 112–114
- Charge-induced dipole forces, 422–423, 422f
- Charge-to-mass-ratio** The magnitude of the charge of an ion divided by its mass of electrons. For ions in mass spectrometry, the ratio is typically expressed as the number of multiples of  $e$  divided by the mass in atomic mass units of the ion, 17–19  
of ions, 15–16
- Charles, Jacques, 378
- Charles's law** At constant pressure, the volume of a sample of gas is a linear function of its temperature;  $V = V_0 + aV_0t$ , 379, 379f, 380
- Chelates** Complexes in which a ligand coordinates via two or more donors to the same central atom, 335
- Chemical bond, quantum picture of, 221–224
- Chemical equations, writing balanced, 39–43
- Chemical equilibrium, 563–606. *See also* **Equilibrium**
- Chemical formula** A representation of the chemical composition of a substance; refers to either empirical formula or molecular formula, 11
- Chemical kinetics. *See* **Reactions**
- Chemical reaction. *See* **Reactions**
- Chemical shift** ( $\delta$ ) In nuclear magnetic resonance (NMR) spectrometry, the position of a peak in the compound under examination relative to the position of a standard reference peak, 871, 872
- Chemical vapor deposition** A method used in the fabrication of ceramics, 952
- Chemiluminescence, electrogenerated (ECL), 717–721, 717f, 719f
- Chernobyl disaster, 831
- Chiral structures, 344–345
- Chirality** The structural property in which a species is not superimposable on its mirror-image structure, 296
- Chlorofluorocarbons (CFCs), 880, 885, 887–889, 887f
- Chlorophylls, 890, 890f, 893f, 894
- Cholesteric** A type of liquid crystal in which the ordered arrangement of the molecules shifts from one vertical plane to the next to form a helical array that strongly diffracts light, 980, 980f

- Chromatography** A method of separating substances that exploits the difference in the partition coefficients of solute species between two phases, such as a gas and a liquid absorbed on a porous support, 603–605, 604f–605f, 604t column, 603, 604f, 605 gas-liquid, 605, 605f
- Chromophore** Functional groups in molecules that absorb visible light, 722
- Circular motion, A.20
- Circular standing wave, 147–148, 147f
- cis-trans* isomerization, 873
- Classical mechanics** A set of laws describing the motion of macroscopic objects, including  $\vec{F} = m\vec{a}$ , the force on an object equals the mass of the object multiplied by the acceleration of the object, and  $\vec{F}_2 = -\vec{F}_1$ , where  $\vec{F}_2$  is the force exerted on particle 2 by particle 1 and  $\vec{F}_1$  is the force exerted on particle 1 by particle 2. Also called *Newtonian mechanics*, after Isaac Newton, 125.
- Clausius, Rudolf, 385, 536, 537, 556, 558
- Clays** Hydrated aluminosilicates produced by the weathering of primary minerals, 939–940, 940f structured clay products, 943–944
- Closed system** A thermodynamic system that does not gain or lose matter during a process because it is surrounded by impermeable walls, 482
- Coefficient of thermal expansion** ( $\alpha$ ) A value characterizing the change in volume of a substance as its temperature is changed at constant pressure, 417–418, 417t
- Coenzymes, 797
- Cofactors, 797
- Collective behavior, 905
- Colligative properties** Physical properties of a solution that depend only on the concentration of a solute species and not on its nature, 459 boiling-point elevation, 460–463, 461f, 461t freezing-point depression, 461t, 463–465, 463f, 465f osmotic pressure, 465–467, 466f vapor-pressure lowering, 459–460
- Collision cross section** The effective area of a molecule as a target for collisions with other molecules, 783
- Collision theory, 780–788
- Collisions  
inelastic, 840  
kinetic theory of gases and, 386, 386f  
mean free path and, 404–405  
molecule-molecule collisions, 401–404, 403f  
molecule-wall collisions, 399–401  
reactive, hard-sphere, 783–788, 784f
- Colloid** A mixture of two or more substances in which one is suspended in the second as tiny particles that nonetheless exceed molecular size, 472–473, 472f–473f
- Color center. *See* F-center
- Color wheel, 875, 875f
- Colors of coordination complexes, 352–353, 352f–353f
- Column chromatography, 603, 604f, 605
- Combustion, empirical formula determination by, 38
- Combustion train, 38, 38f
- Common logarithms** Logarithms expressed in base 10, A.25
- Common-ion effect** The observation that if a solution and a solid salt to be dissolved in it have an ion in common, the solubility of the salt is depressed, 676–677, 677f
- Complementary color** The color opposite a given color on the color wheel, 352, 875, 875f
- Complex ion** An ion in which a central metal ion is bound to one or more ligand molecules or ions that are capable of independent existence in solution, 680 acidity and amphoterism of, 684–685 complex-ion equilibria, 680–684 formation constant, 681, 681t
- Composite ceramic** A ceramic in which one ceramic is reinforced by the admixture before firing of another ceramic, 952, 952f
- Compound** A substance containing two or more elements, 7 binary, 8 empirical formula of, 36–39 nonstoichiometric, 10 quaternary, 8 ternary, 8
- Compressibility** The measure of the change of the volume of a substance with pressure, 416–417, 417t
- Compressibility factor** ( $z$ ) The ratio  $PV/nRT$ , which differs from 1 for a real gas, 394
- Compression of ideal gas, 537–538
- Computerized axial tomography (CAT)/computerized tomography (CT), 824, 826
- Concentration** ( $c$ ) The amount of a solute present in a given amount of solvent or solution, 442
- Concrete** A mixture of portland cement, sand, and aggregate in the proportions 1:3.75:5, 947
- Condensation** The formation of a liquid or solid from a gas, 430, 430f
- Condensation polymerization** Polymerization via condensation reactions, 970–971
- Condensation reaction** The joining together of two molecules as a third, small molecule is split out, 309
- Condensed structural formula** Specifies which atoms in a molecule are bonded to each other and by what types of bonds they are connected, 54–55
- Conductance** ( $G$ ) Proportionality constant relating current through a sample to the voltage applied to the sample; reciprocal of the resistance, and measured in Siemens (S), 953
- Conduction band** (CB) A partially filled band of energy levels in a crystal through which the electrons can move easily, 723, 723f–724f, 957–959, 958f
- Conductivity** ( $\sigma$ ) Property that measures the ability of a substance or material to conduct electricity; reciprocal of the resistivity, and measured in  $(\Omega\text{m})^{-1}$  or  $\text{S m}^{-1}$ , 954, 954t band theory of conduction, 957–959 measurement of, 953–954, 954f in metals, 956–957 microscopic origins of, 954–956 molar, 955 semiconductors, 959–962, 960f–961f
- Confidence limit, A.4

- Conjugate acid-base pairs** A Brønsted–Lowry acid and the base formed when it donates a hydrogen ion, or a Brønsted–Lowry base and the acid formed when it accepts a hydrogen ion, 614
- Conjugated molecules in dyestuffs and biological materials, 176
- Conjugated  $\pi$  electron system** A molecule or portion of a molecule in which double or triple bonds alternate with carbon–carbon single bonds, and electrons are delocalized across several atoms, 274
- Consecutive equilibria, 583
- Conservation of energy, 4, A.16–A.17
- Conservation of matter, 4
- Constraints** A portion of the apparatus in a thermodynamic experiment; it holds one of the properties of the system at a constant value throughout the experiment, 483
- Constructive interference** Interaction of two waves in which their crests are aligned and their sum has greater amplitude than the original waves, 129–130, 129f, 130f, 148, 150f, 910, 910f
- Convection** The net flow of one region of a fluid with respect to another region, 419
- Conversion method, A.10–A.11
- Cooling, spontaneous of a hot body, 541
- Coordinate covalent bond** In coordination chemistry, a covalent bond in which the shared electrons are both supplied by one of the bonded atoms; it also results from the interaction of a Lewis base and a Lewis acid, 616
- Coordination chemistry/complexes, 333–345, 680
- bonding in
- hybrid orbitals, 355–356, 355f–356f, 356t
- molecular orbital theory, 356–364, 357f–358f, 360f–361f
- valence bond theory, 355–356
- chelates, 335
- chiral structures, 344–345
- colors of, 352–353, 352f–353f
- crystal field theory. *See* **Crystal field theory**
- formation constants in aqueous solution, 681t
- formation of, 333–337
- in heme proteins, 342–343
- ligand substitution reactions, 338–339, 339f
- linear geometries, 344
- magnetic properties, 351, 351f
- naming, 337–338, 337t
- octahedral geometries, 339–340, 339f–341f
- square-planar geometries, 340, 341f, 344
- structures of, 339–345
- tetrahedral geometries, 340, 341f, 344
- Coordination complexes** Compounds in which metal atoms or ions are bonded via coordinate covalent bonds to anions or neutral molecules that supply electron pairs, 333–334
- Copper
- in galvanic cells, 694–695, 695f
- native, 738f
- Core electrons** Electrons that are contained in the inner shells of an atom and do not participate in chemical bonding, 76–77
- Correlation diagram** In LCAO–MO theory, a diagram that shows the relative energy of the molecular orbitals in a molecule and their derivation from the atomic orbitals of the constituent atoms, 235, 235f–236f, 244f, 247f, 249f
- Correspondence principle** The requirement that the predictions of quantum mechanics approach the predictions that classical mechanics would make for the same system when the system is sufficiently large or sufficiently excited, 164
- Corrosion** A destructive chemical process in which metals are spontaneously oxidized, 736–738, 737f
- Coulomb (C)** The fundamental unit of charge in the SI system of units, A.19
- Coulomb potential energy** The potential energy of a pair of species that interact by the Coulomb force law, 83, 88, 90, A.19
- Coulomb stabilization energy, 85, 88, 90
- Coulomb's law, 62–69, 87–88
- Covalent bond** A model of chemical bonding in which electrons are shared between atoms participating in the bond, 53, 90–98
- coordinate, 616
- polar, 53, 96
- Covalent compound** A compound formed from electron sharing; tends to be low-melting, low-boiling, and nonconducting, 99
- naming, 116–117, 117t
- Covalent crystals, 920, 921f
- Cracking** The degradation of longer chain alkanes to shorter chain alkenes by means of heat or catalysts, 300
- Crick, Francis, 990
- Critical point** The point in the phase diagram at which the gas–liquid coexistence curve terminates, 434–435, 434f–435f
- Crookes, William, 16
- Crookes tube, 16, 16f, 20, 20f
- Cross-linking nonlinear synthetic polymers, 971–972
- Crutzen, Paul, 886, 888
- Crystal field splitting energy, 347, 353–354, 353t
- Crystal field stabilization energy (CFSE)** The net amount by which the occupied (otherwise equal) energy levels for the *d* electrons of a metal ion are stabilized by the electrostatic field of the surrounding ligands in a coordination complex, 348, 351t
- Crystal field theory** A model for coordination complexes in which the central metal is treated as ionically bonded to surrounding ligands, 345–348
- magnetic properties, 351, 351f
- octahedral complexes, 349, 350f, 351t
- square-planar complexes, 348–349, 349f
- tetrahedral complexes, 348–350, 349f–350f
- Crystal lattice** A three-dimensional array of points that embodies the pattern of repetition in a crystalline solid, 907
- Crystal Solids** whose structures are symmetrical and highly ordered over macroscopic distances, 905
- alloys, 926
- amorphous solids, 923, 926–927
- atomic packing in, 914–915, 915f
- cohesion in, 916–923

- covalent, 920, 921f  
defects, 923–924, 924f  
interstitial sites, 915–916, 916f  
ionic, 916–918, 917f, 928–930, 929f  
lattice energy, 927–930  
  ionic crystal, 928–930, 929f  
  molecular crystal, 927–928, 928t  
liquid crystals. *See* Liquid crystal  
metallic, 918–919, 919f–920f  
molecular, 921, 921f, 927–928, 928t  
nonstoichiometric compounds, 924–925  
octahedral sites, 915–916, 916f  
point defects, 923–924, 924f  
structure, 911–916, 912f, 914t, 915f–916f  
symmetry, 905–911, 906f, 908t  
unit cell, 907–909, 907f–909f  
X-ray scattering by, 909–911, 910f
- Crystallography** The branch of science that studies the properties and structures of crystals, 905
- Cubic system** A category (one of seven) into which a crystalline solid can be classified on the basis of the symmetry of its diffraction pattern, 907, 908f, 908t
- Curie, Marie and Pierre, 21
- Curvature, 155
- Curves  
  areas under, and integrals, A.28–A.30  
  slopes of, and derivatives, A.26–A.28
- Cyclic alkanes, 293–294, 294f
- Cyclic voltammetry, 718–720, 718f
- Cycloalkane** A saturated hydrocarbon with one or more closed rings of carbon atoms, 293–294, 294f
- Cyclotron, 825, 826f
- d orbitals** Atomic orbitals for which the angular momentum quantum number  $\ell$  has the value 2, 192–193, 192f
- Dalton, John, 11, 13, 14, 383
- Dalton (mass unit), 808
- Dalton's atomic theory, 11
- Dalton's law** The total pressure of a gas mixture is the sum of the pressures that would be measured separately if each of the components were present by itself, 383
- Dating, radioactive, 820–822
- Dative bond** A bond formed by transfer of a pair of electrons from one bonding partner to the other, 330, 616
- Davisson, C., 149
- Davy, Sir Humphry, 698, 740
- d-block element** The elements from scandium to zinc, whose electron configurations involve filling the *d*-orbitals in the building up process, 205
- De Broglie, Louis, 143, 147–148
- Debye frequency, 503
- Decomposition potential** The external voltage that must be applied across the electrodes of an electrochemical cell in order to make a reaction occur that would otherwise not be spontaneous on thermodynamic grounds, 745–746
- Definite integral, A.29
- Degeneracy of energy level, 849
- Degenerate** Energy levels that correspond to more than one quantum state, 165, 180
- Degrees of freedom** Different types of motions available to molecules (e.g., translation, vibration, rotation, electronic) and the number of coordinates necessary to describe each type of motion, 498–500, 501t
- Delocalized bonds, linear combination of atomic orbitals method. *See* Linear combination of atomic orbitals (LCAO)
- Delocalized electrons, organic molecules with, 273–275
- Delocalized molecular orbitals, 220
- Democritus, 8
- Densification** The removal of voids in a ceramic body during drying or firing, leading to shrinking, 943
- Density** Typically mass per unit volume, 29–30, 29t, 371  
  charge density (charge per unit volume), 198  
  probability density function, A.33  
  radial probability density, 187, 194f, 198f
- Derivative, A.27–A.28, A.27t
- Destructive interference** Interaction of two waves in which the crest of one is aligned with the trough of the other and interference shows cancellation of the original waves, 129–130, 129f, 130f, 148, 150f, 910, 910f
- Detailed balance principle. *See* Principle of detailed balance
- Detergent** A synthetic analog to natural soaps that contains a hydrophobic chain and a hydrophilic end group, 981
- Diamagnetic** The property of being repelled from an inhomogeneous magnetic field, 203–204, 245f, 351, 351f
- Diamond, 920, 921f
- Diathermal walls** In a thermodynamic system, walls that allow transfer of heat into or out of the system during a process, 482
- Diatom molecule** A molecule containing two atoms, 12  
  dipole moments, 98t  
  heteronuclear. *See* Heteronuclear diatomic molecule

- Diffraction of electrons, 148–151, 149f, 151f
- Diffraction pattern** Arrangement of alternating bright and dark spots produced by constructive and destructive interference of two waves, 130, 130f
- Diffuse** Diffusion is the process by which two materials are mixed by random motion of atoms from one into the other, 418
- Diffusion, 405, 526  
  gaseous diffusion through a porous barrier, 401, 402f  
  in gases, liquids, and solids, 418–419, 418f, 419t  
  in uranium enrichment, 401, 402f, 407–408, 407f
- Diffusion constant** The proportionality constant relating the mean-square displacement of a particle to the elapsed time, 405, 405f, 418–419, 419t

- Diffusion-controlled reaction** A reaction the rate of which is controlled by the rate at which molecules can diffuse toward each other, 793
- Dihedral angle, 106
- Dimensions** Results of measurements expressed as a combination of pure numbers (magnitudes) and units, A.8
- Diol** A compound containing two hydroxyl groups, 309
- Dipeptide, 984
- Dipole moment** ( $\mu$ ) A measure of the separation of charge in a molecule; the product of the charge and the distance that separates it from a charge of equal magnitude and opposite sign, 97, 98t  
of polyatomic molecules, 111
- Dipole-dipole forces** The interactions among polar molecules, 421–422
- Dip-pen lithography** Synthesis of two-dimensional arrays of materials by using scanning probe microscopy tools to “drag” molecules to the desired locations, 33
- Directionality of spontaneous change, 528, 532
- Disaccharides** The result of the condensation (with elimination of water) of two simple sugars, 983, 983f
- Disilicates** Mineral form in which two  $\text{SiO}_4^{4-}$  are linked, 938
- Dispersion forces, 292, 423, 423f
- Displacement, A.12
- Disproportionation** A reaction in which a single species is both oxidized and reduced, 457, 707–708
- Dissolution reaction** A chemical reaction by which a substance dissolves; the reverse of precipitation, 446, 528
- Dissolution-precipitation reactions, 669
- Dissolved species, nature of, 445–448
- Distillation, 469–472, 471f  
petroleum, 292–293, 293f
- Distillation column, 470
- Donor impurity level** A band of orbitals in a semiconducting solid containing electrons contributed by an impurity, 959
- Doping** The deliberate addition of a small amount of an impurity in order to change the properties of the pure substance, 959
- Double arrows notation, 567

- Emission spectrum, 135, 136f, 142
- Empirical equilibrium constant ( $K_p$  or  $K_C$ )** The product of reaction product concentrations each raised to a power equivalent to its stoichiometric coefficient in the balanced equation for the reaction, divided by the product of the reactant concentrations each raised to a power equivalent to its stoichiometric coefficient. This ratio is measured at equilibrium, 568
- Empirical formula** A chemical formula of a compound that expresses the relative chemical amounts of its elements in terms of the smallest integers, 36–39  
 determination from elemental analysis by combustion, 38  
 determination from mass composition, 37

- Empirical formula (*continued*)  
 molecular formula connection to, 39  
 percentage composition and, 37
- Empirical rate expression** Relation between the rate of a reaction and concentration of reactants, determined by experiment, 759
- Endothermic reaction** A reaction in which heat is taken up, so that  $\Delta H$  is positive, 504, 505f, 596
- Endpoint** The point in a titration at which the indicator signals that a stoichiometric amount of the first reactant has been added to the second reactant, 450, 640, 642
- Energy** ( $E$ ) The capacity for doing work, A.15  
 activation, 777  
 blackbody radiation, 131–134, 131f, 134f  
 bond, 92, 92t, 95

 relationships among expressions, 581–582
- Equipartition theorem** Each quadratic term that appears in the energy of a molecule contributes  $RT/2$  to the average energy calculated from the Maxwell-Boltzmann distribution, 500–502, 501t
- Equivalence point** The point in a titration at which the chemical amount of titrant added is equal to the chemical amount of the substance being titrated, 641–642, 641f, 643f
- Equivalent volume** The volume of titrating solution required to bring a titration to the equivalence point, 642
- Ester** An organic compound the molecules of which are characterized by the  $\text{—}\overset{\text{O}}{\parallel}\text{C—O—}$  functional group, 311, 311f, 314–315, 314f
- Ether** An organic compound containing the  $\text{—O—}$  functional group, 308–309, 309f
- Evaporation** The formation of a vapor from a liquid, 430, 430f, 528
- Excess bond energy** ( $\Delta$ ) The difference between the actual bond energy and (hypothetical) covalent bond energy in a polar AB diatomic molecule; a measure of the electronegativity difference between atoms A and B, 81
- Excited electronic states, fate of, 841–843
- Excited state relaxation processes, electronic spectroscopy and, 873–880
- Excluded volume, 395
- Exothermic reaction** A reaction in which heat is given off, so that  $\Delta H$  is negative, 77, 504, 505f, 506f, 596
- Expansion, gas, 528, 531, 531f, 537–538
- Experimental error, A.3–A.5
- Exponential, A.25
- Extensive property** A property that is proportional to the size of a system and is therefore the sum of the corresponding properties for each of the subsystems into which the system can be divided, 483, 505
- Extraction** The removal of a solute from one solvent to another, 602–603
- Extractive metallurgy** The recovery of metals from their sources in the earth, 738
- Face-centered** An adjective describing a solid lattice that has a lattice point at the center of each face of the unit cell (in addition to the ones at the corners), 909, 909f, 916
- Face-centered crystals** A solid lattice in which the unit cell has lattice points at each of the 8 corners of the unit cell and one additional point at the center of each of the 6 faces, 909
- Face-centered cubic (fcc) structure** A crystalline structure that has one atom located at each point of the bcc lattice, and one at the center of each face. The points at each corner are shared among the 8 unit cells meeting at that corner and together contribute one atom to the unit cell. The points in each face are shared by the 2 cells and together contribute 3 atoms to the unit cell. The total number of atoms in the unit cell is four, 912, 914t, 916f
- Faraday, Michael, 15–16, 695, 698
- Faraday constant** ( $F$ ) The magnitude of the charge on one mole of electrons; equal to  $96,485.3 \text{ C mol}^{-1}$ , 699
- Faraday's laws** In an electrochemical cell, the quantities of reactants and products are proportional to the amount of electrical charge passed through the cell; for a given amount of electrical charge, the quantity of a substance produced or consumed at an electrode is proportional to its molar mass divided by the absolute value of the total change in oxidation number required to produce it, 698–699
- Fats, 314–315
- f-block elements** Elements in which  $f$  electrons are involved as valence electrons; lanthanide or actinide elements, 205
- F-center** A site at which an electron replaces an anion in an ionic crystal, 924, 924f
- Feldspars, 939
- Fermi, Enrico, 827, 829
- Fermi level** The uppermost occupied energy level in a crystal at the absolute zero of temperature, 957
- Fibers, 972–974, 974t

- Fibrous protein** Protein formed by amino acids in regular three-dimensional structures, 985, 987
- First excited state** On the energy level diagram of a system, the state immediately above the ground state, 138
- First ionization energy, 70–71, 71f, 72t
- First law of thermodynamics** The change in the internal energy of a system is equal to the work done on it plus the heat transferred to it:  $\Delta U = w + q$ , 485, 490–491, 491f  
heat capacities of ideal gases, 495–497
- First order reaction** A reaction that has a total order of 1, as determined by the sum of the exponents of the concentration terms in the rate law; if a reaction is first order in a single species A, the concentration of A changes with time according to  $[A] = [A]_0 e^{-kt}$ , 759, 762–763, 763f
- Fission** Decay of unstable nuclei by splitting into daughter nuclei, 817, 827–832
- Fletcher, H. A., 19
- Flocculation** Acceleration of the settling out of a colloid through the addition of salts, 472, 473f
- Fluidity** Tendency to flow, 418
- Fluorescence** Emission of light from a molecule in an excited state that leaves the electron spin quantum number unchanged, 842  
laser-induced, 847–849
- Force constant ( $k$ )** The constant of proportionality between force and displacement for a bond, 96, 246f, 840, 859
- Forces  
in molecules, 83–85  
motion of objects changed by, A.13–A.15
- Formal charge** The charge an atom in a molecule would have if the electrons in its Lewis structure were divided equally between the atoms that share them, 100–101
- Formalin, 310
- Formation, standard enthalpy of, 509–510
- Formation constant ( $K_f$ )** The equilibrium constant for the reaction in which ligands replace water molecules in a complex ion, 681, 681t
- Formula unit** The atoms represented by the empirical formula of a compound, 36
- Fourier transform, 847
- Fractional distillation** The separation of two or more components of a liquid solution on the basis of their different boiling points by repeated evaporation and recondensation, 469
- Fractional saturation** The fraction of hemoglobin or myoglobin sites occupied by  $O_2$  molecules, 591
- Franck, James, 137–139
- Franck-Condon principle** An assertion that the most probable transition between electronic states induced by the absorption of electromagnetic radiation leaves the nuclear positions unchanged, 877
- Franck-Hertz experiment, 137–139, 137f–138f
- Frankland, Edward, 219
- Franklin, Rosalind, 990
- Free energy changes, reaction quotient and, 598–599, 599f
- Free radical** A species in which one or more valence electrons are unpaired; radicals are often but not always highly reactive; often occurs as an intermediate in reactions, 296, 306
- Freezing-point depression** Reduction of the freezing point of a pure liquid by solute dissolved in the liquid, 461t, 463–465, 463f, 465f
- Frenkel defect** A lattice imperfection that consists of a lattice vacancy plus a nearby interstitial atom or ion, 924, 924f
- Frequency ( $\nu$ )** The number of cycles of a wave that pass a particular point per unit time, 126
- Frozen orbital approximation** Assumption that the orbitals of an atom remain undistorted upon ionization of the atom, 208
- Fructose, in aqueous solution, 446, 446f

    standard-state free energies, 550–551  
    temperature effects, 551–552, 552f  
**Glass** A solid state characterized by noncrystalline atomic structure, 926–927, 944–946, 945f–946f, 945t  
**Glaze** A thin glass layer applied to the surface of the clay in a ceramic, 944  
**Globular protein** A protein formed from a sequence of amino acids with an irregular folded structure, 987–988  
Glow discharge, 16, 16f  
Glucose sensors, 716–717, 716f  
Goodyear, Charles, 977  
Graham, Thomas, 400  
**Graham's law of effusion** The rate of effusion of a gas through a small hole into a vacuum is inversely proportional to the square root of its molar mass, 400–401  
Graphs, using, A.21–A.22  
Grätzel, Michael, 726  
Grätzel cell, 726, 727f  
Gray (unit of absorbed radiation), 823  
**Ground state** The state of lowest energy for an atom, molecule, or collection of molecules, 138  
**Group** Elements found in the same column in the periodic table, 59  
Guldberg, C. M., 568  
Haber, Fritz, 930  
Hahn, Otto, 827  
**Half-cell** One half of an electrochemical cell, in which either oxidation or reduction occurs at an electrode, 694

- Half-life** ( $t_{1/2}$ ) For a first-order reaction, the time it takes a concentration to decay to one half of its initial value; in nuclear decay processes, the time it takes for half of the radioactive nuclei present initially to decay, 763
- Half-reaction** Either the oxidation or reduction portion of a redox reaction, 454, A.45–A.46
- Halides, 305–306
- Hall, Charles, 740
- Hall–Héroult process** A process for producing aluminum through electrolysis of a solution of bauxite in molten cryolite, 740
- Halogen elements** Element of Group VII of the periodic table, 61, A.50
- Hamiltonian operator** Neither a number or a function, it is an expression that involves taking a second derivative of the function to the right of it, and adding the result to the product of any potential energies multiplied by the same function to the right. If the wave function on which the Hamiltonian operates represents an allowed time-independent quantum state of the system, the result is the total energy of the system multiplied by the same wave function, 159
- Hard acids, 331–333, 332t
- Hard base, 332–333, 332t
- Hardening, 947
- Hardness** Resistance to indentation, 418
- Harmonic oscillator, 94, 851, 858–860, 858f, 860f
- Harpoon mechanism** Model process describing the formation of ionic bonds, 90
- Hartree atomic orbitals** Approximate orbitals used to describe the locations of the electrons in many-electron atoms, 178, 196–201  
energy sequence of, 199–201  
shielding effects, 199–201, 201f, 201t  
sizes and shapes, 197–198
- Haüy, René-Just, 905
- Haüy's law** Interfacial angles remain the same when crystals are cleaved into smaller crystals, 905
- Heat** ( $q$ ) A means by which, without mechanical interaction, energy is transferred from a hot body to a colder body when the two are placed in thermal contact with one another, 488–490  
adiabatic process, 515–517, 517f  
entropy and, 535–537  
for ideal gases, 497–498
- Heat bath, 540
- Heat capacity** ( $C$ ) The amount of heat required to raise the temperature of an object by 1 K, either at constant pressure ( $C_p$ ), or at constant volume ( $C_v$ ), 492, 498t  
contributions estimated by the equipartition theorem, 501t  
ideal gases, 495–497  
molecular contributions to, 498–503  
specific heat capacity, 492, 492f  
temperature dependence of, 501f, 503f
- Heat engine, 535–536, 535f–536f, 554–555
- Heat transfer  
at constant pressure, 494–495  
at constant volume, 493  
spontaneous process, 528
- Heisenberg, Werner, 152
- Heisenberg indeterminacy principle** The statement that the product of the uncertainties in the position and the momentum of an object must exceed a lower limit:  
 $(\Delta p)(\Delta x) \geq h/4\pi$ , 152–154
- Heitler, Walter, 253
- Helium, electron configuration of, 202, 203f
- Helium burning** A stage in the evolution of a star during which helium is converted to heavier elements by nuclear fusion, 832–833
- Helix** Right-handed coiled structure assumed by protein molecules, 987
- Heme proteins, 342–343
- Hemoglobin, 591–592, 591–592f
- Henry's law** The vapor pressure  $P_2$  of a volatile solute above a solution is proportional to its mole fraction  $X_2$  in solution at low mole fractions;  $P_2 = k_2X_2$ , 468
- Herbicides, 317–318, 318f
- Héroult, Paul, 740
- Hertz, Gustav, 137–139
- Hertz, Heinrich, 128
- Hertz** (Hz) The SI unit of frequency; equal to  $1 \text{ s}^{-1}$ , 126
- Hess's law** If two or more chemical equations are combined by addition or subtraction to give another equation, then adding or subtracting changes in enthalpies for these equations in the same way gives the enthalpy change associated with the resultant equation, 506
- Heterogeneous** Having properties that vary from region to region, 6
- Heterogeneous catalysis** A catalyst that is present in a different phase than the reactants, 795
- Heteronuclear diatomic molecule** A molecule formed from more than one type of atom, 101, 246  
linear combination of atomic orbitals (LCAO), 246–249, 247f–249f
- Hexagonal close-packed (hcp) structure** A scheme of packing of equal spheres in which each sphere has 12 immediate neighbors and the symmetry of the lattice generated from the positions of the spheres is hexagonal, 915
- High-density polyethylene, 975–976
- Highest occupied molecular orbital (HOMO)** The highest energy molecular orbital that is occupied by one or more electrons, 717–720, 717f, 723, 723f, 726–727, 874, 876, 892, 894
- High-spin complexes** A transition metal complex in which electrons are placed into orbitals in such a way as to remain unpaired to the fullest extent possible, 347, 348f
- High-spin configuration** Electron configurations with a large number of unpaired spins, 347
- Hill, Archibald, 592
- Hofman, August Wilhelm, 219
- Homogeneous** Having properties that are uniform throughout, 6
- Homogeneous catalysis** A catalyst that is present in the same phase as the reactants, 795
- Homonuclear diatomic molecules** Molecules formed from atoms of the same element, 100, 237  
electron configuration and bond order, 237t  
energy levels, 243f

- linear combination of atomic orbitals (LCAO)  
 first-period atoms, 235–237, 235f–236f  
 second-period atoms, 237–246, 243f–244f  
 molecular orbitals, 245t  
 trends in bond order, bond length, bond energy, and force constant, 246f
- Hooke's law, 851, 858–859
- Hund's rules** Rules for determining the energy ordering of states of multielectron atoms. The introductory version of one of these rules presented in this text is the statement that when electrons are added to orbitals of equal energy, they will half-fill every orbital, with the spins remaining parallel, before pairing in any orbital, 202
- Hybridization** The mixing of atomic orbitals into new atomic orbitals with different shapes, 258  
 hybrid orbitals and bonding in coordination complexes, 355–356, 355f–356f, 356t  
 lone pairs and, 263–264  
 molecular geometry and, 262–263, 262f  
 multiple bonds in organic carbon compounds, 264–266, 264f–266f  
 polyatomic molecules, 259–266  
*sp* hybridization, 259–260, 259f  
*sp*<sup>2</sup> hybridization, 260–262, 261f  
*sp*<sup>3</sup> hybridization, 262–263, 262t
- Hydrated, 671
- Hydraulic cement** A cement that hardens by chemical reactions that incorporate water into the final body, 947
- Hydrocarbons** A substance containing hydrogen and carbon but no other elements, 38  
 aromatic, 300–302, 302f  
 empirical formula determination by combustion, 38, 291  
 petroleum distillation, 292–293, 293f  
 petroleum refining and, 290–291  
 unsaturated, 297
- Hydrodealkylation** The replacement of an alkyl group by hydrogen in a hydrocarbon, 302
- Hydrogen atomic orbital** Wave functions that when squared describe the probability density for the electron in the various states of the hydrogen atom, obtained by exact solution of Schrödinger's equation for the hydrogen atom, 178
- Hydrogen atoms, 178–196  
 electron spin, 195–196  
 energy levels of, 143, 179–181  
 isotopes, 26  
 nucleus of, 26  
 orbitals, 184–195, 185f–188f, 190f–194f  
   *d* orbital, 192–193, 192f  
   *p* orbital, 190–192, 190f–192f  
   *s* orbital, 186–190, 186f–188f  
 spectrum, 135, 136f, 142, 143f  
 wave functions, 181–183, 182t, 185f–189f
- Hydrogen bond** A strong nonbonding interaction that forms when a hydrogen atom bonded to a strongly electronegative atom also interacts with the lone electron pair of a nearby electronegative atom, 427–428  
 ion-dipole forces and, 422, 422f  
 in water, 427–428, 427f
- Hydrogen burning** A stage in the evolution of stars during which hydrogen is converted into helium by nuclear fusion reactions, 832
- Hydrogen molecular ion  
 chemical bond in, nature of, 229–230  
 electron probability density functions, 279, 282f–283f, 284  
 electronic wave functions for, 226–228, 227f  
 linear combination of atomic orbitals (LCAO), 231–235, 233f–235f  
 molecular orbitals for, 225–230, 227f, 230f  
 wave functions, 278–279, 280f–281f
- Hydrogenation** The absorption of hydrogen by a substance in a chemical reaction, 314
- Hydrolases, 797
- Hydrolysis** The reaction of a substance with water, in particular the reaction of an ion in which the pH of the water changes from neutral, 633–635
- Hydrophilic** Having a strong affinity for water, 981
- Hydrophobic** Lacking affinity for water, 981
- Hydroxides, solubility of, 678–679
- Hypothesis** The temporary assumption that a proposed statement is true while its validity is tested in a series of experiments, 3
- Ice, crystal structure of, 429
- Ice calorimeter** An instrument used to measure amounts of heat flowing into or out of a system, 488–489, 489f
- Ideal gas law** A relationship between the pressure, volume, temperature, and number of moles of a gas:  $PV = nRT$ , 381
- Ideal gases  
 adiabatic process, 515–517, 517f  
 compression/expansion of, 537–538  
 heat and work for, 497–498  
 heat capacity of, 495–497  
 irreversible expansion of, 542–544  
 isothermal process, 513–514, 517f, 537–538  
 reactions among, 574–577  
 reversible processes, 512–517
- Ideal solution** A solution that conforms to Raoult's law so that the vapor pressures of its components are proportional to their mole fractions in solution, 459, 459f, 577–578
- Impact parameter, 785
- Impermeable** Walls between thermodynamic systems that prevent flow of matter during a process, 482
- "In excess"** Refers to any reactant in a chemical reaction that is not the limiting reactant, 45
- Indeterminacy** An aspect of quantum mechanics, recognizing that observable properties can be indeterminate, 152
- Indeterminacy principle, 152–154
- Indeterminate** If an observable property does not have a definite value under certain experimental conditions, it is said to be indeterminate, 152
- Indicator, acid-base** A substance the color of which changes noticeably over a fairly small range of pH, 628–630, 628f–630f
- Induced dipole forces** The attraction between an ion and a nonpolar molecule or atom based on the induction of a weak dipole by the ion, 422–423

- Induced dipole-induced dipole forces, 423, 423f  
 Induced fit hypothesis, 801  
 Inequality of Clausius, 543  
**Inert complex** A complex in which the ligands exchange only slowly with other ligands, 338  
**Inert gas** An element of Group VIII of the periodic table, 61. *See also* Noble gases  
**Inhibitor** A substance that slows the rate of a reaction; a negative catalyst, 795  
**Initial rate** The rate of a chemical reaction at the moment that it begins, before any products can start to react in the reverse direction, 757  
**Initiation** The first stage in a chain reaction, 774  
**Initiator** A chemical reagent with bonds weak enough to be broken by heat or light to give radicals that initiate the chain polymerization of monomers, 968  
**Inner coordination sphere** Arrangement of ligands coordinated to metal atoms in well-defined directions in space, 333  
 Inner core, 72–73  
 Inorganic materials, 935–963  
   aluminosilicates, 938–939  
   band theory of conduction, 957–959  
   ceramics. *See* Ceramic  
   clays, 939–940, 940f  
   electrical conduction in, 953–957

   phosphors, 962–963  
   pigments, 962–963  
   semiconductors, 959–962, 960f  
   silicates, 936–938, 937f–938f, 937t  
   zeolites, 940–941, 940f  
 Insecticides, 316–317, 317f  
 Insoluble, 670  
**Instantaneous rate** (of chemical reaction) The average rate, obtained over progressively shorter time intervals, 757, 757f  
**Insulator** A substance that will not conduct electricity because of the large energy band gap between its occupied valence band and unoccupied conduction band, 959  
 Insulators, 963  
 Integrals, A.29–A.30, A.29f, A.30t  
**Integrated rate law** A relation that gives the concentration of a reactant or product as a function of time, 762–765  
 Intensity, 157  
**Intensive property** A property that is independent of the size of a system and is therefore the same for each of the subsystems into which the system can be divided, 483  
 Intercept, A.21  
 Interference, 129–130, 129f, 130f, 148, 150, 150f, 910, 910f  
 Intermolecular forces, 421–426

     potential energy curve, 397, 398f, 424, 425f  
     repulsive forces, 423–424  
**Internal conversion** A nonradiative transition between electronic states of the same spin, 878  
**Internal energy (*U*)** The sum of the internal kinetic and potential energies of the particles composing a system, 488, 488f, A.16  
   molecular contributions to, 498–503  
 Interstellar space, atoms in, 217–218  
**Interstitial alloy** An alloy in which atoms of one or more additional elements enter the interstitial sites of an iron crystal, making the material stronger and harder than pure iron, 926  
**Interstitial sites** Spaces between atoms in a crystal lattice in which an additional atom can be introduced, 915–916, 916f  
**Interstitials** Crystal defects in which atoms are inserted at points different than their usual locations, usually away from lattice sites, 923–924  
**Intersystem crossing** A nonradiative transition between electronic states of different spin, 878  
 Intramolecular forces, difference from intermolecular forces, 421  
**Intrinsic properties** The properties displayed by a substance in very high purity form, before dopants are added, 959  
 Iodine in human diet, 287–288  
**Ion product constant for water** The equilibrium constant for the dissociation of water, it is the product of the concentration of hydronium ions and hydroxide ions in liquid water, 619, 619t  
 Ion–dipole forces, 422, 422f  
**Ionic bond** A bond formed through the Coulomb attraction of two ions of opposite charge; formed from atoms with significantly different electronegativities, 53, 85–90  
**Ionic character** Partial charge separation which leads to a dipole and a polar bond, 81, 97–98, 98f, 98t  
**Ionic compound** Formed by ionic bonding between positive and negative ions, 86  
   names and formulas, 115–116  
 Ionic crystals, 916–918, 917f  
   lattice energy, 928–930, 929f  
 Ionic equilibria between solids and solutions, 671–674  
 Ionic polymerization, 968  
 Ionic solids, solubility of, 669–670, 669f–670f, 671t  
**Ion–ion forces** The Coulombic interactions among ions, 421  
**Ionization energy (*IE*)** The minimum energy required to remove an electron from an atom, molecule, or ion that is in its ground state, 70–73, 71f, 72t, 73f, 141, 250  
   periodic trends in, 212–213, 212f  
 Ionization methods, 57  
**Ionizing radiation** Radiation with wavelengths shorter than that of visible light; includes ultraviolet light, X-rays, and gamma rays, 129  
**Ions** An atom or group of atoms that has lost or gained one or more electrons, thereby becoming electrically charged, 15  
   aqueous solutions of ionic species (electrolytes), 446–448, 447f

- charge-to-mass ratio, 15–16  
 selective precipitation of, 685–688  
 size of, 209–212, 211f  
 solvation of, 422, 422f
- Ion-selective electrodes** Any electrode the potential of which is determined by the concentration of a particular ion in solution, 714, 714f
- Irreversible process** A process that does not proceed through a series of equilibrium states, and cannot be reversed by an infinitesimal change in an external force, 484
- Isetropic process** A process occurring at constant entropy, 539
- Isobaric coefficient of thermal expansion, 417
- Isobaric process** A process occurring at constant pressure, 513, 539
- Isochoric process** A process occurring at constant volume, 513, 539
- Isolated system** A thermodynamic system which is surrounded by walls that prevent it from exchanging energy or matter with its surroundings, 482, 543–544
- Isomerases, 797
- Isomers** Compounds that have the same molecular formula, but different molecular structure and therefore different properties, 56, 56f  
 geometric, 295, 295f, 340, 340f–341f  
 optical, 296, 296f
- Isosurfaces, 169–170
- Isotactic form** Polymer structure in which the side groups are arranged on the same side of the backbone chain, 976, 976f
- Isothermal compressibility. *See* **Compressibility**
- Isothermal process** A process occurring at constant temperature, 513–514  
 entropy changes, 537–539
- Isotope** One of two or more atoms with very nearly identical chemical properties but with different masses, 23–25, 26  
 nuclear medicine and, 825–826
- Isotopic effects in chemical kinetics, 789–791
- Isotropic, isotropy** A property that is the same regardless of direction, 945
- ITER tokamak, 834, 834f
- Iteration, A.23
- Johnston, Harold, 886
- Kamerlingh-Onnes, Heike, 949
- Kekulé, August, 15
- Kelvin temperature scale** The temperature scale on which the zero is the absolute zero of temperature and the unit of measure is equal to 1 K, 380
- Ketone** A compound containing the  $\text{—}\overset{\text{O}}{\parallel}{\text{C}}\text{—}$  functional group, in which the C atom is attached to two alkyl groups, 310–311, 310f
- Kinetic energy** The part of the energy of a body that is associated with its motion, defined as  $mv^2/2$ , A.15–A.16  
 in atoms, 67–68, 69f  
 in photoelectrons, 144–146, 145f
- Kinetic isotopic effects, 789–791
- Kinetic molecular theory of matter, 370
- Kinetic theory of gases** A model for molecular motion that predicts the properties of gases, particularly the relationship between temperature and the distribution of molecular speeds, 385–394  
 assumptions underlying, 385  
 molecular speeds, distribution of, 388–394, 390f–391f, 393f  
 temperature, meaning, 385–388
- Koopmans' approximation** The ionization energy of an electron is the negative of the energy of the orbital in which the electron is bound, 208
- Labile complex** A complex in which the ligands undergo rapid substitution by other ligands, 338
- Lamellar phase** A phase with a structure of membranes, 981
- Lanthanide contraction** The general reduction in the radii of atoms of sixth-period elements that occurs during the filling of the  $4f$  orbitals, 211, 327
- Lanthanide elements** An element from La to Lu in the periodic table; also called a rare-earth element, 59, 60f, A.54
- Laser-induced fluorescence, 847–849
- Lasers, 895–896, 895f–896f
- Lattice energy** The work required to separate the atoms, molecules, or ions in a crystal to an infinite distance at the absolute zero of temperature, 927  
 ionic crystal, 928–930, 929f  
 molecular crystal, 927–928, 928t
- Lattice points, 907
- Lavoisier, Antoine, 9–10
- Law of combining volumes** The volumes of reacting gases at constant temperature and pressure stand in the ratio of simple integers, 13
- Law of conservation of mass** In a chemical change, an equal quantity of matter exists before and after the change, 9–10
- Law of definite proportions** The proportions by mass of the elements that compose a compound are fixed, independent of the origin of the compound or its mode of preparation, 10
- Law of Dulong and Petit, 502
- Law of mass action** The relationship between concentrations or partial pressures of reactants and products of a chemical reaction at equilibrium, 568–569  
 gas-phase reactions, 569–570  
 reactions in solution, 570–571  
 reactions involving pure substances and multiple phases, 571–574  
 for related and simultaneous equilibria, 581–583
- Law of multiple proportions** When two elements form a series of compounds, the masses of one element that combine with a fixed mass of the second stand in the ratio of small integers, 11–12
- Laws of chemical combination** A set of scientific laws that describe how atoms of elements combine to form molecules of compounds, 8–15
- Le Châtelier, Henri, 593
- Le Châtelier's principle** A system in equilibrium that is subjected to a stress will react in a way that counteracts the stress, 593–598, 594f

- Lead-acid battery** An assembly of rechargeable cells that employ the reaction  $\text{Pb}(s) + \text{PbO}_2(s) + 2 \text{SO}_4^{2-}(aq) + 4 \text{H}_3\text{O}^+(aq) \rightarrow 2 \text{PbSO}_4(s) + 6 \text{H}_2\text{O}(\ell)$  to generate a voltage, 730–731, 731f
- Leclanché cell** (also called a zinc-carbon dry cell) A primary cell using the reaction  $\text{Zn}(s) + 2 \text{MnO}_2(s) + 2 \text{NH}_4^+(aq) \rightarrow [\text{Zn}(\text{NH}_3)_2]^{2+}(aq) + \text{Mn}_2\text{O}_3(s) + \text{H}_2\text{O}(\ell)$  to generate a voltage, 728–729, 728f
- Lennard-Jones potential** An expression for the potential energy of interaction of two atoms of nonpolar molecules, 398–399, 398t, 927–928
- Leveling effect** The observation that all acids (bases) stronger than the conjugate acid (base) of a solvent have the same effective strength in that solvent, 620
- Lewis, G. N., 77, 220
- Lewis acid** A species that accepts electron pairs from a Lewis base, 331–332, 332t, 616–618
- Lewis base** A species that donates an electron pair to an acceptor species, 331–332, 332t, 616–618
- Lewis diagrams for molecules, 99–106
- covalent compound, 99–106
  - double bond, 100
  - drawing, 101–102
  - formal charges, 100–101
  - homonuclear diatomic molecule, 100
  - lone pairs, 99
  - octet rule, 99, 104–106
  - resonance forms, 103–104
  - triple bond, 100
- Lewis dot symbol** A representation in which an atom is shown by its symbol surrounded by dots for its valence electrons, 77
- Lewis electron dot diagram** A pictorial representation of covalent bonding in a particular molecule; Lewis dot symbols for the participating atoms are juxtaposed and covalent bonds are represented by dots or lines positioned between the symbols, 53, 55f, 99
- Libby, W. F., 822
- Ligand field theory** A theoretical model for the formation of coordination complexes that uses concepts of molecular orbitals to describe bonding and magnetic properties, 356–364
- Ligand substitution reactions, 338–339, 339f
- Ligands** A molecule or ion bound to a metal atom or ion through coordination of its lone electron pairs, 330, 335, 335t, 336t, 680
- Ligand-to-metal** ( $L \rightarrow M$ ) A model of bond formation in which electrons flow from a ligand to fill a  $\sigma$  molecular orbital with the metal, 359–362, 361f
- Ligases, 797
- Light, 127–130, 135, 135f
- Limiting reactant** The reactant that is used up first in a chemical reaction, 45–46
- Linear combination of atomic orbitals (LCAO)** Method for generating approximate molecular orbitals as linear combinations of atomic orbitals, 220
- heteronuclear diatomic molecules, 246–249, 247f–249f
  - homonuclear diatomic molecules
    - first-period atoms, 235–237, 235f–236f
    - second-period atoms, 237–246, 243f–244f
  - hydrogen molecular ion, 231–235, 233f–235f
  - as qualitative predictive tool, 277–278
  - valence bond (VB) method
    - compared to, 276–277
    - used with, 270–275
- Linear geometries, 344
- Linear low-density polyethylene, 975–976
- Linear momentum** ( $\vec{p}$ ) In linear motion, the product of the mass of the moving particle and its velocity;  $\vec{p} = m\vec{v}$ , 140, A.13
- Linear shape, 107, 107f, 109, 109f, 110t
- Liquid crystal** A liquid state of matter in which some orientational ordering of the molecules persists, 979–982
- micelles and membranes, 980–982, 981f
  - structure of, 979–980, 979f–980f
- Liquids
- boiling point, 432–433
  - bulk properties, 415–420
  - compressibility, 416–417, 417t
  - convection, mixing through, 419
  - diffusion, 418–419, 418f, 419t
  - intermolecular forces, 426–429
    - hydrogen bonds, 427–428, 427f
    - special properties of water, 428–429, 429f
  - molar volume, 415, 416f
  - nonpolar, 427
  - phase diagrams, 434–436, 434f–435f
  - phase equilibrium, 430–432
  - phase transitions, 432–434, 432f–433f
  - polar, 427
  - supercooling, 433
  - supercritical fluid, 435
  - superheating, 433
  - surface tension, 420, 420f
  - thermal expansion, 417–418, 417t
- Lithium, electron configuration of, 202, 203f
- Lithium-ion battery, 731–732, 732f
- Logarithms
- common, A.25
  - natural, A.26
  - powers and, A.24–A.26
- London, Fritz, 253
- London dispersion forces** Attractive forces that arise between neutral, nonpolar atoms or molecules from interactions between fluctuating dipoles in the electron density distribution of the atoms, 423
- Lone-pair electrons** An unshared pair of valence electrons, 99
- hybridization and, 263–264
- Low-density polyethylene, 975–976
- Low-energy electron diffraction (LEED), 151, 151f
- Lowest unoccupied molecular orbital (LUMO)** The lowest energy molecular orbital that is unoccupied by one or more electrons, 717, 717f, 719–720, 723, 723f, 726–727, 874, 876, 892
- Low-spin complexes** Coordination complexes in which the  $d$  electrons of the metal are paired in the lowest energy orbitals available, 347, 348f
- Low-spin configurations** Electron configurations with a small number of unpaired spins, 347
- Lyases, 797

- Macroscopic methods, 4–5, 5f
- Madelung constant** ( $M$ ) The constant of proportionality, dependent on crystal structure, that relates the lattice energy of an ionic crystal to the interatomic separation, 929, 929t
- Magnesia ceramic, 948, 949
- Magnesium and electrometallurgy, 741–742, 742f
- Magnetic fields, 127
- Magnetic properties of coordination complexes, 351, 351f
- Magnetic quantum number** ( $m$ ) The quantum number for a one-electron atom that governs its behavior in a magnetic field; it may have positive or negative integral values ranging from  $\ell$  to  $+\ell$ , including zero, 179–180
- Magnetic resonance imaging (MRI), 873
- Magnetic susceptibility** The tendency of a substance to be attracted or repelled by magnetic fields, 351
- Main group elements. *See* **Representative elements**
- Manganese, 750–751  
oxides of, 114f

- Millikan, Robert, 19–20, A.3
- Minimum basis set, 236
- Minimum-boiling azeotrope, 471, 471f
- Mixed oxide ceramic** A ceramic in which two or more metal oxides are present, 949
- Mixture** A portion of matter that can be separated into two or more substances by physical means alone, 6, 6f
- Mobility** ( $\mu$ ) Proportionality constant relating the drift speed of a charged particle to the magnitude of the applied electric field, 955–956, 955t
- Moderators** Substances that effectively slow high-speed neutrons, 828
- Molality** ( $m$ ) The number of moles of solute present per kilogram of solvent, 443
- Molar absorption coefficient** A measure of the amount of light absorbed by a 1 M solution of a given compound (sometimes also called the molecular extinction coefficient), 846
- Molar conductivity ( $\Lambda_m$ ), 955
- Molar enthalpy of atomization, 511t
- Molar enthalpy of fusion** The energy per mole for melting a solid at constant pressure, 507, 508t
- Molar enthalpy of vaporization** The energy per mole for vaporizing a liquid at constant pressure, 507, 508t
- Molar entropy of vaporization, 539
- Molar mass** ( $M$ ) The mass of one mole of a substance, 28
- Molar volume** The volume occupied by one mole of a substance, 30
- elements in solid state, periodic trends in, 211–212, 211f
- of gases, 415
- of liquids and solids, 415, 416f
- Molarity** ( $M$ ) The number of moles of solute per liter of solution, 442–443
- Mole** (mol) The SI base unit giving the amount of any collection of particles (e.g., atoms or molecules of a given type) having the same number of particles as there are carbon atoms in 0.012 kg of  $^{12}\text{C}$ , 27–29, 28f
- Mole fraction** ( $X_A$ ) The number of moles of a particular component in a mixture divided by the total number of moles of all components;  $X_A = n_A/n_{\text{tot}}$ , 384, 442
- Molecular beams, 791–792, 791f–792f

- Natta, Giulio, 976
- Natural logarithm** Logarithms expressed in the base of  $e = 2.7182818\dots$ , A.26
- Nematic phase** A liquid crystal in which the molecules show a preferred orientation but their centers are distributed at random, 979
- Neon, electron configuration of, 203f, 204
- Nernst, Walther, 544
- Nernst equation** A relationship giving the potential difference developed by an electrochemical cell as a function of the temperature and the concentrations and partial pressures of reactants and products;  $\Delta E = \Delta E^\circ - (RT/nF) \ln Q$ , 544, 708–714
- Nernst heat theorem** The statement that the entropy change in any process approaches zero as the temperature approaches absolute zero, 544
- Net ionic equation** A chemical equation in which only those ions and molecules involved in the chemical change are represented; spectator ions are omitted, 448
- Network solid, 950
- Neutralization reaction** A reaction between an acid and a base, 451
- Neutron, 26
- Neutron emission** Decay mechanism for nuclides with very large  $N/Z$  ratios, involving loss of neutrons, 817
- Newton** The unit of force in the SI system, 66
- Nickel, purification of, 561–562
- Nickel metal hydride battery, 732
- Nitrogen, electron configuration of, 203f, 204
- Nobel-gas crystals, 927–928, 928t
- Noble gases** Elements of Group VIII of the periodic table, 61, A.51
- Nodal line, 168
- Node** A region of no vibration (of zero amplitude) of a standing wave, 147, 154
- Nomenclature  
binary covalent compounds, 116–117, 117t  
common anions, 113t  
inorganic, 114–116  
prefixes, 117, 117t
- Nonbonding atomic orbitals** Atomic valence orbitals that do not participate in formation of the bond in a particular molecule, 249
- Nonideal solution** A solution in which the vapor pressures of the components deviate from the predictions of Raoult's law, 459
- Nonmetals** Substances lacking a metallic luster, having poor ability to conduct electricity, and lacking the malleability of metals, 61
- Nonoxide ceramics, 942, 950–952, 950t
- Nonpolar** Having no dipole moment, 111
- Nonpolar liquids** Liquids whose molecules are nonpolar, and in which only dispersion forces operate between molecules, 427
- Nonprimitive unit cell, 909
- Nonradiative process, 842–843, 842f
- Nonstoichiometric compound** A solid compound in which the proportions of the constituent elements are continuously variable over some range, 10, 924–925
- Nonvolatile solutes, phase equilibrium in, 459–467
- Normal alkanes ( $n$ -alkanes), 291–293, 291f–292f, 291t
- Normal boiling point** The temperature at which the vapor pressure of a liquid equals one atmosphere, 433
- Normal hydrogen electrode** (NHE) A standard reference electrode constructed from inert platinum metal,  $H_2$  gas, and an acidic solution, with the latter two components at unit acidity, 773. *See* **Standard hydrogen electrode** (SHE)
- Normal melting point** The temperature at which the solid and liquid phases of a substance are in equilibrium at a pressure of one atmosphere, 433
- Normalized** A probability distribution in which the probability weight for each possible event, summed over all possible events, has the value 1, 157, A.32
- $n$ -type semiconductor** A semiconductor that conducts electric current through the motion of negatively charged particles (electrons) in its conduction band, 959, 960f
- Nuclear chemistry, 807–836  
alpha decay, 816  
beta decay, 813–814  
decay kinetics, 818–822, 819f  
decay processes, 812–818  
electron capture, 815–816  
fission, 817, 827–832  
mass–energy relationships, 808–812  
neutron emission, 817

- Nuclear chemistry (*continued*)  
 nuclear fusion, 832–835  
 positron emission, 814–815  
 proton emission, 817  
 radiation in biology and medicine, 822–827  
 radioactive dating, 820–822  
 radioactivity, detection and measurement of, 817–818
- Nuclear fission, 817, 827–832
- Nuclear fusion** The exothermic union of two light nuclei to form a heavier nuclide, 832–835
- Nuclear magnetic resonance (NMR) spectroscopy, 869–873, 870f–872f
- Nuclear magneton** A fundamental electromagnetic physical constant used to express nuclear magnetic moments, 870
- Nuclear power reactors** Controlled nuclear reactors that generate heat to drive electrical power generation plants, 830–832, 830f–831f
- Nucleic acids, 989–991, 990f
- Nucleons** General name for protons and neutrons, the building blocks for nuclei, 808
- Nucleosynthesis** The production of heavier nuclides from lighter ones, especially in the interiors of stars, 833
- Nucleotides** Component of the genetic material DNA composed of a pyrimidine or purine base, a sugar, and a phosphate group, 989–991, 989f
- Nucleus, atomic, 20–22, 25–26
- Nuclide** A distinct atomic species characterized by atomic number  $Z$ , mass number  $A$ , and nuclear energy state, 808
- Number density** Number of molecules per unit volume, usually number  $\text{cm}^{-3}$ , 371
- Number of moles** To group atoms or molecules in counting units of  $N_A = 6.0221420 \times 10^{23}$  to measure the moles in a substance, 27
- Octahedral complexes, 349, 350f, 351t  
 Octahedral geometries, 339–340, 339f–341f  
 Octahedral shape, 107, 107f, 110t  
 Octahedral sites, 915–916, 916f
- Octane number** A measure of the smoothness of combustion of gasoline in an automobile engine, 296
- Octet rule** Main-group elements lose, gain, or share electrons in chemical bonding in such a way as to attain a valence octet, 99, 104–105
- Octet-deficient molecules, 104–105
- Odd-electron molecules, 104
- Oersted, H. C., 740
- Olivines** Complex silicates of magnesium and iron used in refractories, 938
- Opal, 472, 472f
- Open system** A thermodynamic system in which both matter and energy may be freely exchanged with the surroundings, 482
- Open-circuit potentials, 703
- Oppenheimer, J. Robert, 223
- Optical absorption spectroscopy, 844–847
- Optical displays, 962–963
- Optical isomerism** An isomer that is not superimposable on its own mirror image and therefore is capable of rotating the plane of polarization of a beam of plane-polarized light passed through it or its solutions, 296, 296f
- Optical properties of transition-metal elements, 352–354, 353t
- Orbital** A wave function that is an allowed solution of the Schrödinger equation for an atom or molecule, 182  
 atomic. *See Atomic orbitals (AOs)*  
 $d$  orbital, 192–193, 192f  
 Hartree orbitals, 178, 196–201

- Organic molecules with delocalized electrons, 273–275
- Organic synthesis, electrochemical, 715–716
- Orthosilicates, 937
- Oscillator, 132–134, 132f, 133f
- Osmotic pressure ( $\pi$ )** The pressure that must be applied to a solution to prevent the net diffusion of pure solvent through a semipermeable membrane into the solution, 465–467, 466f
- Outcomes, A.31

- Outer coordination sphere** Nondirectional arrangement of ligands coordinated to metal atoms, 333
- Overall reaction order** The sum of the exponents of the species appearing in the rate expression for a reaction, 761
- Overlap of orbitals, 239, 240f, 248–249, 248f
- Oxidation, 453
- Oxidation number** A number assigned to an atom in a molecule that reflects its state of oxidation, 112–114, 452
- Oxidation states, transition-metal element, 329–331, 329t
- Oxidation–reduction reaction** (also called a *redox reaction*) A reaction in which electrons are transferred; a reaction in which the oxidation number of at least one element changes, 452–453
- Oxidation–reduction titrations, 452–458
- Oxide ceramics** A class of ceramics in which silicon is a minor or nonexistent component, 942, 948–949
- Oxides, metal. *See* Metal oxides
- Oxides of manganese, 114f
- Oxidized** Having lost electrons in a chemical reaction, 452
- Oxidizing agents** Substances that causes the oxidation of another substance, while it itself is reduced, 706–707
- Oxidoreductases, 797
- Oxoacid** An acid containing a hydrogen ion in combination with an oxoanion, 627–628, 627f, 628t
- Oxygen transport, 591–592, 592f
- Ozone, 707, 880, 882–883, 885–887, 885f–888f
- p* orbital** A set of three degenerate atomic orbitals with angular momentum quantum number  $\ell = 1$ , 190–192, 190f–192f
- PANs** Abbreviation for polyacynitrates, a class of nitrogen containing molecules that are associated with photochemical smog, 884
- Paramagnetic** The property of being attracted into an inhomogeneous magnetic field, 202–204, 243, 245f, 351, 351f
- Partial pressure** ( $P_A$ ) That part of the total pressure of a gas mixture due to one particular component, 383–385, 383f equilibrium partial pressures, 583
- Particle-in-a-box models, 158–166
- one-dimensional boxes, 158–164, 164f
  - three-dimensional boxes, 164–165
  - two-dimensional boxes, 164–165
  - wave functions for particles in cubic boxes, 169–170, 169f–170f
  - wave functions for particles in square boxes, 166–169, 167f
- Partition coefficient** ( $K$ ) The equilibrium constant describing the distribution of a solute species between two immiscible solvents, 602
- Pascal** (Pa) The SI unit of pressure; equal to  $1 \text{ N m}^{-2}$ , 374
- Passivation** The phenomenon in which an active metal is protected from further oxidation by the formation of a thin oxide layer at its surface, 738
- Pauli exclusion principle** The statement that no two electrons in an atom may have the same set of quantum numbers; more specifically, two electrons with the same spin may not occupy the same spatial orbital, 202
- Pauling, Linus, 81, 258
- p*-block element** An element that arises with the filling of a *p* orbital in the building up of the periodic table, 204
- Pearson, Ralph, 331
- Peptide linkage** The linkage formed by the reaction of the carboxyl group of one amino acid with the amine group of a second, with elimination of water, 984
- Percent ionic character, 97–98, 98f, 98t
- Percentage composition, 37
- Percentage yield** The actual yield of a reaction divided by the theoretical yield (and multiplied by 100%), 47
- Period** A row in the periodic table, 59
- Periodic behavior in chemical bonding, 75–77
- Periodic law** The chemical and physical properties of the elements are periodic properties of their atomic numbers, 59
- Periodic properties
- electron affinity, 213–214, 213f
  - sizes of atoms and ions, 209–212, 211f
  - trends in ionization energies, 212–213, 212f
- Periodic table** A table that organizes the elements by atomic number and chemical properties into groups and periods, 53, 59–62, 60f
- electron configuration and, 206, 206f
  - molar volumes of elements in solid state, 211–212, 211f
- Permittivity of vacuum ( $\epsilon_0$ ), 63
- Perovskite, 949–950, 949f–950f
- Peroxides, structure and bonding in, 12
- Pesticides, 316
- Petroleum distillation, 292–293, 293f
- Petroleum refining, 290–291
- pH** A measure of the hydronium ion concentration in a solution;  $\text{pH} = -\log [\text{H}_3\text{O}^+]$ , 621–622, 621f
- acid–base indicators, 628–630, 628f–630f
  - blood, 650–651, 651f
  - solubility, effect on, 678–680
  - solution composition, effect on, 647–649
- pH meter** A galvanic cell in which the voltage is a linear function of the pH of the solution in the cell, 621, 621f, 712–714, 713f–714f
- Phase** A sample of matter that is uniform throughout, both in its chemical constitution and in its physical state, 430, 547
- Phase diagram** For a one-component system, a plot of temperature against pressure, showing the state or states of matter that are stable under each set of conditions, 434–436, 434f–435f
- Phase equilibrium** Equilibrium state in which two or more different phases coexist, for example, solid and liquid, 430–432, 430f, 442
- double arrow notation, 567
  - in solution
    - nonvolatile solutes, 459–467
    - volatile solutes, 467–472
  - vapor pressure and, 430–431, 431f, 431t
- Phase transitions** Abrupt changes in the physical state of a substance, 432–434, 432f–433f, 538–539
- Gibbs free energy and, 549, 550f
- Phenol** An organic compound which has an  $-\text{OH}$  substituted on an aromatic ring, 308, 308f
- Phlogiston, 9
- Phosphorescence** The emission of light from an excited triple state, 842–843

- Phosphors** Doped semiconductor capable of emitting light when excited, 962–963
- Phosphorus, states of, 933–934
- Photocathode, 143
- Photochemical process** Chemical reactions initiated by the absorption of electromagnetic radiation, almost always visible or ultraviolet radiation, 878
- Photocurrent, 143–145, 145f
- Photodissociation** The breaking of a chemical bond in a substance by the absorption of light, 878
- Photoelectric effect** The ejection of electrons from the surface of a substance by light; the energy of the electrons depends upon the wavelength of the light, not the intensity, 143–147, 144f–145f
- Photoelectrochemistry, 722–725, 722f–724f
- Photoelectron spectroscopy** A type of spectroscopy in which the kinetic energies of electrons ejected by photons from an atom, molecule, or solid are measured; allows orbital energies to be determined, 207–209, 208f–210f, 250–251, 250f–252f, 877, 877f
- Photoelectrons, 143–145, 207, 207f
- Photographic emulsion, 817
- Photon** A packet of electromagnetic radiation; the “particle” of light, 145, 148  
angular momentum, 852–853, 852f
- Photophysical processes** Physical processes initiated by the absorption of electromagnetic radiation, almost always visible or ultraviolet radiation, 878
- Photosynthesis** The process by which organisms harness the energy in sunlight to drive the synthesis of compounds of high free energy, 889–895, 893f–894f  
artificial, 726
- Photosystems, 893
- Physics overview, A.11–A.20
- $\pi$  acceptors** Alternate name for strong field ligands, 364
- Pi ( $\pi$ ) bond** A bond resulting from the occupancy of  $\pi$  molecular orbitals by electrons, 256
- $\pi$  donors** Alternate name for weak field ligands, 364
- Pigments, 962–963
- Pimentel, George C., 83
- Pitch, 980
- Planck, Max, 131, 132, 518
- Planck’s constant** ( $h$ ) The proportionality constant between the energy and the frequency of a photon; equal to  $6.62607 \times 10^{-34}$  J s, 133
- Planck’s quantum hypothesis, 131–134
- Planetary model of the atom, 22–23, 62, 139
- Plastics** A polymeric material that is molded when hot and that hardens upon cooling, 974–977, 975t
- Platinum, 366–367, 796f
- p-n* junctions, 726, 960, 961f
- Point defects, 923–924, 924f
- Point mass, A.11
- Polanyi, John, 90
- Polar** Having a dipole moment, 111
- Polar covalent bond** A bond intermediate in character between covalent and ionic, 53, 96
- Polar liquids** Liquids whose molecules have permanent dipole moments, 427
- Polarity, 96
- Polarizability** A measure of the extent to which electrons in atoms or molecules are displaced by electric fields, most often the electric fields due to a nearby ion or electromagnetic radiation, leading to induced dipole moments, 422–423, 855
- Polarization** The distortion of the charge distribution of an atom or ion due to a nearby charge, 89
- Polyatomic molecules  
dipole moments of, 111  
orbital hybridization for, 259–266  
rotational spectroscopy, 865  
valence bond (VB) theory and, 257–258  
vibrational spectroscopy, 865–869
- Polyenes, 300
- Polymer** A compound of high molar mass comprised of repeating subunits, 967–968  
amino acids, 984–988, 984f, 986t  
carbohydrates, 982–984, 982f–984f  
electrically conducting polymers, 978–979  
monomers, 967  
nucleic acids, 989–991, 990f  
nucleotides, 989–991, 989f  
polymerization reactions for synthetic polymers, 968–972  
polysaccharides, 983–984, 984f  
proteins, 984–988, 987f  
random copolymer, 971  
synthetic. *See* Synthetic polymers
- Polymer electrolyte membrane (PEM) fuel cells, 733–735, 734f
- Polymerization  
addition polymerization, 968–970, 969f  
condensation polymerization, 970–971
- Polypeptide** A polymer of amino acid monomer units, 984–985
- Polyprotic acid** An acid capable of donating more than one hydrogen ion per molecule to base acceptors, 645–649  
titration of, 659–660, 660f
- Polysaccharides** Polymers formed by linking simple sugars together in long chains, 983–984, 984f
- Population inversion, 895
- Portland cement** A building material made by a high-temperature reaction of lime with clay to form a calcium aluminum silicate; when mixed with water, sand, and aggregate, it makes a concrete that can be poured in place and allowed to harden to give a strong solid, 946–947, 947t
- Positive charge, A.19
- Positron** A positively charged fundamental particle; the anti-particle of the electron, 812
- Positron emission** A mode of radioactive decay in which a nuclide emits a positron and a neutrino as one of its protons transforms into a neutron, 814–815
- Positron emission tomography (PET), 824–826, 826f
- Postulates, 8
- Potassium sulfate, 447–448, 447f, 448f

- Potential energy curve** Representation of the potential energy of an object as a function of its position relative to a selected reference point, 67f, 424, 425f  
force, stability and, A.17–A.18  
for gases, 397, 398f  
for oscillator, 132f
- Potential energy surface, 425
- Potential energy** ( $E_p$ ) The energy that a particle has by virtue of having changed its position because it was attracted to (or repelled by) other particles, A.15–A.16  
in atoms, 62–69, 64f  
Coulomb, A.19  
in molecules, 83–85
- Pottery, 943–944
- Power, 534

- Precipitation  
selective precipitation of ions, 685–688  
solubility product and, 674–678  
from solution, 674–676, 675f
- Precipitation reaction** The formation of a solid from solution; the reverse of dissolution, 448
- Precision, A.3
- Prefixes** Greek prefixes used in the SI system of units to indicate orders of magnitudes, 117, 117t, A.10, A.10t
- Pressure** ( $P$ ) The force exerted by a gas or other material per unit area on the walls of its container  
gases and, 373–377  
Gibbs free energy of an ideal gas, dependence of, 574–575  
heat transfer at constant pressure, 494–495  
isobaric process, 513, 539  
partial pressure, 383–385, 383f  
units of, 374–375, 375t
- Pressure-volume work, 486–487
- Priestly, Joseph, 372, 977
- Primary alcohol, 307
- Primary amine, 315
- Primary cells** A battery (galvanic cell) that must be discarded when its energy has been transferred and its voltage gone to zero, 728
- Primary kinetic isotope effects, 790
- Primitive** A unit cell of minimal size that typically has all the symmetry elements of the crystal lattice. At each corner is a lattice point, and accounting for the sharing with neighboring unit cells gives a net of one lattice point per primitive, 907, 909f
- Principal quantum number** The quantum number  $n$  for a one-electron atom that determines the energy of the atom. Together with  $\ell$ , it also determines the radial part of a wave function.  $n$  is an integer ranging from 1 to infinity, 179
- Principle of detailed balance** At equilibrium the rate of each elementary process is equal to the rate of its reverse process, 768
- Prism, 135, 136f
- Probability, 157, 531, A.30–A.31  
experimental tests of theoretical, A.33  
random variables, A.31  
average values of, A.32–A.33  
continuous and probability functions, A.33
- Probability density function** A continuous function that describes the probability per unit change in the dependent variable of finding the value of a dependent variable within an infinitesimally small region around each value of the independent variable, A.33
- Probability function** ( $P[X]$ ) A function, which may be discrete or continuous, that describes the probability of finding the value of a dependent variable at or near each value of the independent variable, A.31–A.32, A.32f
- Product, 510  
concentration, effect on equilibrium of changing, 579–580
- Promotion** A concept introduced by Linus Pauling to account for the filling of nearly degenerate hybrid orbitals, 258
- Propagation** The second stage in a chain reaction, 774
- Proportional counters** A class of radiation counters that measures both the energy and the intensity of ionizing radiation, 818
- Proteins** A naturally occurring longchain polymer composed of amino acid subunits, 984–988, 987f  
functional groups in, 312–313
- Proton ( $p$ ), 26
- Proton emission** A rare event in which a proton is emitted from a nucleus to bring the neutron/proton ratio closer to the line of stability, 817
- Proust, Joseph, 10
- p-type semiconductor** A semiconductor that conducts electricity through the apparent motion of positively charged particles (holes) in its valence band, 959–960, 960f
- Pure substance** A sample of matter that cannot be separated into different components by a physical process, 7  
law of mass action for reactions involving pure substances and multiple phases, 571–573
- Pyrometallurgy** The recovery of elemental metals from their ores through high-temperature chemical reactions, 738
- Quanta, 132
- Quantum electrodynamics** A relativistic quantum theory that accounts for the interactions between matter and radiation, 156
- Quantum mechanics** The fundamental branch of physics that describes the properties, interactions, and motions of atomic and subatomic particles, 52, 124–172  
atomic structure and, 177–215  
Bohr model, 139–142  
bonds. *See* **Bond(s)**  
discrete energy levels, predicting, 139–142  
electromagnetic radiation, 127–130

- Quotient of integers, 12
- Rad (radiation absorbed dose), 823
- Radial charge density distribution function  $p(r)$ , 198
- Radial node** A sphere about the nucleus on which  $\psi$  and  $\psi^-$  are zero, 190
- Radial probability density** The probability per unit volume of finding a particle (such as an electron) at a distance  $r$  (in an atom, typically the distance  $r$  from the nucleus), 187, 194f, 198f
- Radiation  
 annihilation, 812, 825, 825f  
 in biology and medicine, 822–827  
 electromagnetic, 127–130  
 ionizing, 129
- Radiation in biology and medicine, 822–827
- Radical** A species in which one or more valence electrons are unpaired; radicals are often but not always highly reactive; often occurs as an intermediate in reactions, 296
- Radioactive dating, 820–822
- Radioactive decay, 21–22, 812  
 characteristics of radioactive nuclei, 819t  
 decay processes, 812–818  
 kinetics of, 818–822, 819f
- Radioactive** The spontaneous emission of radiation by the nuclei in a substance, 812
- Radioactive waste disposal, 831–832
- Radioactivity, detection and measurement of, 817–818
- Radiotracers** A radioactive element, or a compound that contains a radioactive element, that is used to follow the course of chemical reactions or to follow the movement of substances, primarily in living organisms, 825, 827
- Radon in the environment, 837–838
- Raman scattering** A form of inelastic light scattering in which part of the energy of an incident photon is transferred to an atom or molecule resulting in a scattered photon with lower energy, 840
- Random copolymer** A polymer made from two or more types of monomer units, arranged at random along the chain, 971
- Random error, A.5
- Random variables, A.31  
 average values of, A.32–A.33  
 continuous and probability functions, A.33
- Raoult, François-Marie, 459
- Raoult's law** A relationship between the vapor pressure  $P_1$  of component 1 of an ideal solution, its mole fraction  $X_1$ , and the vapor pressure  $P^\circ$  of the pure substance:  $P_1 = X_1P^\circ$ , 459
- Rate constant ( $k$ )** The proportionality constant between the rate of a reaction and the concentrations of the species that appear in the rate law, raised to the appropriate powers, 759  
 gas-phase reaction, 775–778
- Rate laws, 758–765
- Rate-determining step** A step that is significantly slower than the other steps in a reaction mechanism, and that therefore determines the overall rate of a reaction, 769–771
- Reactant, 510  
 concentration, effect on equilibrium of changing, 579–580  
 limiting, 45–46
- Reaction dynamics** That branch of chemistry concerned with understanding the microscopic details of reactive encounters as they relate to chemical kinetics, 780
- Reaction enthalpy** The energy change in a chemical reaction carried out at constant pressure, 504–508, 507f, 508t
- Reaction intermediate** A chemical species that is formed and consumed in the course of a reaction and does not appear in the chemical equation representing the reaction, 767
- Reaction mechanism** A series of elementary reactions, together with their rates, that describe the detailed steps by which a reaction proceeds, 755, 766–775
- Reaction path** The route followed as reactant molecules, atoms, or ions interact to give products, 778–779
- Reaction quotient ( $Q$ )** A positive number in which the ratio of concentrations or partial pressures of products raised to powers corresponding to their stoichiometric coefficients are divided by concentrations or partial pressures of reactants similarly raised to powers, 590  
 free energy changes and, 598–599
- Reaction rate, 755–758

- Reactive cross section** The cross sectional area of a molecule that is effective as a target for collision and reaction, 784, 786f
- Recrystallization** Powerful method of the purification of substances by dissolution and subsequent precipitation, 668–669
- Rectification** The conversion of alternating current into direct current, 960
- Redox titrations, 457–458, 458f
- Reducing agents** Any substance that causes the reduction of another substance, while it itself is oxidized, 707
- Reduction potential diagram** A convenient diagram that summarizes the potentials for oxidations and reductions of a chemical species and for determining its propensity to disproportionate, 707–708
- Reference state, 574
- Reforming reactions** [1] Generation of aromatic hydrocarbons from straight-chain alkanes, 302, 302f
- Reforming reactions** [2] Generation of hydrogen and carbon monoxide by the high-temperature reaction of methane (or another hydrocarbon) with water, 306, 569
- Refractory** A ceramic material that withstands a temperature of more than 1500°C without melting, 949
- Relative atomic mass** The dimensionless mass of an atom, measured on a relative scale with the mass of a  $^{12}\text{C}$  atom equal to 12, 14, 23–25, 24f
- Relative molecular mass** The sum of the relative atomic masses of the elements contained in the molecule, each one multiplied by the number of atoms of that element in the molecule, 25
- Rem (roentgen equivalent in man), 823
- Representative elements** Elements of Groups I through VIII of the periodic table; a main-group elements, 59, 60–62  
 acidity of oxides, 618t  
 oxidation states of, 114, 114f
- Repulsive force** A force that accelerates two objects to move away from each other (so increasing their separation  $r$  decreases their potential energy  $V$ ;  $dV/dr$  is negative), 423–424, A.19
- Resistance** ( $R$ ) Property of a system that measures the difficulty of passing electrical current through that system; depends on geometry and composition of the system, 953–954
- Resistivity** ( $\rho$ ) Property of a substance or material that measures the difficulty of passing electrical current through it, regardless of geometry, 954
- Resonance, 103
- Resonance hybrid** The “true” Lewis structure represented by the combination of two or more resonance structures, 103–104
- Reverse micelles, 981
- Reverse osmosis** The nonspontaneous movement of a solvent through a semipermeable membrane driven by an external force, 467
- Reversible process** A process that proceeds through a series of equilibrium states, and can be reversed by an infinitesimal change in an external force, 484  
 entropy changes, 537–541  
   for isothermal processes, 537–539  
   for processes with changing temperature, 539–540  
   for surroundings, 540–541
- Rigid walls** Walls that do not deform when arbitrarily large external forces are applied, 482
- Rigidity** Tendency to maintain shape under stress, 418, 904
- Rocket fuel, ammonium perchlorate as, 412
- Rock-salt structure of ionic crystals, 916, 917f. *See also*  
   **Sodium chloride structure of ionic crystals**
- Roentgen, Wilhelm, 909
- Root-mean-square speed** ( $v_{\text{rms}}$ ) A measure of the typical speed of molecules at thermal equilibrium; equal to the square root of the average of the squares of the speeds of the molecules, 388
- Rotational spectroscopy, 93–94, 94f  
 diatomic molecules, 851–857  
 polyatomic molecules, 865

 Rutherford, Ernest, 21, 22–23, 22f, 62, 67, A.19–A.20  
**Rydberg (Ry)** A unit of energy used in atomic spectroscopy; equal to  $2.18 \times 10^{-18}$  J, 140
- s orbital** Nondegenerate atomic orbitals with angular momentum quantum number  $\ell = 0$ , 186–190, 186f–188f
- Sacrificial anode** A piece of an active metal (such as magnesium) placed in electrical contact with a metal (such as iron) that is to be protected from oxidation, 738
- Salt bridge** A tube containing a salt solution that is used to connect two half-cells in an electrochemical cell; allows the passage of ions, but prevents mixing of the half-cell electrolytes, 695
- Salts of bases, solubility of, 679–680
- Saturated** A carbon atom bonded to four other atoms, the maximum number allowed by its valence, 297, 314
- Saturated calomel electrode** A standard electrode that consists of a platinum wire in contact with a paste of liquid mercury, calomel ( $\text{Hg}_2\text{Cl}_2$ ), and a saturated solution of  $\text{Hg}_2\text{Cl}_2$ , 713–714, 713f
- Saturated solution** A solution in equilibrium with a solid solute, 668
- s-block element** An element that arises with the filling of an s orbital in the building up of the periodic table, 204
- Scanning tunneling microscopy, 31–33, 31f–32f, 163, 164f
- Schottky defect** A vacant site in a crystal where the pattern indicates an atom should be found, 924, 924f
- Schrödinger, Erwin, 154
- Schrödinger equation** The fundamental equation of quantum mechanics that relates the wave function of one or more particles to their masses and potential energies, 154–158, 859  
 interpretation of energy in, 156  
 interpretation of wave function in, 157–158  
 origins of, 154–156  
 procedures for solving, 158  
 validity of, 156
- Scientific law** A relationship between physical observables, often represented by a mathematical formula, tested and developed with numerous and diverse experimental observations. A scientific law holds to a high level of accuracy under a prescribed set of conditions, 3
- Scientific notation, A.2  
 Scientific revolution, 124
- Scintillation counter** An instrument for the detection of radioactive decay based on the counting of light pulses produced by radiation when it enters a crystal, 817–818
- Seaborg, Glenn, 833
- Second ionization energy, 71, 72t
- Second law of thermodynamics, 535–536
- Second order reaction** A reaction that has a total order of 2, as determined by the sum of the exponents of the concentration terms in the rate law; if a reaction is second order in a single species A, the concentration of A changes with time according to  $1/[A] = 2kt + 1/[A]_0$ , 759, 764–765, 764f
- Secondary alcohol, 307  
 Secondary amine, 315
- Secondary cells** Refers to batteries that cannot be recharged in electrochemistry or to isotope effects at atoms adjacent to the reactive site in kinetics, 728
- Seesaw shape, 109, 109f
- Selection rule** A rule that governs the probability of a particular transition between quantum states, 853
- Selective precipitation of ions, 685–688
- Self-consistent field (SCF) orbital approximation method** Generating approximate one-electron wave functions for each electron in a many-electron atom or molecule by estimating the effective field set up by all the other electrons and obtaining the wave function for that effective field; the process is repeated iteratively until the effective field and approximate wave function no longer change upon further iterations, 196
- Semiconductors** Substances having electrical conductivity that is small but still greater than that of an electrical insulator and that increases with temperature, 61, 922, 959–962, 960f
- Semimetals** Materials intermediate in character between a metal and a nonmetal, 61
- Semipermeable** Allowing passage of small molecules but not of large molecules, 465
- Separation of variables, 165
- Sequester** To coordinate a species so strongly that it is prevented from taking part in its ordinary reactions, 345
- Shear viscosity** The measure of the resistance of a substance to flow, 418
- Shell** A group of subshells in the electron configuration of an atom that have similar energies, 198
- Shell model for atomic structure** A model of the atom in which the electrons are envisaged as occupying a series of concentric shells centered around the nucleus, 73–75, 75f
- Shell models  
 for many-electron atoms, 196–201  
 periodic table and, 206–209
- SI units, A.8–A.11, A.8t–A.9t
- Sialons** Alloys of silicon, aluminum, oxygen, and nitrogen, 952
- Side-centered** An adjective describing a solid lattice that has a lattice point on one pair of parallel faces of the unit cell (in addition to the ones at the corners). For a tetragonal unit cell, the term *base-centered* is also commonly used, with the square faces having the centered lattice points, 909, 909f
- Sievert (unit for effective dosage of radiation), 823
- Sigma ( $\sigma$ ) bond** A bond resulting from the occupancy of s molecular orbitals by electrons, 256
- Sigma ( $\sigma$ ) donors** Alternate name for intermediate field ligands, 364
- Significant figures, A.5–A.7
- Silicate ceramics** Ceramics made from aluminosilicate clay minerals, 942, 943–948

- Silicates** Compounds containing silicon and oxygen and formed from the linking together of structural units, 936–938, 937f–938f, 937t  
aluminosilicates, 938–939
- Silicon, band picture of bonding in, 957–959, 958f
- Silicon carbide, 952, 952f
- Silicon nitride, 950–952, 951f
- Simple cubic lattice** A crystal lattice in which the unit cell comprises a simple cube, with one atom located at each vertex, 912, 914t
- Simple harmonic oscillator, 132–133
- Simultaneous algebraic equations, 583
- Single bonds, 253–256, 253f, 255f–256f
- Sintering** The partial merging of grains in a solid by diffusion at a temperature less than the melting point, 943
- Slater, John C., 253
- Slightly soluble, 670
- Slope of line, A.21
- Smectic phases** Liquid crystal phases in which molecules show a preferred orientation and a layered structure, 979–980
- Smelting** The melting and reduction of metals from their ores, 739
- Soda-lime glass** Common glass of approximate composition  $\text{Na}_2\text{O} \cdot \text{CaO} \cdot (\text{SiO}_2)_6$ , 946, 946f
- Sodium chloride structure of ionic crystals** An ionic crystal structure that consists of two interpenetrating face-centered cubic lattices of cations and anions, 916–917, 917f
- Sodium–sulfur battery, 733, 733f
- Soft acids, 332–333, 332t
- Soft base, 332–333, 332t

supersaturated, 669
- Solvate** The process of surrounding solute molecules with solvent molecules, 668
- Solvation shell** The shell of solvent molecules that surrounds a solute molecule, 447
- Solvent** The major component in a solution, 441
- $sp$  hybrid atomic orbitals** A pair of hybrid orbitals constructed from one  $s$  and one  $p$  orbital oriented  $180^\circ$  with respect to one another, 259–260, 259f
- $sp^2$  hybrid atomic orbitals** A set of three hybrid orbitals constructed from one  $s$  and two  $p$  orbitals oriented  $120^\circ$  with respect to each other, 260–262, 261f
- $sp^3$  hybrid atomic orbitals** A set of four hybrid orbitals constructed from one  $s$  and three  $p$  orbitals oriented  $109.5^\circ$  with respect to each other, 262–263, 262t

- Space, atoms in interstellar, 217–218
- Space-filling models, 55f, 56, 59f
- Specific heat capacity** ( $c_s$ ) The amount of heat required to raise the temperature of one gram of a substance by one kelvin at constant pressure, 489, 492, 492t
- Spectator ion** An ion that does not take part directly in a chemical reaction but is present in the reaction system, 448
- Spectrochemical series** An ordering of ligands according to their ability to cause crystal field splittings, 354
- Spectrograph** An instrument used to record the wavelengths of light emitted by atoms or molecules, 135
- Spectroscopy**
- electron energy loss spectroscopy, 139
  - electron impact spectroscopy, 139
  - electronic spectroscopy. *See* Electronic spectroscopy
  - molecular. *See* Molecular spectroscopy

- Spectrum**, 135, 136f
- photoelectron, 250f–252f
- Speed of light**, 128
- Speed** ( $v$ ) The rate at which a molecule is moving, in meters per second, 385
- average, 392, A.12
  - mean-square speed, 387–388
  - molecular speeds, distribution of, 388–394, 390f–391f, 393f
  - root-mean-square speed, 388
- Spherical harmonics** A set of functions used to describe angular momenta in atoms, 181, 183
- Spin quantum number** ( $m_s$ ) A quantum number that describes the magnetic properties of a particle; takes on the values  $\pm\frac{1}{2}$  for an electron, 196
- Spin-spin coupling** The presence of nuclear spins on atoms adjacent to the atom to which a nucleus of interest is bonded affects the local magnetic field at that nucleus, leading to characteristic patterns used to identify functional groups in NMR spectroscopy, 872
- Spin-spin splitting** In NMR spectrometry, the separation of peaks in a chemically identical group of protons on a molecule due to their interaction with other protons in a different group, 872
- Spontaneity**
- entropy and, 530–535
  - entropy changes and, 541–544
  - molecular motions, 531–532
- Spontaneous cooling of a hot body**, 541
- Spontaneous processes**
- entropy. *See* Entropy ( $S$ )
  - at fixed temperature and pressure, 547–548, 547f
  - Gibbs free energy. *See* Gibbs free energy
  - nature of, 527–530
- Square-planar complexes**, 348–349, 349f
- Square-planar geometries**, 340, 341f, 344
- Stable equilibrium** That state of a system in which the net force acting is zero, A.18
- Stable octets**, 76
- Standard atmosphere** (atm) A unit of pressure; equal to 101,325 Pa; the daily pressure at sea level varies in the vicinity of one standard atmosphere, 374
- Standard cell potential** The potential of an electrochemical potential when all of its components exist under standard conditions, as defined thermodynamically, 703
- Standard deviation** A measure of the uncertainty in the average value of a property described by a Gaussian distribution, A.4
- Standard enthalpy** ( $\Delta H^\circ$ ) The enthalpy change for the reaction that produces products in their standard states from the reactants, also in their standard states, 509
- Standard enthalpy of formation** ( $\Delta H_f^\circ$ ) The enthalpy change for the reaction that produces one mole of a compound in its standard state from its elements, also in their standard states, 509–510
- Standard hydrogen electrode** (SHE) A standard reference electrode constructed from inert platinum metal,  $H_2$  gas, and an acidic solution, with the latter two components at unit activity, 703–704, 704f
- Standard molar entropy** ( $S^\circ$ ) The entropy of one mole of a substance, in its standard state, typically 1 atm for ideal gases, 545–546, 546f
- Standard molar Gibbs free energy of formation** ( $\Delta G_f^\circ$ ) The Gibbs free energy of formation of one mole of a substance from the most stable forms of its elements in their standard states at a specified temperature, 550–551
- Standard reduction potentials**, A.45–A.46
- Standard states**, 508–510, 702–703
- Standard-state free energies**, 550–551
- Standing wave** A wave that vibrates in a fixed region, 147–148, 147f
- State functions** A property of a system that is uniquely determined by the present state of a system and not at all by its history, 484–485, 529
- States, thermodynamics**, 483–485, 483–485f
- Stationary state** A standing wave that exists indefinitely, 156
- Statistical fluctuations**, 532
- Statistical mechanics** The branch of science that studies the relation between the structure of molecules and macroscopic observations, 370
- Statistical thermodynamics** The study of the relation between the statistical properties of a large number of particles and macroscopic observations, 530
- Steady states**, 567–568, 886
- Steady-state approximation** The approximation that the concentrations of reactive intermediates remain approximately constant during the course of a reaction, 773–774
- Steric factor** A factor (less than unity) in the Arrhenius equation that accounts for the fact that reactants must have a particular range of relative orientations in order to react, 787–788, 788t
- Steric number** ( $SN$ ) The number of atoms bonded to a central atom plus the number of lone pairs on the central atom, 107–108
- Steric strain**, 294
- Stern, Otto**, 195
- Stern-Gerlach experiment**, 195
- Steroids** Naturally occurring compounds that derive formally from cholesterol, 321, 321f
- Stoichiometric calculation, steps in**, 44f

- Stoichiometry** The study of mass relationships in chemical reactions, 39
- Straight-chain alkanes** A type of hydrocarbon consisting of chains of carbon atoms bonded to one another by single bonds, with enough hydrogen atoms on each carbon atom to bring it to the maximum bonding capacity of four, 291–293, 291f–292f, 291t
- Strain energy, 294
- Strassmann, Fritz, 827
- Stratosphere** The layer of the earth's atmosphere extending from 12 to 50 km above the surface of the earth, 881, 881f
- Stratospheric chemistry, 885–889
- Strong acid** An acid that has a  $K_a$  greater than 1, 620–621, 624f  
titration with strong base, 640–642, 641f
- Strong base** A base that has a  $K_b$  greater than 1, 620–621, 624f  
titration of strong acid with, 640–642, 641f  
titration of weak acid with, 642–645, 643f
- Strong field configurations** Alternates for low-spin configurations, used because they occur at large values of the crystal field, 347
- Strong field ligands** Ligands that induces a large crystal field splitting in a transition-metal complex, 348
- Structural formula, 99  
condensed, 54–55
- Sublimation** A phase transition in which gas forms directly from a solid, 435–436, 436f
- Subshell** A group of orbitals in an atom with the same energy, 198
- Substance** A material that cannot be separated by physical means into two or more materials with different properties, 7
- Substitution reactions, 338–339, 339f
- Substitutional alloy** An alloy in which some of the metal atoms in a crystal lattice are replaced by other atoms, 926
- Substrates** Reactant molecules that is capable of binding to the active site of an enzyme, 797
- Sugars** Small carbohydrate rings with the empirical formula  $\text{CH}_2\text{O}$ , 982–983, 982f–983f
- Sulfite and sulfate kinetics in atmospheric chemistry, 805–806
- Sulfuric acid manufacturing, 41–42, 42f, 609–610
- Superconductor** A material offering zero resistance to the passage of an electric current, 949–950, 950f
- Supercooling** A process by which materials reach kinetically metastable states at temperatures below their equilibrium melting points, 433
- Supercritical fluid** Term applied to a substance held at a temperature and pressure that exceed its critical pressure and temperature; at these conditions the distinction between liquid and gas no longer exists, 435
- Superheating** The phenomenon in which a liquid temporarily attains a temperature exceeding its boiling point without boiling, 433
- Superposition, 129
- Supersaturated** An adjective describing a solution that temporarily contains more of a solute than the equilibrium quantity, 669
- Supersaturated solutions, 669
- Surface tension** The resistance of the surface of a liquid to an increase in its area, 420, 420f
- Surroundings** The part of the universe that lies outside a system, 482–483, 482f  
entropy change for, 540–541
- Suspensions, colloidal, 472–473, 472f–473f
- Symmetry elements** Elements in a molecule or crystal, the set of rotations, reflections, and other changes that, when applied to the structure, give a structure indistinguishable from the original, 905
- Syndiotactic form** Polymer structure in which side groups alternate in regular position between sides along the backbone chain, 976, 976f
- Synthesis gas** A mixture of hydrogen and carbon monoxide, produced by the reaction of water vapor and a hydrocarbon (or coke) that is used as the starting point in the synthesis of methanol and other chemicals, 306
- Synthetic metals, 978
- Synthetic polymers  
applications for, 972–979  
cross-linking nonlinear, 971–972  
electrically conducting polymers, 978–979  
fibers, 972–974, 974t  
plastics, 974–977, 975t  
polymerization reactions for synthetic polymers, 968–972  
rubber, 977–978
- System** A real or imagined portion of the universe that is confined by boundaries or mathematical constraints, 482–485, 482f
- Systematic error, A.5
- Tangent line, A.27
- Temperature** ( $T$  or  $t$ ) The degree of hotness or coldness of an object as measured on some defined scale, 377–380  
absolute zero, 379–380  
effect on equilibrium of changing, 596–597, 597f  
entropy change for processes with changing temperature, 539–540  
equilibrium constants, temperature dependence of, 599–601, 599f–600f  
Gibbs free energy change and, 551–552, 552f  
isothermal process, 513–514, 517f, 537–539  
Kelvin temperature scale, 380  
kinetic theory of gases, 385–388  
reaction rates, effect on, 775–780  
solubility, effect on, 669, 670f  
vapor pressure, temperature dependence of, 601
- Termination** The final stage in a chain reaction, 774
- Termolecular reaction** An elementary reaction that involves the simultaneous collision of three reactants, 766
- Ternary compounds, 8
- Tertiary alcohol, 307
- Tertiary amine, 315
- Tetrahedral complexes, 348–350, 349f–350f
- Tetrahedral geometries, 340, 341f, 344
- Tetrahedral shape, 107, 107f, 110t
- Tetrahedral site, 916

- Theoretical probability** A prediction of the outcome(s) of an experiment based upon a theoretical model, A.33
- Theoretical yield** The amount of a product of a reaction predicted from stoichiometry assuming that the reaction proceeds without loss or side-reaction, 46–47
- Thermal cracking** The breaking down of long-chain hydrocarbon molecules in petroleum through heat, 300
- Thermal energy** The energy content directly related to temperature, such as the average kinetic energy of the molecules of a monatomic ideal gas, 480, 480f, A.15.
- Thermal equilibrium** A macroscopic condition of a system characterized by the constancy of its pressure and temperature, 394
- Thermal expansion, 417–418, 417t
- Thermal occupation of molecular energy levels, 849–850
- Thermal radiation, 131
- Thermal shock** The failure of a ceramic due to large, localized thermal expansion, 941
- Thermochemistry** The study of heat effects in chemical reactions, 504–512  
reaction enthalpy, 504–508, 507f, 508t
- Thermodynamic efficiency** ( $\epsilon$ ) The ideal efficiency an engine would have if it could be operated in a purely reversible fashion, 536, 555
- Thermodynamic equilibrium constant, 570, 576
- Thermodynamic equilibrium state, 564
- Thermodynamic process** A process that leads to a change in the thermodynamic state of a system, 483–484
- Thermodynamic properties, A.37–A.44
- Thermodynamic state** A macroscopic, time-independent condition of a system at thermal and mechanical equilibrium characterized by a well-defined temperature and pressure, 483–485, 484f–485f
- Thermodynamic universe** The system and the surroundings for a process, 482, 482f, 529
- Thermodynamics, 480–481  
calorimeters  
bomb, 493, 494f  
ice, 488–489, 489f  
direction of change in chemical reactions, 598–601  
enthalpy, 494–495  
equilibrium, thermodynamic description of, 574–581  
first law of thermodynamics, 485, 490–491, 491f  
heat, 488–490  
heat capacity, 492–493, 492f, 495–503, 498t, 501f, 501t, 503f  
heat transfer  
at constant pressure, 494–495  
at constant volume, 493  
internal energy, 488, 488f, 498–503  
processes, 483–484  
reversible processes in ideal gases, 512–517  
adiabatic process, 515–517, 517f  
isothermal process, 513–514, 517f  
second law of, 535–536  
specific heat capacity, 489, 492, 492t  
state functions, 484–485  
states, 483–485, 483–485f  
statistical, 530  
systems, 482–485, 482f  
thermochemistry. *See* Thermochemistry  
third law, 544–546  
work, 485–487
- Thermosphere** The portion of the earth's atmosphere extending out from 80 km, 881, 881f
- Third law of thermodynamics** The entropy of any pure substance in its equilibrium state approaches zero at the absolute zero of temperature, 544–546
- Thompson, Benjamin, 489
- Thomson, J. J., 16, 19, 21, 23, 57, 62, 698
- Three Mile Island accident, 831
- Titanium, 49
- Titration** A process in which a measured volume of solution of known concentration of one reactant is added to a second solution containing the other reactants; an indicator is added to signal the point at which the reaction is complete, 450, 450f  
acid-base titrations, 448–452, 640–645  
oxidation-reduction titrations, 452–458  
polyprotic acid, 659–660, 660f  
strong acid with strong base, 640–642, 641f  
weak acid with strong base, 642–645, 643f
- Titration curve** A plot of the pH of a solution as a function of the amount of acid or base added to a base or acid, 640–645, 641f, 643f, 660f
- Torricelli, Evangelista, 373–374
- Total energy, 68, 69f, 83
- Trans fats, 315
- Transactinide elements, A.55
- Transferases, 797
- Transistor** Solid state amplifiers in which the current that pass through the device is controlled by a voltage, much like the flow through a faucet is controlled by the position of the valve, 962
- Transition state** The location of the highest energy configuration of a reacting system on a potential energy diagram, 778–779, 788–789
- Transition state theory, 788–789
- Transition-metal elements** An element in the 10 middle groups of the third, fourth, and fifth periods of the periodic table, 59, 60f  
chemistry of, 326–333  
coordination chemistry. *See* Coordination chemistry/complexes  
crystal field theory. *See* Crystal field theory  
electron configuration of, 205–206, 206f  
optical properties, 352–354, 353t  
oxidation states, 329–331, 329t  
physical properties, 326–329, 326t, 327f–329f, A.51–A.53  
spectrochemical series, 354
- Transmittance, 846
- Transuranic element** Man-made elements with atomic numbers greater than that of uranium, 833
- Traveling wave** A wave that propagates through space, 147
- Triatomic nonhydrides, 270–273  
linear, 271–272, 271f–272f  
nonlinear, 272–273, 273f

- Trienes, 300
- Triglycerides** Esters formed from glycerol by reacting all three of its hydroxy groups with fatty acids, 314–315
- Trigonal bipyramidal shape, 107, 107f, 109, 109f, 110t
- Trigonal planar shape, 107, 107f, 110t
- Triple bond** Three pairs of electrons shared between two atoms, 100
- Triple point** The condition of temperature and pressure in which three phases of a substance coexist in equilibrium, 434, 434f–435f
- Triplet electronic state** An excited state of a molecule with a total electron spin quantum number  $S = 1$ , so  $2S + 1 = 3$ , 843, 843f, 849
- Troposphere** The lowest layer of the earth's atmosphere, extending out 1 km from the surface of the earth, 881, 881f
- Tropospheric chemistry, 882–885
- Trouton's rule, 539
- Turning point, 67
- Turnover number** ( $k_{\text{cat}}$ ) The number of substrate molecules that react per enzyme molecule per second, 799
- Two-electron functions, 254
- Ultraviolet catastrophe, 132
- Unbound motion, 68, 69f
- Uncertainty, 153–154
- Unimolecular reaction** An elementary reaction in which a single reactant molecule decomposes, 766
- Unit cell** The repeating motif or building unit from which a crystal could be constructed by simple stacking operations, 907–909, 907f–909f
- Unit conversion method, A.10–A.11
- Units, A.8–A.10
- Universal constant, 381
- Unsaturated hydrocarbon** A compound of hydrogen and carbon that contains double or triple carbon–carbon bonds, 297
- Unsaturated solution, 668
- Uranium enrichment, 401, 402f, 406–408, 406f–407f
- Vacancies, 923
- Valence** Refers to the outermost electrons in an atom, 53
- Valence band** (VB) A band of occupied electron energy states responsible for bonding in a semiconductor, 723, 723f–724f
- Valence bond (VB) method** Bonding theory in which electrons are viewed as localized either between particular pairs of atoms or as lone pairs on atoms, 220, 253–259
- coordination complex bonding, 355–356
- LCAO method compared to, 276–277
- LCAO method used with, 270–275
- multiple bonds, 256–257, 257f
- orbital hybridization. *See* **Hybridization**
- polyatomic molecules, 257–258
- as qualitative predictive tool, 277–278
- single bonds, 253–256, 253f, 255f–256f
- Valence electrons** Electrons (in the valence shell of an atom) that can take part in chemical bonding, 53, 76–77
- Valence shell electron pair repulsion (VSEPR) theory, 53, 106–111, 266–267, 268t
- Valence shell** The outermost unfilled shell of electrons surrounding the nucleus of an atom, 76–77
- Valence shell expansion** The participation of more than eight electrons in the bonding of a molecule or molecule-ion, 105–106
- van der Waals constants, 396t
- van der Waals equation of state** An equation of state used to express the physical behavior of a real gas:  
 $(P + an^2/V^2)(V - nb) = nRT$ , 395–397
- van der Waals radius** The effective size of an atom or molecule; equal to the maximum distance at which nonbonded interaction with other atoms or molecules causes repulsion, 424
- van't Hoff, Jacobus, 219, 600
- van't Hoff equation** An equation relating the temperature dependence of the equilibrium constant to the enthalpy change in the reaction;  $(K_2/K_1) (\Delta H^\circ/R) [(1/T_1) - (1/T_2)]$ , 600
- Vapor pressure** ( $P_{\text{vap}}$ ) The pressure of the vapor coexisting with a confined liquid or solid at any specified temperature, 430–431, 431f, 431t
- temperature dependence of, 601
- Vaporization
- molar enthalpy of vaporization, 507, 508t
- molar entropy of vaporization, 539
- Vapor-pressure lowering** The vapor pressure of a solvent decreases when a nonvolatile solute is added, 460
- Variational principle** A principle in quantum mechanics that states that the energy of a molecule calculated using an approximate wave function will always be higher than the true energy, 277
- Vector** A geometrical representation of a physical characteristic that has both magnitude and direction, such as force or velocity. For example if a car were traveling 60 miles per hour to the northeast, then the vector  $\vec{v}$  has magnitude 60 miles per hour and direction northeast. In this text, we indicate vector quantities with an arrow about the symbol, and the magnitude of the vector by the same variable, but with no over arrow. Some other texts write the symbol for the vector  $\mathbf{v}$  in boldface type and the magnitude by  $||\mathbf{v}||$ , 16, A.34–A.36
- Velocity** A vector that specifies both the speed and direction of motion, 385–386, 386f, A.12
- average velocity, A.12
- Vibrational energy distribution, 518–520
- Vibrational fine structure** Peaks appearing in electronic absorption, emission, or photoelectron spectroscopy that are attributable to the excitation of vibrational transitions, 877
- Vibrational spectroscopy, 94
- diatomic molecules, 858–864
- polyatomic molecules, 865–869
- Volatile solutes, phase equilibrium in, 467–472
- Volt (unit), 697
- Volta, Alessandro, 698
- Voltmeter** An instrument used to measure electrical potential differences, 697
- Volume
- effect on equilibrium of changing, 595–596, 596f
- heat transfer at constant volume, 493
- isochoric process, 513, 539
- law of combining volumes, 13

Volume (*continued*)

- molar volume, 30
- pressure-volume work, 486–487

**Volumetric flask** A flask that contains an accurately known volume of liquid when filled exactly to a calibration mark at a specified temperature, 444, 445f

von Laue, Max, 909

**VSEPR (Valence Shell Electron Pair Repulsion) theory** A qualitative theory that predicts molecular shape based on the electrostatic argument that electron pairs in a molecule repel each other, 53, 106–111, 266–267, 268t

**Vulcanization** The process of treating crude or synthetic rubber or similar plastic material chemically to give it useful properties, 977

Waage, P., 568

## Water

- autoionization of, 619
- crystal structure of ice, 429
- decomposition potential, 745–746
- density, 428–429, 429f
- electrolysis, 744–746
- electrostatic potential energy map, 428, 428f
- empirical formula of, 37
- hydrogen bonds in, 427–428, 427f
- ion product constant for water, 619, 619t
- photochemical splitting, 724–726, 724f, 726f
- special properties of, 428–429
- structure of, 108f
- vapor pressure, 430–431, 431f, 431t
- waves, 126, 126t, 127f

**Water gas shift reaction** The reaction between carbon monoxide and water that is the dominant method for the commercial production of hydrogen gas, 569

Watson, James, 990

## Wave(s)

- amplitude, wavelength, frequency, and speed, 126
- interference, 129–130, 129f, 130f
- kinds of waves, 126, 126t
- motion, 126–130

**Wave function ( $\psi$ )** A function that describes the properties of a particle; its square ( $\psi^2$ ) is proportional to the probability of finding the particle at a particular point in space, 154

electronic wave functions for hydrogen molecular ion, 226–228, 227f

- hydrogen atoms, 181–183, 182f
- hydrogen molecular ion, 278–279, 280f–281f
- for particles in cubic boxes, 169–170, 169f–170f
- for particles in square boxes, 166–169, 167f
- in Schrödinger equation, 157–158

Wave numbers, 843

Wave theory of light, 127–130

**Wavelength ( $\lambda$ )** The distance between two successive crests or two successive troughs in a wave, 126

**Wave-particle duality** The result that light and small particles such as electrons behave as waves in some experiments and as particles in others, 143

de Broglie waves, 147–148

electron diffraction, 148–151, 149f, 151f

evidence for, 142–154

Heisenberg indeterminate principle, 152–154

indeterminacy and uncertainty, 152–154

photoelectric effect, 143–147, 145f

**Weak acid** An acid that has a  $K_a$  smaller than 1, 622, 624f, 630–632

polyprotic acids, 645–649

titration with strong base, 642–645, 643f

**Weak base** A base that has a  $K_b$  smaller than 1, 624f, 633

**Weak electrolyte** An electrolyte that dissociates only to a negligible extent in solution, 622

**Weak field configurations** High-spin configurations that result from small crystal field splittings, 348

**Weak field ligands** Ligands that induces only a small crystal field splitting in a transition-metal complex, 348

Werner, Alfred, 333–334, 339–340

Wien, Wilhelm, 20–21

Wilkins, Maurice, 990

**Work function** The energy required to ionize an electron from a bulk solid, analogous to the ionization energy for gas-phase atoms and molecules, 146

**Work ( $w$ )** The product of the external force  $F$  acting on a body and its displacement  $d$ ; when work is done on a system, the system's energy increases; when work is done by a system, the system's energy decreases if no heat is transferred at the same time, 485–487

for ideal gases, 497–498

pressure-volume work, 486–487

Writing balanced chemical equations, 39–43

X-ray diffraction, 149, 149f, 872–873

X-ray scattering by crystals, 909–911, 910f

Yield, 563

actual, 46–47

percentage, 47

theoretical, 46–47

Yield of reaction, maximizing, 597–598, 597f

Yttria ceramic, 948

**Zeolites** Aluminosilicates having significant amounts of open space in its interior structure, 940–941, 940f

**Zero-point energy** The quantized energy associated with zero-point motion;  $E_0 = (1/2)h\nu$ , 164, 221, 860

**Zero-point motion** Nuclear motion that occurs even at absolute zero (0 K), 860

**Zeroth order reactions** Reactions that has a total order of 0; that is, ones that proceeds at a rate that is independent of the concentrations of the species present in the reaction mixture, 759

Ziegler, Karl, 975–976

Zinc-carbon dry cell, 728–729

**Zinc-mercuric oxide cell** A primary cell using the reaction  $\text{Zn}(s) + \text{HgO}(s) + \text{H}_2\text{O}(\ell) \rightarrow \text{Zn}(\text{OH})_2(s) + \text{Hg}(\ell)$  to generate a voltage, 729–730, 729f

### Locations of Some Important Tables of Data

Boiling-Point Elevation and Freezing-Point Depression Constants	page 461
Bond Enthalpies	page 511
Formation Constants of Coordination Complexes in Aqueous Solution	page 681
Ionization Constants $K_a$ of Acids in Water at 25°C	page 623
Masses of Selected Elementary Particles and Atoms	page 809
Physical Properties of the Elements	page A.47
Radioisotope Decay Modes and Rates	page 819
Standard Reduction Potentials at 25°C	page A.45
Solubility Product Constants $K_{sp}$ at 25°C	page 672
Standard Chemical Thermodynamic Properties	page A.37
Vapor Pressure of Water at Various Temperatures	page 431
Angular and Radial Parts of Wave Functions for One-Electron Atoms	page 182

## Physical Constants

Avogadro's number	$N_A = 6.02214129 \times 10^{23} \text{ mol}^{-1}$
Bohr radius	$a_0 = 0.52917721092 \text{ \AA} = 5.2917721092 \times 10^{-11} \text{ m}$
Boltzmann's constant	$k_B = 1.3806488 \times 10^{-23} \text{ J K}^{-1}$
Electron charge magnitude	$e = 1.602176565 \times 10^{-19} \text{ C}$
Faraday constant	$F = 96,485.3365 \text{ C mol}^{-1}$
Masses of fundamental particles:	
Electron	$m_e = 9.10938291 \times 10^{-31} \text{ kg}$
Proton	$m_p = 1.672621777 \times 10^{-27} \text{ kg}$
Neutron	$m_n = 1.674927351 \times 10^{-27} \text{ kg}$
Permittivity of vacuum	$\epsilon_0 = 8.854187817 \times 10^{-12} \text{ C}^2 \text{ J}^{-1} \text{ m}^{-1}$
Planck's constant	$h = 6.62606957 \times 10^{-34} \text{ J s}$
Ratio of proton mass to electron mass	$m_p/m_e = 1836.152672$
Speed of light in a vacuum	$c = 2.99792458 \times 10^8 \text{ m s}^{-1}$ (exactly)
Standard acceleration of terrestrial gravity	$g = 9.80665 \text{ m s}^{-2}$ (exactly)
Universal gas constant	$R = 8.3144621 \text{ J mol}^{-1} \text{ K}^{-1}$ $= 0.0820574 \text{ L atm mol}^{-1} \text{ K}^{-1}$

Values are taken from the 2010 CODATA recommended values, as listed by the National Institute of Standards and Technology.

## Conversion Factors

Ångström 1	$\text{\AA} = 10^{-10} \text{ m}$
Atomic mass unit	$1 \text{ u} = 1.660538921 \times 10^{-27} \text{ kg}$ $1 \text{ u} = 1.492417955 \times 10^{-10} \text{ J} = 931.494061 \text{ MeV}$ (energy equivalent from $E = mc^2$ )*
Calorie	$1 \text{ cal} = 4.184 \text{ J}$ (exactly)
Electron volt	$1 \text{ eV} = 1.602177 \times 10^{-19} \text{ J}$ $= 96.485336 \text{ kJ mol}^{-1}$
Foot	$1 \text{ ft} = 12 \text{ in} = 0.3048 \text{ m}$ (exactly)
Gallon (U.S.)	$1 \text{ gallon} = 4 \text{ quarts} = 3.785412 \text{ L}$
Liter	$1 \text{ L} = 10^{-3} \text{ m}^3 = 10^3 \text{ cm}^3$ (exactly)
Liter-atmosphere	$1 \text{ L atm} = 101.325 \text{ J}$ (exactly)
Metric ton	$1 \text{ t} = 1000 \text{ kg}$ (exactly)
Pound	$1 \text{ lb} = 16 \text{ oz} = 0.45359237 \text{ kg}$ (exactly)
Rydberg	$1 \text{ Ry} = 2.17987217 \times 10^{-18} \text{ J}$ $= 1312.7498 \text{ kJ mol}^{-1}$ $= 13.60569252 \text{ eV}$
Standard atmosphere	$1 \text{ atm} = 1.01325 \times 10^5 \text{ Pa}$ $= 1.01325 \times 10^5 \text{ kg m}^{-1} \text{ s}^{-2}$ (exactly)
Torr	$1 \text{ torr} = 133.3224 \text{ Pa}$

\*Chapter 19 uses the 2006 CODATA energy equivalent  $1 \text{ u} = 931.494028 \text{ MeV}$ .
