Beryllium has had a long history of use in atomic energy as neutron sources, reflectors, and moderators in thermal and intermediate reactors. Applications of beryllium to aerospace usually provides weight saving up to 60% of that of a competing material on the same design basis. Extensive use of beryllium in reentry structures depends on high-temperature strength and thermal capacity. The metal's transparency to radiation (as used in x-ray windows) also is important to missile structures, which must withstand electromagnetic pulse conditions created by antimissile tactics. Finally, ability to machine to high tolerance coupled with dimensional stability has created almost exclusive employment of beryllium in inertial guidance navigation and control devices. [W.W.Be./W.D.T.]

Beryllium minerals Minerals containing beryllium as an essential component. Over 50 beryllium minerals have been identified, even though beryllium is a scarce element in the Earth's crust. The unusual combination of low charge (+2) and small ionic radius (0.035 nanometer) of the beryllium ion accounts for this diverse group of minerals and their occurrence in many natural environments. *See* BERYLLIUM.

Nearly all beryllium minerals can be included in one of three groups: compositionally simple oxides and silicates with or without aluminum; sodium- and calcium-bearing silicates; and phosphates and borates. The first group is by far the most abundant; it contains beryl, the most common beryllium mineral, plus the common minerals phenakite, bertrandite, chrysoberyl, and euclase. Of this group, only beryl shows a wide compositional variation.

The beryllium minerals have many structural characteristics similar to the major rock-forming silicate minerals, but are distinguished by containing large quantities of tetrahedrally coordinated beryllium ion (Be^{2+}) in place of, or in addition to, tetrahedrally coordinated aluminum ion (Al^{3+}) and silicon ion (Si^{4+}). *See* SILICATE MINERALS.

Beryllium minerals occur in many geological environments, where they are generally associated with felsic (abundant feldspar ± quartz) igneous rocks and related, metasomatically altered rocks.

Beryl and bertrandite, mined from granitic pegmatites and altered volcanic rocks, are the principal ores of beryllium; deposits of chrysoberyl and phenakite may become economically significant in the future. The colored varieties of beryl (emerald, aquamarine, morganite) are valued gemstones; chrysoberyl, phenakite, and a few of the other minerals are less common gemstones. *See* CHRYSOBERYL; EMERALD; GEM. [M.D.B.]

Bessel functions The solutions of Bessel's differential equation, Eq. (1). Bessel functions, also called cylinder functions,

$$z^2 d^2 y/dz^2 + z\, dy/dz + (z^2 - \upsilon^2)y = 0 \qquad (1)$$

are examples of special functions which are introduced by a differential equation. Bessel functions are of great interest in purely mathematical concepts and in mathematical physics. They constitute additional functions which, like the elementary functions z^n, $\sin z$, e^z, can be used to express physical phenomena.

Applications of Bessel functions are found in such representative problems as heat conduction or diffusion in circular cylinders, oscillatory motion of a sphere in a viscous fluid, oscillations of a stretched circular membrane, diffraction of waves by a circular cylinder of infinite length or by a sphere, acoustic or electromagnetic oscillations in a circular cylinder of finite length or in a sphere, electromagnetic wave propagation in the waveguides of circular cross section, in coaxial cables, or along straight wires, and in the skin effect in conducting wires of circular cross section. In these problems Bessel functions are used to represent such quantities as the temperature, the concentration, the displacements, the electric and magnetic field strengths, and the current density as a function of space coordinates. The Bessel functions enter into all these problems because boundary values

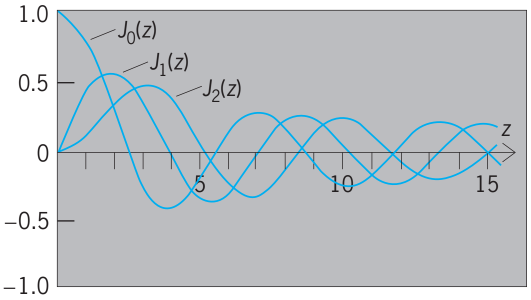

Fig. 1. Bessel functions $j_0(z)$, $j_1(z)$, $j_2(z)$ for $v = 0, 1, 2$ and for positive values of z.

on circles (two-dimensional problems), on circular cylinders, or on spheres are prescribed, and the solutions of the respective problems are sought either inside or outside the boundary, or both.

The independent variable z in Bessel's differential equation may in applications assume real or complex values. The parameter v is, in general, also complex. Its value is called the order of the Bessel function. Since there are two linearly independent solutions of a linear differential equation of second order, there are two independent solutions of Bessel's differential equation. They cannot be expressed in finite form in terms of elementary functions such as z^n, sin z, or e^z unless the parameter is one-half of an odd integer. They can, however, be expressed as power series with an exception for integer values of v. The function defined by Eq. (2) is designated as Bessel's function of the first

$$J_v(z) = \left(\frac{z}{2}\right)^v \sum_{l=0}^{\infty} \frac{(-z^2/4)l}{l!\,\Gamma(v+l+1)} \tag{2}$$

kind, or simply the Bessel function of order v. $\Gamma(v + l + 1)$ is the gamma function. The infinite series in Eq. (2) converges absolutely for all finite values, real or complex, of z. Along with $J_v(z)$, there is a second solution $J_{-v}(z)$. It is linearly independent of $J_v(z)$ unless v is an integer n. In this case $J_{-n}(z) = (-1)^n J_n(z)$. *See* GAMMA FUNCTION.

The Bessel function of the second kind, also called the Neumann function, is defined by Eq. (3).

$$Y_v(z) = \frac{\cos v\pi\, J_v(z) - J_{-v}(z)}{\sin v\pi} \tag{3}$$

If $v = n$, this expression is indeterminate, and the limit of the right member is to be taken. There are two Bessel functions of the third kind, designated as first and second Hankel functions. They are defined as Eqs. (4).

$$\begin{aligned} H_v^{(1)}(z) &= J_v(z) + i\,Y_v(z) \\ H_v^{(2)}(z) &= J_v(z) + i\,Y_v(z) \end{aligned} \tag{4}$$

Figures 1 and 2 give the Bessel and Neumann functions for $v = 0, 1, 2$ and positive values of z. [J.Meix.]

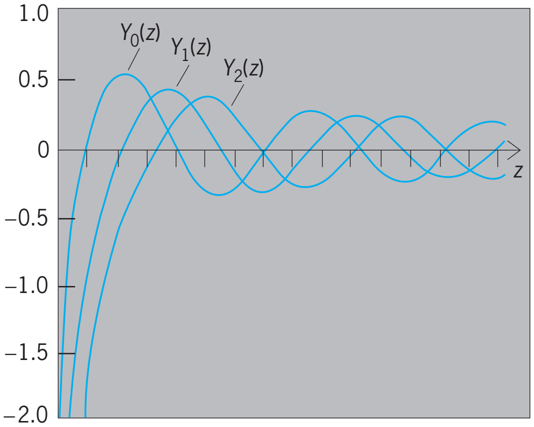

Fig. 2. Neumann functions $Y_0(z)$, $Y_1(z)$, $Y_2(z)$ for $v = 0, 1, 2$ and for positive values of z.

Beta particles The name first applied in 1897 by Ernest Rutherford to one of the forms of radiation emitted by radioactive nuclei. Beta particles can occur with either negative or positive charge (denoted β^- or β^+) and are now known to be either electrons or positrons, respectively. Electrons and positrons are now referred to as beta particles only if they are known to have originated from nuclear beta decay. Their observed kinetic energies range from zero up to about 5 MeV in the case of naturally occurring radioactive isotopes, but can reach values well over 10 MeV for some artificially produced isotopes. *See* RADIOACTIVITY; ALPHA PARTICLES; ELECTRON; GAMMA RAYS; POSITRON.

When a nucleus beta-decays, it emits two particles at the same time: One is a beta particle; the other, a neutrino or antineutrino. With this emission, the nucleus itself undergoes a transformation, changing from one element to another. In the case of isotopes that β^+-decay, each decaying nucleus emits a positron and a neutrino, simultaneously reducing its atomic number by one unit; for those isotopes that β^--decay, each nucleus emits an electron and an antineutrino while increasing its atomic number by one. In both classes of decay, the energy released by the nuclear transformation is shared between the two emitted particles. Though the energy released by a particular nuclear transformation is always the same, the fraction of this energy carried away by the beta particle is different for each decaying nucleus. (The neutrino always carries away the remainder, thus conserving energy overall.) When observed collectively, the decaying nuclei of a simple radioactive source emit their beta particles with a continuous distribution of kinetic energies covering the range from zero up to the total nuclear decay energy available.

Radioactive samples often contain several radioactive isotopes. Since each isotope has its own decay energy and beta-particle energy distribution, the energy spectrum of beta particles observed from such a sample would be the sum of a number of distributions, each with a different end-point energy. Indeed, many isotopes, especially those artificially produced with accelerators, can themselves beta-decay by additional paths that also release part of the energy in the form of gamma radiation.

As a beta particle penetrates matter, it loses its energy in collisions with the constituent atoms. Two processes are involved. First, the beta particle can transfer a small fraction of its energy to the struck atom. Second, the beta particle is deflected from its original path by each collision and, since any change in the velocity of a charged particle leads to the emission of electromagnetic radiation, some of its energy is lost in the form of low-energy x-rays (bremsstrahlung). Though the energy lost by a beta particle in a single collision is very small, many collisions occur as the particle traverses matter, causing it to follow a zigzag path as it slows down. *See* BREMSSTRAHLUNG.

The thickness of material that is just sufficient to stop all the beta particles of a particular energy is called the range of those particles. For the continuous energy distribution normally associated with a source of beta particles, the effective range is the one that corresponds to the highest energy in the primary spectrum. That thickness of material stops all of the beta particles from the source. The range depends strongly on the electron energy and the density of the absorbing material.

The slowing-down processes have the same effect on both β^- and β^+ particles. However, as antimatter, the positron (β^+) cannot exist for long in the presence of matter. It soon combines with an atomic electron, with which it annihilates, the masses of both particles being replaced by electromagnetic energy. Usually this annihilation occurs after the positron has come to rest and formed a positronium atom, a bound but short-lived positron-electron system. In that case, the electromagnetic energy that is emitted from the annihilation takes the form of two 511-keV gamma rays that are emitted in opposite directions to conserve momentum. *See* POSITRONIUM.

Beta particles are detected through their interaction with matter. One class of detectors employs gas as the detection medium. Ionization chambers, proportional counters, and Geiger-Müller counters are of this class. In these detectors, after entering through a thin window, the beta particles produce positive ions and free electrons as they collide with atoms of the gas in the process of their slowing down. An electric field applied across the volume of gas causes these ions and electrons to drift along the field lines, causing an ionization current that is then processed in external electronic devices. *See* IONIZATION CHAMBER; PARTICLE DETECTOR.

More precise energy information can be achieved with scintillation detectors. In certain substances, the ion-electron pairs produced by the passage of a charged particle result in the emission of a pulse of visible or near-ultraviolet light. If a clear plastic scintillator is used, it can be mounted on a photomultiplier tube, which converts the transmitted light into a measurable electrical current pulse whose amplitude is proportional to the energy deposited by the incident beta particle. *See* SCINTILLATION COUNTER.

Even better energy information comes from semiconductor detectors, which are effectively solid-state ionization chambers. When a beta particle enters the detector, it causes struck electrons to be raised into the conduction band, leaving holes behind in the valence band. The electrons and holes move under the influence of an imposed electric field, causing a pulse of current to flow. Such detectors are useful mainly for low-energy beta particles. *See* JUNCTION DETECTOR.

Any one of these detectors can be combined with a magnetic spectrometer. Beta particles, like any charged particles, follow curved paths in a perpendicular magnetic field, their radius of curvature being proportional to the square of their energy. Their detected position on exiting the magnetic field can be precisely related to their energy. The best current measurement of the electron antineutrino mass comes from a spectrometer measurement of the tritium beta-decay spectrum. *See* NEUTRINO. [J.Hard.]

Betatron

Betatron A device for accelerating charged particles in an orbit by means of the electric field E from a slowly changing magnetic flux Φ. The electric field is given by $E = -(1/2\pi r_o)\, d\Phi/dt$ (in SI or mks units), where r_o is the orbit radius. The name was chosen because the method was first applied to electrons. In the usual betatron both the accelerating core flux and a guiding magnetic field rise with similar time dependence, with the result that the orbit is circular. However, the orbit can have a changing radius as acceleration progresses. For the long path (usually more than 60 mi or 100 km), variations of axial and radial magnetic field components provide focusing forces, while space charge and space current forces due to the particle beam itself also contribute to the resulting betatron oscillations about the equilibrium orbit. In many other instances of particle beams, the term betatron oscillations is used for the particle oscillations about a beam's path.

Collective effects from self-fields of the beam have been found important and helpful in injecting. Circulating currents of about 3 amperes are contained in the numerous industrial and therapeutic betatrons, although the average currents are below 10^{-7} A. *See* PARTICLE ACCELERATOR. [D.W.K.]

Betel nut The dried, ripe seed of the palm tree *Areca catechu* (Palmae), a native of Ceylon and Malaya. The nuts, slightly larger than a chestnut, have a faint odor when broken open and a somewhat acrid taste. Betel nuts are chewed by the inhabitants together with the leaves of the betel pepper, *Piper betle* (Piperaceae), and lime. The mixture discolors and eventually destroys the teeth. Frequently, habitual chewers of the nut are toothless by the age of 25. The seeds contain a narcotic that produces some stimulation and a sense of well-being. *See* NARCOTIC; PIPERALES. [P.D.St./E.L.C.]

Betelgeuse A cool and highly luminous star, prominently located in the right shoulder of the constellation Orion and noticeably red in color. Betelgeuse, or α Orionis, is a supergiant star about 130 parsecs (430 light-years) from the Sun. Its spectral type of M2 indicates an effective temperature of approximately 3500 K (5800°F). This temperature would result in a low overall luminosity were it not for the enormous diameter of the star, about 1100 times that of the Sun. Replacing the Sun, Betelgeuse would fill the solar system to beyond the orbit of Mars. Betelgeuse is a supergiant star with approximately 150,000 times the Sun's luminosity. Its mean density is extremely low, less than one-millionth the density of water, and the low surface gravity of the rarefied outer layers results in a continual loss of matter, presently at the rate of 1 solar mass every 250,000 years. Observations at infrared and radio wavelengths show a complex system of dust and gas shells extending out as far as a few hundred stellar radii. *See* SPECTRAL TYPE; STELLAR EVOLUTION; SUPERGIANT STAR; VARIABLE STAR.

Speckle interferometry techniques have also produced the first images of the disk of a star and show asymmetric brightness variations over the surface that change with time and are possibly due to large-scale convection of material within the star's atmosphere. Betelgeuse has also been imaged by the Hubble Space Telescope at ultraviolet wavelengths showing the asymetric inner atmosphere of the star and a central hot spot. *See* SPECKLE; STAR. [H.A.McA.]

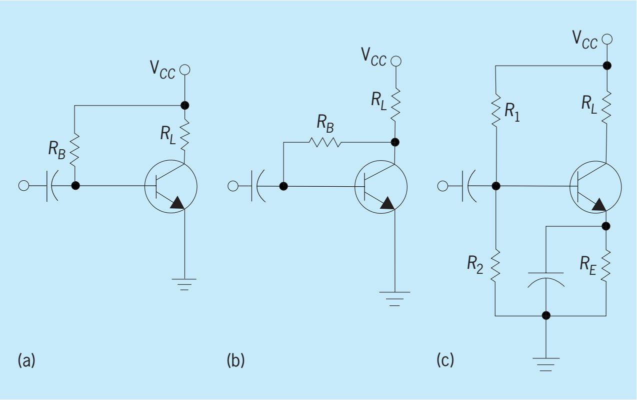
Bias (electronics) The establishment of an operating point on the transistor volt-ampere characteristics by means of direct voltages and currents.

Since the transistor is a three-terminal device, any one of the three terminals may be used as a common terminal to both input and output. In most transistor circuits the emitter is used as the common terminal, and this common emitter, or grounded emitter, is indicated in illus. *a*. If the transistor is to used as a linear device, such as an audio amplifier, it must be biased to operate in the active region. In this region the collector is biased in the reverse direction and the emitter in the forward direction. The area in the common-emitter transistor characteristics to the right of the ordinate $V_{CE} = 0$ and above $I_C = 0$ is the active region. Two more biasing regions are of special interest for those cases in which the transistor is intended to operate as a switch. These are the saturation and cutoff regions. The saturation region may be defined as the region where the collector current is independent of base current for given values of V_{CC} and R_L. Thus, the onset of saturation can be considered to take place at the knee of the common-emitter transistor curves. *See* AMPLIFIER; TRANSISTOR.

In saturation, the transistor current I_C is nominally V_{CC}/R_L. Since R_L is small, it may be necessary to keep V_{CC} correspondingly small in order to stay within the limitations imposed by the transistor on maximum-current and collector-power dissipation. In the cutoff region it is required that the emitter current I_E be zero, and to accomplish this it is necessary to reverse-bias the emitter junction so that the collector current is approximately equal to the reverse saturation current I_{CO}. A reverse-biasing voltage of the order of 0.1 V across the emitter junction will ordinarily be adequate to cut off either a germanium or silicon transistor.

The particular method to be used in establishing an operating point on the transistor characteristics depends on whether the transistor is to operate in the active, saturation or cutoff regions; on the application under consideration; on the thermal stability of the circuit; and on other factors.

In a fixed-bias circuit, the operating point for the circuit of illus. *a* can be established by noting that the required current I_B is constant, independent of the quiescent collector current I_C, which is why this circuit is called the fixed-bias circuit. Transistor



Translator circuits. (*a*) Fixed-bias. (*b*) Collector-to-base bias. (*c*) Self-bias.

biasing circuits are frequently compared in terms of the value of the stability factor $S = \partial I_C/\partial I_{CO}$, which is the rate of change of collector current with respect to reverse saturation current. The smaller the value of S, the less likely the circuit will exhibit thermal runaway. S, as defined here, cannot be smaller than unity. Other stability factors are defined in terms of dc current gain h_{FE} as $\partial I_C/\partial h_{FE}$, and in terms of base-to-emitter voltage as $\partial I_C/\partial V_{BE}$. However, bias circuits with small values of S will also perform satisfactorily for transistors that have large variations of h_{FE} and V_{BE}. For the fixed-bias circuit it can be shown that $S = h_{FE} + 1$, and if $h_{FE} = 50$, then $S = 51$. Such a large value of S makes thermal runaway a definite possibility with this circuit.

In collector-to-base bias, an improvement in stability is obtained if the resistor R_B in illus. *a* is returned to the collector junction rather than to the battery terminal. Such a connection is shown in illus. *b*. In this bias circuit, if I_C tends to increase (either because of a rise in temperature or because the transistor has been replaced by another), then V_{CE} decreases. Hence I_B also decreases and, as a consequence of this lowered bias current, the collector current is not allowed to increase as much as it would if fixed bias were used. The stability factor S is shown in Eq. (1).

$$S = \frac{h_{FE} + 1}{1 + h_{FE} R_L/(R_L + R_B)} \tag{1}$$

This value is smaller than $h_{FE} + 1$, which is the value obtained for the fixed-bias case.

If the load resistance R_L is very small, as in a transformer-coupled circuit, then the previous expression for S shows that there would be no improvement in the stabilization in the collector-to-base bias circuit over the fixed-bias circuit. A circuit that can be used even if there is zero dc resistance in series with the collector terminal is the self-biasing configuration of illus. *c*. The current in the resistance R_E in the emitter lead causes a voltage drop which is in the direction to reverse-bias the emitter junction. Since this junction must be forward-biased (for active region bias), the bleeder R_1-R_2 has been added to the circuit.

If I_C tends to increase, the current in R_E increases. As a consequence of the increase in voltage drop across R_E, the base current is decreased. Hence I_C will increase less than it would have had there been no self-biasing resistor R_E. The stabilization factor for the self-bias circuit is shown by Eq. (2), where $R_B = R_1R_2/(R_1 + R_2)$. The smaller the value of R_B, the better the stabilization.

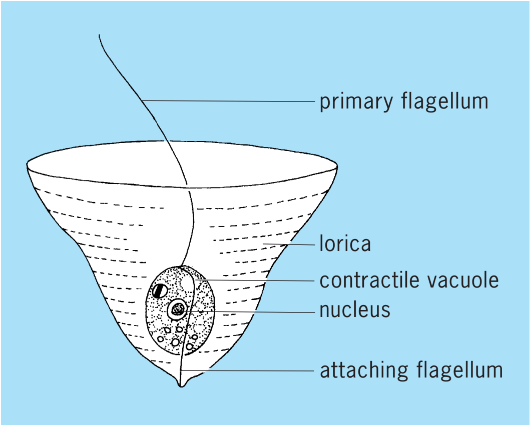
$$S = (1 + h_{FE}) \frac{1 + R_B/R_E}{1 + h_{FE} + R_B/R_E} \tag{2}$$

Even if R_B approaches zero, the value of S cannot be reduced below unity.

In order to avoid the loss of signal gain because of the degeneration caused by R_E, this resistor is often bypassed by a very large capacitance, so that its reactance at the frequencies under consideration is very small.

The selection of an appropriate operating point (I_D, V_{GS}, V_{DS}) for a field-effect transistor (FET) amplifier stage is determined by considerations similar to those given to transistors, as discussed previously. These considerations are output-voltage swing, distortion, power dissipation, voltage gain, and drift of drain current. In most cases it is not possible to satisfy all desired specifications simultaneously. [C.C.H.]

Bicosoecida An order of Zoomastigophorea (Protozoa). They are colorless, free-living cells, each with two flagella, one of which is used for attaching the organism to its exoskeleton (lorica). Although the attachment is normally from the front end, the flagellum emerges alongside the primary or vibrating one (see illustration). The anterior end in many species (*Codomonas annulata, Poteriodendron petiolatum*, and *Stephanocodon stellatum*) is ameboid, or at times appears to be formed into a lip which can turn in and engulf a bacterium.



A bicosoecid, *Codomonas annulata*.

These Bicosoecida are common in fresh water and often seen attached to desmids or other algae. *Bicosocca mediterranea* is common at times in salt water, where assemblages of it are found on diatoms. The order has very few genera and species. *See* PROTOZOA; ZOOMASTIGOPHOREA. [J.B.L.]

Big bang theory The theory that the universe began in a state of extremely high density and has been expanding since some particular instant that marked the origin of the universe. The big bang is the generally accepted cosmological theory; the incorporation of developments in elementary particle theory has led to the inflationary universe version. The predictions of the inflationary universe and older big bang theories are the same after the first 10^{-35} s. *See* INFLATIONARY UNIVERSE COSMOLOGY.

Two observations are at the base of observational big bang cosmology. First, the universe is expanding uniformly, with objects at greater distances receding at a greater velocity. Second, the Earth is bathed in the cosmic background radiation, an isotropic glow of radiation that has the characteristics expected from the remnant of a hot primeval fireball.

Tracing the expansion of the universe back in time shows that the universe would have been compressed to infinite density approximately 8–16 × 10^9 years ago. In the big bang theory, the universe began at that time as a so-called big bang began the expansion. The big bang was the origin of space and time.

In 1917, Albert Einstein found a solution to his own set of equations from his general theory of relativity that predicted the nature of the universe. His universe, though, was unstable: it could only be expanding or contracting. This seemed unsatisfactory at the time, for the expansion had not yet been discovered, so Einstein arbitrarily introduced a special term—the cosmological constant—into his equations to make the universe static. The need for the cosmological constant seemed to disappear with

Hubble's discovery of the expansion, though the cosmological constant has subsequently reappeared in some models.

Further solutions to Einstein's equations, worked out in the 1920s, are at the basis of the cosmological models that are now generally accepted. These solutions indicate that the original "cosmic egg" from which the universe was expanding was hot and dense. This is the origin of the current view that the universe was indeed very hot in its early stages.

Modern theoretical work has been able to trace the universe back to the first instants in time. In the big bang theory and in related theories that also propose a hot, dense early universe, the universe may have been filled in the earliest instants with exotic elementary particles of the types now being studied by physicists with large accelerators. Individual quarks may also have been present. By 1 microsecond after the universe's origin, the exotic particles and the quarks had been incorporated in other fundamental particles. *See* ELEMENTARY PARTICLE; QUARKS.

Work in the early 1980s incorporated the effect of elementary particles in cosmological models. The research seems to indicate that the universe underwent a period of extremely rapid expansion in which it inflated by a factor of billions in a very short time. This inflationary universe model provides an explanation for why the universe is so homogeneous: Before the expansion, regions that now seem too separated to have been in contact were close enough to interact. After the inflationary stage, the universe is in a hot stage and is still dense; the models match the big bang models thereafter.

In the inflationary universe models, the universe need not have arisen from a single big bang. Rather, matter could have appeared as fluctuations in the vacuum.

It is not definitely known why there is an apparent excess of matter over antimatter, though attempts in elementary particle physics to unify the electromagnetic, the weak, and the strong forces show promise in explaining the origin of the matter-antimatter asymmetry. The asymmetry seems to have arisen before the first millisecond. The asymmetry in the decay of certain mesons may provide a clue to resolving this question. *See* ANTIMATTER; FUNDAMENTAL INTERACTIONS.

By 5 s after the origin of the universe, the temperature had cooled to 10^9 K (2×10^9°F), and only electrons, positrons, neutrinos, antineutrinos, and photons were important. A few protons and neutrons were mixed in, and they grew relatively more important as the temperature continued to drop. The universe was so dense that photons traveled only a short way before being reabsorbed. By the time 1 min had gone by, nuclei of the light elements had started to form.

After about a million years, when the universe cooled to 3000 K (5000°F) and the density dropped sufficiently, the protons and electrons suddenly combined to make hydrogen atoms, a process called recombination. Since hydrogen's spectrum absorbs preferentially at the wavelengths of sets of spectral lines rather than continuously across the spectrum, and since there were no longer free electrons to interact with photons, the universe became transparent at that instant. The average path traveled by a photon—its mean free path—became very large. The blackbody spectrum of the gas at the time of recombination was thus released and has been traveling through space ever since. As the universe expands, this spectrum retains its blackbody shape though its characteristic temperature drops. *See* BLACKBODY; HEAT RADIATION.

As the early universe cooled, the temperatures became sufficiently low for element formation to begin. By about 100 s, deuterium (comprising one proton plus one neutron) formed. When joined by another neutron to form tritium, the amalgam soon decayed to form an isotope of helium. Ordinary helium, with still another neutron, also resulted.

Big bang nucleosynthesis, although at first thought to be a method of forming all the elements, foundered for the heavy elements at mass numbers 5 and 8. Isotopes of these mass numbers are too unstable to form heavier elements quickly enough. The gap is bridged only in stars, through processes worked out in 1957. Thus the lightest elements were formed as a direct result of the big bang while the heavier elements as well as additional quantities of most of the lighter elements were formed later in stars or supernovae. *See* NUCLEOSYNTHESIS.

The two extreme possibilities for the future of the universe are that the universe will continue to expand forever, or that it will cease its expansion and begin to contract. It can be shown that the case where the universe will expand forever corresponds to an infinite universe. The term applied is the open universe. The case where the universe will begin to contract corresponds to a finite universe. The term applied is the closed universe. The inflationary universe scenario has the univere on the boundary between open and closed, as signified by the parameter Ω taking the value of 1. Such a universe will expand forever but at an ever-decreasing rate. *See* COSMOLOGY; UNIVERSE.

The inflationary universe model provides a natural explanation for the universe being on this dividing line. After expansion slows down at the close of the inflationary stage (thus causing a phase change, much like water boiling into steam), the universe necessarily approaches this line. Further work on inflationary scenarios is necessary to see whether certain problems, such as the inflationary model's predictions of the density fluctuations that lead to the coalescence of galaxies, can be accounted for. *See* COSMOLOGY; UNIVERSE. [J.M.P.]

Bilirubin The predominant orange pigment of bile. It is the major metabolic breakdown product of heme, the prosthetic group of hemoglobin in red blood cells, and other chromoproteins such as myoglobin, cytochrome, and catalase. The breakdown of hemoglobin from the old red cells takes place at a rapid rate in the reticuloendothelial cells of the liver, spleen, and bone marrow. The steps in this breakdown process include denaturation and removal of the protein globin, oxidation and opening of the tetrapyrrole ring, and the removal of iron to form the green pigment biliverdin, which is then reduced to bilirubin by the addition of hydrogen. The formed bilirubin is transported to the liver, probably bound to albumin, where it is conjugated into water-soluble mono- and diglucuronides and to a lesser extent with sulfate. *See* LIVER.

In mammalian bile essentially all of the bilirubin is present as a glucuronide conjugate. Bilirubin glucuronide is passed through the liver cells into the bile caniculi and then into the intestine. The bacterial flora further reduces the bilirubin to colorless urobilinogen. Most of the urobilinogen is either reduced to stercobilinogen or oxidized to urobilin. These two compounds are then converted to stercobilin, which is excreted in the feces and gives the stool its brown color. *See* HEMOGLOBIN. [M.K.S.]

Binary star Two stars held together by their mutual gravitational attraction in a permanent (or long-term) association. The stellar universe is hierarchical. Stars exist singly, in binary pairs, in multiple systems, and in clusters. On large scales, roughly 10^5 light-years, astronomical objects congregate into galaxies. In fact, most stars are in binary systems. The Sun, with its collection of planets, is an exception. Stars in binaries revolve around their common center of mass (which itself moves through space). This star-star gravitational interaction makes possible the measurement of stellar masses and other basic properties. Stellar evolution in some binary systems can lead to spectacularly energetic activity. *See* GALAXY, EXTERNAL; SOLAR SYSTEM.

Binary systems are observed in various ways. They may be classified as visual binaries, spectroscopic binaries, or spectroscopic-eclipsing binaries, according to the means of observation.

In visual binary systems the stars are widely separated compared to their sizes and appear as separate points of light in the telescope. Binary stars provide the only proof that has been found so far of gravitation's validity beyond the solar system. *See* CELESTIAL MECHANICS; GRAVITATION.

More detailed observations reveal the apparent orbit of each star relative to the center of mass, leading directly to the stellar mass ratio of the two components. If the binary's parallax (distance) can be measured, individual stellar masses can be found. Without a knowledge of masses, stellar evolution cannot be understood.

There is a large class of nonvisual binaries in which the stars are separated by only a few stellar diameters. They cannot be resolved in telescopes, and are referred to as close binaries. The closeness of the stars profoundly affects their evolution. It also creates high orbital speeds (tens to hundreds of kilometers per second), rendering them easily detectable through Doppler shifts of their spectral lines.

If the two stars are of comparable luminosity, both stars contribute equally to their combined spectra and stellar lines are double over much of the orbital cycle. These are double-line spectroscopic binaries. The inverse ratio of their velocity amplitudes is the stellar mass ratio. *See* ASTRONOMICAL SPECTROSCOPY; DOPPLER EFFECT.

In spectroscopic-eclipsing binaries, the orbital plane of a close binary is nearly in the sight line. Mutual stellar eclipses occur, yielding a brightness-time variation called the light curve. Analysis of the light curve yields the inclination which, coupled with radial velocity curves of both stars, leads to both stellar masses and stellar sizes.

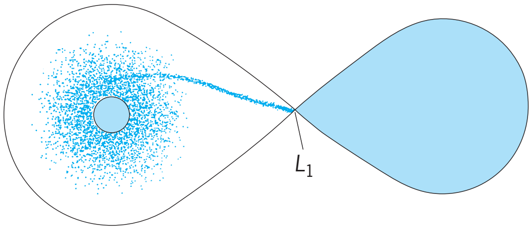
Stellar evolution in close binaries is drastically changed by the second star. The more massive star will exhaust its core hydrogen first and begin its evolution to a red giant. Its expansion is halted when the star's surface reaches the so-called inner lagrangian surface. This is a teardrop-shaped equipotential surface, usually called the Roche lobe, that touches the lagrangian surface of the less massive companion at the inner lagrangian point L_1.

Instead of expanding through this surface, matter flows along the Roche lobe to L_1, evaporates from L_1, and forms a stream that accelerates hypersonically toward the companion (see illustration). In other words, the post-main-sequence star transfers matter to its companion. One star loses mass (the loser) while the other gains mass (the gainer).

A visual binary, in which both stars are far from their Roche lobes, is referred to as detached. A system in which one star has evolved to fill its Roche lobe is called semidetached (see illustration). W Ursa Majoris stars are a class of main sequence binaries where both stars fill their lobes and share in effect a common envelope. Their periods are usually less than a day, and they are called contact binaries.

Algol eclipsing binaries illustrate evolution in close binaries. They contain a fairly massive main sequence gainer and a less massive, evolved subgiant (or giant) loser that fills its Roche lobe. Their existence posed the Algol paradox: how could the less massive star be the more evolved? The more evolved star must have originally been the more massive; mass transfer through L_1 to the companion has reversed the mass ratio.

At some point the gainer will itself evolve from the main sequence. Its envelope expansion may well engulf the original loser, whose orbit will then decay because of friction with the envelope gas (the so-called common-envelope phase). *See* STELLAR EVOLUTION; SYMBIOTIC STAR.



Roche lobes surrounding the stars in a binary system. The contact point is L_1. The less massive star on the right already fills its lobe. A mass-transferring stream supplies an accretion disk around the other star. (*Matthew Senay*)

Stellar evolution with a common-envelope stage may produce cataclysmic variables, in which a white dwarf is paired with a Roche-lobe-filling main-sequence loser. Orbital periods are typically less than a day. The mass-transferring stream from the loser supplies an accretion disk rotating around the white dwarf. Matter in the stream is rapidly accelerated toward the white dwarf, producing significant shock heating on impact with the disk. *See* WHITE DWARF STAR.

The cataclysmic binary zoo includes novae, dwarf novae, recurrent novae, and novalike variables. Much of their light comes from the thick accretion disk. Thermal instabilities in the disk may trigger mass dumps onto the white dwarf, producing eruptive brightenings. In some cases, hydrogen-rich matter from the loser slowly accumulates on the high-gravity surface of the white dwarf. At a critical density this matter becomes electron-degenerate, igniting a thermonuclear runaway that is a nova outburst. The explosion does not destroy the star, and outbursts may recur after many centuries of quiescence. *See* CATACLYSMIC VARIABLE; NOVA.

Neutron stars in close binary systems, where the companion fills its Roche lobe and transfers mass, can tap the enormous gravitation energy of in-falling matter. The strong magnetic field interferes with the formation of an accretion disk and funnels transferred mass onto the magnetic poles of the neutron star. This matter, enormously accelerated, strikes the surface at about half the speed of light and heats the poles to 10^8 K. Thermal radiation at such enormous temperatures (hotter than the solar core) is mainly x-rays. An x-ray binary results. *See* NEUTRON STAR.

High- and low-mass x-ray binaries are now recognized. The former are born with stars of comparable mass, totaling more than 20 solar masses. The more massive component explodes as a supernova and leaves a neutron star (or a black hole) remnant, but the binary is not disrupted. As the second star evolves and expands, it feeds mass to the neutron star. The resulting x-radiation may reach 10^5 solar luminosities, making these high-mass binaries among the most luminous objects in the Milky Way Galaxy. *See* BLACK HOLE; SUPERNOVA.

Low-mass x-ray binaries form with stars of differing mass (typically 10 and less than 2 solar masses). The more massive star suffers a supernova explosion and leaves a neutron star remnant. Mass accreted from the other star may spin up the neutron star to make a so-called millisecond pulsar. The enormous radiation from the neutron star may literally strip the companion to its degenerate helium core, as seems to be happening in the Black Widow Pulsar.

If the unseen x-ray source in a close binary has a mass significantly larger than about 3 solar masses, it cannot exist as a neutron star. According to current theory, it must have collapsed into a stellar-mass black hole. A handful of such candidates exist in the Milky Way Galaxy.

When the evolution of a moderate-mass binary results in two carbon-oxygen white dwarfs orbiting each other inside a common envelope, a remarkable event may occur. Viscous friction with the envelope causes the stars to spiral inward. If they merge into a total mass larger the about 1.4 solar masses (the Chandrasekhar limit), extremely intense thermonuclear reactions produce iron-peak elements, the structure abruptly runs out of thermonuclear energy, and an implosion-explosion occurs, producing a type Ia supernova. These highly luminous objects are seen in distant galaxies. They behave as standard candles (distance indicators), and are used to study the long-term evolution of the expansion rate of the universe. *See* COSMOLOGY; NUCLEOSYNTHESIS; UNIVERSE. [E.C.Ol.]

Binaural sound system A sound-reproducing system in which sound is recorded or transmitted by using two microphones mounted at the ears of a dummy human head. To preserve the binaural effect, the sound must be monitored by a listener wearing a set of earphones identically spaced. In an ideal binaural transmission system, both the amplitude and phase of the sound waves incident on the dummy's ears are duplicated at the listener's ears.

Binaural systems have been made so perfect that the listener is unable to distinguish the monitored sound from the real sound. For example, when a person walks around the dummy head, the listener, upon hearing the footsteps, has the compelling illusion of someone walking around him. No other sound system thus far devised can even approximate such an effect. *See* SOUND-REPRODUCING SYSTEMS; STEREOPHONIC SOUND. [H.F.O.]

Binoculars Optical instruments consisting of a parallel pair of matched telescopes, used to extend the range of stereoscopic vision to far distances. Each half of a binocular consists of a telescope objective, a prism for inverting the image, and an eyepiece (see illustration). *See* EYEPIECE; STEREOSCOPY; VISION.

Modern prism binocular. (*Bausch and Lomb Optical Co.*)

The characteristics of a binocular are stated by using a pair of numbers, such as 7 × 50 (seven by fifty), where the first number is the magnifying power of the binocular and the second is the diameter of the objective of the binocular in millimeters.

Since a lens forms an inverted image, the straight-through combination of an objective and eyepiece would provide an inverted field of view to the eye, as in an astronomical telescope. Almost all binoculars use prisms with an odd number of reflecting surfaces to invert the image correctly. The choice of prisms must also provide for the adjustment in pupil separation by having the optical axes on either side of the prism displaced but parallel. The most frequently used prism is a Porro prism, which is a combination of two 45°–90° prisms. These lead to a bulky mechanical construction, so that many modern binoculars use straight-through prisms. *See* MIRROR OPTICS; OPTICAL PRISM.

Binoculars require some ability to change the separation between the eyepiece and the objective to provide focusing to accommodate different object distances and possible refractive errors in the eye. Most binoculars provide for a joint focus adjustment of both tubes with one eye having an additional focus range to compensate for users who have differing refractive errors in each eye. Another optical feature often available in binoculars is a variable magnification or zoom system. *See* ZOOM LENS.

Selection of binoculars should be made with some consideration of the intended use. A larger objective will permit use of the binoculars at lower light levels. However, binoculars with larger-diameter objectives and higher powers are heavier and less convenient to use. The jitter produced while holding the binoculars will be magnified by the binocular, so that very high power binoculars usually require a stable support, such as a tripod, to be used properly. A modest power such as 6 is usually more comfortable than a high power such as 10.

Opera glasses are a type of low-power binoculars which use simpler optics. The use of a negative lens as an eyepiece, as in a Galilean telescope, limits the power and the field of view but permits a lighter and less expensive instrument. *See* TELESCOPE. [R.R.S.]

Binomial theorem One of the most important algebraic identities, with many applications in a variety of fields. The binomial theorem, discovered by Isaac Newton, expresses the result of multiplying a binomial by itself any number of times:

$$(a+b)^n = a^n + c_1 a^{n-1} b + c_2 a^{n-2} b^2 + c_3 a^{n-3} b^3$$

$$+ \cdots + cr\,a^{n-}r\,b^{r} + \cdots + b^{n}$$

where the coefficients $c_1, c_2, c_3, \ldots, c_r, \ldots$ are

$$c_1 = \frac{n}{1} \quad c_2 = \frac{n(n-1)}{1 \cdot 2} \quad c_3 = \frac{n(n-1)(n-2)}{1 \cdot 2 \cdot 3}$$

$$c_r = \frac{n(n-1)(n-2)\cdots(n-r+1)}{1 \cdot 2 \cdot 3 \cdots r}$$

The standard notation for these coefficients is

$$c_1 = \binom{n}{1}, c_2 = \binom{n}{2}, \ldots, c_r = \binom{n}{r}$$

Here $\binom{n}{r}$ is the coefficient of the term containing b_r in the expansion of $(a + b)n$. It is a fraction with the numerator and denominator each containing r factors; those in the denominator begin with 1 and increase by 1; those in the numerator begin with n and decrease by 1. It is easily shown that

$$\binom{n}{4} = \binom{n}{n-r}$$

Under suitable conditions the binomial formula is valid when n is not a positive integer. In this case the formula does not terminate, but generates an infinite series.

Much of the utility of the binomial theorem stems from the properties of the coefficients. In particular, the coefficient $(n\backslash r)$ gives the number of combinations of n distinct objects taken r at a time. The set of coefficients for any value of n forms a distribution that has fundamental importance in the study of probability and statistics. *See* ALGEBRA; SERIES. [H.R.C.]

Bioacoustics, animal The study of the role of sounds in the life history of animals. The field of animal bioacoustics can be subdivided into the acoustics of terrestrial animals and aquatic animals. Each field of study can be subdivided into (1) auditory capabilities and processes, (2) characteristics of sound emissions and mechanisms of sound production, and (3) the function and meaning of specific vocalizations.

Airborne acoustics, associated with terrestrial animals, and underwater acoustics, associated with aquatic animals, have three primary differences. First, the amount of acoustic energy that is absorbed and transformed into heat is much higher in air than underwater. Acoustic transmission loss in both media has a geometric spreading loss component plus an absorption loss component. The geometric spreading loss is dependent on the propagation geometry and not the medium, whereas absorption loss is directly dependent on the medium. Absorption loss in both media increases with frequency, although it is much higher in air than underwater. Therefore, the acoustic range of most aquatic animals is considerably larger than for terrestrial animals. Animals interested in long-range communications naturally use lower-frequency sounds. *See* SOUND ABSORPTION.

Second, airborne acoustics and underwater acoustics differ greatly in the respective values of the acoustic impedance, ρc, where ρ is the density of the medium and c is the sound velocity in that medium. The density of water is approximately 1000 times greater than that of air, and the sound velocity in water is about 4.5 times greater than in air. Therefore, the acoustic impedance of water is approximately 3600 times greater than air. This difference in acoustic impedance has great ramifications on how sounds are produced and received in both media. For example, the middle-ear ossicular chain of terrestrial mammals serves as an impedance-matching transformer between the air in the external auditory meatus and the fluid in the cochlea, or inner ear. Such a chain is not needed for animals hearing underwater since the impedance of water is already matched to the fluid of the inner ear. The impedance difference issue becomes rather complex with regard to hearing and sound production in amphibians and pinnipeds, which must have good in-air and underwater hearing. *See* ACOUSTIC IMPEDANCE; AMPHIBIA; PINNIPEDS.

Third, between airborne acoustics and underwater acoustics there is a large pressure difference. Pressure underwater increases by 1 atmosphere for approximately every 10-m (34-ft) increase in depth. As animals in an underwater environment swim deeper, the pressure they experience will be considerably higher than at the surface and will cause the air in body cavities to compress and increase in density, which in turn affects the production and reception of sounds. *See* ATMOSPHERIC ACOUSTICS; HYDROSTATICS; SOUND; UNDERWATER SOUND.

The hearing sensitivity of animals is determined by careful laboratory psychophysical experiments in which the subjects are trained to respond to an acoustic stimulus of varying frequency and amplitude. Intensity rather than pressure of the acoustic stimulus must be used to compare the hearing sensitivity of terrestrial and aquatic animals, because of the difference in the acoustic impedances of the respective media. A unit of acoustic pressure conveys different amounts of energy in the two media. Dolphins have the highest upper-frequency limit of hearing and have the most acute hearing sensitivity of all animals. Fishes tend to have a limited frequency range of hearing. *See* AUDIOMETRY; EAR (VERTEBRATE); PHONORECEPTION; PSYCHOACOUSTICS.

Animals use a wide variety of different sounds in different frequency ranges and for different purposes. Sounds can be very short events lasting less than 100 microseconds for some echolocating dolphins or can be very long duration events lasting several hours for singing humpback whales. The sounds can be infrasonic, with frequencies below the human hearing capability, or ultrasonic, with frequencies above the human hearing range. Most terrestrial animals, including mammals, birds, amphibians, and reptiles, produce sounds that are within the human frequency range, or sonic sounds. Many aquatic animals, including fishes and marine mammals, also produce sounds that are in the sonic range; however, some marine mammals also produce sounds that can extend either beyond (ultrasonic) or below (infrasonic) the human frequency range. Dolphins can produce very high frequency echolocation sounds having frequency components up to 200 kHz. *See* DECAPODA (CRUSTACEA); INFRASOUND; ULTRASONICS.

The mechanism of sound production in most animals is well known. Mammals and birds typically use their lungs as a source of air that is forced through a small orifice such as a larynx in mammals or a syrinx in birds. Amphibians such as frogs also use their lungs to force air through a larynx; however, the acoustic energy is coupled to an expandable air sac in the throats, which resonates to amplify sounds. Insects and crustaceans strike or rub certain appendages against other parts of their bodies. Some fishes produce sounds by inflating and compressing their swim bladder, causing vibrations in the water, while others may use the swim bladder as a resonator of sounds produced by stridulation between bony parts of their bodies.

The sound production mechanism of the odontocete, or toothed, whales baffled researchers for many years. In 1997, T. Cranford demonstrated that dolphins produce sounds with a pair of phonic lips previously called the monkey lips-dorsal bursae complex that are embedded in the nasal system. The simultaneous manipulation of these phonic lips and the production of echolocation clicks and whistles have been documented. Sperm whales probably use a similar set of phonic lips of the museau de singe, which are located in the forward portion of the animal's forehead. The exact mechanism of sound production by baleen whales is still a mystery.

Careful studies in the field are often required in order to determine the function and meaning of specific vocalizations to conspecifics and to other species. Birds sing to mark territory and to attract potential mating partners. Some nonhuman primates use specific sounds as alarm calls indicating whether the threat is a predator bird or a mammal. Male frogs use their sound to attract females for mating. Dolphins and bats emit ultrasonic echolocation signals to detect and localize prey. Pinniped and dolphin mother-calf pairs use specific acoustic signals for identification purposes. Elephants use their infrasonic calls to maintain social contact and to coordinate family group movements. *See* ECHOLOCATION.

The meaning of many animal sounds still escapes human understanding. The infrasonic sounds of blue whales can propagate over hundreds of kilometers if trapped in a surface duct or in the deep sound channel of the ocean. Unfortunately, the aquatic environment has made it very difficult to study the behavior of blue whales and to determine how they respond to different sounds. Certain dolphins such as spinner and spotted dolphins often are found in groupings of up to several hundred animals. These dolphins may be swimming in the same direction but are spread out over hundreds of meters. Yet, some of these schools have been observed to suddenly change their course abruptly as a response to some kind of signal, probably acoustic in nature. However, the difficulty in conducting research in the ocean has made it next to impossible to determine the specific acoustic signals used in group coordination. Humpback whales have been known to "sing" for hours on end, yet there is no consensus on the role of the songs in their natural history. *See* ANIMAL COMMUNICATION. [W.W.L.A.]

Bioarcheology The study of skeletal remains from archeological sites by biological (or physical) anthropologists. Bioarcheology differs in several ways from traditional skeletal research. Previous work focused on individual case studies (for example, individuals with identifiable diseases), or on typological analyses of cranial form, the object of which was to classify collections into racial or ethnic groups. Bioarcheology looks at populations rather than individuals, often highlighting variation within groups as much as differences between them. In addition, it considers the interaction of biology with human culture and behavior, and the effects of the latter upon skeletal morphology or form. Technological advances in computers and methodology have opened up new fields of study, such as biomechanics and paleonutrition, while revolutionizing older interests, such as biological distance studies. *See* ANTHROPOLOGY; ARCHEOLOGY; BONE; PHYSICAL ANTHROPOLOGY.

The field of bioarcheology is built in large part upon the traditional study of human disease in prehistoric remains, or paleopathology. Bioarcheologists are more interested in the effect of disease on populations, and interrelationships between disease and social systems. For example, infectious diseases increase in frequency in agricultural communities due to a variety of factors, including population growth, increasing sedentism, and an expansion in trade contacts with other societies. *See* DISEASE; PATHOLOGY.

The study of prehistoric diet has been revolutionized by work on bone chemistry and isotopic variation. Essentially, this research focuses on the fact that some dietary ingredients leave a chemical or isotopic trace in bones. For example, carbon isotope analyses of bone indicate when maize (corn), the main component of historic Native American diets, was introduced into North America. Such studies have also uncovered differences in the level of reliance on maize within populations based on sex and status, and between societies.

Traumatic injuries and osteoarthritis (arthritis in the bony sections of joints) are extremely common in prehistoric populations. Bioarcheologists can identify examples of violent death in prehistory. Studies indicate that violence escalated in late prehistory in North America as societies became increasingly agricultural and population size rose. Osteoarthritis is common throughout prehistory and may be tied in part to levels of activities, although it is also caused by other factors, including injuries and infections of the joints. *See* ARTHRITIS.

An area of research that has only recently become feasible through computer-aided technology is biomechanics. Like muscles, bones respond to higher-than-normal physical activities by increasing in mass, and can therefore indicate the usual level of physical exertion during life. Biomechanical studies have shown that physical activities changed as populations adopted agriculture, although the nature of the change varies in different regions of North America. *See* BIOMECHANICS.

With more sophisticated computer technology, biodistance studies, which seek to establish genetic relationships between populations, are increasingly complex. However, biodistance studies can be used productively to answer questions about the evolution of regional societies, as well as to illuminate such practices as residence patterns. [P.S.Br.]

Bioassay A method for the quantitation of the effects on a biological system by its exposure to a substance, as well as the quantitation of the concentration of a substance by some observable effect on a biological system. The biological material in which the effect is measured can range from subcellular components and microorganisms to groups of animals. The substance can be stimulatory, such as an ion increasing taxis behavior in certain protozoans, or inhibitory, such as an antibiotic for bacterial growth. Bioassays are most frequently used when there is a number of steps, usually poorly understood, between the substance and the behavior observed, or when the substance is a complex mixture of materials and it is not clear what the active components are. Bioassays can be replaced, in time, by either a more direct measure of concentration of the active principle, such as an analytical method (for example, mass spectrometry, high-pressure liquid chromatography, radioimmunoassay), or a more direct measurement of the effect, such as binding to a surface receptor in the case of many drugs, as the substance or its mechanism of action is better characterized.

Assays to quantitate the effects of an exposure model the effect of a substance in the real world. Complex biological responses can be estimated by laboratory culture tests, which use, for example, bacteria or cells cultured in a petri dish (usually to model an effect either on the organism of interest, such as bacteria, or on some basic cellular function); by tissue or organ culture, which isolates pieces of tissue or whole organs in a petri dish (usually to model organ function); or in whole animals (usually to model complex organismic relationships). [R.W.Har.; A.Tu.]

Biocalorimetry The measurement of the energetics of biological processes such as biochemical reactions, association of ligands to biological macromolecules, folding of proteins into their native conformations, phase transitions in biomembranes, and enzymatic reactions, among others. Two types of instruments have been developed to study these processes: differential scanning calorimeters and isothermal titration calorimeters. Differential scanning calorimeters measure the heat capacity at constant pressure of a sample as a continuous function of temperature. Isothermal titration calorimeters measure directly the energetics (through heat effects) associated with biochemical reactions or processes occurring at constant temperatures. In all cases, the uniqueness of calorimetry resides in its capability to measure directly and in a model-independent fashion the heat energy associated with a process. *See* CALORIMETRY; THERMOCHEMISTRY; TITRATION. [E.Fr.]

Biochemical engineering The application of engineering principles to conceive, design, develop, operate, or use processes and products based on biological and biochemical phenomena. Biochemical engineering, a subset of chemical engineering, impacts a broad range of industries, including health care, agriculture, food, enzymes, chemicals, waste treatment, and energy. Historically, biochemical engineering has been distinguished from biomedical engineering by its emphasis on biochemistry and microbiology and by the lack of a health care focus. However, now there is increasing participation of biochemical engineers in the direct development of health care products. Biochemical engineering has been central to the development of the biotechnology industry, especially with the need to generate prospective products (often using genetically engineered microorganisms) on scales sufficient for testing, regulatory evaluation, and subsequent sale. *See* BIOTECHNOLOGY.

In the discipline's initial stages, biochemical engineers were chiefly concerned with optimizing the growth of microorganisms under aerobic conditions at scales of up to thousands of liters. While the scope of the discipline has expanded, this focus remains. Often the aim is the development of an economical process to maximize biomass production (and hence a particular chemical, biochemical, or protein), taking into consideration raw-material and other operating costs. The elemental constituents of biomass (carbon, nitrogen, oxygen, hydrogen, and to a lesser extent phosphorus, sulfur, mineral salts, and trace amounts of certain metals) are added to the biological reactor (often called a fermentor) and consumed by the bacteria as they reproduce and carry out metabolic processes. Sufficient amounts of oxygen (usually supplied as sterile air) are added to the fermentor in such a way as to promote its availability to the growing culture. *See* BIOMASS; CHEMICAL REACTOR; FERMENTATION.

In some situations, microorganisms may be cultivated whose activity is adversely affected by the presence of dissolved oxygen. Anaerobic cultures are typical of fermentations in which organic acids and solvents are produced; these systems are usually characterized by slower growth rates and lower biomass yields. The largest application of anaerobic microorganisms is in waste treatment, where anaerobic digesters containing mixed communities of anaerobic microorganisms are used to reduce the quantity of solids in industrial and municipal wastes.

While the operation and optimization of large-scale, aerobic cultures of microorganisms is still of major importance in biochemical engineering, the capability of cultivating a wide range of cell types has become important also. Biochemical engineers are often involved in the culture of plant cells, insect cells, and mammalian cells, as well as the genetically engineered versions of these cell types. Metabolic engineering uses the tools of molecular genetics, often coupled with quantitative models of metabolic pathways and bioreactor operation, to optimize cellular function for the production of specific metabolites and proteins. Enzyme engineering focuses on the identification, design, and use of biocatalysts for the production of useful chemicals and biochemicals. Tissue engineering involves material, biochemical, and medical aspects related to the transplant of living cells to treat diseases. Biochemical engineers are also actively involved in many aspects of bioremediation, immunotechnology, vaccine development, and the use of cells and enzymes capable of functioning in extreme environments. [R.M.Ke.]

Biochemistry The study of the substances and chemical processes which occur in living organisms. It includes the identification and quantitative determination of the substances, studies of their structure, determining how they are synthesized and degraded in organisms, and elucidating their role in the operation of the organism.

Substances studied in biochemistry include carbohydrates (including simple sugars and large polysaccharides), proteins (such as enzymes), ribonucleic acid (RNA) and deoxyribonucleic acid (DNA), lipids, minerals, vitamins, and hormones. *See* CARBOHYDRATE; DEOXYRIBONUCLEIC ACID (DNA); ENZYME; HORMONE; LIPID; PROTEIN; RIBONUCLEIC ACID (RNA); VITAMIN.

Metabolism and energy production. Many of the chemical steps involved in the biological breakdown of sugars, lipids (fats), and amino acids are known. It is well established that living organisms capture the energy liberated from these reactions by forming a high-energy compound, adenosine triphosphate

(ATP). In the absence of oxygen, some organisms and tissues derive ATP from an incomplete breakdown of glucose, degrading the sugar to an alcohol or an acid in the process. In the presence of oxygen, many organisms degrade glucose and other foodstuff to carbon dioxide and water, producing ATP in a process known as oxidative phosphorylation. *See* BIOLOGICAL OXIDATION; CARBOHYDRATE METABOLISM; LIPID METABOLISM.

Structure and function studies. The relationship of the structure of enzymes to their catalytic activity is becoming increasingly clear. It is now possible to visualize atoms and groups of atoms in some enzymes by x-ray crystallography. Some enzyme-catalyzed processes can now be described in terms of the spatial arrangement of the groups on the enzyme surface and how these groups influence the reacting molecules to promote the reaction. It is also possible to explain how the catalytic activity of an enzyme may be increased or decreased by changes in the shape of the enzyme molecule. An important advance has been the development of an automated procedure for joining amino acids together into a predetermined sequence. This technology will permit the synthesis of slightly altered enzymes and will improve the understanding of the relationship between the structure and the function of enzymes. In addition, this procedure permits the synthesis of medically important polypeptides (short chains of amino acids) such as some hormones and antibiotics.

Molecular genetics. A subject of intensive investigation has been the explanation of genetics in molecular terms. It is now well established that genetic information is encoded in the sequence of nucleotides of DNA and that, with the exception of some viruses which utilize RNA, DNA is the ultimate repository of genetic information. The sequence of amino acids in a protein is programmed in DNA; this information is first transferred by copying the nucleotide sequence of DNA into that of messenger RNA, from which this sequence is translated into the specific sequence of amino acids of the protein. *See* GENETIC CODE; MOLECULAR BIOLOGY.

The biochemical basis for a number of genetically inherited diseases, in which the cause has been traced to the production of a defective protein, has been determined. Sickle cell anemia is a striking example; it is well established that the change of a single amino acid in hemoglobin has resulted in a serious abnormality in the properties of the hemoglobin molecule. *See* DISEASE.

Regulation. Increased understanding of the chemical events in biological processes has permitted the investigation of the regulation of these proceses. An important concept is the chemical feedback circuit: the product of a series of reactions can itself influence the rates of the reactions. For example, the reactions which lead to the production of ATP proceed vigorously when the supply of ATP within the cell is low, but they slow down markedly when ATP is plentiful. These observations can be explained, in part, by the fact that ATP molecules bind to some of the enzymes involved, changing the surface features of the enzymes sufficiently to decrease their effectiveness as catalysts. It is also possible to regulate these reactions by changing the amounts of the enzymes; the amount of an enzyme can be controlled by modulating the synthesis of its specific messenger RNA or by modulating the translation of the information of the RNA molecule into the enzyme molecule. Another level of regulation involves the interaction of cells and tissues in multicellular organisms. For instance, endocrine glands can sense certain tissue activities and appropriately secrete hormones which control these activities. The chemical events and substances involved in cellular and tissue "communication" have become subjects of much investigation.

Photosynthesis and nitrogen fixation. Two subjects of substantial interest are the processes of photosynthesis and nitrogen fixation. In photosynthesis, the chemical reactions whereby the gas carbon dioxide is converted into carbohydrate are understood, but the reactions whereby light energy is trapped and converted into the chemical energy necessary for the synthesis of carbohydrate are unclear. The process of nitrogen fixation involves the conversion of nitrogen gas into a chemical form which can be utilized for the synthesis of numerous biologically important substances; the chemical events of this process are not fully understood. *See* NITROGEN CYCLE; PHOTOSYNTHESIS. [A.S.L.H.]

Biodegradation The destruction of organic compounds by microorganisms. Microorganisms, particularly bacteria, are responsible for the decomposition of both natural and synthetic organic compounds in nature. Mineralization results in complete conversion of a compound to its inorganic mineral constituents (for example, carbon dioxide from carbon, sulfate or sulfide from organic sulfur, nitrate or ammonium from organic nitrogen, phosphate from organophosphates, or chloride from organochlorine). Since carbon comprises the greatest mass of organic compounds, mineralization can be considered in terms of CO_2 evolution. Radioactive carbon-14 (^{14}C) isotopes enable scientists to distinguish between mineralization arising from contaminants and soil organic matter. However, mineralization of any compound is never 100% because some of it (10–40% of the total amount degraded) is incorporated into the cell mass or products that become part of the amorphous soil organic matter, commonly referred to as humus. Thus, biodegradation comprises mineralization and conversion to innocuous products, namely biomass and humus. Primary biodegradation is more limited in scope and refers to the disappearance of the compound as a result of its biotransformation to another product. *See* HUMUS.

Compounds that are readily biodegradable are generally utilized as growth substrates by single microorganisms. Many of the components of petroleum products (and frequent ground-water contaminants), such as benzene, toluene, ethylbenzene, and xylene, are utilized by many genera of bacteria as sole carbon sources for growth and energy.

The process whereby compounds not utilized for growth or energy are nevertheless transformed to other products by microorganisms is referred to as cometabolism. Chlorinated aromatic hydrocarbons, such as diphenyldichloroethane (DDT) and polychlorinated biphenyls (PCBs), are among the most persistent environmental contaminants; yet they are cometabolized by several genera of bacteria, notably *Pseudomonas*, *Alcaligenes*, *Rhodococcus*, *Acinetobacter*, *Arthrobacter*, and *Corynebacterium*. Cometabolism is caused by enzymes that have very broad substrate specificity. *See* BACTERIAL GROWTH; POLYCHLORINATED BIPHENYLS.

The use of microorganisms to remediate the environment of contaminants is referred to as bioremediation. This process is most successful in contained systems such as surface soil or ground water where nutrients, mainly inorganic nitrogen and phosphorus, are added to enhance growth of microorganisms and thereby increase the rate of biodegradation. The process has little, if any, applicability to a large open system such as a bay or lake because the nutrient level (that is, the microbial density) is too low to effect substantive biodegradation and the system's size and distribution preclude addition of nutrients.

Remediation of petroleum products from ground waters is harder to achieve than surface soil because of the greater difficulty in distributing the nutrients throughout the zone of contamination, and because of oxygen (O_2) limitations. [D.D.Fo.]

Biodiversity The variety of all living things; a contraction of biological diversity. Biodiversity can be measured on many biological levels ranging from genetic diversity within a species to the variety of ecosystems on Earth, but the term most commonly refers to the number of different species in a defined area.

Recent estimates of the total number of species range from 7 to 20 million, of which only about 1.75 million species have been scientifically described. The best-studied groups include plants and vertebrates (phylum Chordata), whereas poorly

Numbers of extant species for selected taxonomic groups

Kingdom	Phylum	Number of species described	Estimated number of species	Percent described
Protista		100,000	250,000	40.0
Fungi	Eumycota	80,000	1,500,000	5.3
Plantae	Bryophyta	14,000	30,000	46.7
	Tracheophyta	250,000	500,000	50.0
Animalia	Nematoda	20,000	1,000,000	2.0
	Arthropoda	1,250,000	20,000,000	5.0
	Mollusca	100,000	200,000	50.0
	Chordata	40,000	50,000	80.0

*With permission, modified from G. K. Meffe and C. R. Carroll, *Principles of Conservation Biology*, 1997.

described groups include fungi, nematodes, and arthropods (see table). Species that live in the ocean and in soils remain poorly known. For most groups of species, there is a gradient of increasing diversity from the Poles to the Equator, and the vast majority of species are concentrated in the tropical and subtropical regions.

Human activities, such as direct harvesting of species, introduction of alien species, habitat destruction, and various forms of habitat degradation (including environmental pollution), have caused dramatic losses of biodiversity; current extinction rates are estimated to be 100–1000 times higher than prehuman extinction rates.

Some measure of biodiversity is responsible for providing essential functions and services that directly improve human life. For example, many medicines, clothing fibers, and industrial products and the vast majority of foods are derived from naturally occurring species. In addition, species are the key working parts of natural ecosystems. They are responsible for maintenance of the gaseous composition of the atmosphere, regulation of the global climate, generation and maintenance of soils, recycling of nutrients and waste products, and biological control of pest species. Ecosystems surely would not function if all species were lost, although it is unclear just how many species are necessary for an ecosystem to function properly. [M.A.Ma.]

Bioelectromagnetics The study of the interactions of electromagnetic energy (usually referring to frequencies below those of visible light with biological systems. This includes both experimental and theoretical approaches to describing and explaining biological effects. Diagnostic and therapeutic uses of electromagnetic fields are also included in bioelectromagnetics.

The induction of cataracts has been associated with exposure to intense microwave fields. Although heating the lens of the eye with electromagnetic energy can cause cataracts, the threshold for cataract production is so high that, for many species, if the whole animal were exposed to the cataractogenic level of radiation, it would die before cataracts were produced. In 1961 it was reported that people can "hear" pulsed microwaves at very low averaged power densities (50 microwatts/cm^2). It is now generally accepted that the perceived sound is caused by elastic-stress waves which are created by rapid thermal expansion of the tissue that is absorbing microwaves. There are reports that microwave irradiation at very low intensities can affect behavior, the central nervous system, and the immune system, but many of these reports are controversial. Most biological effects of microwaves can be explained by the response of the animal to the conversion of electromagnetic energy into thermal energy within the animal. However, a few experiments yield results that are not readily explained by changes of temperature.

In an industrial society, an appreciation of the effects of stationary electric and magnetic fields, and of extremely low-frequency fields are important because of the ubiquitous nature of electricity. The possibility of hazard from occupational exposure to 50- or 60-Hz electric and magnetic fields has not been documented and is a subject of debate. Epidemiological studies have been undertaken to determine the health implications for workers and the general public exposed to these possible hazards. In addition, laboratory experiments have been designed to study the interactions of electric and magnetic fields with biological systems. *See* BIOMAGNETISM; MICROWAVE; RADIATION BIOLOGY.

The most common mechanism by which electromagnetic fields interact with biological systems is by inducing motion in polar molecules. Water and other polar molecules experience a torque when an electric field is applied. The excitation of water, or other polar molecules, in the form of increased rotational energy is manifest as increased kinetic energy (elevation of temperature), but molecular structure is essentially unaltered if elevations are not excessive. Electromagnetic energy absorbed by biological material can be converted into stress by thermal expansion. This phenomenon is caused by a rapid rise of temperature either deep within or at the surface of the material, and thus creates a time-varying thermal expansion that generates elastic stress waves in the tissue.

The therapeutic heating of tissue, diathermy, has been used by physicians for many years. Short-wave diathermy provides deeper, more uniform heating than does diathermy at higher frequencies. High-intensity radio-frequency fields have been used to produce hyperthermia in cancer patients. The development of bone tissue (osteogenesis) can be stimulated electrically either with implanted electrodes or by inductive coupling through the skin. This therapy has been used successfully to join fractures that have not healed by other means. Electromagnetic fields were first used for medical diagnosis in 1926 when the electrical resistance across the chest cavity was used to diagnose pulmonary edema (water in the lungs). Another diagnostic tool, magnetic resonance imaging, uses the behavior of protons, or other nuclei, in an electromagnetic field to obtain images of organs in the body. Internally generated fields associated with nerve activity (electroencephalography) and with muscle activity (electrocardiography, magnetocardiography) are used to monitor normal body functions. There may be other uses of electric currents or fields in growth differentiation or development which have not yet been explored. Electric fields now play a role in biotechnology. Intense, pulsed electric fields (about 60,000 V/m) produce short-lived pores in cell membranes by causing a reversible rearrangement of the protein and lipid components. This permits the entrance of deoxyribonucleic acid (DNA) fragments or other large molecules into the cell (electroporation). The fusion of cells using electric fields (electrofusion) is easy to control and provides high yields. *See* CARDIAC ELECTROPHYSIOLOGY; ELECTROENCEPHALOGRAPHY; ELECTROMAGNETIC RADIATION; ELECTROMYOGRAPHY; MEDICAL IMAGING; RADIOLOGY; THERMOTHERAPY. [E.P.]

Bioelectronics A discipline in which biotechnology and electronics are joined in at least three areas of research and development: biosensors, molecular electronics, and neuronal interfaces. Some workers in the field include so-called biochips and biocomputers in this area of carbon-based information technology. They suggest that biological molecules might be incorporated into self-structuring bioinformatic systems which display novel information processing and pattern recognition capabilities, but these applications—although technically possible—are speculative.

Of the three disciplines—biosensors, molecular electronics, and neuronal interfaces—the most mature is the burgeoning area of biosensors. The term biosensor is used to describe two sometimes very different classes of analytical devices—those that measure biological analytes and those that exploit biological recognition as part of the sensing mechanism—although it is the latter concept which truly captures the spirit of bioelectronics. Molecular electronics is a term coined to describe the exploitation of biological molecules in the fabrication of electronic materials with novel electronic, optical, or magnetic properties. Finally, and more speculatively, bioelectronics incorporates the development of functional neuronal interfaces which permit contiguity between neural tissue and conventional solid-state and computing technology in order to achieve applications such as aural and visual prostheses, the restoration of movement to the paralyzed, and even expansion of the human faculties of memory and intelligence. The common feature of all of this research activity is the close juxtaposition of biologically active molecules, cells, and tissues with conventional electronic systems for advanced applications in analytical science, electronic materials, device fabrication, and neural prostheses. [C.R.Lo.]

Biofilm An adhesive substance, the glycocalyx, and the bacterial community which it envelops at the interface of a liquid and a surface. When a liquid is in contact with an inert surface, any bacteria within the liquid are attracted to the surface and adhere to it. In this process the bacteria produce the glycocalyx. The bacterial inhabitants within this microenvironment benefit as the biofilm concentrates nutrients from the liquid phase. However, these activities may damage the surface, impair its efficiency, or develop within the biofilm a pathogenic community that may damage the associated environment. Microbial fouling or biofouling are the terms applied to these actual or potentially undesirable consequences.

Microbial fouling affects a large variety of surfaces under various conditions. Microbial biofilms may form wherever bacteria can survive; familiar examples are dental plaque and tooth decay. Dental plaque is an accumulation of bacteria, mainly streptococci, from saliva. The process of tooth decay begins with the bacteria colonizing fissures in and contact points between the teeth. Dietary sucrose is utilized by the bacteria to form extracellular glucans that make up the glycocalyx and assist adhesion to the tooth. Within this microbial biofilm or plaque the metabolic by-products of the bacterial inhabitants are trapped; these include acids that destroy the tooth enamel, dentin, or cementum. [H.L.Sc.; J.W.C.]

Biogeochemistry The study of the cycling of chemicals between organisms and the surface environment of the Earth. The chemicals either can be taken up by organisms and used for growth and synthesis of living matter or can be processed to obtain energy. The chemical composition of plants and animals indicates which elements, known as nutrient elements, are necessary for life. The most abundant nutrient elements, carbon (C), hydrogen (H), and oxygen (O), supplied by the environment in the form of carbon dioxide (CO_2) and water (H_2O), are usually present in excess. The other nutrient elements, which are also needed for growth, may sometimes be in short supply; in this case they are referred to as limiting nutrients. The two most commonly recognized limiting nutrients are nitrogen (N) and phosphorus (P).

Biogeochemistry is concerned with both the biological uptake and release of nutrients, and the transformation of the chemical state of these biologically active substances, usually by means of energy-supplying oxidation-reduction reactions, at the Earth's surface. Emphasis is on how the activities of organisms affect the chemical composition of natural waters, the atmosphere, rocks, soils, and sediments. Thus, biogeochemistry is complementary to the science of ecology, which includes a concern with how the chemical composition of the atmosphere, waters, and so forth affects life. *See* Ecology; Oxidation-reduction.

The two major processes of biogeochemistry are photosynthesis and respiration. Photosynthesis involves the uptake, under the influence of sunlight, of carbon dioxide, water, and other nutrients by plants to form organic matter and oxygen. Respiration is the reverse of photosynthesis and involves the oxidation and breakdown of organic matter and the return of nitrogen, phosphorus, and other elements, as well as carbon dioxide and water, to the environment. *See* Photosynthesis; Plant respiration.

Biogeochemistry is usually studied in terms of biogeochemical cycles of individual elements. There are short-term cycles ranging from days to centuries and long-term (geological) cycles ranging from thousands to millions of years.

There has been increasing interest in biogeochemistry because the human influence on short-term biogeochemical cycling has become evident. Perhaps the best-known example is the changes in the biogeochemical cycling of carbon due to the burning of fossil fuels and the cutting and burning of tropical rainforests. The cycles of nitrogen and phosphorus have been altered because of the use of fertilizer and the addition of wastes to lakes, rivers, estuaries, and the oceans. Acid rain, which results from the addition of sulfur and nitrogen compounds to the atmosphere by humans, affects biological systems in certain areas.

Carbon cycle. Carbon is the basic biogeochemical element. The atmosphere contains carbon in the form of carbon dioxide gas. There is a large annual flux of atmospheric carbon dioxide to and from forests and terrestrial biota, amounting to nearly 7% of total atmospheric carbon dioxide. This is because carbon dioxide is used by plants to produce organic matter through photosynthesis, and when the organic matter is broken down through respiration, carbon dioxide is released to the atmosphere. The concentration of atmospheric carbon dioxide shows a yearly oscillation because there is a strong seasonal annual cycle of photosynthesis and respiration in the Northern Hemisphere.

Photosynthesis and respiration in the carbon cycle can be represented by the reaction below. Breakdown of organic matter via respiration is accomplished mainly by bacteria that live in soils, sediments, and natural waters. There is a very large reservoir of terrestrial carbon in carbonate rocks, which contain calcium carbonate ($CaCO_3$), and in rocks such as shales which contain organic carbon. Major exchange of carbon between rocks and the atmosphere is very slow, on the scale of thousands to millions of years, compared to exchange between plants and the atmosphere, which can even be seasonal. *See* Microbial ecology; Soil microbiology.

$$CO_2 + H_2O \underset{\text{respiration}}{\overset{\text{photosynthesis}}{\rightleftharpoons}} CH_2O + O_2$$

The oceans taken as a whole represent a major reservoir of carbon. Carbon in the oceans occurs primarily as dissolved $(HCO_3)^-$ and to a lesser extent as dissolved carbon dioxide gas and carbonate ion $[(CO_3)^{2-}]$. The well-mixed surface ocean (the top 250 ft or 75 m) rapidly exchanges carbon dioxide with the atmosphere. However, the deep oceans are cut off from the atmosphere and mix with it on a long-term time scale of about 1000–2000 years. Most of the biological activity in the oceans occurs in the surface (or shallow) water where there is light and photosynthesis can occur. *See* Maritime meteorology.

The main biological process in seawater is photosynthetic production of organic matter by phytoplankton. Some of this organic matter is eaten by animals, which are in turn eaten by larger animals farther up in the food chain. Almost all of the organic matter along the food chain is ultimately broken down by bacterial respiration, which occurs primarily in shallow water, and the carbon dioxide is quickly recycled to the atmosphere. *See* Food web; Nearshore processes; Phytoplankton; Seawater.

Another major biological process is the secretion of shells and other hard structures by marine organisms. A biogeochemical cycle of calcium and bicarbonate exists within the oceans, linking the deep and shallow water areas. Bottom dwellers in shallow water, such as corals, mollusks, and algae, provide calcium carbonate skeletal debris. Since the shallow waters are saturated with respect to calcium carbonate, this debris accumulates on the bottom and is buried, providing the minerals that form carbonate rocks such as limestone and dolomite. Calcium carbonate is also derived from the shells of organisms inhabiting surface waters of the deep ocean; these are tiny, floating plankton such as foraminiferans, pteropods, and coccoliths. Much of the calcium carbonate from this source dissolves as it sinks into the deeper ocean waters, which are undersaturated with respect to calcium carbonate. The undissolved calcium carbonate accumulates on the bottom to form deep-sea limestone. The calcium and the bicarbonate ions [Ca^{2+} and $(HCO_3)^-$] dissolved in the deep ocean water eventually are carried to surface and shallow water, where they are removed by planktonic and bottom-dwelling organisms to form their skeletons. *See* CARBONATE MINERALS; LIMESTONE.

The long-term biogeochemical carbon cycle occurs over millions of years when the calcium carbonate and organic matter that are buried in sediments are returned to the Earth's surface. There, weathering occurs which involves the reaction of oxygen with sedimentary organic matter with the release of carbon dioxide and water (analogous to respiration), and the reaction of water and carbon dioxide with carbonate rocks with the release of calcium and bicarbonate ions. *See* WEATHERING PROCESSES.

Fossil fuels (coal and oil) represent a large reservoir of carbon. Burning of fossil fuels releases carbon dioxide to the atmosphere, and an increase in the atmospheric concentration of carbon dioxide has been observed since the mid-1950s. While much of the increase is attributed to fossil fuels, deforestation by humans accompanied by the decay or burning of trees is another possible contributor to the problem.

When estimates are made of the amount of fossil fuels burned from 1959 to 1980, only about 60% of the carbon dioxide released can be accounted for in the atmospheric increase in carbon dioxide. The remaining 40% is known as excess carbon dioxide. The surface oceans are an obvious candidate for storage of most of the excess carbon dioxide by the reaction of carbon dioxide with dissolved carbonate to form bicarbonate. Because the increase in bicarbonate concentration in surface waters due to excess carbon dioxide uptake would be small, it is difficult to detect whether such a change has occurred. Greater quantities of excess carbon dioxide could be stored as bicarbonate in the deeper oceans, but this process takes a long time because of the slow rate of mixing between surface and deep oceans.

An increase in atmospheric carbon dioxide is of concern because of the greenhouse effect. The carbon dioxide traps heat in the atmosphere; notable increases in atmospheric carbon dioxide should cause an increase in the Earth's surface temperature by as much as several degrees. This temperature increase would be greater at the poles, and the effects could include melting of polar ice, a rise in sea level, and changes in rainfall distribution, with droughts in interior continental areas such as the Great Plains of the United States. *See* DROUGHT; GREENHOUSE EFFECT.

Nitrogen cycle. Nitrogen is dominantly a biogenic element and has no important mineral forms. It is a major atmospheric constituent with a number of gaseous forms, including molecular nitrogen gas (N_2), nitrogen dioxide (NO_2), nitric oxide (NO), ammonia (NH_3), and nitrous oxide (N_2O). As an essential component of plant and animal matter, it is extensively involved in biogeochemical cycling. On a global basis, the nitrogen cycle is greatly affected by human activities.

Nitrogen gas (N_2) makes up 80% of the atmosphere by volume; however, nitrogen is unreactive in this form. In order to be available for biogeochemical cycling by organisms, nitrogen gas must be fixed, that is, combined with oxygen, carbon, or hydrogen. There are three major sources of terrestrial fixed nitrogen: biological nitrogen fixation by plants, nitrogen fertilizer application, and rain and particulate dry deposition of previously fixed nitrogen. Biological fixation occurs in plants such as legumes (peas and beans) and lichens in trees, which incorporate nitrogen from the atmosphere into their living matter; about 30% of worldwide biological fixation is due to human cultivation of these plants. Nitrogen fertilizers contain industrially fixed nitrogen as both nitrate and ammonium. *See* FERTILIZER.

Fixed nitrogen in rain is in the forms of nitrate [$(NO_3)^-$] and ammonium [$(NH_4)^+$] ions. Major sources of nitrate, which is derived from gaseous atmospheric nitrogen dioxide (and nitric oxide), include (in order of importance) combustion of fossil fuel, especially by automobiles; forest fires (mostly caused by humans); and lightning. Nitrate in rain, in addition to providing soluble fixed nitrogen for photosynthesis, contributes nitric acid (HNO_3), a major component of acid rain. Sources of ammonium, which is derived from atmospheric ammonia gas (NH_3), include animal and human wastes, soil loss from decomposition of organic matter, and fertilizer release.

The basic land nitrogen cycle involves the photosynthetic conversion of the nitrate and ammonium ions dissolved in soil water into plant organic material. Once formed, the organic matter may be stored or broken down. Bacterial decomposition of organic matter (ammonification) produces soluble ammonium ion which can then be either taken up again in photosynthesis, released to the atmosphere as ammonia gas, or oxidized by bacteria to nitrate ion (nitrification).

Nitrate ion is also soluble, and may be used in photosynthesis. However, part of the nitrate may undergo reduction (denitrification) by soil bacteria to nitrogen gas or to nitrous oxide which are then lost to the atmosphere. Compared to the land carbon cycle, the land nitrogen cycle is considerably more complex, and because of the large input of fixed nitrogen by humans, it is possible that nitrogen is building up on land. However, this is difficult to determine since the amount of nitrogen gas recycled to the atmosphere is not known and any changes in the atmospheric nitrogen concentration would be too small to detect. *See* NITROGEN CYCLE.

The oceans are another major site of nitrogen cycling: the amount of nitrogen cycled biogenically, through net primary photosynthetic production, is about 13 times that on land. The main links between the terrestrial and the oceanic nitrogen cycles are the atmosphere and rivers. Nitrogen gases carried in the atmosphere eventually fall as dissolved inorganic (mainly nitrate) and organic nitrogen and particulate organic nitrogen in rain on the oceans. The flux of river nitrogen lost from the land is only about 9% of the total nitrogen recycled biogeochemically on land each year and only about 25% of the terrestrial nitrogen flux from the biosphere to the atmosphere.

River nitrogen is an important nitrogen source to the oceans; however, the greatest amount of nitrogen going into ocean surface waters comes from the upwelling of deeper waters, which are enriched in dissolved nitrate from organic recycling at depth. Dissolved nitrate is used extensively for photosynthesis by marine organisms, mainly plankton. Bacterial decomposition of the organic matter formed in photosynthesis results in the release of dissolved ammonium, some of which is used directly in photosynthesis. However, most undergoes nitrification to form nitrate, and much of the nitrate may undergo denitrification to nitrogen gas which is released to the atmosphere. A small amount of organic-matter nitrogen is buried in ocean sediments, but this accounts for a very small amount of the nitrogen recycled each year. There are no important inorganic nitrogen minerals such as those that exist for carbon and phosphorus, and thus there is no mineral precipitation and dissolution. *See* UPWELLING.

Phosphorus cycle. Phosphorus, an important component of organic matter, is taken up and released in the form of dissolved inorganic and organic phosphate. Phosphorus differs from nitrogen and carbon in that it does not form stable atmospheric gases and therefore cannot be obtained from the atmosphere. It does form minerals, most prominently apatite (calcium phosphate), and insoluble iron (Fe) and aluminum (Al) phosphate minerals, or it is adsorbed on clay minerals. The amount of phosphorus used in photosynthesis on land is large compared to phosphorus inputs to the land. The major sources of phosphorus are weathering of rocks containing apatite and mining of phosphate rock for fertilizer and industry. A small amount comes from precipitation and dry deposition. *See* PHOSPHATE MINERALS.

Phosphorus is lost from the land principally by river transport, which amounts to only 7% of the amount of phosphorus recycled by the terrestrial biosphere; overall, the terrestrial biosphere conserves phosphorus. Humans have greatly affected terrestrial phosphorus: deforestation and agriculture have doubled the amount of phosphorus weathering; phosphorus is added to the land as fertilizers and from industrial wastes, sewage, and detergents. Thus, about 75% of the terrestrial input is anthropogenic; in fact, phosphorus may be building up on the land.

In the oceans, phosphorus occurs predominantly as dissolved orthophosphates [PO_4^{3-}, $(HPO_4)^{2-}$ and $(H_2PO_4)^{-}$]. Since it follows the same cycle as do carbon and nitrogen, dissolved orthophosphate is depleted in surface ocean waters where both photosynthesis and respiration occur, and the concentration builds up in deeper water where organic matter is decomposed by bacterial respiration. The major phosphorus input to the oceans is from rivers, with about 5% coming from rain. However, 75% of the river phosphorus load is due to anthropogenic pollutants; humans have changed the ocean balance of phosphorus. Most of the dissolved oceanic orthophosphate is derived from recycled organic matter. The output of phosphorus from the ocean is predominantly biogenic: organic phosphorus is buried in sediments; a smaller amount is removed by adsorption on volcanic iron oxides. In the geologic past, there was a much greater inorganic precipitation of phosphorite (apatite) from seawater than at present, and this has resulted in the formation of huge deposits which are now mined.

Nutrients in lakes. Biogeochemical cycling of phosphorus and nitrogen in lakes follows a pattern that is similar to oceanic cycling: there is nutrient depletion in surface waters and enrichment in deeper waters. Oxygen consumption by respiration in deep water sometimes leads to extensive oxygen depletion with adverse effects on fish and other biota. In lakes, phosphorus is usually the limiting nutrient.

Many lakes have experienced greatly increased nutrient (nitrogen and phosphorus) input due to human activities. This stimulates a destructive cycle of biological activity: very high organic productivity, a greater concentration of plankton, and more photosynthesis. The result is more organic matter falling into deep water with increased depletion of oxygen and greater accumulation of organic matter on the lake bottom. This process, eutrophication, can lead to adverse water quality and even to the filling up of small lakes with organic matter. *See* Eutrophication; Limnology.

Biogeochemical sulfur cycle. A dominant flux in the global sulfur cycle is the release of 65–70 teragrams of sulfur per year to the atmosphere from burning of fossil fuels. Sulfur contaminants in these fuels are released to the atmosphere as sulfur dioxide (SO_2) which is rapidly converted to aerosols of sulfuric acid (H_2SO_4), the primary contributor to acid rain. Forest burning results in an additional release of sulfur dioxide. Overall, the broad range of human activities contribute 75% of sulfur released into the atmosphere. Natural sulfur sources over land are predominantly the release of reduced biogenic sulfur gases [mainly hydrogen sulfide (H_2S) and dimethyl sulfide] from marine tidal flats and inland waterlogged soils and, to much lesser extent, the release of volcanic sulfur. The atmosphere does not have an appreciable reservoir of sulfur because most sulfur gases are rapidly returned (within days) to the land in rain and dry deposition. There is a small net flux of sulfur from the atmosphere over land to the atmosphere over the oceans.

Ocean water constitutes a large reservoir of dissolved sulfur in the form of sulfate ions [$(SO_4)^{2-}$]. Some of this sulfate is thrown into the oceanic atmosphere as sea salt from evaporated sea spray, but most of this is rapidly returned to the oceans. Another major sulfur source in the oceanic atmosphere is the release of oceanic biogenic sulfur gases (such as dimethyl sulfide) from the metabolic activities of oceanic organisms and organic matter decay. Marine organic matter contains a small amount of sulfur, but sulfur is not a limiting element in the oceans.

Another large flux in the sulfur cycle is the transport of dissolved sulfate in rivers. However, as much as 43% of this sulfur may be due to human activities, both from burning of fossil fuels and from fertilizers and industrial wastes. The weathering of sulfur minerals, such as pyrite (FeS_2) in shales, and the evaporite minerals, gypsum and anhydrite, make an important contribution to river sulfate. The major mechanism for removing sulfate from ocean water is the formation and burial of pyrite in oceanic sediments, primarily nearshore sediments. (The sulfur fluxes of sea salt and biogenic sulfur gases do not constitute net removal from the oceans since the sulfur is recycled to the oceans.)

Biogeochemical cycles and atmospheric oxygen. The main processes affecting atmospheric oxygen are photosynthesis and respiration; however, these processes are almost perfectly balanced against one another and, thus, do not exert a simple effect on oxygen levels. Only the very small excess of photosynthesis over respiration, manifested by the burial of organic matter in sediments, is important in raising the level of oxygen. This excess is so small, and the reservoir of oxygen so large, that if the present rate of organic carbon burial were doubled and the other rates remained constant, it would take 5–10 million years for the amount of atmospheric oxygen to double. Nevertheless, this is a relatively short time from a geological perspective. *See* Atmosphere; Atmosphere, evolution of; Biosphere; Geochemistry; Hydrosphere; Marine sediments. [E.K.B.; R.A.Ber.]

Biogeography A synthetic discipline that describes the distributions of living and fossil species of plants and animals across the Earth's surface as consequences of ecological and evolutionary processes. Biogeography overlaps and complements many biological disciplines, especially community ecology, systematics, paleontology, and evolutionary biology. *See* Zoogeography.

Based on relatively complete compilations of species within well-studied groups, such as birds and mammals, biogeographers identified six different realms within which species tend to be closely related and between which turnovers in major groups of species are observed (see table). The boundaries between biogeographic realms are less distinct than was initially thought, and the distribution of distinctive groups such as parrots, marsupials, and southern beeches (*Nothofagus* spp.) implies that modern-day biogeographic realms have been considerably mixed in the past. *See* Animal evolution; Paleobotany; Paleoecology; Paleontology; Plant evolution; Speciation.

Two patterns of species diversity have stimulated a great deal of progress in developing ecological explanations for geographic patterns of species richness. The first is that the number of species increases in a regular fashion with the size of the geographic area being considered. The second is the nearly universal observation that there are more species of plants and animals in tropical regions than in temperate and polar regions.

In order to answer questions about why there are a certain number of species in a particular geographic region, biogeography has incorporated many insights from community ecology. Species number at any particular place depends on the amount of resources available there (ultimately derived from the amount of primary productivity), the number of ways those resources can be apportioned among species, and the different kinds of ecological requirements of the species that can colonize the region. The equilibrium theory of island biogeography arose as an

Biogeographic realms

Realm	Continental areas included	Examples of distinctive or endemic taxa
Palearctic	Temperate Eurasia and northern Africa	Hynobiid salamanders
Oriental	Tropical Asia	Lower apes
Ethiopian	Sub-Saharan Africa	Great apes
Australian	Australia, New Guinea, and New Zealand	Marsupials
Nearctic	Temperate North America	Pronghorn antelope, ambystomatid salamanders
Neotropic	Subtropical Central America and South America	Hummingbirds, antbirds, marmosets

application of these insights to the distribution of species within a specified taxon across an island archipelago. This theory generated specific predictions about the relationships among island size and distance from a colonization source with the number and rate of turnover of species. Large islands are predicted to have higher equilibrium numbers of species than smaller islands; hence, the species area relationship can be predicted in principle from the ecological attributes of species. Experimental and observational studies have confirmed many predictions made by this theory. *See* ECOLOGICAL COMMUNITIES; ISLAND BIOGEOGRAPHY.

The latitudinal gradient in species richness has generated a number of explanations, none of which has been totally satisfactory. One explanation is based on the observation that species with more temperate and polar distributions tend to have larger geographic ranges than species from tropical regions. It is thought that since species with large geographic ranges tend to withstand a wider range of physical and biotic conditions, this allows them to penetrate farther into regions with more variable climates at higher latitudes. If this were true, then species with smaller geographic ranges would tend to concentrate in tropical regions where conditions are less variable. While this might be generally true, there are many examples of species living in high-latitude regions that have small geographic regions. *See* ALTITUDINAL VEGETATION ZONES.

Biogeography is entering a phase where data on the spatial patterns of abundance and distribution of species of plants and animals are being analyzed with sophisticated mathematical and technological tools. Geographic information systems and remote sensing technology have provided a way to catalog and map spatial variation in biological processes with a striking degree of detail and accuracy. These newer technologies have stimulated research on appropriate methods for modeling and analyzing biogeographic patterns. Modern techniques of spatial modeling are being applied to geographic information systems data to test mechanistic explanations for biogeographic patterns that could not have been attempted without the advent of the appropriate technology. *See* GEOGRAPHIC INFORMATION SYSTEMS. [B.A.M.]

Bioherm A lenslike to moundlike structure of strictly organic origin. This term involves two concepts: shape and organic internal composition.

The term shape denotes original topographic relief above the sea floor as well as a three-dimensional quality: crudely conical (sugar loaf–shaped) or ellipsoidal (bread loaf–shaped). Such forms are massive or unbedded, their upbuilding resulting from the very rapid rate of accretion of organic carbonate once it starts in a favorable locality. There are size limitations: bioherms a meter or so in diameter are known, and some rise 300 ft (100 m) or more above the sea floor.

The second concept, organic internal composition, not only embraces sessile, bottom-dwelling organisms forming framebuilding reefy bondstone but also includes piles of organically derived debris replete with organisms which encrust it and cement it in place. Even inorganic cement precipitated from marine and meteoric water is known to play a role in a buildup of massive, moundlike structures. When the internal material is coarse and identifiable, no problem is encountered in applying the term bioherm in its original sense. In some buildups, however, an appreciable amount of lime mud is present, and relatively few organisms are identifiable which could have secreted, bound, encrusted, or trapped carbonate mud (as in some early Carboniferous mounds). In such cases, problems arise in applying that part of the definition based on internal composition. In fact, as a field term, bioherm can hardly ever be completely diagnostic because careful petrographic study is commonly necessary for details of internal composition to be ascertained.

Bioherms may occur on shelves (where they are normally lens-shaped) or in shallow basins, often at the basin margin. In the latter position, they have been called reef knolls or pinnacle reef. *See* BIOSTROME; REEF; STROMATOLITE. [J.L.Wi.]

Bioinorganic chemistry The field at the interface between biochemistry and inorganic chemistry; also known as inorganic biochemistry or metallobiochemistry. This field involves the application of the principles of inorganic chemistry to problems of biology and biochemistry. Because most biological components are organic, that is, they involve the chemistry of carbon compounds, the combination of the prefix bio- and inorganic may appear contradictory. However, organisms require a number of other elements to carry out their basic functions. Many of these elements are present as metal ions that are involved in crucial biological processes such as respiration, metabolism, cell division, muscle contraction, nerve impulse transmission, and gene regulation. The characterization of the interactions between such metal centers and biological components is the heart of bioinorganic chemistry. *See* BIOCHEMISTRY.

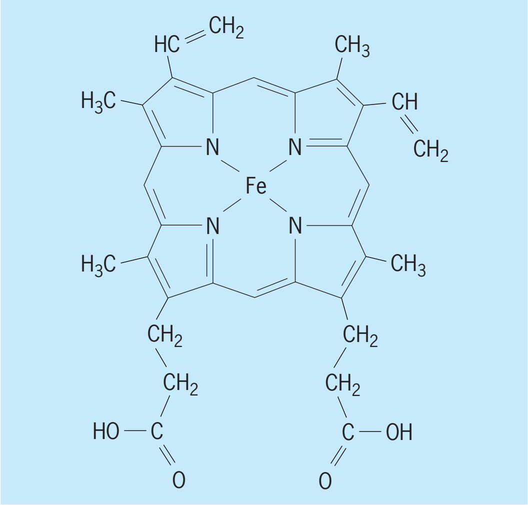
Metal ions influence biological phenomena by interacting with organic functional groups on biomolecules, forming metal complexes. From this perspective, much of bioinorganic chemistry may be considered as coordination chemistry applied to biological questions. In general, bioinorganic chemists tackle such problems by first focusing on the elucidation of the structure of the metal complex of interest and then correlating structure with function. The attainment of solutions usually requires a combination of physical, chemical, and biological approaches. Biochemistry and molecular biology are often used to provide sufficient amounts of the system for investigation. Physical approaches such as crystallography and spectroscopy are useful in defining structural properties of the metal site. Synthetic methods can be used for the design and assembly of structural, spectroscopic, and functional models of the metal site. All these approaches then converge to elucidate how such a site functions. *See* COORDINATION CHEMISTRY; CRYSTALLOGRAPHY; SPECTROSCOPY.

Low-molecular-weight compounds. A number of coordination compounds found in organisms have relatively low molecular weights. Ionophores, molecules that are able to carry ions across lipid barriers, are polydentate ligands designed to bind alkali and alkaline-earth metal ions; they span membranes and serve to transport such ions across these biological barriers. Molecular receptors known as siderophores are also polydentate ligands; they have a very high affinity for iron. *See* IONOPHORE.

Other low-molecular-weight compounds are metal-containing cofactors that interact with macromolecules to promote important biological processes. Perhaps the most widely studied of the metal ligands found in biochemistry are the porphyrins; iron protoporphyrin IX (see illustration) is an example of the all-important complex in biology known as heme. Chlorophyll and vitamin B_{12} are chemically related to the porphyrins. Magnesium is the central metal ion in chlorophyll, which is the green pigment in plants used to convert light energy into chemical energy. Cobalt is the central metal ion in vitamin B_{12}; it is converted into coenzyme B_{12} in cells, where it participates in a variety of enzymatic reactions. *See* CHLOROPHYLL; HEMOGLOBIN; PORPHYRIN.

Metalloproteins and metalloenzymes. These are metal complexes of proteins. In many cases, the metal ion is coordinated directly to functional groups on amino acid residues. In some cases, the protein contains a bound metallo-cofactor such as heme. In metalloproteins with more than one metal-binding site, the metal ions may be found in clusters. Examples include ferredoxins, which contain iron-sulfur clusters (Fe_2S_2 or Fe_4S_4), and nitrogenase, which contains both Fe_4S_4 units and a novel $MoFe_7S_8$ cluster. *See* PROTEIN.

Some metalloproteins are designed for the storage and transport of the metal ions themselves—for example, ferritin and transferrin for iron and metallothionein for zinc. Others, such as the yeast protein Atx1, act as metallochaperones that aid in the insertion of the appropriate metal ion into a metalloenzyme. Still others function as transport agents. Cytochromes and ferredoxins facilitate the transfer of electrons in various metabolic processes.



Iron complex of protoporphyrin IX, or heme.

Many metalloproteins catalyze important cellular reactions and are thus more specifically called metalloenzymes. For example, cytochrome oxidase is the respiratory enzyme in mitochondria responsible for disposing of the electrons generated by mammalian metabolism; it does so by reducing O_2 to water with the help of both heme and copper centers. In contrast, the conversion of water to O_2 is carried out in the photosynthetic apparatus by manganese centers. Other metalloenzymes are involved in the transformation of organic molecules in cells. For example, tyrosine hydroxylase (an iron enzyme) and dopamine β-hydroxylase (a copper enzyme) carry out oxidation reactions important for the biosynthesis of neurotransmitters. Alternatively, the metal center can serve as a Lewis acidic site to activate substrates for nucleophilic displacement reactions (that is, hydrolysis).

Metals in medicine. Metal complexes have also been found to be useful as therapeutic or diagnostic agents. Prominent among metal-based drugs is cisplatin, which is particularly effective in the treatment of testicular and ovarian cancers. Gold, gallium, and bismuth compounds are used for the treatment of rheumatoid arthritis, hypercalcemia, and peptic ulcers, respectively.

In clinical diagnosis, metal complexes can be used as imaging agents. The convenient half-life and radioemission properties of technetium-99 make its complexes very useful for a number of applications; by varying the ligands bound to the metal ion, diagnostic agents have been developed for imaging the heart, brain, and kidneys. Complexes of paramagnetic metal ions such as gadolinium(III), iron(III), and manganese(II) are also used as contrast agents to enhance images obtained from magnetic resonance imaging (MRI). *See* COORDINATION COMPLEXES; ORGANOMETALLIC COMPOUND. [L.Q.]

Bioleaching

The dissolution of metals from their mineral source by certain naturally occurring microorganisms. Dozens of bacterial species have been identified as having bioleaching capabilities; those of commercial interest include species of *Thiobacillus, Leptospirillum*, *Sulfobacillus*, and *Sulfolobus. Thiobacillus ferrooxidans* is by far the most widely studied and commercially useful species. It is an aerobic rod-shaped microorganism that derives its energy from the oxidation of various sulfide minerals and soluble ferrous ion (Fe^{2+}). The use of this organism is of considerable interest to the mining industry since many important metals are extracted and refined from sulfide minerals. *Thiobacillus ferrooxidans* thrives in acidic environments of pH 1–3, conditions that would be fatal to most other life forms, and can rapidly oxidize many sulfide minerals. This is of great commercial importance since most sulfide minerals are inert and oxidize very slowly at room temperature and pressure. *See* SOLUTION MINING.

A typical bioleach reaction, using pyrite as the mineral source, is shown below; here pyrite is oxidized to produce soluble ferric

$$2FeS_2 + {}^{15}/{}_2O_2 \rightarrow Fe_2(SO_4)_3 + H_2SO_4$$

sulfate [$Fe_2(SO_4)_3$] and sulfuric acid (H_2SO_4). A considerable amount of oxygen is required in this reaction; it is extracted from the air.

Commercial applications of bioleaching have been developed for the solution mining of copper and uranium from low-grade ores and waste products. Uranium minerals are often found associated with the mineral pyrite. *Thiobacillus ferrooxidans* is used to oxidize pyrite and release the uranium according to the reaction discussed above. The ferric sulfate and sulfuric acid generated in this reaction then dissolve the uranium.

The use of sulfide oxidizing bacteria to enhance gold and silver recovery from ores that are difficult to treat is considered a major development in bioleaching technology. Bioleaching has gained acceptance because it offers a potentially inexpensive and nonpolluting way to pretreat these ores. The process consists essentially of two stages. In the first step, the ore is bioleached at acidic pH to oxidize the sulfide minerals. In the second step, the oxidized gold-bearing solids are mixed with lime to raise the pH to 10–11, and then subjected to conventional cyanide leaching to dissolve the precious metals. Often, overall gold or silver recovery can be improved to over 90%. *See* GOLD METALLURGY; HYDROMETALLURGY; LEACHING; SILVER METALLURGY; SOLVENT EXTRACTION. [R.Hac.]

Biological clocks

Self-sustained circadian (approximately 24-hour) rhythms regulating daily activities such as sleep and wakefulness were described as early as 1729. By the midtwentieth century it had become clear that the period of self-sustained (free-running) oscillations usually does not match that of the Earth's rotation (environmental cycle), therefore the expression "approximately 24 hours." Moreover, the free-running period varies among species and also somewhat from one individual to another. Circadian rhythmicity is often referred to as the biological clock. *See* PHOTOPERIODISM.

Almost all organisms display circadian rhythms, indicating an evolutionary benefit, most likely facilitating adaptation to the cyclic nature of the environment. Physiological processes that occur with a circadian rhythm range from conidiation (spore production) in the bread mold, *Neurospora crassa*, and leaf movements in plants to rest-activity behavior in animals. Despite the diversity of these phenomena, the basic properties of the rhythms are the same—they synchronize to environmental cues, predominantly light, but are maintained in the absence of such cues, and they display a constant periodicity over a wide temperature range.

In humans, circadian rhythmicity is manifested in the form of sleep-wake cycles, and control of body temperature, blood pressure, heart rate, and release of many endocrine hormones. It is increasingly apparent that temporal ordering is a fundamental aspect of physiological processes. In fact, several disorders such as asthma, stroke, and myocardial infarction also tend to occur more frequently at certain times of the day. Awareness of circadian control has led to the concept of chronotherapeutics, which advocates drug delivery timed to the host's circadian rhythms.

In mammals the "master clock" controlling circadian rhythms is located in the hypothalamus, within a small group of neurons called the suprachiasmatic nucleus. Available data suggest that the suprachiasmatic nucleus transmits signals in the form of humoral factors as well as neural connections. For many years the suprachiasmatic nucleus was thought to be the only site of a clock in mammals. This was in contrast to several other vertebrates where clocks were known to be present in the pineal gland and the eye as well. However, it is now clear that the mammalian eye also contains an oscillator (something that generates an approximately 24-h cycle) whose activity can be assayed by measuring melatonin release in isolated retinas. *See* NERVOUS SYSTEM (INVERTEBRATE); NERVOUS SYSTEM (VERTEBRATE).

The genetic basis of circadian rhythms was established through the identification of altered circadian patterns that were inherited. Such mutants were found first in *Drosophila* and then in *Neurospora* in the early 1970s. In addition, there is now an impetus to identify circadian abnormalities or naturally occurring variations in human populations. For instance, the difference between people that wake up and function most effectively in the early morning hours as opposed to those who prefer to sleep late into the morning may well lie in polymorphisms within clock genes.

It is now known that a feedback loop composed of cycling gene products that influence their own synthesis underlies overt rhythms in at least three organisms (*Drosophila*, *Neurospora*, and cyanobacteria) and most likely in a fourth (mammals). Similar feedback loops have also been found in plants, although it is not clear that they are part of the clock. [A.Se.]

Biological oxidation Oxidation occurs in over one-quarter of the known chemical reactions catalyzed by enzymes in living cells. In many cases this is accomplished by the transfer of hydrogen atoms or electrons from one molecule (hydrogen or electron donor) to another (the acceptor). Reactions of this type are the major source of energy for life processes. In other cases molecular oxygen is involved directly in the oxidation reaction. In all cases the enzymic oxidation reaction involves the participation of a cofactor which may merely serve as a second substrate (known as a coenzyme) or which may be an integral part of the enzyme, acting as a carrier of reducing equivalents (known as a prosthetic group). The principal sources of reducing equivalents are the numerous specific metabolic breakdown products of the major foodstuffs: carbohydrates, fats, and proteins. Energy release from these metabolites occurs in a stepwise series of hydrogen and electron transfers to molecular oxygen. *See* COENZYME; ENZYME. [V.Ma.]

Biological productivity The amount and rate of production which occur in a given ecosystem over a given time period. It may apply to a single organism, a population, or entire communities and ecosystems. Productivity can be expressed in terms of dry matter produced per area per time (net production), or in terms of energy produced per area per time (gross production = respiration + heat losses + net production). In aquatic systems, productivity is often measured in volume instead of area. *See* BIOMASS.

Ecologists distinguish between primary productivity (by autotrophs) and secondary productivity (by heterotrophs). Plants have the ability to use the energy from sunlight to convert carbon dioxide and water into glucose and oxygen, producing biomass through photosynthesis. Primary productivity of a community is the rate at which biomass is produced per unit area by plants, expressed in either units of energy [joules/(m^2)(day)] or dry organic matter [kg/(m^2)(year)]. The following definitions are useful in calculating production: Gross primary production (GPP) is the total energy fixed by photosynthesis per unit time. Net primary production (NPP) is the gross production minus losses due to plant respiration per unit time, and it represents the actual new biomass that is available for consumption by heterotrophic organisms. Secondary production is the rate of production of biomass by heterotrophs (animals, microorganisms), which feed on plant products or other heterotrophs. *See* PHOTOSYNTHESIS.

Productivity is not spread evenly across the planet. For instance, although oceans cover two-thirds of Earth's surface, they account for only one-third of the Earth's productivity. Furthermore, the factors that limit productivity in the ocean differ from those limiting productivity on land, producing differences in geographic patterns of productivity in the two systems. In terrestrial ecosystems, productivity shows a latitudinal trend, with highest productivity in the tropics and decreasing progressively toward the Poles; but in the ocean there is no latitudinal trend, and the highest values of net primary production are found along coastal regions. [D.C.C.; E.Gry.]

Biological specificity The orderly patterns of metabolic and developmental reactions giving rise to the unique characteristics of the individual and of its species. Biological specificity is most pronounced and best understood at the cellular and molecular levels of organization, where the shapes of individual molecules allow them to selectively recognize and bind to one another. The main principle which guides this recognition is termed complementarity. Just as a hand fits perfectly into a glove, molecules which are complementary have mirror-image shapes that allow them to selectively bind to each other.

This ability of complementary molecules to specifically bind to one another plays many essential roles in living systems. For example, the transmission of specific hereditary traits from parent to offspring depends upon the ability of the individual strands of a deoxyribonucleic acid (DNA) molecule to specifically generate two new strands with complementary sequences. Similarly, metabolism, which provides organisms with both the energy and chemical building blocks needed for survival, is made possible by the ability of enzymes to specifically bind to the substrates whose interconversions they catalyze. During embryonic development, individual cells associate with each other in precise patterns to form tissues, organs, and organ systems. These ordered interactions are ultimately dependent upon the ability of individual cells to recognize and specifically bind to other cells of a similar type. *See* DEOXYRIBONUCLEIC ACID (DNA); ENZYME; METABOLISM.

In addition to binding to one another, cells can interact by releasing hormones into the bloodstream. Though all of an organism's cells are exposed to hormones circulating in the bloodstream, only a small number of target cells respond to any particular hormone. This selectivity occurs because the specific receptor molecules to which hormones bind are restricted to certain cell types. Thus each hormone exerts its effects on a few selected cell types because only those cells contain the proper receptor. Specific receptors are also involved in interactions between neurotransmitters and the cells they stimulate or inhibit, between certain types of drugs and the cells they affect, and between viruses and the cells they infect. This last phenomenon has an important influence on the susceptibility of individuals to virally transmitted diseases. *See* ENDOCRINE MECHANISMS; HORMONE.

Although most examples of biological specificity are based upon interactions occurring at the molecular level, such phenomena affect many properties manifested at the level of the whole organism. The ability of individuals to defend against infectious diseases, for example, requires the production of antibody molecules which specifically bind to bacteria and viruses. The fertilization of an egg by a sperm is facilitated by specific recognition between molecules present on the surfaces of the sperm and egg cells. Even communication between organisms can be mediated by specific chemical signals, called pheromones. Such chemical signals are utilized in trail marking by ants and bees, in territory marking by certain mammals, and as sexual attractants. Specific molecular interactions thus exert influences ranging from the replication of genes to the behavior of organisms. *See* FERTILIZATION; IMMUNOLOGY; MOLECULAR BIOLOGY; PHEROMONE. [L.J.Kl.]

Biologicals Biological products used to induce immunity to various infectious diseases or noxious substances of biological origin. The term is usually limited to immune serums, antitoxins, vaccines, and toxoids that have the effect of providing protective substances of the same general nature that a person develops naturally from having survived an infectious disease or having experienced repeated contact with a biological poison. As a matter of governmental regulatory convenience, certain therapeutic substances which have little to do with conferring immunity have been classified as biological products primarily because they are derived from human or animal sources and are tested for safety by methods similar to those used for many biological products. *See* IMMUNITY.

One major class of biologicals includes the animal and human immune serums. All animals, including humans, develop protective substances in their blood plasma during recovery from many (but not all) infectious diseases or following the injection of toxins or killed bacteria and viruses. These protective substances, called antibodies, usually are found in the immunoglobulin fraction of the plasma and are specific since they react with and neutralize only substances identical or closely similar to those that caused them to be formed. *See* ANTIBODY; IMMUNOGLOBULIN; SERUM.

Antibody-containing serum from another animal is useful in the treatment, modification, or prevention of certain diseases of humans when it is given by intramuscular or intravenous injection. The use of these preformed "borrowed" antibodies is called passive immunization, to distinguish it from active immunization, in which each person develops his or her own antibodies. Passive immunization has the advantage of providing immediate protection, but it is temporary because serum proteins from other animals and even from other humans are rapidly destroyed in the recipient.

Serums which contain antibodies active chiefly in destroying the infecting virus or bacterium are usually called antiserums or immune serums; those containing antibodies capable of neutralizing the secreted toxins of bacteria are called antitoxins. Immune serums have been prepared to neutralize the venoms of certain poisonous snakes and black widow spiders; they are called antivenins.

Because all products used for passive immunization are immune serums, or globulin fractions from such serums, they are named to indicate the diseases that they treat or prevent, the substances that they inhibit or neutralize, the animal from which they came, and whether they are whole serums or the globulin fractions thereof. Thus there is, for example, antipertussis immune rabbit serum, measles immune globulin (human), diphtheria antitoxic globulin (horse), tetanus immune globulin (human), and anti-Rh_0 (D) gamma globulin (human).

The general methods of preparation of various immune serums and antitoxins differ only in details. Horses, cows, rabbits, or humans are injected with slowly increasing amounts of either the virus, bacterium, toxin, erythrocyte, or venom as antigens against which immunity is to be developed. Injections are given over several months and the animals respond by producing relatively large amounts of specific antibody against the injected material, which are then processed to obtain the concentrated antibody-globulin fraction free of albumin and other nonantibody fractions.

The use of animal immune serums for prevention of therapy in humans has certain disadvantages. The serum proteins themselves may cause the production of specific antibodies in the recipient of the immune serum, and thus the person may become allergically sensitized to the serum protein of this animal species. *See* ANAPHYLAXIS; HYPERSENSITIVITY.

A second and less acute type of reaction resulting from the injection of animal immune serum is so-called serum sickness. About 4–10 days after the administration of serum, the patient develops fever, urticarial (hivelike) rash, and sometimes joint pains. These reactions are not ordinarily fatal.

Products used to produce active immunity constitute the other large class of biological products. They contain the actual toxins, viruses, or bacteria that cause disease, but they are modified in a manner to make them safe to administer. Because the body does not distinguish between the natural toxin or infectious agent and the same material when properly modified, immunity is produced in response to injections of these materials in a manner very similar to that which occurs during the natural disease. Vaccines are suspensions of the killed or attenuated (weakened) bacteria or viruses or fractions thereof. Toxoids are solutions of the chemically altered specific bacterial toxins which cause the major damage produced by bacterial infections. Biological products producing active immunity are usually named to indicate the disease they immunize against and the kind of substance they contain: thus typhoid vaccine, diphtheria toxoid, tetanus toxoid, measles vaccine, mumps vaccine, and poliomyelitis vaccine. *See* VACCINATION.

Another group of biological products consists of reagents used in the diagnosis of infectious diseases. These include immune serums for the serological typing and identification of pathogenic bacteria and viruses, and various antigens for the detection of antibodies in patients' serums as a means of assisting in diagnosis. In addition to these substances used in the laboratory diagnosis of disease, certain extracts of bacteria and fungi have been prepared for injection into the skin to detect allergic hypersensitivity. In certain diseases such as tuberculosis and brucellosis, the patient usually becomes hypersensitive to certain components of the infecting organism. Extracts of these organisms injected into the skin of such a person cause inflammation, whereas no reaction occurs in a person who has not been infected. These skin tests therefore are of assistance in the diagnosis of various infectious diseases. Allergenic products are administered to humans for the diagnosis, prevention, or treatment of allergies to various plant and animal substances. [L.F.S.]

Biology A natural science concerned with the study of all living organisms. Although living organisms share some unifying themes, such as their origin from the same basic cellular structure and their molecular basis of inheritance, they are diverse in many other aspects. The diversity of life leads to many divisions in biological science involved with studying all aspects of living organisms. The primary divisions of study in biology consist of zoology (animals), botany (plants), and protistology (one-celled organisms), and are aimed at examining such topics as origins, structure, function, reproduction, growth and development, behavior, and evolution of the different organisms. In addition, biologists consider how living organisms interact with each other and the environment on an individual as well as group basis. Therefore, within these divisions are many subdivisions such as molecular and cellular biology, microbiology (the study of microbes such as bacteria and viruses), taxonomy (the classification of organisms into special groups), physiology (the study of function of the organism at any level), immunology (the investigation of the immune system), genetics (the study of inheritance), and ecology and evolution (the study of the interaction of an organism with its environment and how that interaction changes over time).

The study of living organisms is an ongoing process that allows observation of the natural world and the acquisition of new knowledge. Biologists accomplish their studies through a process of inquiry known as the scientific method, which approaches a problem or question in a well-defined orderly sequence of steps so as to reach conclusions. The first step involves making systematic observations, either directly through the sense of sight, smell, taste, sound, or touch, or indirectly through the use of special equipment such as the microscope. Next, questions are asked regarding the observations. Then a hypothesis—a tentative explanation or educated guess—is formulated, and predictions about what will occur are made. At the core of any scientific study is testing of the hypothesis. Tests or experiments are designed so as to help substantiate or refute the basic assumptions set forth in the hypothesis. Therefore, experiments are repeated many times. Once they have been completed, data are collected and organized in the form of graphs or tables and the results are analyzed. Also, statistical tests may be performed to help determine whether the data are significant enough to support or disprove the hypothesis. Finally, conclusions are drawn that provide explanations or insights about the original problem. By employing the scientific method, biologists aim to be objective rather than subjective when interpreting the results of their experiments. Biology is not absolute: it is a science that deals with theories or relative truths. Thus, biological conclusions are always subject to change when new evidence is presented. As living organisms continue to evolve and change, the science of biology also will evolve. *See* ANIMAL; BOTANY; CELL BIOLOGY; ECOLOGY; GENETICS; IMMUNOLOGY; MICROBIOLOGY; PLANT; TAXONOMY; ZOOLOGY. [L.Co.]

Bioluminescence The emission of light by living organisms that is visible to other organisms. The enzymes and other proteins associated with bioluminescence have been developed and exploited as markers or reporters of other biochemical processes in biomedical research. Bioluminescence provides a unique tool for investigating and understanding numerous basic physiological processes, both cellular and organismic.

Although rare in terms of the total number of luminous species, bioluminescence is phylogenetically diverse, occurring in many different groups (see table). Luminescence is unknown in higher plants and in vertebrates above the fishes, and is also absent in several invertebrate phyla. In some phyla or taxa, a substantial proportion of the genera are luminous (for example, ctenophores, about 50%; cephalopods, greater than 50%). Commonly, all members of a luminous genus emit light, but in some cases there are both luminous and nonluminous species.

Major groups having luminous species

Group	Features of luminous displays
Bacteria	Organisms glow constantly; system is autoinduced
Fungi	Mushrooms and mycelia produce constant dim glow
Dinoflagellates	Flagellated algae flash when disturbed
Coelenterates	Jellyfish, sea pansies, and comb jellies emit flashes
Annelids	Marine worms and earthworms exude luminescence
Mollusks	Squid and clams exude luminous clouds; also have photophores
Crustacea	Shrimp, copepods, ostracodes; exude luminescence; also have photophores
Insects	Fireflies (beetles) emit flashes; flies (Diptera) glow
Echinoderms	Brittle stars emit trains of rapid flashes
Fish	Many bony and cartilaginous fish are luminous; some use symbiotic bacteria; others are self-luminous; some have photophores

Bioluminescence is most prevalent in the marine environment; it is greatest at midocean depths, where some daytime illumination penetrates. In these locations, bioluminescence may occur in over 95% of the individuals. Where high densities of luminous organisms occur, their emissions can exert a significant influence on the communities and may represent an important component in the ecology, behavior, and physiology of the latter. Above and below midocean depths, luminescence decreases to less than 10% of all individuals and species; among coastal species, less than 2% are bioluminescent. Firefly displays of bioluminescence are among the most spectacular, but bioluminescence is rare in the terrestrial environment. Other terrestrial luminous forms include millipedes, centipedes, earthworms, and snails, but the display in these is not very bright.

While not metabolically essential, light emission can confer an advantage on the organism. The light can be used in diverse ways. Most of the perceived functions of bioluminescence fall into four categories: defense, offense, communication, and dispersal to enhance propagation.

Bioluminescence does not come from or depend on light absorbed by the organism. It derives from an enzymatically catalyzed chemiluminescence, a reaction in which the energy released is transformed into light energy. One of the reaction intermediates or products is formed in an electronically excited state, which then emits a photon. *See* CHEMILUMINESCENCE.

Bioluminescence originated and evolved independently many times, and is thus not an evolutionarily conserved function. It has been estimated that present-day luminous organisms come from as many as 30 different evolutionarily distinct origins. In the different groups of organisms, the genes and proteins involved are unrelated, and it may be confusing that the substrates and enzymes, though chemically different, are all referred to as luciferin and luciferase, respectively. To be correct and specific, each should be identified with the organism.

Luminous bacteria typically emit a continuous light, usually blue-green. When strongly expressed, a single bacterium may emit 10^4 or 10^5 photons per second. A primary habitat where most species abound is in association with another (higher) organism, dead or alive, where growth and propagation occur. Luminous bacteria are ubiquitous in the oceans and can be isolated from most seawater samples. The most exotic specific associations involve specialized light organs (for example, in fish and squid) in which a pure dense culture of luminous bacteria is maintained. In teleost fishes, 11 different groups carrying such bacteria are known, an exotic example being the flashlight fish.

Of the approximately 70,000 insect genera, only about 100 are classed as luminous. But their luminescence is impressive, especially in the fireflies and their relatives. Fireflies possess ventral light organs on posterior segments; the South American railroad worm, *Phrixothrix*, has paired green lights on the abdominal segments and red head lights; while the click and fire beetles, Pyrophorini, have both running lights (dorsal) and landing lights (ventral). The dipteran cave glow worm, in a different group and probably different biochemically, exudes beaded strings of slime from its ceiling perch, serving to entrap minute flying prey, which are attracted by the light emitted by the animal. The major function of light emission in fireflies is for communication during courtship, typically involving the emission of a flash by one sex as a signal, to which the other sex responds, usually in a species-specific pattern. The time delay between the two may be a signaling feature; for example, it is precisely 2 s in some North America species. But the flashing pattern is also important in some cases, as is the kinetic character of the individual flash (duration; onset and decay kinetics).

The firefly system was the first in which the biochemistry was characterized. In 1947 it was discovered that adenosine triphosphate (ATP) functions to form a luciferyl adenylate intermediate from firefly luciferin. This then reacts with oxygen to form a cyclic luciferyl peroxy species, which breaks down to yield CO_2 and an excited state of the carbonyl product (thus emitting a photon). Luciferase catalyzes both the reaction of luciferin with ATP and the subsequent steps leading to the excited product.

Bioluminescence and chemiluminescence have come into widespread use for quantitative determinations of specific substances in biology and medicine. Luminescent tags have been developed that are as sensitive as radioactivity, and now replace radioactivity in many assays. The biochemistry of different luciferase systems is different, so many different substances can be detected. One of the first, and still widely used, assays involves the use of firefly luciferase for the detection of ATP. The amount of oxygen required for bioluminescence in luminescent bacteria is small, and therefore the reaction readily occurs. Luminous bacteria can be used as a very sensitive test for oxygen, sometimes in situations where no other method is applicable. An oxygen electrode incorporating luminous bacteria has been developed.

Luciferases have also been exploited as reporter genes for many different purposes. Analytically, such systems are virtually unique in that they are noninvasive and nondestructive: the relevant activity can be measured as light emission in the intact cell and in the same cell over the course of time. Examples of the use of luciferase genes are the expression of firely and bacterial luciferases under the control of circadian promoters; and the use of coelenterate luciferase expressed transgenically (in other organisms) to monitor calcium changes in living cells over time. Green fluorescent protein is widely used as a reporter gene for monitoring the expression of some other gene under study, and for how the expression may differ, for example at different stages of development or as the consequence of some experimental procedure. [J.W.H.]

Biomagnetism The production of a magnetic field by a living object. The living object presently most studied is the human body, for two purposes: to find new techniques for medical diagnosis, and to gain information about normal physiology. Smaller organisms studied include birds, fishes, and objects as small as bacteria; many scientists believe that biomagnetics is involved in the ability of these creatures to navigate. The body produces magnetic fields in two main ways: by electric currents and by ferromagnetic particles. The electric currents are the ion currents generated by the muscles, nerves, and other organs. For example, the same ion current generated by heart muscle, which provides the basis for the electrocardiogram, also produces a magnetic field over the chest; and the same ion current generated by the brain, which provides the basis for the electroencephalogram, also produces a magnetic field over the head. Ferromagnetic particles are insoluble contaminants of the body; the most important of these are the ferromagnetic dust particles in the lungs, which are primarily Fe_3O_4 (magnetite). Magnetic fields can give information about the internal organs not otherwise available.

These magnetic fields are very weak, usually in the range of 10^{-14} to 10^{-9} tesla; for comparison, the Earth's field is about 10^{-4} T (1 T = 10^4 gauss, the older unit of field). The fields at the upper end of this range, say stronger than 10^{-4} T, can be measured with a simple but sensitive magnetometer called the fluxgate; the weaker fields are measured with the extremely sensitive cryogenic magnetometer called the SQUID (superconducting quantum interference device). The levels of the body's fields, whether they are fluctuating or steady, are orders of magnitude weaker than the fluctuating or steady background fields. They can, however, be measured by using either a magnetically shielded room or two detectors connected in opposition so that much of the background is canceled, or a combination of both methods. The organs producing magnetic fields which are of most interest are the brain, the lungs, and the liver. *See* BIOELECTROMAGNETICS; ELECTROENCEPHALOGRAPHY; MIGRATORY BEHAVIOR; SQUID. [D.C.]

Biomass The organic materials produced by plants, such as leaves, roots, seeds, and stalks. In some cases, microbial and animal metabolic wastes are also considered biomass. The term "biomass" is intended to refer to materials that do not directly go into foods or consumer products but may have alternative industrial uses. Common sources of biomass are (1) agricultural wastes, such as corn stalks, straw, seed hulls, sugarcane leavings, bagasse, nutshells, and manure from cattle, poultry, and hogs; (2) wood materials, such as wood or bark, sawdust, timber slash, and mill scrap; (3) municipal waste, such as waste paper and yard clippings; and (4) energy crops, such as poplars, willows, switchgrass, alfalfa, prairie bluestem, corn (starch), and soybean (oil). *See* BIOLOGICAL PRODUCTIVITY.

Biomass is a complex mixture of organic materials, such as carbohydrates, fats, and proteins, along with small amounts of minerals, such as sodium, phosphorus, calcium, and iron. The main components of plant biomass are carbohydrates (approximately 75%, dry weight) and lignin (approximately 25%), which can vary with plant type. The carbohydrates are mainly cellulose or hemicellulose fibers, which impart strength to the plant structure, and lignin, which holds the fibers together. Some plants also store starch (another carbohydrate polymer) and fats as sources of energy, mainly in seeds and roots (such as corn, soybeans, and potatoes). *See* CELLULOSE; LIGNIN.

A major advantage of using biomass as a source of fuels or chemicals is its renewability. Utilizing sunlight energy in photosynthesis, plants metabolize atmospheric carbon dioxide to synthesize biomass. An estimated 140 billion metric tons of biomass are produced annually.

Major limitations of solid biomass fuels are difficulty of handling and lack of portability for mobile engines. To address these issues, research is being conducted to convert solid biomass into liquid and gaseous fuels. Both biological means (fermentation) and chemical means (pyrolysis, gasification) can be used to produce fluid biomass fuels. For example, methane gas is produced in China for local energy needs by anaerobic microbial digestion of human and animal wastes. Ethanol for automotive fuels is currently produced from starch biomass in a two-step process: starch is enzymatically hydrolyzed into glucose; then yeast is used to convert the glucose into ethanol. About 1.5 billion gallons of ethanol are produced from starch each year in the United States. *See* ALCOHOL FUEL; GASOLINE. [B.Y.Ta.]

Biome A major community of plants and animals having similar life forms or morphological features and existing under similar environmental conditions. The biome, which may be used at the scale of entire continents, is the largest useful biological community unit. In Europe the equivalent term for biome is major life zone, and throughout the world, if only plants are considered, the term used is formation. *See* ECOLOGICAL COMMUNITIES.

Each biome may contain several different types of ecosystems. For example, the grassland biome may contain the dense tallgrass prairie with deep, rich soil, while the desert grassland has a sparse plant canopy and a thin soil. However, both ecosystems have grasses as the predominant plant life form, grazers as the principal animals, and a climate with at least one dry season. Additionally, each biome may contain several successional stages. A forest successional sequence may include grass dominants at an early stage, but some forest animals may require the grass stage for their habitat, and all successional stages constitute the climax forest biome. *See* DESERT; ECOLOGICAL SUCCESSION; ECOSYSTEM; GRASSLAND ECOSYSTEM.

Distributions of animals are more difficult to map than those of plants. The life form of vegetation reflects major features of the climate and determines the structural nature of habitats for animals. Therefore, the life form of vegetation provides a sound basis for ecologically classifying biological communities. Terrestrial biomes are usually identified by the dominant plant component, such as the temperate deciduous forest. Marine biomes are mostly named for physical features, for example, for marine upwelling, and for relative locations, such as littoral. Many biome classifications have been proposed, but a typical one might include several terrestrial biomes such as desert, tundra, grassland, savanna, coniferous forest, deciduous forest, and tropical forest. Aquatic biome examples are fresh-water lotic (streams and rivers), fresh-water lentic (lakes and ponds), and marine littoral, neritic, upwelling, coral reef, and pelagic. *See* FRESH-WATER ECOSYSTEM; MARINE ECOLOGY; PLANTS, LIFE FORMS OF. [P.Ri.]

Biomechanics A field that combines the disciplines of biology and engineering mechanics and utilizes the tools of physics, mathematics, and engineering to quantitatively describe the properties of biological materials. One of its basic properties is embodied in so-called constitutive laws, which fundamentally describe the properties of constituents, independent of size or geometry, and specifically how a material deforms in response to applied forces. For most inert materials, measurement of the forces and deformations is straightforward by means of commercially available devices or sensors that can be attached to a test specimen. Many materials, ranging from steel to rubber, have linear constitutive laws, with the proportionality constant (elastic modulus) between the deformation and applied forces providing a simple index to distinguish the soft rubber from the stiff steel. While the same basic principles apply to living tissues, the complex composition of tissues makes obtaining constitutive laws difficult.

Most tissues are too soft for the available sensors, so direct attachment not only will distort what is being measured but also will damage the tissue. Devices are needed that use optical, Doppler ultrasound, electromagnetic, and electrostatic principles to measure deformations and forces without having to touch the tissue.

All living tissues have numerous constituents, each of which may have distinctive mechanical properties. For example, elastin fibers give some tissues (such as blood vessel walls) their spring-like quality at lower loads; inextensible collagen fibers that are initially wavy and unable to bear much load become straightened to bear almost all of the higher loads; and muscle fibers contract and relax to dramatically change their properties from moment to moment. Interconnecting all these fibers are fluids, proteins, and other materials that contribute mechanical properties to the tissue.

The mechanical property of the tissue depends not only upon the inherent properties of its constituents but also upon how the constituents are arranged relative to each other. Thus, different mechanical properties occur in living tissues than in inert materials. For most living tissues, there is a nonlinear relationship between the deformations and the applied forces, obviating a simple index like the elastic modulus to describe the material. In addition, the complex arrangement of the constituents leads to material properties that possess directionality; that is, unlike most inert materials that have the same properties regardless of which direction is examined, living tissues have distinct properties dependent upon the direction examined. Finally, while most inert materials undergo small (a few percent) deformations, many living tissues and cells can deform by several hundred percent. Thus, the mathematics necessary to describe the deformations is much more complicated than with small deformations. [F.C.P.Y.]

The biomechanical properties and behaviors of organs and organ systems stem from the ensemble characteristics of their component cells and extracellular materials, which vary widely in structure and composition and hence in biomechanical properties. An example of this complexity is provided by the cardiovascular system, which is composed of the heart, blood vessels, and blood. *See* CARDIOVASCULAR SYSTEM.

Blood is a suspension of blood cells in plasma. The mammalian red blood cell consists of a membrane enveloping a homogeneous cytoplasm rich in hemoglobin, but it has no nucleus or organelles. While the plasma and the cytoplasm behave as fluids, the red blood cell membrane has viscoelastic properties; its elastic modulus in uniaxial deformation at a constant area is four orders of magnitude lower than that for areal deformation. This type of biomechanical property, which is unusual in nonbiological materials, is attributable to the molecular structure of the membrane: the lipid membrane has spanning proteins that are linked to the underlying spectrin network. The other blood cells (leukocytes and platelets) and the endothelial cells lining the vessel wall are more complex in composition and biomechanics; they have nuclei, organelles, and a cytoskeletal network of proteins. Furthermore, they have some capacity for active motility. *See* BLOOD; CYTOSKELETON.

Cardiac muscle and vascular smooth muscle cells have organized contractile proteins that can generate active tension in addition to passive elasticity. Muscle cells, like other cells, are surrounded by extracellular matrix, and cell-matrix interaction plays an important role in governing the biomechanical properties and functions of cardiovascular tissues and organs. The study of the overall performance of the cardiovascular system involves measurements of pressure and flow. The pressure-flow relationship results from the interaction of the biomechanical functions of the heart, blood, and vasculature. To analyze the biomechanical behavior of cells, tissues, organs, and systems, a combination of experimental measurements and theoretical modeling is necessary. *See* MUSCLE.

Other organ systems present many quantitative and qualitative differences in biomechanical properties. For example, because the cardiovascular system is composed of soft tissues whereas bone is a hard tissue, the viscoelastic coefficients and mechanical behaviors are quite different. Cartilage is intermediate in stiffness and requires a poro- elastic theory to explain its behavior in lubrication of joints. In general, living systems differ from most physical systems in their nonhomogeneity, nonlinear behavior, capacity to generate active tension and motion, and ability to undergo adaptive changes and to effect repair. The biomechanical properties of the living systems are closely coupled with biochemical and metabolic activities, and they are controlled and regulated by neural and humoral mechanisms to optimize performance. While the biomechanical behaviors of cells, tissues, and organs are determined by their biochemical and molecular composition, mechanical forces can, in turn, modulate the gene expression and biochemical composition of the living system at the molecular level. Thus, a close coupling exists between biomechanics and biochemistry, and the understanding of biomechanics requires an interdisciplinary approach involving biology, medicine, and engineering.

[S.Chi.; R.Sk.]

Biomedical chemical engineering The application of chemical engineering principles to the solution of medical problems due to physiological impairment. A knowledge of organic chemistry is required of all chemical engineers, and many also study biochemistry and molecular biology. This training at the molecular level gives chemical engineers a unique advantage over other engineering disciplines in communication with life scientists and clinicians in medicine. Practical applications include the development of tissue culture systems, the construction of three-dimensional scaffolds of biodegradable polymers for cell growth in the laboratory, and the design of artificial organs. *See* BIOCHEMISTRY.

Cell transplantation is explored as a means of restoring tissue function. With this approach, individual cells are harvested from a healthy section of donor tissue, isolated, expanded in culture, and implanted at the desired site of the functioning tissue. Isolated cells cannot form new tissues on their own and require specific environments that often include the presence of supporting material to act as a template for growth. Three-dimensional scaffolds can be used to mimic their natural counterparts, the extracellular matrices of the body. These scaffolds serve as both a physical support and an adhesive substrate for isolated parenchymal cells during cell culture and subsequent implantation. The scaffold must be made of biocompatible materials. As the transplanted cell population grows and the cells function normally, they will begin to secrete their own extracellular matrix support. The need for an artificial support will gradually diminish; and thus if the implant is biodegradable, it will be eliminated as its function is replaced. The development of processing methods to fabricate reproducibly three-dimensional scaffolds of biodegradable polymers that will provide temporary scaffolding to transplanted cells will be instrumental in engineering tissues.

Chemical engineers have made significant contributions to the design and optimization of many commonly used devices for both short-term and long-term organ replacement. Examples include the artificial kidney for hemodialysis and the heart-lung machine employed in open heart surgery. The artificial kidney removes waste metabolites (such as urea and creatinine) from blood across a polymeric membrane that separates the flowing blood from the dialysis fluid. The mass transport properties and biocompatibility of these membranes are crucial to the functioning of hemodialysis equipment. The heart-lung machine replaces both the pumping function of the heart and the gas exchange function of the lung in one fairly complex device. While often life saving, both types of artificial organs only partially replace real organ function. Long-term use often leads to problems with control of blood coagulation mechanisms to avoid both excessive clotting initiated by blood contact with artificial surfaces and excessive bleeding due to platelet consumption or overuse of anticoagulants. *See* DIALYSIS; MEMBRANE SEPARATIONS.

Other chemical engineering applications include methodology for development of artificial bloods, utilizing fluorocarbon emulsions or encapsulated or polymerized hemoglobin, and controlled delivery devices for release of drugs or of specific molecules (such as insulin) missing in the body because of disease or genetic alteration. *See* POLYMER. [L.V.M.; A.G.M.]

Biomedical engineering An interdisciplinary field in which the principles, laws, and techniques of engineering, physics, chemistry, and other physical sciences are applied to facilitate progress in medicine, biology, and other life sciences. Biomedical engineering encompasses both engineering science and applied engineering in order to define and solve problems in medical research and clinical medicine for the improvement of health care. Biomedical engineers must have training in anatomy, physiology, and medicine, as well as in engineering.

A wide variety of instrumentation is available to the physician and surgeon to facilitate the diagnosis and treatment of diseases and other malfunctions of the body. Instrumentation has been developed to extend and improve the quality of life. A primary objective in the development of medical instrumentation is to obtain the required results with minimal invasion of the body. Responsibility for the correct installation, use, and maintenance of all medical instrumentation in the hospital is usually assigned to individuals with biomedical engineering training. This phase of biomedical engineering is termed clinical engineering, and often involves providing training for physicians, nurses, and other hospital personnel who operate the equipment. Another responsibility of the clinical engineer is to ensure that the instrumentation meets functional specifications at all times and poses no safety hazard to patients. In most hospitals, the clinical engineer supervises one or more biomedical engineering technicians in the repair and maintenance of the instrumentation.

The application of engineering principles and techniques has a significant impact on medical and biological research aimed at finding cures for a large number of diseases, such as heart disease, cancer, and AIDS, and at providing the medical community with increased knowledge in almost all areas of physiology and biology. Biomedical engineers are involved in the development of instrumentation for nearly every aspect of medical and biological research, either as a part of a team with medical professionals or independently, in such varied fields as electrophysiology, biomechanics, fluid mechanics, microcirculation, and biochemistry. A number of fields, such as cellular engineering and tissue engineering, have evolved from this work.

A significant role for biomedical engineers in research is the development of mathematical models of physiological and biological systems. A mathematical model is a set of equations that are derived from physical and chemical laws and that describe a physiological or biological function. Modeling can be done at various physiological levels, from the cellular or microbiological level to that of a complete living organism, and can be of various degrees of complexity, depending on which kinds of functions they are intended to represent and how much of the natural function is essential for the purpose of the model. A major objective of biomedical engineering is to create models that more closely approximate the natural functions they represent and that satisfy as many of the conditions encountered in nature as possible. *See* MATHEMATICAL BIOLOGY; SIMULATION.

A highly important contribution of biomedical engineering is in the design and development of artificial organs and prosthetic devices which replace or enhance the function of missing, inoperative, or inadequate natural organs or body parts. A major goal in this area is to develop small, self-contained, implantable artificial organs that function as well as the natural organs, which they can permanently supersede. *See* PROSTHESIS.

The goal of rehabilitation engineering is to increase the quality of life for the disabled. One major part of this field is directed toward strengthening existing but weakened motor functions through use of special devices and procedures that control exercising of the muscles involved. Another part is devoted to enabling disabled persons to function better in the world and live more normal lives. Included in this area are devices to aid the blind and hearing-impaired. Human-factors engineering is utilized in modifying the home and workplace to accommodate the special needs of disabled persons. *See* BIOMECHANICS; HUMAN-FACTORS ENGINEERING. [F.J.W.]

Biomedical ultrasonics The applications to medicine and biology of sound waves that have a frequency higher than the audible spectrum. Biomedical applications of ultrasound range from cell sonicators using frequencies in the kilohertz range to ultrasonic imaging in the megahertz range. The best-known application, ultrasonic imaging, is the second most utilized diagnostic imaging modality, after x-rays. High-intensity ultrasound has been used for therapeutic applications.

Ultrasonic imaging possesses numerous advantages over other imaging modalities of similar capabilities such as x-ray computed tomography, radionuclide imaging, and magnetic resonance imaging. It uses radiation that is noninvasive to the human body at the diagnostic intensity level, produces images at a very fast rate of 30 frames per second, and can be used to yield blood flow information by applying the Doppler principle. It has been used in a variety of medical disciplines, including cardiology, obstetrics, and radiology. *See* MEDICAL IMAGING.

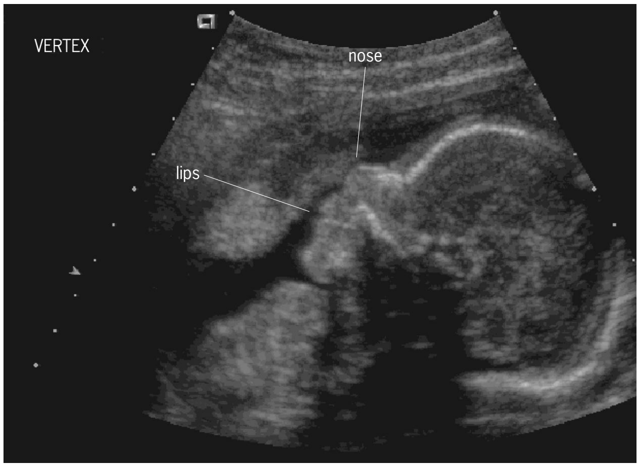
Notable disadvantages of ultrasound are that organs containing gases and bony structures cannot be adequately imaged, and only a limited acoustic window (space or opening between bones) is available for examination of organs such as the heart and the neonatal brain.

Ultrasound at high intensity levels has been used for hyperthermia treatment of tumors, frequently in combination with chemotherapy or radiotherapy, and for tissue ablation. *See* ONCOLOGY; THERMOTHERAPY.

Ultrasonic wave propagation. Ultrasound is a form of acoustic wave with a frequency higher than 20 kHz. Ultrasound velocity and wavelength in water are approximately 1.48×10^5 cm/s and 0.03 cm at 5 MHz and 20°C (68°F). The sound speeds in soft biological tissues are similar to that in water. The sound speeds of shear and longitudinal waves are different. Biological tissues other than bone can be treated as fluidlike media, and as such they cannot support shear-wave propagation. *See* SOUND.

Ultrasonic imaging. An ultrasonic image is formed from echoes returned from tissues. Although there are a number of ways of displaying the image, the B (brightness) mode is the most common (see illustration). In this mode, the echo amplitude is displayed in gray scale as a function of the distance into the tissue. The center of the B-mode imaging system is an energy-conversion device, the ultrasonic transducer, which converts the electric signal into ultrasound and vice versa. *See* MEDICAL ULTRASONIC TOMOGRAPHY; TRANSDUCER.

Transducers. An ultrasonic transducer contains one or more elements made from a piezoelectric ceramic such as lead zirconate titanate. Depending upon how a transducer is driven, ultrasonic scanners are classified as mechanical-sector and electronic-array scanners. Electronic-array systems produce images of better quality and are faster. Mechanical-sector scanners are no longer used except for special applications. A typical array



B-mode image of a fetus in the uterus.

consists of 128 or more small rectangular piezoelectric elements. In a linear sequenced array, or simply a linear array, a subaperture of 32 elements or more is fired simultaneously to form a beam. The beam is electronically focused and swept across the aperture surface from one end to the other. Electronic dynamic focusing can be achieved by appropriately controlling the timing of the signals to each individual element.

Flow measurements. The Doppler principle has been used to estimate blood flow in a blood vessel noninvasively. Two approaches have been used for ultrasonic Doppler flow measurements: continuous-wave and pulsed-wave Doppler. A probe consisting of two piezoelectric elements, one for transmitting the ultrasound signal and one for receiving the echoes returned from blood, is used in continuous-wave Doppler. A pulsed-wave Doppler may be used to alleviate the problem that a continuous-wave Doppler is unable to differentiate the origins of the Doppler signals produced within the ultrasound beam. Ultrasound bursts of 5–10 cycles are used, and the time of flight of the returned signal yields information about the signal's origin.

Color Doppler flow imaging scanners are capable of obtaining both B-mode images and Doppler blood flow data simultaneously in real time. The Doppler information is encoded in color. Red and blue are assigned to indicate flow toward and away from the transducer, respectively. The magnitude of the velocity is represented by the shade of the color. The color Doppler image is superimposed on the gray-scale B-mode image.

Contrast media. Ultrasonic contrast agents have been successfully developed to enhance the image contrast of anatomic structures that contain the agents. A majority of these agents utilize microscopic encapsulated gas bubbles, which are strong scatterers because of the acoustic impedance mismatch. Moreover, the bubbles can resonate when insonified by an ultrasonic wave, and therefore the echoes from the bubbles can be further enhanced if the incident wave is tuned to the resonant frequency of the bubbles. These bubbles have a mean diameter of less than 5 micrometers and can be injected intravenously.

Biological effects of ultrasound. Although ultrasound is known as a form of noninvasive radiation, biological effects inevitably result if its intensity is increased beyond some limit. Two types of ultrasound bioeffects can be produced: thermal and mechanical. No bioeffects have been found for ultrasound with a spatial peak temporal average intensity less than 100 mW/cm^2. *See* CAVITATION. [K.K.S.]

Biometeorology A branch of meteorology and ecology that deals with the effects of weather and climate on plants, animals, and humans.

The principal problem for living organisms is maintaining an acceptable thermal equilibrium with their environment. Organisms have natural techniques for adapting to adverse conditions. These techniques include acclimatization, dormancy, and hibernation, or in some cases an organism can move to a more favorable environment or microenvironment. Humans often establish a favorable environment through the use of technology. *See* DORMANCY; MICROMETEOROLOGY.

Homeotherms, that is, humans and other warm-blooded animals, maintain relatively constant body temperatures under a wide range of ambient thermal and radiative conditions through physiological and metabolic mechanisms. Poikilotherms, that is, cold-blooded animals, have a wide range in body temperature that is modified almost exclusively by behavioral responses. Plants also experience a wide range of temperatures, but because of their immobility they have less ability than animals to adapt to extreme changes in environment. *See* THERMOREGULATION.

Humans are physically adapted to a narrow range of temperature, with the metabolic mechanism functioning best at air temperatures around 77°F (25°C). There is a narrow range above and below this temperature where survival is possible. To regulate heat loss, warm-blooded animals developed hair, fur, and feathers. Humans invented clothing and shelter. The amount of insulation required to maintain thermal equilibrium is governed by the conditions in the atmospheric environment. There are a limited number of physiological mechanisms, controlled by the hypothalamus, that regulate body heat.

Clothing, shelter, and heat-producing objects can largely compensate for environmental cold, but with extensive exposure to cold, vasoconstriction in the peripheral organs can lead to chilblains and frostbite on the nose, ears, cheeks, and toes. This exposure is expressed quantitatively as a wind chill equivalent temperature that is a function of air temperature and wind speed. The wind chill equivalent temperature is a measure of convective heat loss and describes a thermal sensation equivalent to a lower-than-ambient temperature under calm conditions, that is, for wind speeds below 4 mi/h (1.8 m/s). Persons exposed to extreme cold develop hypothermia, which may be irreversible when the core temperature drops below 91°F (33°C.) *See* HYPOTHERMIA.

The combination of high temperature with high humidity leads to a very stressful thermal environment. The combination of high temperature with low humidity leads to a relatively comfortable thermal environment, but such conditions create an environment that has a very high demand for water.

Conditions of low humidity exist principally in subtropical deserts, which have the highest daytime temperatures observed at the Earth's surface. Human and animal bodies are also exposed to strong solar radiation and radiation reflected from the surface of the sand. This combination makes extraordinary demands on the sweat mechanism. Water losses of 1.06 quarts (1 liter) per hour are common in humans and may be even greater with exertion. Unless the water is promptly replaced by fluid intake, dehydration sets in. *See* DESERT; HUMIDITY; SOLAR RADIATION.

When humans are exposed to warm environments, the first physiological response is dilation of blood vessels, which increases the flow of blood near the skin. The next response occurs through sweating, panting, and evaporative cooling. Since individuals differ in their physiological responses to environmental stimuli, it is difficult to develop a heat stress index based solely on meteorological variables. Nevertheless, several useful indices have been developed.

Since wind moves body heat away and increases the evaporation from a person, it should be accounted for in developing comfort indices describing the outdoor environment. One such index, used for many years by heating and ventilating engineers, is the effective temperature. People will feel uncomfortable at effective temperatures above 81°F (27°C) or below 57°F (15°C); between 63°F (17°C) and 77°F (25°C) they will feel comfortable.

Both physiological and psychological responses to weather changes (meteorotropisms) are widespread and generally have their origin in some bodily impairment. Reactions to weather changes commonly occur in anomalous skin tissue such as scars and corns; changes in atmospheric moisture cause differential hygroscopic expansion and contraction between healthy and abnormal skin, leading to pain. Sufferers from rheumatoid arthritis are commonly affected by weather changes; both pain and swelling of affected joints have been noted with increased atmospheric humidity. Sudden cooling can also trigger such symptoms. Clinical tests have shown that in these individuals the heat regulatory mechanism does not function well, but the underlying cause is not understood.

Weather is a significant factor in asthma attacks. Asthma as an allergic reaction may, in rare cases, be directly provoked by sudden changes in temperature that occur after passage of a cold front. Often, however, the weather effect is indirect, and attacks are caused by airborne allergens, such as air pollutants and pollen. An even more indirect relationship exists for asthma attacks in autumn, which often seem to be related to an early outbreak of cold air. This cold air initiates home or office heating, and dormant dust or fungi from registers and radiators are convected into rooms, irritating allergic persons. *See* ALLERGY; ASTHMA.

A variety of psychological effects have also been attributed to heat. They are vaguely described as lassitude, decrease in men-j tal and physical performance, and increased irritability. Similar reactions to weather have been described for domestic animals, particularly dogs; hence hot, humid days are sometimes known as dog days.

Meteorological and seasonal changes in natural illumination have a major influence on animals. Photoperiodicity is widespread. The daily cycle of illumination triggers the feeding cycle in many species, especially birds. In insectivores the feeding cycle may result from the activities of the insects, which themselves show temperature-influenced cycles of animation. Bird migration may be initiated by light changes, but temperature changes and availability of food are also involved. In the process of migration, especially over long distances, birds have learned to take advantage of prevailing wind patterns. In humans, light deprivation, as is common in the cold weather season in higher latitudes, is suspected as a cause of depression. Exposure to high-intensity light for several hours has been found to be an effective means of treating this depression. *See* AFFECTIVE DISORDERS; MIGRATORY BEHAVIOR; PHOTOPERIODISM.

Humans and animals often exhibit a remarkable ability to adapt to harsh or rapidly changing environmental conditions. An obvious means of adaptation is to move to areas where environmental conditions are less severe; examples are birds and certain animals that migrate seasonally, animals that burrow into the ground, and animals that move to shade or sunshine depending on weather conditions. Animals can acclimatize to heat and cold. The acclimatization process is generally complete within 2–3 weeks of exposure to the stressful conditions. For example, in hot climates heat regulation is improved by the induction of sweating at a lower internal body temperature and by the increase of sweating rates. The acclimatization to cold climates is accomplished by increase in the metabolic rate, by improvement in the insulating properties of the skin, and by the constriction of blood vessels to reduce the flow of blood to the surface. *See* BURROWING ANIMALS.

Unlike humans and animals, plants cannot move from one location to another; therefore, they must adapt genetically to their atmospheric environment. Plants are often characteristic for their climatic zone, such as palms in the subtropics and birches or firs in regions with cold winters. Whole systems of climatic classification are based on the native floras. *See* ALTITUDINAL VEGETATION ZONES; ECOLOGY; METEOROLOGY. [B.L.B.; H.E.L.]

Bioorganic chemistry The science that describes the structure, interactions, and reactions of organic compounds of biological significance at the molecular level. It represents the meeting of biochemistry, as attempts are made to describe the structure and physiology of organisms on an ever smaller scale, with organic chemistry, as attempts are made to synthesize and understand the behavior of molecules of ever-increasing size and complexity. Areas of research include enzymatic catalysis, the structure and folding of proteins, the structure and function of biological membranes, the chemistry of poly(ribonucleic acids) and poly(deoxyribonucleic acids), biosynthetic pathways, immunology, and mechanisms of drug action.

Being at the interface of two disciplines, bioorganic chemistry utilizes experimental techniques and theoretical concepts drawn from both. Important experimental techniques include organic synthesis, kinetics, structure-activity relationships, the use of model systems, methods of protein purification and manipulation, genetic mutation, cloning and overexpression (engineered enhancement of gene transcription), and the elicitation of monoclonal antibodies. Theoretical concepts important to bioorganic chemistry include thermodynamics, transition-state theory, acid-base theory, concepts of hydrophobicity and hydrophilicity, theories of stereocontrol, and theories of adaptation of organisms to selective pressures.

Historically, a major focus of bioorganic research has been the study of catalysis by enzymes. Enzymes have a dramatic ability to increase the rates at which reactions occur. One of the ways that enzymes increase the rates of bimolecular reactions is to overcome the entropic barrier associated with bringing two particles together to form one. *See* ENZYME.

Enzymes also catalyze reactions by facilitating proton transfers. Many of the reactions catalyzed by enzymes, such as the formation and hydrolysis of esters and amides, require the deprotonation of a nucleophile (base catalysis) or the protonation of an electrophile (acid catalysis).

Enzymes may act as preorganized solvation shells for transition states. If the active site of an enzyme has just the right size, shape, and arrangement of functional groups to bind a transition state, it will automatically bind the reactants less well. Selective binding of the transition state lowers the energy of the transition state relative to that of the reactants. Because the energy barrier between reactants and transition state is reduced, the reaction proceeds more rapidly.

The selectivity of enzymes makes them useful as catalysts for organic synthesis. Surprisingly, enzymes are able to catalyze not only the reactions that they mediate in living systems but also similar, selective transformations of unnatural substrates. Because of their selectivity, several enzyme-catalyzed reactions may run simultaneously in the same vessel. Thus, a reactant can undergo several reactions in series without the need for isolation of intermediates. Enzymes can be combined so as to reconstitute within a reaction vessel naturally occurring metabolic pathways or to create new, artificial metabolic pathways. Sequences of up to 12 serial reactions have been executed successfully in a single reaction vessel. *See* CATALYSIS.

The biological activity of a protein, whether binding, catalytic, or structural, depends on its full three-dimensional or conformational structure. The linear sequence of amino acids that make up a protein constitutes its primary structure. Local regions of highly organized conformation (α-helices, β-pleats, β-turns, and so on) are called secondary structure. Further folding of the protein causes regions of secondary structure to associate or come into correct alignment. This action establishes the tertiary structure of the native (active) protein. A goal of bioorganic chemistry is to achieve an understanding of the process of protein folding. *See* AMINO ACIDS; BIOCHEMISTRY; ORGANIC CHEMISTRY; PROTEIN. [H.K.C.]

Biophysics A hybrid science involving the overlap of physics, chemistry, and biology. A dominant aspect is the use of the ideas and methods of physics and chemistry to study and explain the structures of living organisms and the mechanisms of life processes. The recognition of biophysics as a separate field is relatively recent, having been brought about, in part, by the invention of physical tools such as the electron microscope, the ultracentrifuge, and the electronic amplifier, which greatly facilitate biophysical research. These tools are peculiarly adapted to the study of problems of great current importance to medicine, problems related to virus diseases, cancer, heart disease, and the like.

The major areas of biophysics are the following:

Molecular biophysics has to do with the study of large molecules and particles of comparable size which play important roles in biology. The most important physical tools for such research are the electron microscope, the ultracentrifuge, and the x-ray diffraction camera. *See* MOLECULAR BIOLOGY; ULTRACENTRIFUGE; X-RAY DIFFRACTION.

Radiation biophysics consists of the study of the response of organisms to ionizing radiations, such as alpha, beta, gamma, and x-rays, and to ultraviolet light. The biological responses are death of cells and tissues, if not of whole organisms, and mutation, either somatic or genetic.

Physiological biophysics, called by some classical biophysics, is concerned with the use of physical mechanisms to explain the behavior and the functioning of living organisms or parts of living organisms and with the response of living organisms to physical forces.

Mathematical and theoretical biophysics deals primarily with the attempt to explain the behavior of living organisms on the basis of mathematics and physical theory. Biological processes are being examined in terms of thermodynamics, hydrodynamics, and statistical mechanics. Mathematical models are being investigated to see how closely they simulate biological processes. *See* BIOMECHANICS; BIOPOTENTIALS AND IONIC CURRENTS; MATHEMATICAL BIOLOGY; MICROMANIPULATION; MICROSCOPE; MUSCLE PROTEINS; MUSCULAR SYSTEM; OXIMETRY; SKELETAL SYSTEM; SPACE BIOLOGY; THERMOREGULATION; THERMOTHERAPY. [M.A.L.]

Biopolymer A macromolecule derived from natural sources; also known as biological polymer. Some biopolymers are used as structural materials, food sources, or catalysts. Others have evolved as entities for information storage and transfer. Examples of biopolymers include polypeptides; polysaccharides; polypeptide/polysaccharide hybrids; polynucleotides, which are polymers derived from ribonucleic acid (RNA) and deoxyribonucleic acid (DNA); polyhydroxybutyrates, a class of polyesters produced by certain bacteria; and *cis*-1,4-polyisoprene, the major component of rubber tree latex. *See* POLYMER.

Amino acids are the monomers from which polypeptides are derived. Polypeptides alone, as well as multipolypeptide complexes or complexes with other molecules, are known as proteins, and each has a specific biological function. There are numerous examples of biopolymers having a polysaccharide and polypeptide in the same molecule, usually with a polysaccharide as a side chain in a polypeptide, or vice versa. *See* PEPTIDE; POLYSACCHARIDE; PROTEIN. [G.E.W.]

Biopotentials and ionic currents The voltage differences which exist between separated points in living cells, tissues, organelles, and organisms are called biopotentials. Related to these biopotentials are ionic charge transfers, or currents, that give rise to much of the electrical changes occurring in nerve, muscle, and other electrically active cells. Electrophysiology is the science concerned with uncovering the structures and functions of bioelectrical systems, including the entities directly related to biological potentials and currents. According to their function, these structures are given descriptive names such as channels, carriers, ionophores, gates, and pumps.

The potential difference measured with electrodes between the interior cytoplasm and the exterior aqueous medium of the living cell is generally called the membrane potential or resting potential (E_{RP}). This potential is usually in the order of several tens of millivolts and is relatively constant or steady. The range of E_{RP} values in various striated muscle cells of animals from insects through amphibia to mammals is about -50 to -100 mV (the voltage is negative inside with respect to outside). Nerve cells show a similar range in such diverse species as squid, cuttlefish, crabs, lobsters, frogs, cats, and humans. Similar potentials have been recorded in single tissue-culture cells.

Biopotentials arise from the electrochemical gradients established across cell membranes. In most animal cells, potassium ions are in greater concentration internally than externally, and sodium ions are in less concentration internally than externally. Generally, chloride ions are in less concentration inside cells than outside cells, even though there are abundant intracellular fixed negative charges. While calcium ion concentration is relatively low in body fluids external to cells, the concentration of ionized calcium internally is much lower (in the nanomolar range) than that found external to the cells.

Sodium pump. Measurements of ionic movements through cell membranes of muscle fibers by H. B. Steinbach and by L. A. Heppel in the late 1930s and early 1940s found that radioisotopically labeled sodium ion movement through the cell membrane from inside to outside seemed to depend upon the metabolism of the cell. I. M. Glynn showed that the sodium efflux from red cells depended on the ambient glucose concentration, and A. L. Hodgkin and R. D. Keynes demonstrated in squid and *Sepia* giant axons that the sodium efflux could be blocked by a variety of metabolic inhibitors (cyanide, 2,4-dinitrophenol, and azide). It was proposed that a metabolic process (sodium pump) located in the cell membrane extruded sodium from the cell interior against an electrochemical gradient. P. C. Caldwell's experiments on the squid's giant axon in the late 1950s indicated that there was a close relation between the activity of the sodium pump and the intracellular presence of high-energy compounds, such as adenosine triphosphate (ATP) and arginine phosphate. Caldwell suggested that these compounds might be directly involved in the active transport mechanism. Evidence by R. L. Post for red cells and by Caldwell for the giant axon also suggested that there was a coupling between sodium extrusion and potassium uptake. Convincing evidence has been presented that ATP breakdown to adenosine diphosphate and phosphorus (ADP + P) provides the immediate energy for sodium pumping in the squid giant axon. It seems that the sodium pump is a sufficient explanation to account for the high internal potassium and the low internal sodium concentrations in nerve, muscle, and red blood cells. *See* ABSORPTION (BIOLOGY); CELL PERMEABILITY.

Channels. In living cells there are two general types of ion transport processes. In the first, the transported ionic species flows down the gradient of its own electrochemical potential.

In the second, there is a requirement for immediate metabolic energy. This first category of bioelectrical events is associated with a class of molecules called channels, embedded in living cell membranes. It is now known that cell membranes contain many types of transmembrane channels. Channels are protein structures that span the lipid bilayers forming the backbones of cell membranes. The cell membranes of nerve, muscle, and other tissues contain ionic channels. These ionic channels have selectivity filters in their lumens such that in the open state only certain elementary ion species are admitted to passage, with the exclusion of other ion species. *See* CELL MEMBRANES.

There are two general types of channels, and these are classified according to the way in which they respond to stimuli. Electrically excitable channels have opening and closing rates that are dependent on the transmembrane electric field. Chemically excitable channels (usually found in synaptic membranes) are controlled by the specific binding of certain activating molecules (agonists) to receptor sites associated with the channel molecule.

Calcium channels are involved in synaptic transmission. When a nerve impulse arrives at the end of a nerve fiber, calcium channels open in response to the change in membrane potential. These channels admit calcium ions, which act on synaptic vesicles, facilitating their fusion with the presynaptic membrane. Upon exocytosis, these vesicles release transmitter molecules, which diffuse across the synaptic cleft to depolarize the postsynaptic membrane by opening ionic channels. Transmitter activity ceases from the action of specific transmitter esterases or by reabsorption of transmitter back into vesicles in the presynaptic neuron. Calcium channels inactivate and close until another nerve impulse arrives at the presynaptic terminal. Thus biopotentials play an important role in both the regulation and the genesis of synaptic transmission at the membrane channel level. *See* NERVE.

Ionic currents flow through open channels. The ion impermeable membrane lipid bilayer acts as a dielectric separating two highly conductive salt solutions. Ionic channels have the electrical property of a conductance between these solutions. The membrane conductance at any moment depends on the total number of channels, the type of channels, the fraction of channels found in the open state, and the unit conductances of these open channels. The most common channels directly giving rise to biopotentials are those admitting mainly sodium ions, potassium ions, chloride ions, or calcium ions. These channels are named after the predominant charge carrier admitted in the open state, such as potassium channels. It is now known that there are charged amino acid groups lining the channel lumen that determine the specificity of the channel for particular ions. These selectivity filters admit only ions of the opposite charge.

Hodgkin and A. F. Huxley proposed in 1952 that there were charged molecular entities responsible for the opening and closing of the ionic conductance pathways. These structures had to be charged to be able to move in response to changing electrical forces when the membrane voltage changed. Any movement of the gating structures would require a movement of charge and hence should have a detectable component of current flow across the membrane. It was not until 1973 that the existence of a gating current in squid axon sodium channels was demonstrated, and gating currents and their significance became a lively endeavor in membrane biophysics. *See* BIOPHYSICS. [W.J.A.]

Biopyribole A member of a chemically diverse, structurally related group of minerals that comprise substantial fractions of both the Earth's crust and upper mantle. The term was coined by Albert Johannsen in 1911; it is a contraction of biotite (a mica), pyroxene, and amphibole.

The pyroxene minerals contain single chains of corner-sharing silicate (SiO_4) tetrahedra, and the amphiboles contain double chains. Likewise, the micas and other related biopyriboles (talc, pyrophyllite, and the brittle micas) contain two-dimensionally infinite silicate sheets, which result in their characteristic sheetlike physical properties. In the pyroxenes and amphiboles, the silicate chains are articulated to strips of octahedrally coordinated cations, such as magnesium and iron; and in the sheet biopyriboles, the silicate sheets are connected by two-dimensional sheets of such cations. In addition to the classical single-chain, double-chain, and sheet biopyriboles, several biopyriboles that contain triple silicate chains have been discovered. *See* BIOTITE; MICA; PYROXENE; SILICATE MINERALS.

Pyroxenes, amphiboles, and micas of various compositions can occur in igneous, metamorphic, and sedimentary rocks. Pyroxenes are the second most abundant minerals in the Earth's crust (after feldspars) and in the upper mantle (after olivine). Unlike the pyroxenes, amphiboles, and micas, the wide-chain biopyriboles do not occur as abundant minerals in a wide variety of rock types. However, some of them may be widespread in nature as components of fine-grain alteration products of pyroxenes and amphiboles and as isolated lamellae in other biopyriboles. *See* IGNEOUS ROCKS; METAMORPHIC ROCKS; SEDIMENTARY ROCKS. [D.R.V.]

Biorheology The study of the flow and deformation of biological materials. The behavior and fitness of living organisms depend partly on the mechanical properties of their structural materials. Thus, biologists are interested in biorheology from the point of view of evolution and adaptation to the environment. Physicians are interested in it in order to understand health and disease. Bioengineers devise methods to measure or to change the rheological properties of biological materials, develop mathematical descriptions of biorheology, and create new practical applications for biorheology in agriculture, industry, and medicine.

The rheological behavior of most biological materials is more complex than that of air, water, and most structural materials used in engineering. Air and water are viscous fluids; all fluids whose viscosity is similar to that of air and water are called newtonian fluids. Biological fluids such as protoplasm, blood, and synovial fluid behave differently, however, and they are called non-newtonian fluids. For example, blood behaves like a fluid when it flows, but when it stops flowing it behaves like a solid with a small but finite yield stress. *See* FLUID FLOW; NON-NEWTONIAN FLUID; VISCOSITY.

Most materials used in engineering construction, such as steel, aluminum, or rock, obey Hooke's law, according to which stresses are linearly proportional to strains. These materials deviate from Hooke's law only when approaching failure. A structure made of Hookean materials behaves linearly: load and deflection a relinearly proportional to each other in such a structure. Some biological materials, such as bone and wood, also obey Hooke's law in their normal state of function, but many others, such as skin, tendon, muscle, blood vessels, lung, and liver, do not. These materials, referred to as non-Hookean, become stiffer as stress increases. *See* BONE; ELASTICITY; STRESS AND STRAIN.

In biorheology, so-called constitutive equations are used to describe the complex mechanical behavior of materials in terms of mathematics. At least three kinds of constitutive equations are needed: those describing stress-strain relationships of material in the normal state of life; those describing the transport of matter, such as water, gas, and other substances, in tissues; and those describing growth or resorption of tissues in response to long-term changes in the state of stress and strain. The third type is the most fascinating, but there is very little quantitative information available about it except for bone. The second type is very complex because living tissues are nonhomogeneous, and since mass transport in tissues is a molecular phenomenon, it is accentuated by nonhomogeneity at the cellular level. The best-known constitutive equations are therefore of the first kind. *See* BIOMECHANICS. [Y.C.F.]

Biosensor An integrated device consisting of a biological recognition element and a transducer capable of detecting the biological reaction and converting it into a signal which can be processed. Ideally, the sensor should be self-contained, so that it is not necessary to add reagents to the sample matrix to obtain the desired response. There are a number of analytes (the target substances to be detected) which are measured in biological media: pH, partial pressure of carbon dioxide (pCO_2), partial pressure of oxygen (pO_2), and the ionic concentrations of sodium, potassium, calcium, and chloride. However, these sensors do not use biological recognition elements, and are considered chemical sensors. Normally, the biological recognition element is a protein or protein complex which is able to recognize a particular analyte in the presence of many other components in a complex biological matrix. This definition has since been expanded to include oligonucleotides. The recognition process involves a chemical or biological reaction, and the transducer must be capable of detecting not only the reaction but also its extent. An ideal sensor should yield a selective, rapid, and reliable response to the analyte, and the signal generated by the sensor should be proportional to the analyte concentration.

Biosensors are typically classified by the type of recognition element or transduction element employed. A sensor might be described as a catalytic biosensor if its recognition element comprised an enzyme or series of enzymes, a living tissue slice (vegetal or animal), or whole cells derived from microorganisms such as bacteria, fungi, or yeast. The sensor might be described as a bioaffinity sensor if the basis of its operation were a biospecific complex formation. Accordingly, the reaction of an antibody with an antigen or hapten, or the reaction of an agonist or antagonist with a receptor, could be employed. In the former case, the sensor might be called an immunosensor.

Since enzyme-based sensors measure the rate of the enzyme-catalyzed reaction as the basis for their response, any physical measurement which yields a quantity related to this rate can be used for detection. The enzyme may be immobilized on the end of an optical fiber, and the spectroscopic properties (absorbance, fluorescence, chemiluminescence) related to the disappearance of the reactants or appearance of products of the reaction can be measured. Since biochemical reactions can be either endothermic (absorbing heat) or exothermic (giving off heat), the rate of the reaction can be measured by microcalorimetry. Miniaturized thermistor-based calorimeters, called enzyme thermistors, have been developed and widely applied, especially for bioprocess monitoring.

In the case of affinity biosensors, as is true of catalytic biosensors, many physical techniques can be used to detect affinity binding: microcalorimetry (thermometric enzyme-linked immunosorbent assay, or TELISA), fluorescence energy transfer, fluorescence polarization, or bioluminescence.

The quality of the results obtained from sensors based on biological recognition elements depends most heavily on their ability to react rapidly, selectively, and with high affinity. Antibodies and receptors frequently react with such high affinity that the analyte does not easily become unbound. To reuse the sensor requires a time-consuming regeneration step. Nonetheless, if this step can be automated, semicontinuous monitoring may be possible. [G.S.W.]

Biosphere All living organisms and their environments at the surface of the Earth. Included in the biosphere are all environments capable of sustaining life above, on, and beneath the Earth's surface as well as in the oceans. Consequently, the biosphere overlaps virtually the entire hydrosphere and portions of the atmosphere and outer lithosphere. *See* ATMOSPHERE; HYDROSPHERE; LITHOSPHERE.

Neither the upper nor lower limits of the biosphere are sharp. Spores of microorganisms can be carried to considerable heights in the atmosphere, but these are resting stages that are not actively metabolizing. A variety of organisms inhabit the ocean depths, including the giant tubeworms and other creatures that were discovered living around hydrothermal vents. Evidence exists for the presence of bacteria in oil reservoirs at depths of about 6600 ft (2000 m) within the Earth. The bacteria are apparently metabolically active, utilizing the paraffinic hydrocarbons of the oils as an energy source. These are extreme limits to the biosphere; most of the mass of living matter and the greatest diversity of organisms are within the upper 330 ft (100 m) of the lithosphere and hydrosphere, although there are places even within this zone that are too dry or too cold to support much life. Most of the biosphere is within the zone which is reached by sunlight and where liquid water exists.

The biosphere is characterized by the interrelationship of living things and their environments. Communities are interacting systems of organisms tied to their environments by the transfer of energy and matter. Such a coupling of living organisms and the nonliving matter with which they interact defines an ecosystem. An ecosystem may range in size from a small pond, to a tropical forest, to the entire biosphere. Ecologists group the terrestrial parts of the biosphere into about 12 large units called biomes. Examples of biomes include tundra, desert, grassland, and boreal forest. *See* BIOME; ECOLOGICAL COMMUNITIES; ECOSYSTEM.

Human beings are part of the biosphere, and some of their activities have an adverse impact on many ecosystems and on themselves. As a consequence of deforestation, urban sprawl, spread of pollutants, and overharvesting, both terrestrial and marine ecosystems are being destroyed or diminished, populations are shrinking, and many species are dying out. In addition to causing extinctions of some species, humans are expanding the habitats of other organisms, sometimes across oceanic barriers, through inadvertent transport and introduction into new regions. Humans also add toxic or harmful substances to the outer lithosphere, hydrosphere, and atmosphere. Many of these materials are eventually incorporated into or otherwise affect the biosphere, and water and air supplies in some regions are seriously fouled. *See* HAZARDOUS WASTE. [R.M.M.]

Biostrome An evenly bedded and generally horizontally layered stratum composed mostly of organic remains, normally considered to be those of sedentary organisms which lived, died, and were buried essentially in place.

The criterion of formation by in-place growth of organisms is subject to some interpretation. Crinoidal limestones obviously resulted from the accumulation of decayed pieces of millions of these stalked echinoderms, often with accompanying detritus of associated fenestrate bryozoans. Usually it is impossible to ascertain whether such debris dropped vertically a few centimeters or meters through the water column as the organisms died and collapsed (an essentially in-place deposit) or whether the layers of crinoidal grainstone were piled mechanically by currents. The same is true of coquinas of many other thin-shelled calcareous tests, such as those of brachiopods, bryozoans, and trilobites.

Biostromal layers need not have been horizontally deposited when they occur as flanking beds around organic buildups. Dips of up to 25 or 30° are possible here. Such biostromes are probably veneers of sessile organisms which lived somewhat above the realm of deposition and were buried as sediment cascaded down the flank of a mound. [J.L.Wi.]

Biosynthesis The synthesis of more complex molecules from simpler ones in cells by a series of reactions mediated by enzymes. The overall economy and survival of the cell is governed by the interplay between the energy gained from the breakdown of compounds and that supplied to biosynthetic reaction pathways for the synthesis of compounds having a functional role, such as deoxyribonucleic acid (DNA), ribonucleic acid (RNA), and enzymes. Biosynthetic pathways give rise to two distinct classes of metabolite, primary and secondary. Primary metabolites (DNA, RNA, fatty acids, α-amino acids, chlorophyll in green plants, and so forth) are essential to the metabolic functioning of the cells. Secondary metabolites (antibiotics, alkaloids, pheromones, and so forth) aid the functioning and survival of the whole organism more generally. Unlike primary metabolites, secondary metabolites are often unique to individual organisms or classes of organisms. *See* ENZYME; METABOLISM.

The selective pressures that drive evolution have ensured a diverse array of secondary metabolite structures. Secondary metabolites can be grouped to some extent by virtue of their origin from key biosynthetic pathways. It is often in the latter stages of these pathways that the structural diversity is introduced. All terpenes, for example, originate from the C_5 (five-carbon) intermediate isopentenyl pyrophosphate via mevalonic acid. The mammalian steroids, such as cholesterol, derive from the C_{30} steroid lanosterol, which is constructed from six C_5 units. Alternatively, C_{10} terpenes (for example, menthol from peppermint leaves) and C_{15} terpenes (for example, juvenile hormone III from the silk worm) are derived after the condensation of two and three C_5 units, respectively, and then with further enzymatic customization in each case. *See* CHOLESTEROL; ORGANIC EVOLUTION; STEROID; TERPENE; TRITERPENE. [D.O'H.]

Biot-Savart law A law of physics which states that the magnetic flux density (magnetic induction) near a long, straight conductor is directly proportional to the current in the conductor and inversely proportional to the distance from the conductor. The field near a straight conductor can be found by application of Ampère's law. The magnetic flux density near a long, straight conductor is at every point perpendicular to the plane determined by the point and the line of the conductor. Therefore, the lines of induction are circles with their centers at the conductor. Furthermore, each line of induction is a closed line. This observation concerning flux about a straight conductor may be generalized to include lines of induction due to a conductor of any shape by the statement that every line of induction forms a closed path. *See* AMPÈRE'S LAW. [K.V.M.]

Biotechnology Generally, any technique that is used to make or modify the products of living organisms in order to improve plants or animals, or to develop useful microorganisms. In modern terms, biotechnology has come to mean the use of cell and tissue culture, cell fusion, molecular biology, and in particular, recombinant deoxyribonucleic acid (DNA) technology to generate unique organisms with new traits or organisms that have the potential to produce specific products. Some examples of products in a number of important disciplines are described below.

Recombinant DNA technology has opened new horizons in the study of gene function and the regulation of gene action. In particular, the ability to insert genes and their controlling nucleic acid sequences into new recipient organisms allows for the manipulation of these genes in order to examine their activity in unique environments, away from the constraints posed in their normal host. Genetic transformation normally is achieved easily with microorganisms; new genetic material may be inserted into them, either into their chromosomes or into extrachromosomal elements, the plasmids. Thus, bacteria and yeast can be created to metabolize specific products or to produce new products. *See* GENE; GENE ACTION; PLASMID.

Genetic engineering has allowed for significant advances in the understanding of the structure and mode of action of antibody molecules. Practical use of immunological techniques is pervasive in biotechnology. *See* ANTIBODY.

Few commercial products have been marketed for use in plant agriculture, but many have been tested. Interest has centered on producing plants that are resistant to specific herbicides. This resistance would allow crops to be sprayed with the particular herbicide, and only the weeds would be killed, not the genetically engineered crop species. Resistances to plant virus diseases have been induced in a number of crop species by transforming plants with portions of the viral genome, in particular the virus's coat protein.

Biotechnology also holds great promise in the production of vaccines for use in maintaining the health of animals. Interferons are also being tested for their use in the management of specific diseases.

Animals may be transformed to carry genes from other species including humans and are being used to produce valuable drugs. For example, goats are being used to produce tissue plasminogen activator, which has been effective in dissolving blood clots.

Plant scientists have been amazed at the ease with which plants can be transformed to enable them to express foreign genes. This field has developed very rapidly since the first transformation of a plant was reported in 1982, and a number of transformation procedures are available.

Genetic engineering has enabled the large-scale production of proteins which have great potential for treatment of heart attacks. Many human gene products, produced with genetic engineering technology, are being investigated for their potential use as commercial drugs. Recombinant technology has been employed to produce vaccines from subunits of viruses, so that the use of either live or inactivated viruses as immunizing agents is avoided. Cloned genes and specific, defined nucleic acid sequences can be used as a means of diagnosing infectious diseases or in identifying individuals with the potential for genetic disease. The specific nucleic acids used as probes are normally tagged with radioisotopes, and the DNAs of candidate individuals are tested by hybridization to the labeled probe. The technique has been used to detect latent viruses such as herpes, bacteria, mycoplasmas, and plasmodia, and to identify Huntington's disease, cystic fibrosis, and Duchenne muscular dystrophy. It is now also possible to put foreign genes into cells and to target them to specific regions of the recipient genome. This presents the possibility of developing specific therapies for hereditary diseases, exemplified by sickle-cell anemia.

Modified microorganisms are being developed with abilities to degrade hazardous wastes. Genes have been identified that are involved in the pathway known to degrade polychlorinated biphenyls, and some have been cloned and inserted into selected bacteria to degrade this compound in contaminated soil and water. Other organisms are being sought to degrade phenols, petroleum products, and other chlorinated compounds. *See* GENETIC ENGINEERING; MOLECULAR BIOLOGY. [M.Z.]

Biotelemetry The use of telemetry methods for sending signals from a living organism over some distance to a receiver. Usually, biotelemetry is used for gathering data about the physiology, behavior, or location of the organism. Generally, the signals are carried by radio, light, or sound waves. Consequently, biotelemetry implies the absence of wires between the subject and receiver. *See* ANTENNA (ELECTROMAGNETISM); RADIO RECEIVER; RADIO TRANSMITTER.

Generally, biotelemetry techniques are necessary in situations when wires running from a subject to a recorder would inhibit the subject's activity; when the proximity of an investigator to a subject might alter the subject's behavior; and when the movements of the subject and the duration of the monitoring make it impractical for the investigator to remain within sight of the subject. Biotelemetry is widely used in medical fields to monitor patients and research subjects, and now even to operate devices such as drug delivery systems and prosthetics. Sensors and transmitters placed on or implanted in animals are used to study physiology and behavior in the laboratory and to study the movements, behavior, and physiology of wildlife species in their natural environments.

Biotelemetry is an important technique for biomedical research and clinical medicine. Perhaps cardiovascular research and treatment have benefited the most from biotelemetry. Heart rate, blood flow, and blood pressure can be measured in ambulatory subjects and transmitted to a remote receiver-recorder. Telemetry also has been used to obtain data about local oxygen pressure on the surface of organs (for example, liver and myocardium) and for studies of capillary exchange (that is, oxygen supply and discharge). Biomedical research with telemetry includes measuring cardiovascular performance during the weightlessness of space flight and portable monitoring of radioactive indicators as they are dispersed through the body by the blood vessels. *See* SPACE BIOLOGY.

Telemetry has been applied widely to animal research, for example, to record electroencephalograms, heart rates, heart muscle contractions, and respiration, even from sleeping mammals and birds. Telemetry and video recording have been combined in research of the relationships between neural and cardiac activity and behavior. Using miniature electrodes and transmitters, ethologists have studied the influence of one bird's song on the heart rate and behavior of a nearby bird.

Many species of wildlife are difficult to find and observe because they are secretive, nocturnal, wide-ranging, or move rapidly. Most commonly, a transmitter is placed on a wild animal so that biologists can track or locate it by homing toward the transmitted signal or by estimating the location by plotting the intersection of two or more bearings from the receiver toward the signal. For some purposes, after homing to a transmitter-marked animal, the biologists observe its behavior. For other studies, successive estimates of location are plotted on a map to describe movement patterns, to delineate the amount of area the animal requires, or to determine dispersal or migration paths. Ecologists can associate the vegetation or other features of the environment with the locations of the animal.

There are usually two concerns associated with the use of biotelemetry: the distance over which the signal can be received, and the size of the transmitter package. Often, both of these concerns depend on the power source for the transmitter. Integrated circuits and surface mount technology allow production of very small electronic circuitry in transmitters, making batteries the largest part of the transmitter package. However, the more powerful transmitters with their larger batteries are more difficult to place on or implant in a subject without affecting the subject's behavior or energetics. *See* BATTERY. [M.R.F.]

Biotin A vitamin, widespread in nature. It is only sparingly soluble in water; it is stable in boiling water solutions, but can be destroyed by oxidizing agents, acids, and alkalies. Under some conditions, it can be destroyed by oxidation in the presence of rancid fats. Biotin's occurrence in nature is so widespread that it is difficult to prepare a natural deficient diet. Biotin deficiency in animals is associated with dermatitis, loss of hair, muscle incoordination and paralysis, and reproductive disturbances. Biotin deficiency produced in humans by feeding large amounts of egg white resulted in dermatitis, nausea, depression, muscle pains, anemia, and a large increase in serum cholesterol. *See* COENZYME. [S.N.G.]

Biotite An iron-magnesium-rich layer silicate; it is also known as black mica. Biotite is the most abundant of the mica group of minerals. The name is derived from that of the French chemist J. Biot. The formula for the ideal end member, phlogopite, is $KMg_3AlSi_3O_{10}(OH)_2$. The more general formula is $AX_3Y_4O_{12}(Z)_2$, where A (interlayer cation) = K, Na, Ca, Ba, or vacancies; X (octahedral cations) = Li, Mg, Fe^{2+}, Fe^{3+}, Al, Ti, or vacancies; and Y (tetrahedral cation) = Fe^{3+}, Al, Si; Z = (OH), F, Cl, O^{2-}. This formula is more indicative of the wide range of compositions known for this mineral. Biotite has no commercial value, but vermiculite, an alteration product of magnesium-rich biotite, is used as insulation, as packing material, and as an ingredient for potting soils. *See* VERMICULITE.

Biotites are found commonly in igneous and metamorphic rocks. They are the common ferromagnesian phase in most granitic rocks, and are also found in some siliceous and intermediate volcanic rocks. In basaltic rocks biotite sometimes occurs in the crystalline groundmass, and is a common late interstitial phase in gabbroic rocks. It has been recognized in samples of the Earth's mantle found as inclusions in volcanic rocks. Biotites are not stable at the surface of the Earth, as they decompose by both hydrolysis and oxidation when exposed to the Earth's atmosphere. They alter to vermiculite, chlorite, and iron oxides, and thus are uncommon in sedimentary rocks. Biotites are important constituents of metamorphic rocks such as schist and gneiss, and the first appearance of biotite is an important marker in metamorphism. Biotite persists to very high grades of metamorphism, where it reacts with quartz to form granulites made up of potassium feldspar and orthopyroxene, garnet, or cordierite, in addition to quartz and plagioclase. Under conditions of ultrametamorphism, biotite reacts with quartz, plagioclase, and alkali feldspar to form siliceous melts. Biotite is also a common gangue mineral in ore deposits. The mineral has been used as an indicator of H_2O, HF, O_2, and S_2 activities in both rock- and ore-forming processes. *See* IGNEOUS ROCKS; METAMORPHIC ROCKS; METAMORPHISM; MICA; SILICATE MINERALS. [D.R.W.]

Birch A deciduous tree of the genus *Betula* which is distributed over much of North America, in Asia south to the Himalaya, and in Europe. About 40 species are known. The birches comprise the family Betulaceae in the order Fagales. The sweet birch, *B. lenta*, the yellow birch, *B. alleghaniensis*, and the paper birch, *B. papyrifera*, are all important timber trees of eastern United States. The yellow and the paper species extend into Canada. The gray birch, *B. populifolia*, is a smaller tree of the extreme northeastern United States and adjacent Canada. Both sweet (black) and yellow birches can be recognized by the wintergreen taste of the bark of the young twigs. A flavoring similar to oil of wintergreen is obtained from the bark of the sweet birch. The paper and gray birches can be easily identified by their white bark. The bark of the paper birch peels off in thin papery sheets, a characteristic not true of the gray birch. The river birch, *B. nigra*, is a less common tree of wet soils and banks of streams and is important as an ornamental and for erosion control. The hard, strong wood of the yellow and the sweet birches is used for furniture, boxes, baskets, crates, and woodenware. The European birches, *B. pubescens* and *B. pendula*, are the counterparts of the paper and gray birches in the United States. European birches are also cultivated in America. *See* FAGALES. [A.H.G./K.P.D.]

Birefringence The splitting which a wavefront experiences when a wave disturbance is propagated in an anisotropic material; also called double refraction. In anisotropic substances the velocity of a wave is a function of displacement direction. Although the term birefringence could apply to transverse elastic waves, it is usually applied only to electromagnetic waves.

In birefringent materials either the separation between neighboring atomic structural units is different in different directions, or the bonds tying such units together have different characteristics in different directions. Many crystalline materials, such as calcite, quartz, and topaz, are birefringent. Diamonds, on the other hand, are isotropic and have no special effect on polarized light of different orientations. Plastics composed of long-chain molecules become anisotropic when stretched or compressed. Solutions of long-chain molecules become birefringent when they flow. This first phenomenon is called photoelasticity; the second, streaming birefringence. *See* CRYSTAL OPTICS; PHOTOELASTICITY; POLARIZED LIGHT; REFRACTION OF WAVES. [B.H.Bi.]

Birth control Methods of fertility control, including contraception, that are intended to prevent pregnancy, and means of interrupting early pregnancy. The efficacy of the various methods and consistency of use vary widely. Factors associated with degree of effectiveness include user age, income, marital status, and intention (that is, whether contraception is used to delay or to prevent pregnancy). The available methods consist of hormonal methods (including oral contraceptives, subdermal implants, and injectable formulations), sterilization, intrauterine devices, barrier and chemical methods, and fertility awareness methods.

Oral contraceptives contain one or both of two compounds (estrogen and progestin) similar to the hormones that regulate the menstrual cycle. Each monthly series of pills either suppresses ovulation or alters the uterine lining and the cervical mucus, or both. *See* Estrogen; Menstruation; Progesterone.

Postcoital contraception is another hormonal method. In emergency situations (for example, rape) high dosages of oral contraception can be used. One dose is given within 72 h after the episode of unprotected intercourse, and an additional dose is given 12 h later.

The subdermal implant consists of small hollow rods that are placed under the skin of a woman's upper arm and release a low, continuous dose of a progestin. It is more effective than the oral contraceptives and, because it lacks estrogens, does not pose a risk of cardiovascular complications. It is reversible, lasts for 5 years, is nearly as reliable as sterilization, and is less expensive than birth control pills.

An injection of progestin suppresses ovulation and can be given every 3 months. It can be used by women who should not take estrogens. Women experience irregular bleeding in the first 6 months of use, often followed by cessation of menses with continuing use. It has been shown to be as safe and reliable as sterilization, yet is readily reversible.

The main mode of action for the intrauterine device (IUD) is considered to be prevention of fertilization. Of the two commercially available IUDs in the United States, the one containing copper is designed to remain in place for 10 years; for users over the age of 25, the pregnancy rate is less than 1%. The other one releases a daily dosage of the natural hormone progesterone to suppress the uterine lining and requires annual replacement.

Barrier methods include the male condom, female intravaginal pouch, diaphragm, cervical cap, vaginal contraceptive sponge, and various chemical preparations. The condom is a sheath of thin latex (sometimes coated with spermicide) or animal tissue that covers the penis. The intravaginal pouch, also known as a female condom, is a loose-fitting vaginal liner with an external rim designed to hold it in place. The diaphragm is a shallow rubber cup with a ring rim that fits securely in the vagina to cover the cervix. The cervical cap is a smaller, thimble-shaped latex device that fits over the cervix. The diaphragm and cervical cap are used with spermicides. The vaginal contraceptive sponge is a soft, synthetic, disposable sponge that fits over the cervix and, when moistened, continuously releases spermicide.

Fertility awareness methods enable a woman to estimate when she is fertile so that she can practice abstinence or use a barrier method during those times. Techniques used to determine fertility include cervical mucus observation, and body signs with temperature tracking. Such methods are often less effective for contraception.

Sterilization is the most commonly used method of birth control for women and men both in the United States and worldwide. The procedures do not adversely affect the production of male or female hormones, so that individual sexual characteristics such as sex drive and menses usually remain unchanged. Vasectomy is a minor male surgical procedure that occludes the vas deferens by various means (such as by cautery or suture). In the United States, tubal sterilization in the female is an operation commonly performed through the laparoscope. The instrument that performs the tubal occlusion may be either attached to the laparoscope or inserted through the lower abdomen. *See* Fertilization; Pregnancy. [L.B.T.]

Bismuth The metallic element, Bi, of atomic number 83 and atomic weight 208.980 belonging in the periodic table to group V. Bismuth is the most metallic element in this group in both physical and chemical properties. The only stable isotope is that of mass 209. It is estimated that the Earth's crust contains about 0.00002% bismuth. It occurs in nature as the free metal and in ores. The principal ore deposits are in South America. However, the primary source of bismuth in the United States is as a by-product in refining of copper and lead ores. *See* Periodic table.

The main use of bismuth is in the manufacture of low-melting alloys which are used in fusible elements in automatic sprinklers, special solders, safety plugs in compressed gas cylinders, and automatic shutoffs for gas and electric water-heating systems. Some bismuth alloys, which expand on freezing, are used in castings and in type metal. Another important use of bismuth is in the manufacture of pharmaceutical compounds.

Bismuth is a gray-white, lustrous, hard, brittle, coarsely crystalline metal. It is one of the few metals which expand on solidification. The thermal conductivity of bismuth is lower than that of any metal, with the exception of mercury. The table cites the chief physical and mechanical properties of bismuth. Bismuth is inert in dry air at room temperature, although it oxidizes slightly in moist air. It rapidly forms an oxide film at temperatures above its melting point, and it burns at red heat, forming the yellow oxide, Bi_2O_3. The metal combines directly with halogens and with sulfur, selenium, and tellurium; however, it does not combine directly with nitrogen or phosphorus. Bismuth is not attacked at ordinary temperatures by air-free water, but it is slowly oxidized at red heat by water vapor.

Physical and mechanical properties of bismuth

Property	Value	Temperature
Melting point, °C	271.4	
Boiling point, °C	1559	
Heat of fusion, kcal/mole	2.60	
Heat of vaporization, kcal/mole	36.2	
Vapor pressure, mm Hg	1	917°C
	10	1067°C
	100	1257°C
Density, g/cm^3	9.80	20° (solid)
	10.03	300° (liquid)
	9.91	400° (liquid)
	9.66	600° (liquid)
Mean specific heat, cal/g	0.0294	0–270°C
	0.0373	300–1000°C
Coefficient of linear expansion	13.45×10^{-6}/°C	
Thermal conductivity, cal/(s)(cm^2)(°C)	0.018	100° (solid)
	0.041	300° (liquid)
	0.037	400° (liquid)
Electrical resistivity, μohm-cm	106.5	0° (solid)
	160.2	100° (solid)
	267.0	269° (solid)
	128.9	300° (liquid)
	134.2	400° (liquid)
	145.3	600° (liquid)
Surface tension, dynes/cm	376	300°C
	370	400°C
	363	500°C
Viscosity, centipoise	1.662	300°C
	1.280	450°C
	0.996	600°C
Magnetic susceptibility, cgs units	-1.35×10^{-6}	
Crystallography	Rhombohedral, $a_0 = 0.47457$ nm	
Thermal-neutron absorption cross section, barns	0.032 ± 0.003	
Modulus of elasticity, lb/cm^2	4.6×10^6	
Shear modulus, lb/cm^2	1.8×10^6	
Poisson's ratio	0.33	
Hardness, Brinell	4–8	

Almost all compounds of bismuth contain trivalent bismuth. However, bismuth can occasionally be pentavalent or monovalent. Sodium bismuthate and bismuth pentafluoride are perhaps the most important compounds of Bi(V). The former is a powerful oxidizing agent, and the latter a useful fluorinating agent for organic compounds. [S.J.Y.]

Bison The name for two species of the Bovidae in the mammalian order Artiodactyla, found in North America and Europe. The European bison (*Bison bonasus*) is commonly known as the wisent. The American species (*B. bison*), shown in the illustration, is often called buffalo but should not be confused with the African buffalo.

The European bison was originally abundant in the forested areas of western Europe during the late Cenozoic Era. The wisent is a browsing, woodland animal which congregates in relatively small herds. It is almost extinct in its natural range and, although a few herds exist, it is known mainly from a few hundred specimens preserved in zoological gardens and zoos.

North American bison (*Bison bison*).

An intensive effort has been made to preserve the species by breeding and maintaining this animal in captivity.

Although there are differences, the wisent is closely allied to the American species. The wisent has a small head carried in a high position and a short mane, and is more graceful and less massive than the North American species. The hump is less noticeable, the legs are longer, the horns are more slender, and the body is not so shaggy.

Enormous herds of the American bison existed on the Plains area of North America in western Canada and the western United States during the 19th century. It is estimated that there are still about 20,000 bison in Canada and the United States on preserves and national parks. These bovines are massive, with the males attaining a length of 9 ft (2.7 m), a height of 6 ft (1.8 m) at the shoulder, and weight up to 3000 lb (1350 kg). They are herbivorous, and migrated originally when the grass or forage became scarce. The large head is held in a low position, and behind the neck region is a characteristic hump. The forequarters are shaggy with the hair more pronounced in the male than the female. The senses of smell and hearing are well developed, while vision is poor. Both the male and female have horns which are small and set far apart. *See* Artiodactyla; Buffalo; Mammalia. [C.B.C.]

Bit A binary digit. In the computer, electronics, and communications fields, "bit" is generally understood as a shortened form of "binary digit." In a numerical binary system, a bit is either a 0 or 1. Bits are generally used to indicate situations that can take one of two values or one of two states, for example, on and off, true or false, or yes or no. If, by convention, 1 represents a particular state, then 0 represents the other state. For example, if 1 stands for "yes," then 0 stands for "no." *See* Boolean algebra.

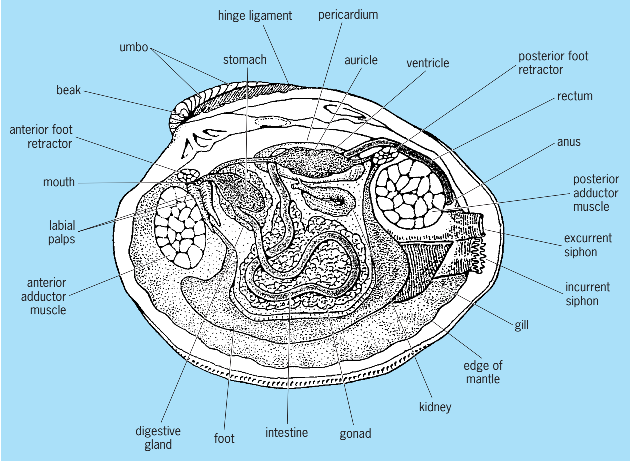
In a computer system a bit is thought of as the basic unit of memory where, by convention, only either a 0 or 1 can be stored. In a computer memory, consecutive bits are grouped to form smaller or larger "units" of memory. Depending upon the design of the computer, units up to 64 bits long have been considered. Although there is common agreement as to the number of bits that make up a byte, for larger memory units the terminology depends entirely on the convention used by the manufacturer. In all of these units the leftmost bit is generally called the most significant bit (msb) and the rightmost the least significant bit (lsb).

Bytes and larger units can be used to represent numerical quantities. In these cases the most significant bit is used to indicate the "sign" of the value being represented. By convention a 0 in the msb represents a positive quantity; a 1 represents a negative quantity. Depending on the convention used to represent these numbers, the remaining bits may then be used to represent the numerical value. In addition to numerical quantities, bytes are used to represent characters inside a computer. These characters include all letters of the English alphabet, the digits 0 through 9, and symbols such as comma, period, right and left parentheses, spaces, and tabs. Characters can be represented using ASCII (American Standard Code for Information Interchange) or EBCDIC (Extended Binary Coded Decimal Interchange Code). The latter is used by some mainframe computers. Computers are set up to handle only one of these two character codes. Generally, the internal representation of a character is different in the two codes. For instance, in ASCII the plus sign is represented by the numerical sequence 00101011, and in EBCDIC, by 01001110. [R.A.M.T.]

Bitumen A term used to designate naturally occurring or pyrolytically obtained substances of dark to black color consisting almost entirely of carbon and hydrogen with very little oxygen, nitrogen, and sulfur. Bitumen may be of variable hardness and volatility, ranging from crude oil to asphaltites, and is largely soluble in carbon disulfide. *See* Asphalt and asphaltite. [I.A.B.]

Bivalvia One of the five classes in the phylum Mollusca, sometimes known as Pelecypoda. All bivalves are aquatic, living at all depths of the sea and in brackish and fresh waters. With about 25,000 living species, Bivalvia is second to class Gastropoda (over 74,000) in molluscan species diversity. However, the total biomass of bivalves is much greater, and certain bivalve species are numerically dominant in many benthic ecosystems. The most primitive bivalves are infaunal, burrowing into soft sediments, but many families are epifaunal, attached to rocks or shells or residing on the sediment surface. Bivalves are well represented in the fossil record from the early Paleozoic because of their calcareous shells.

In general, bivalves are bilaterally symmetrical and laterally compressed. They have a fleshy mantle that secretes the shell



Bivalve anatomy.

enclosing the body (see illustration). The mouth is located anteriorly in bivalves; and in the Lamellibranchiata, the largest subclass, the mouth is flanked by paired labial palps that act to sort food prior to ingestion. Sensory organs are located on the outer mantle margin that has the closest contact with the environment. Frequently these sensory organs are borne on tentacles, and they are sensitive to tactile and chemical stimuli. Certain species of scallops have highly developed light-sensing organs or "eyes" on their mantle tentacles.

The shell consists of two valves with a noncalcified connecting ligament holding the valves together at a hinge plate. The shell layers consist of an outer horny periostracum (protective layer) that can be either absent or eroded in some species, a middle prismatic layer consisting of crystalline calcium carbonate, and an inner lamellar or nacreous layer. In some families such as the Mytilidae (mussels) or the Pteriidae (winged or pearl oysters), the nacreous layer can exhibit a beautiful iridescent sheen, whereas in most bivalves the inner layer is smooth but with a chalky appearance. Hinge ligament tension holds the valves in a gaping position, with valve closure effected by adductor muscles.

The ciliated molluscan gills, properly called ctenidia, are enlarged in the subclass Lamellibranchiata and occupy a substantial portion of the mantle cavity. The ctenidia consist of layered filaments which function primarily to pump water into the mantle cavity and to filter particulate food from the incurrent water stream. The ctenidia of bivalves of the subclass Protobranchia also serve to pump water, but they are smaller and less developed than in the lamellibranchs and do not serve to filter food particles. Protobranch bivalves are deposit feeders that gather food by extending thin muscular palp proboscides to probe soft sediments and entrap organic detrital particles. Bivalves of the subclass Septibranchia (sometimes called Anomalodesmata) have highly modified ctenidia that lack filaments. A septum divides the mantle cavity into dorsal and ventral chambers, and water is pumped by muscular contraction of the septum wall.

Some bivalves have a foot for locomotion. If present, the foot can be extended from the shell by blood pressure and dilated to act as an external anchor while movement is effected by contraction of retractor muscles. Some bivalves of the family Pectinidae (scallops) lack a foot but are highly active swimmers through clapping their valves and jetting water through orifices (openings) near the hinge. Some bivalves, such as oysters and giant clams, are sedentary and lack a foot as adults.

Bivalves exhibit a wide range of reproductive strategies. Most bivalves are dioecious or have separate sexes, while others exhibit various forms of hermaphrodism. For example, as mature adults, scallops carry both eggs and sperm, while oysters exhibit protandric hermaphrodism in which the oysters first develop as males and in subsequent years change sex to develop ovaries. Most species of bivalves shed eggs and sperm directly into the water, where fertilization occurs; in others, eggs may be held in a brood chamber, where they are fertilized by sperm in incurrent water, and released as well-developed larvae into the water. Most bivalves go through several planktonic stages prior to settlement and metamorphosis to their benthic form.

Many species of bivalves are actively farmed either for human consumption of the meats or for shell products. Most of the gem-quality pearls sold in the world originate from farmed pearl oysters of the genus *Pinctada* in Japan, Australia, and islands of the tropical Pacific. Fresh-water pearls are produced from freshwater mussels in the United States, China, and Japan. Other species of bivalves are of economic concern by virtue of being pest organisms or biological invaders.

The fossil record of the Bivalvia can be traced to the Lower Cambrian *Fordilla*. The Ordovician was a major period of bivalve speciation, but throughout the Paleozoic the Bivalvia remained second to bivalves of the phylum Brachiopoda in species diversity and abundance. During the Mesozoic Era, the brachiopods declined in importance. It is probable that diverse adaptations of the Bivalvia to avoid predatory gastropods, arthropods, and fish evolving during the Mesozoic were a major factor in the replacement of the more exposed brachiopods as the dominant bivalves. The evolutionary radiation occurring during the Mesozoic includes the emergence of many species of bivalves that bore into rocks, hard corals, and wood. The Mesozoic emergent family Ostreidae, which includes oysters, remains to the present. The transition from the Mesozoic to Cenozoic began with the extinction of many ancient families and the emergence of several modern families. *See* LAMELLIBRANCHIA; MOLLUSCA; PROTOBRANCHIA; SEPTIBRANCHIA. [M.A.Ric.]

Black hole One of the end points of gravitational collapse, in which the collapsing matter fades from view, leaving only a center of gravitational attraction behind. General relativity predicts that if a star of more than about 3 solar masses has completely burned its nuclear fuel, it should collapse to a configuration known as a black hole. The resulting object is independent of the properties of the matter that produced it and can be completely described by stating its mass, spin, and charge. The most striking feature of this object is the existence of a surface, called the horizon, which completely encloses the collapsed matter. The horizon is an ideal one-way membrane: that is, particles and light can go inward through the surface, but none can go outward. As a result, the object is dark, that is, black, and hides from view a finite region of space (a hole). *See* GRAVITATIONAL COLLAPSE; RELATIVITY.

The possible formation of black holes depends critically on what other end points of stellar evolution are possible. There can always be chunks of cold matter which are stable, but their mass must be considerably less than that of the Sun. For masses on the order of a solar mass, only two stable configurations are known for cold, evolved matter. The first, the white dwarf, is supported against gravitational collapse by the same quantum forces that keep atoms from collapsing. However, these forces cannot support a star which has a mass in excess of about 1.2 solar masses. The second stable configuration, the neutron star, is supported against gravitational collapse by the same forces that keep the nucleus of an atom from collapsing. There is also a maximum mass for a neutron star, estimated to be between 1 and 3 solar masses.

It would appear from the theory that if a collapsing star of over 3 solar masses does not eject matter, it has no choice but to become a black hole. There are, of course, many stars with mass larger than 3 solar masses, and it is expected that a significant number of them will reach the collapse stage without having ejected sufficient matter to take them below the 3-solar-mass limit. Further, more massive stars evolve more rapidly, enhancing the rate of formation of black holes. It seems reasonable to conclude that a considerable number of black holes should exist in the universe.

The black hole solutions of general relativity, ignoring quantum-mechanical effects, are completely stable. Once massive black holes form, they will remain forever; and subsequent processes, for example, the accumulation of matter, only increase their size. Steven Hawking showed that when quantum effects are property taken into account, a black hole should emit thermal radiation, composed of all particles and quanta of radiation which exist. Since a radiating system loses energy and therefore loses mass, a black hole can shrink and decay if it is radiating faster than it is accumulating matter. However, for black holes formed from the collapse of stars, the ambient radiation incident on the black hole from other stars, and from the big bang itself, is much larger than the thermal radiation emitted by the black hole, implying that the black hole would not shrink. Even if the ambient radiation is shielded from the black hole, the time for the black hole to decay is much longer than the age of the universe, so that, in practice, black holes formed from collapse of a star are essentially as stable as they were thought to be before the Hawking radiation was predicted.

Because black holes themselves are unobservable, their existence must be inferred from their effect on other matter. Such is the case with the binary x-ray star system Cygnus X-l. There are a number of binary x-ray systems known. The model which best explains the data is one in which a fairly normal star is in mutual orbit about a very compact object. Because these two are so close, mass flows from the star onto an accreting disk about the compact object. As the mass in the disk spirals inward, it heats up by frictional forces. Because the central body is so compact, the matter heats to a temperature at which thermal x-rays are produced. The only compact objects known that could accomplish this are neutron stars and black holes. The existence of very short-time bursts of radiation also points to an object of small diameter, that is, compact. In some of these binary x-ray systems, there is also a regular pulsed component to the x-rays, indicating a rotating neutron star (by reasoning similar to that given for pulsars). In these systems, the compact object could not be a black hole because that would imply a more complicated structure than a black hole would allow. In other systems, however, there are only irregular pulsations or fluctuations; they are candidates for possible black holes.

The crucial evidence comes from the mass determination of the compact object. Because the inclination of the orbit is not known, a range of masses is found; however, there will be a typical mass obtained by assuming that the orbit is not in an extreme orientation. For three x-ray binaries, Cygnus X-1, LMC X-3, and A0620-00, the typical mass of the compact body is about 10 solar masses, much larger than the maximum mass of a neutron star. In fact, the compact objects in the first and third binary systems are more massive than the maximum mass of a neutron star, no matter what orientation the orbit is assumed to have. Assuming that general relativity is the correct theory of gravitation (and this assumption is now supported very well experimentally), there can be no compact objects of such a mass other than a black hole. In this sense it can now be said that black holes exist.

While the evidence is less direct and more model-dependent, there is growing acceptance of the idea that supermassive black holes exist at the cores of nuclei of active galaxies, including quasars and radio galaxies. Here, the black hole is assumed to interact with accreting matter in such a way as to provide a source of energy to power these ultraluminous objects.

Black holes are thought to exist in the nuclei of other galaxies as well, their presence not giving rise to amounts of radiation as spectacular as for active galactic nuclei only because of differing conditions near the black hole. In the Milky Way Galaxy, observations of the proper motions of stars within a fraction of a parsec of the galactic center demonstrate unambiguously that a central mass concentration of 2×10^6 solar masses is present in a region so compact that no explanation other than that of a central black hole is feasible. Similar, although less convincing, observations of the presence of central black holes have been made for several nearby galaxies. The existence of supermassive black holes is virtually certain. *See* ASTROPHYSICS, HIGH-ENERGY; BINARY STAR; X-RAY ASTRONOMY. [P.C.P.; J.Si.]

Black pepper One of the oldest and most important of the spices. It is the dried, unripe fruit of a weak climbing vine, *Piper nigrum*, a member of the pepper family (Piperaceae), and a native of India or Indomalaysia. The fruits are small one-seeded berries which, in ripening, undergo a color change from green to red to yellow. When in the red stage, they are picked, sorted, and dried. The dry, wrinkled berries (peppercorns) are ground to make the familiar black pepper of commerce. White pepper is obtained by grinding the seed separately from the surrounding pulp. *See* PIPERALES. [P.D.St./E.L.C.]

Black Sea A semienclosed marginal sea with an area of 420,000 km^2 (160,000 mi^2) bounded by Turkey to the south, Georgia to the east, Russia and Ukraine to the north, and Romania and Bulgaria to the west. The physical and chemical structure of the Black Sea is critically dependent on its hydrological balance. As a result, it is the world's largest anoxic basin. It has recently experienced numerous types of environmental stress.

The Black Sea consists of a large basin with a depth of about 2200 m (7200 ft). The continental shelf is mostly narrow except for the broad shelf in the northwest region. Fresh-water input from rivers, especially the Danube, Dniester, and Don, and precipitation exceeds evaporation. Low-salinity surface waters are transported to the Mediterranean as a surface outflow. High-salinity seawater from the Mediterranean enters the Black Sea as a subsurface inflow through the Bosporus. This estuarine circulation (seawater inflow at depth and fresh-water outflow at the surface) results in an unusually strong vertical density gradient determined mainly by the salinity. Thus the Black Sea has a two-layered structure with a lower-salinity surface layer and a higher-salinity deep layer.

The vertical stratification has a strong effect on the chemistry of the sea. Respiration of particulate organic carbon sinking into the deep water has used up all the dissolved oxygen. Thus, conditions favor bacterial sulfate reduction and high sulfide concentrations. As a result, the Black Sea is the world's largest anoxic basin and is commonly used as a modern analog of an environment favoring the formation of organic-rich black shales observed in the geological sedimentary record.

Before the 1970s the Black Sea had a highly diverse and healthy biological population. Its species composition was similar to that of the Mediterranean but with less quantity. The phytoplankton community was characterized by a large diatom bloom in May-June followed by a smaller dinoflagellate bloom. The primary zooplankton were copepods, and there were 170 species of fish, including large commercial populations of mackerel, bonito, anchovies, herring, carp, and sturgeon.

Since about 1970 there have been dramatic changes in the food web due to anthropogenic effects and invasions of new species. It is now characterized as a nonequilibrium, low-diversity, eutrophic state. The large increase in input of nitrogen due to eutrophication and decrease in silicate due to dam construction have increased the frequency of noxious algal blooms and resulted in dramatic shifts in phytoplankton from diatoms (siliceous) to coccolithophores and flagellates (nonsiliceous). The most dramatic changes have been observed in the northwestern shelf and the western coastal regions, which have the largest anthropogenic effects. The water overlying the sediments in these shallow areas frequently go anoxic due to this eutrophication. In the early 1980s the grazer community experienced major increases of previously minor indigenous species such as the omnivorous dinoflagellate *Noctilluca scintillans* and the medusa *Aurelia aurita*. The ctenophore *Mnemopsis leidyi* was imported at the end of the 1980s from the east coast of the United States as ballast water in tankers and experienced an explosive unregulated growth. These changes plus overfishing resulted in a collapse of commercial fish stocks during the 1990s. [J.W.M.]

Black Shale A dark mud rock rich in organic carbon. Black shales are typically very fine-grained and contain pyrite, phosphate, and abnormally large amounts of heavy metals. They commonly display excellent fissility and well-preserved planktonic and nektonic faunas and plant debris. Benthic fossils are rare or absent. Some black shales are sources of hydrocarbons. *See* SHALE.

Black shales are enigmatic deposits. Although the large organic carbon content (3–15%) must have required reducing conditions of deposition, there are few unambiguous indicators of the specific environment, most especially of the depth of water. *See* MARINE SEDIMENTS; SEDIMENTOLOGY.

Black shales are typically well laminated on a scale of millimeters. Laminae are produced by variations in the supply of sediment, such as seasonal alternations of clay and planktonic algae. Delicate laminae can be preserved only in the total absence of benthic life, for burrowing animals disrupt lamination, producing bioturbated texture. Hence it is possible to differentiate between totally anaerobic conditions of deposition and marginally oxygenated (dysaerobic) conditions by recognizing laminated or bioturbated fabrics in a shale. [C.W.By.]

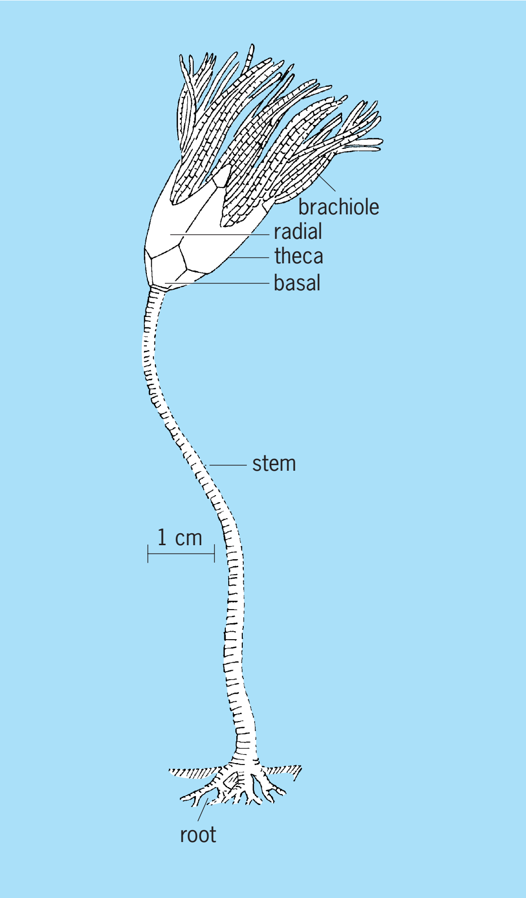
Blackberry Any of several species of the genus *Rubus* (family Rosaceae) having fruit consisting of many drupelets attached to a common fleshy, elongated core (receptacle) which is removed with the fruit. Ripe fruit is usually black or dark purple, and often sweet and flavorful. The bushy plants have perennial roots from which arise long, often thorny, biennial stems (canes) with compound leaves. Many species are native to temperate regions, especially in the Northern Hemisphere, to which they are best adapted. They are commonly found on the edges of forests, along streams, and in clearings. Because of their thorns and prolific growth habit, blackberries are a nuisance in some areas. *See* ROSALES.

Commercial blackberry production occurs mainly in the United States, but appreciable quantities are grown in the United Kingdom and in New Zealand. In commercial plantings in the United States, harvesting is often done by machines which shake the canes and catch the ripe fruit, most of which is frozen or canned for use in bakery products and yogurt or made into jelly, jam, or wine. Some fruit is hand-harvested and sold fresh. The Pacific Coast states account for about 80% of the annual North American production, with Oregon the major producer. *See* FRUIT. [P.J.Bre.]

Blackbody An ideal energy radiator, which at any specified temperature emits in each part of the electromagnetic spectrum the maximum energy obtainable per unit time from any radiator due to its temperature alone. A blackbody also absorbs all the energy which falls upon it. The radiation properties of real radiators are limited by two extreme cases—a radiator which reflects all incident radiation, and a radiator which absorbs all incident radiation. Neither case is completely realized in nature. Carbon and soot are examples of radiators which, for practical purposes, absorb all radiation. Both appear black to the eye at room temperature, hence the name blackbody. Often a blackbody is also referred to as a total absorber. *See* HEAT RADIATION. [H.G.S.; P.J.W.]

Blackleg An acute, usually fatal, disease of cattle and occasionally of sheep, goats, and swine. The infection is caused by *Clostridium chauvoei* (*C. feseri*), a strictly anaerobic, sporeforming bacillus of the soil. The disease is also called symptomatic anthrax or quarter-evil. The characteristic lesions in the natural infection consist of crepitant swellings in involved muscles, which at necropsy are dark red, dark brown, or blue black. Artificial immunization is possible; animals surviving an attack of blackleg are permanently immune to recurrence of the disease. *See* IMMUNITY. [L.S.McC.]

Blastoidea A class of extinct Pelmatozoa in the subphylum Crinozoa, which arose in the Ordovician and flourished during Carboniferous times; they did not survive the Permian. The symmetrical bud-shaped theca comprised 13 rigid plates arranged in three horizontal rings of three basals, five radials, and five deltoids. There was often a jointed aboral stem. The ambulacral grooves were carried on five lancet plates lying in notches in the radial and deltoid plates. Series of lateral plates margined the lancet plates on either side, and each lateral plate supported a brachiole (see illustration). Each brachiole carried a branch of the ambulacral groove. Underneath the ambulacra the radial and deltoid plates were thrown into vertical pleats whose folds hung into the coelom. The reverse folds on the upper side opened to the exterior via pores. *See* CRINOIDEA; CRINOZOA; ECHINODERMATA; PELMATOZOA. [H.B.F.]



A blastoid, *Pentremites*.

Blastomycetes A class of the subdivision Deuteromycotina comprising anamorphic (asexual or imperfect) yeast fungi that lack fruit bodies (conidiomata), have no dikaryophase, and are usually unicellular rather than filamentous. The thallus consists of individual cells. Approximately 80 genera comprising about 600 species are recognized.

The Blastomycetes, like other groups of deuteromycetes, are artificial, composed entirely of anamorphic fungi of ascomycete or basidiomycete affinity. Taxa are referred to as form genera and form species because the absence of sexual, perfect, or meiotic states forces classification and identification by artificial rather than phylogenetic means. Black yeasts are distinguished from anamorphic yeasts by the presence of melanin in the cell walls, abundant production of septate mycelium (filamentous), and aerial dispersal of conidia. Unlike other deuteromycetes, the number of morphological and developmental features for classification of Blastomycetes, although useful, is limited. The emphasis in yeast systematics has therefore been on physiological and biochemical tests, supplemented extensively by serological, electrophoretic, and molecular techniques.

Anamorphic yeasts can be recovered from most ecological niches—animals, plants and their surfaces, fresh and marine water, soils, and environments such as manufacturing plants, tanning fluids, and mineral oils. Blastomycetes are of great economic importance in two respects: the production of products and the spoilage of raw materials and products. Selected strains of *Saccharomyces cerevisiae* are used in the baking, brewing, distilling, and wine industries.

Blastomycetes are also recognized pathogens in medicine. Both *Candida*, causing candidiasis or candidosis, and *Cryptococcus*, causing cryptococcosis, are opportunistic pathogens that cause systemic infections only in individuals with lowered resistance. Esophageal candidiasis and cryptococcosis of the central nervous system are both regarded as being particularly strong indicators of AIDS. *See* DEUTEROMYCOTINA; EUMYCOTA; FUNGI; YEAST. [B.C.S.]

Blastulation The formation of a segmentation cavity or blastocoele within a mass of cleaving blastomeres and rearrangement of blastomeres around this cavity in such a way as to form the type of definitive blastula characteristic of each species. The blastocoele originates as an intercellular space which sometimes arises as early as the four- or eight-cell stage. Thus blastulation is initiated during early cleavage stages, and formation of the definitive blastula is thought to terminate cleavage and to initiate gastrulation. Initially the diameter of the blastula is no greater than that of the activated egg; subsequently it increases. *See* GASTRULATION.

The blastula is usually a hollow sphere. Its wall may vary from one to several cells in thickness. In eggs which contain considerable amounts of yolk the blastocoele may be eccentric in position, that is, shifted toward the animal pole. The animal portion of its wall is always completely divided into relatively small cells, whereas the vegetative portion tends to be composed of relatively large cells and may be incompletely cellulated in certain species. The blastocoele contains a gelatinous or jellylike fluid, which originates in part as a secretion by the blastomeres and in part by passage of water through the blastomeres or intercellular material, or both, into the blastocoele.

The wall of the blastula is a mosaic of cellular areas, each of which will normally produce a certain structure during subsequent development. In other words, each area of cells in the wall of the blastula has a certain prospective fate which will be realized in normal development. [R.L.W.]

Bleaching The process in which natural coloring matter is removed from a fiber to make it white. The process may be used on fiber, yarn, or fabric. Prior to the bleaching of a fabric, preliminary purification processes should be used. These processes remove applied encrustants (desizing) and natural encrustants (scouring or boil-off) so that the bleaching agent may act uniformly on the material free of impediment.

Bleaching is also classified as a purification process and varies with the content of the substrate or fibrous content of the material. It should not be confused with the stripping process, which is the removal of applied color.

The fabric off the loom is called gray, grey, or greige goods to distinguish it from the partially or completely finished fabric.

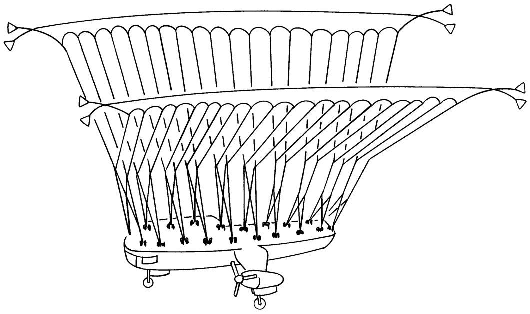
The three most prominent commercial bleaching processes are the peroxide, the chlorine, and the chlorite, in that order.

In home bleaching the predominant bleach is the chlorine bleach, followed by the use of peroxygen compounds such as persulfates and perborates. The latter two are recommended for minimum care and permanent-press fabrics to preclude the yellowing of the whites and the stripping of colored fabrics, which are always potential problems when chlorine bleaches are used.

Optical bleaching uses organic compounds which are capable of absorbing waves shorter than visual waves and emitting waves within the visible range. The most notable of the short waves absorbed is the ultraviolet light present in daylight. These compounds absorb ultraviolet light which is less than 400 micrometers (0.02 in.) and emit blue light which is in the visible range of 400–700 micrometers (0.02–0.03 in.). This emitted blue light will counteract the yellow on the fabric surface and by the subtractive theory of color will produce a white. These agents are also characterized as brighteners and are extensively used in household detergents.

There are several bleaching systems which are classified as combination bleaches because two different bleaching agents are used together or in tandem. These have been projected to lower the cost, lower the degradation, or shorten the cycle as well as to preclude equipment damage in certain cases. *See* NATURAL FIBER; OXIDIZING AGENT; TEXTILE CHEMISTRY. [J.J.McD.]

Blimp A name originally applied to nonrigid airships and usually implying small size. Early blimps contained about 100,000 ft^3 (2800 m^3) and were only a fraction of the size of the rigid airships of that period. The nonrigid pressure-type airship, however, did not stay small; each succeeding model built was substantially larger than its predecessor until ships with volumes of approximately 1,500,000 ft^3 (42,000 m^3) were operational in the U.S. Navy. With the advent of these larger sizes it appeared that the name blimp would be replaced by the more general term airship. However, the principles of construction of these ships are basically the same regardless of the size. *See* AIRSHIP.



Typical internal rigging of nonrigid airships.

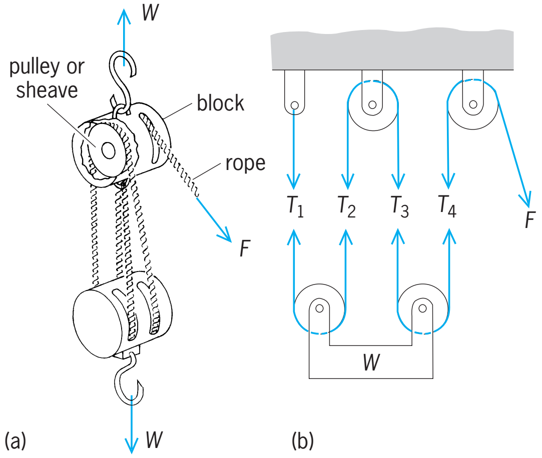
The fabric of the main envelope or pressure hull is usually made up of two or three plies of cloth impregnated with an elastomer; at least one of these plies is placed in a bias direction with respect to the others. This tends to make the fabric more resistant to shear loads and results in a stabilized structure. The materials used for the envelope must be lightweight, extremely strong, and resistant to gas diffusion. The airship envelope is a symmetrical airfoil in the form of a body of revolution, circular in cross section and elliptical along its longitudinal axis.

Inside the envelope are catenary curtains (see illustration). They support the weight of the car by distributing the loads imposed by it into the envelope fabric. This suspension system can be arranged in a number of ways, depending upon the particular airship configuration. Basically, however, they all consist of cable systems attached to the car which terminate in fabric curtains, which in turn are cemented and sewed or otherwise sealed to the envelope proper. The envelope also contains one or more air cells, fastened to the bottom or sides of the envelope, which are used to maintain the required pressure in the envelope without adding or valving of gas as the ship ascends or descends. These air cells are called ballonets and are usually made of a fabric much lighter in weight than that of the envelope, because they must merely retain gas tightness and do not have to withstand the normal envelope pressure.

Up until the late 1980s, the only commercial airships operating in the United States were the Goodyear Tire and Rubber Company advertising blimps of about 150,000 ft^3 (4200 m^3). Fundamentally, they were communications platforms used for public service where airship characteristics are superior to other forms of flight. During the 1980s, several companies other than Goodyear began to produce blimps for advertising purposes, passenger operations, and even possible military missions. Typical of these was Airship Industries of England, which produces the Skyships 500 and 600, used in Europe, the United States, Australia, and Japan, primarily as advertising billboards. In 1988, Goodyear introduced the GZ-22, the largest and most advanced blimp flying at the time, featuring a unique X-configuration tail and shrouded, swivable turboprop power plants. [R.S.R.]

Bloch theorem A theorem that specifies the form of the wave functions that characterize electron energy levels in a periodic crystal. Electrons that move in a constant potential, that is, a potential independent of the position $\mathbf{r}$, have wave functions that are plane waves, having the form $\exp(i\mathbf{k}\cdot\mathbf{r})$. Here, $\mathbf{k}$ is the wave vector, which can assume any value, and describes an electron having momentum $\hbar\mathbf{k}$. (The quantity $\hbar$ is Planck's constant divided by 2π.) Electrons in a crystal experience a potential that has the periodicity of the crystal lattice. *See* BAND THEORY OF SOLIDS. [A.O.]

Block and tackle Combination of a rope or other flexible material and independently rotating frictionless pulleys; the pulleys are grooved or flat wheels used to change the direction of motion or application of force of the flexible member (rope or chain) that runs on the pulleys (see illustration). The block and tackle is used where a large multiplication of the applied forces is desirable. Examples are: lifting weights, sliding heavy machinery into position, and tightening fences. *See* PULLEY; SIMPLE MACHINE. [R.M.Ph.]



Block and tackle. (*a*) Actual view. (*b*) Schematic. Tension $T_1 = T_2 = T_3 = T_4 = 1/4$ weight W; applied force $F = W/4$.

Block diagram A convenient graphical representation of input-output behavior of a system, where the signal into the block represents the input and the signal out of the block represents the output. The flow of information (the signal) is unidirectional from the input to the output. The primary use of the block diagram is to portray the interrelationship of distinct parts of the system.

A block diagram consists of two basic functional units that represent system operations. The individual block symbols portray the dynamic relations between the input and output signals. The second type of unit, called a summing point, is represented by a circle with arrows feeding into it. The operation that results is a linear combination of incoming signals to generate the output signal. The sign appearing alongside each input to the summing point indicates the sign of that signal as it appears in the output.

Block diagrams are widely used in all fields of engineering, management science, criminal justice, economics, and the physical sciences for the modeling and analysis of systems. In modeling a system, some parameters are first defined and equations governing system behavior are obtained. A block diagram is constructed, and the transfer function for the whole system is determined.

If a system has two or more input variables and two or more output variables, simultaneous equations for the output variables can be written. In general, when the number of inputs and outputs is large, the simultaneous equations are written in matrix form. *See* MATRIX THEORY.

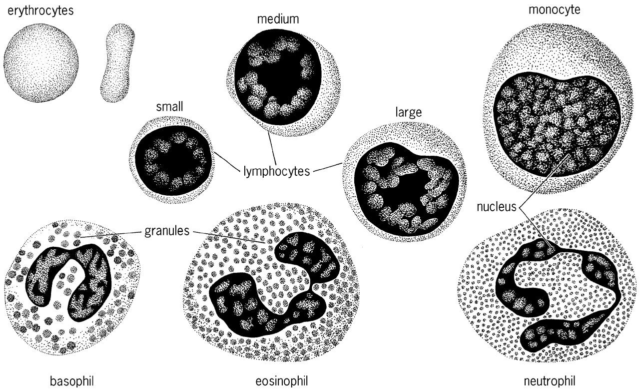
Block diagrams can be used to portray nonlinear as well as linear systems, such as a cascade containing a nonlinear amplifier and a motor. *See* COMPUTER PROGRAMMING; GAIN; NONLINEAR CONTROL THEORY; SYSTEMS ENGINEERING. [G.V.S.R.]

Blood The fluid that circulates in the blood vessels of the body. Blood consists of plasma and cells floating within it. The cells are derived from extravascular sites and then enter the circulatory system. They frequently leave the blood vessels to enter the extravascular spaces, where some of them may be transformed into connective tissue cells. The fluid part of the blood is in equilibrium with the tissue fluids of the body. The circulating blood carries nutrients and oxygen to the body cells, and is thus an important means of maintaining the homeostasis of the body. It carries hormones from their sites of origin throughout the body, and is thus the transmitter of the chemical integrators of the body. Blood plasma also circulates immune bodies and contains several of the components essential for the formation of blood clots. Finally, blood transports waste products to excretory organs for elimination from the body. Because of its basic composition (cells surrounded by a matrix), development, and ability to modify into other forms of connective tissues, blood can be regarded as a special form of connective tissue. *See* CONNECTIVE TISSUE.

Formed elements. The cells of the blood include the red blood cells and the white blood cells. In all vertebrates, except nearly all mammals, the red blood cells or corpuscles contain a nucleus and cytoplasm rich in hemoglobin. In nearly all mammals the nucleus has been extruded during the developmental stages.

In normal adult men the blood contains about 5,000,000 red blood corpuscles or erythrocytes per cubic millimeter; in normal adult women, about 4,500,000. Human erythrocytes are about 8 micrometers in diameter and about 2 μm at their thickest and have a biconcave shape. They contain hemoglobin, which imparts to them their color, and possess an envelope. When circulating in the blood vessels, the red blood cells are not evenly dispersed. In the capillaries the erythrocytes are often distorted. In certain conditions they may be densely aggregated. This is known as a sludge. The erythrocytes respond to changes in osmotic pressure of the surrounding fluid by swelling in hypotonic fluids and by shrinking irregularly in hypertonic fluids. Shrunken red blood cells are referred to as crenated cells. The average life of the mature red blood cells is surprisingly long, having a span of about 120 days. *See* HEMATOLOGIC DISORDERS; HEMOGLOBIN.

In humans the white blood cells in the blood are fewer in number. There are about 5000–9000/mm^3. In general, there are two varieties, agranular and granular. The agranular cells include the small, medium, and large lymphocytes and the monocytes



Diagrammatic representation of human blood cells.

(see illustration). The small lymphocytes are spherical, about the diameter of erythrocytes or a little larger, and constitute about 20–25% of the white blood cells. The medium and large lymphocytes are relatively scarce. In all lymphocytes the nucleus occupies nearly the whole volume of the cell, and the cytoplasm which surrounds it forms a thin shell. The typical monocyte is commonly as large as a large lymphocyte (12 μm), and constitutes 3–8% of the white blood cells. The nucleus is relatively small, eccentric, and oval or kidney-shaped. The cytoplasm is relatively larger in volume than that in lymphocytes.

The granular leukocytes are of three varieties: neutrophil, eosinophil, and basophil. Their structure varies somewhat in different species, and the following applies to those of humans. The neutrophils make up 65–75% of the leukocytes. They are about as large as monocytes with a highly variable nucleus, consisting of three to five lobes joined together by threads of chromatin. The cytoplasm contains numerous minute granules which stain with neutral dyes and eosin. The eosinophils (also called acidophils) are about the same size as the neutrophils but are less numerous, constituting about 1% of the leukocytes. The nucleus commonly contains but two lobes joined by a thin thread of chromatin. The granules which fill the cytoplasm are larger than those of the neutrophils and stain with acid dyes. The basophils are about the same size as the other granular leukocytes. The nucleus may appear elongated or with one or more constrictions. The granules are moderately large, stain with basic dyes, and are water-soluble.

The functions of the leukocytes while they are circulating in the blood are not known. However, when they leave the blood vessels and enter the connective tissue, they constitute an important part of the defense mechanism and of the repair mechanism. Many of the cells are actively phagocytic and engulf debris and bacteria. Lymphocytes are of two major kinds, T cells and B cells. They are involved in the formation of antibodies and in cellular immunity.

The blood platelets are small spindle-shaped or rodlike bodies about 3 μm long and occur in large numbers in circulating blood. In suitably stained specimens they consist of a granular central portion (chromomere) embedded in a homogeneous matrix (hyalomere). They change their shape rapidly on contact with injured vessels or foreign surfaces and take part in clot formation. The platelets are not to be regarded as cells and are thought to be cytoplasmic bits broken off from their cells of origin in bone marrow, the megakaryocytes. [I.G.]

Plasma. Plasma is the residual fluid of blood left after removal of the cellular elements. Serum is the fluid which is obtained after blood has been allowed to clot and the clot has been removed. Serum and plasma differ only in their content of fibrinogen and several minor components which are in large part removed in the clotting process. *See* SERUM.

The major constituents of plasma and serum are proteins. The total protein concentration of human serum is approximately 7 g/ml, and most other mammals show similar levels. By various methods it can be demonstrated that serum protein is a heterogeneous mixture of a large number of constituents. Only a few are present in higher concentrations, the majority being present in trace amounts. More than 60 protein components have been identified and characterized. Albumin makes up more than one-half of the total plasma proteins and has a molecular weight of 69,000. Because of its relatively small molecular size and its high concentration, albumin contributes to 75–80% of the colloid osmotic pressure of plasma. The immunoglobulins, which represent approximately one-sixth of the total protein, largely constitute the γ-globulin fraction. The immunoglobulins are antibodies circulating in the blood, and therefore are also called humoral antibodies. They are of great importance in the organism's defense against infectious agents, as well as other foreign substances. *See* IMMUNOGLOBULIN.

In addition to the proteins, many other important classes of compounds circulate in the blood plasma. Most of these are smaller molecules which diffuse freely through cell membranes and are, therefore, more similarly distributed throughout all the fluids of the body and not as characteristic for plasma or serum as the proteins. In terms of their concentration and their function, the electrolytes are most important. They are the primary factors in the regulation of the osmotic pressure of plasma, and contribute also to the control of the pH. The chief cations are sodium, potassium, calcium, and magnesium. The chief anions are chloride, bicarbonate, phosphate, sulfate, and organic acids. The circulating blood also contains the many small compounds which are transported to the sites of synthesis of larger molecules in which they are incorporated, or which are shifted as products of metabolic breakdown to the sites of their excretion from the body. [H.Cl.]

Coagulation. When mammalian blood is shed, it congeals rapidly into a gelatinous clot of enmeshed fibrin threads which trap blood cells and serum. Modern theories envision a succession of reactions leading to the formation of insoluble fibrin from a soluble precursor, fibrinogen (factor I). Blood also clots when it touches glass or other negatively charged surfaces, through reactions described as the intrinsic pathway. Several of the steps in this process are dependent upon the presence in blood of calcium ions and of phospholipids, the latter derived principally from blood platelets. The coagulation of blood can also be induced by certain snake venoms which either promote the formation of thrombin or clot fibrinogen directly, accounting in part for their toxicity.

Platelets, besides furnishing phospholipids for the clotting process, help to stanch the flow of blood from injured blood vessels by accumulating at the point of injury, forming a plug. Platelets participate in the phenomenon of clot retraction, in which the blood clot shrinks, expelling liquid serum. Although the function of retraction is unknown, individuals in whom this process is impaired have a bleeding tendency.

Hereditary deficiencies of the function of each of the protein-clotting factors have been described, notably classic hemophilia and Christmas disease, which are disorders of males and clinically indistinguishable. The various hereditary functional deficiencies are associated with a bleeding tendency with one inexplicable exception. Acquired deficiencies of clotting factors, sometimes of great complexity, are also recognized. Therapy for bleeding due to deficiencies of clotting factors often includes the transfusion of blood plasma or fractions of plasma rich in particular substances the patient may lack. *See* HUMAN GENETICS.

Clinical tests of the coagulability of the blood include (1) determination of the clotting time, that is, the time elapsing until shed blood clots; (2) the prothrombin time, the time elapsing until plasma clots in the presence of tissue thromboplastin (and therefore a measure of the extrinsic pathway of clotting); (3) the partial thromboplastin time, the time elapsing until plasma clots in the presence of crude phospholipid (and therefore a measure of the intrinsic pathway of clotting); (4) the enumeration of platelets; and (5) crude quantification of clot retraction and of the various plasma protein-clotting factors.

Heparin, a polysaccharide–sulfuric acid complex found particularly in the liver and lungs, impairs coagulation; its presence in normal blood is disputed. Both coumarin and heparin are used clinically to impede coagulation in thrombotic states, including thrombophlebitis and coronary heart disease. *See* FIBRINOGEN. [O.D.R.]

Blood groups Genetically determined markers on the surface of cellular blood elements (red and white blood cells, platelets). In medicine, the matching of ABO and Rh groups of recipients and donors before blood transfusion is of paramount importance; other blood groups also can be implicated in incompatibility. Markers on white cells (histocompatibility antigens) are shared by a number of body tissue cells; these markers are important to the survival of transplanted organs and bone marrow. In law, the recognition of identity between bloodstains found

Table 1. ABO blood group system

Blood group	RBC antigens	Possible genotypes	Plasma antibody
A	A	*A/A or A/O*	anti-B
B	B	*B/B or B/O*	anti-A
O	—	*O/O*	Anti-A and anti-B
AB	A and B	*A/B*	—

at the scene of a crime and those on clothing of a suspect has resulted in many convictions, and blood typing has served to resolve paternity disputes. From an anthropologic standpoint, some blood groups are unique to specific populations and can be a reflection of tribal origin or migration patterns. Blood groups are also valuable markers in gene linkage analysis, and their study has contributed enormously to the mapping of the human genome.

Antibodies. Human blood can be classified into different groups based on the reactions of red blood cells with blood group antibodies (Table 1). Naturally acquired antibodies, such as anti-A and anti-B antibodies, are normally found in serum from persons whose red blood cells lack the corresponding antigen. It is thought that they are stimulated by antigens present in the environment, and are acquired by infants within months of birth. Because anti-A and anti-B antibodies can cause rapid, life-threatening destruction of incompatible red blood cells, blood for transfusion is always selected to be compatible with the plasma of the recipient. *See* ANTIBODY; ANTIGEN.

Most blood group antibodies, including Rh antibodies, are immune in origin and do not appear in serum or plasma unless the host is exposed directly to foreign red blood cell antigens. The most common stimulating event is blood transfusion or pregnancy. Because of the large number of different blood group antigens, it is impossible, when selecting blood for transfusion, to avoid transfusing antigens that the recipient lacks. However, these foreign antigens may or may not be immunogenic. A single-unit transfusion of Rh D-positive to an Rh D-negative recipient causes production of anti-D in about 85% of cases. Consequently, in addition to matching for ABO types, Rh D-negative blood is almost always given to Rh D-negative recipients. In pregnancy, fetal red blood cells cross the placenta and enter the maternal circulation, particularly at delivery. The fetal red blood cells may carry paternally derived antigens that are foreign to the mother and stimulate antibody production. These antibodies may affect subsequent pregnancies by destroying the fetal red blood cells and causing a disease known as erythroblastosis fetalis.

Antigens, genes, and blood group systems. Approximately 700 distinct blood group antigens have been identified on human red blood cells. Biochemical analysis has revealed that most antigen structures are either protein or lipid in nature; in some instances, blood group specificity is determined by the presence of attached carbohydrate moieties. The human A and B antigens, for example, can be either glycoprotein or glycolipid, with the same attached carbohydrate structure. With few exceptions, blood group antigens are an integral part of the cell membrane.

A number of different concepts have been put forth to explain the genetics of the human blood groups. The presence of a gene in the host is normally reflected by the presence of the corresponding antigen on the red blood cells. Usually, a single locus determines antigen expression, and there are two or more forms of a gene or alleles (for example, *a* and *b*) that can occupy a locus. Each individual inherits one allele from each parent. For a given blood group, when the same allele (for example, allele *a*) is inherited from both parents, the offspring is homozygous for *a* and only the antigen structure defined by *a* will be present on the red blood cells. When different alleles are inherited (that is, *a* and *b*), the individual is heterozygous for *a* (and *b*), and both a and b antigens will be found on the red blood cells. In some blood group systems, several loci govern the expression of multiple blood group antigens within that system. These loci are usually closely linked, located adjacent to each other on the chromosome. Such complex loci may contain multiple alleles and are referred to as haplotypes.

Some 200 antigens have been assigned to 25 different blood group systems. Eight such systems are shown in the Table 2. For a system to be established, the genes involved must be distinct from other blood group system genes, and either they must be polymorphic (that is, two or more alleles, each with an appreciable frequency in a population) or the chromosome location must be known. Antigens that do not meet the criteria for assignment to a specific blood group system have been placed into collections, based primarily on biochemical data or phenotypic association, or into a series of either high- or low-frequency antigens.

ABO was the first human blood group system to be described. Three major alleles at the *ABO* locus on chromosome 9 govern the expression of A and B antigens. Gene *A* encodes for a protein (α-*N*-acetylgalactosaminyl transferase) that attaches a blood group–specific carbohydrate (α-*N*-acetyl-D-galactosamine) and

Table 2. Human blood group systems

System name	ISBT[*] symbol	System number	Antigens in system	Chromosome location[†]	Gene products

[*] International Society of Blood Transfusion.

[†] Chromosome locations of genes/loci are identified by the arm (p = short; q = long), followed by the region, then by the band within the region, in both cases numbered from the centromere; ter = end.

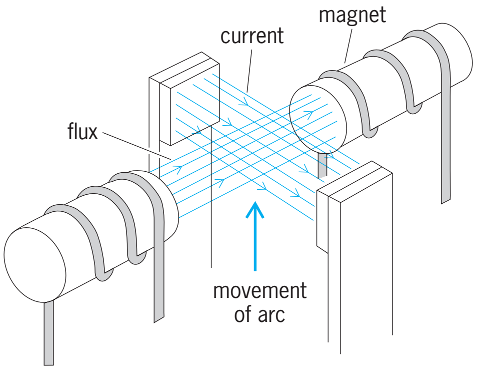
confers blood group A activity to a preformed carbohydrate structure called H antigen. Gene *B* encodes for an α-galactosyl transferase that attaches α-D-galactose and confers blood group B activity to H antigen. In both instances, some H remains unchanged. The *O* gene has no detectable product; H antigen remains unchanged and is strongly expressed on red blood cells. These three genes account for the inheritance of four common phenotypes: A, B, AB, and O. A and O blood types are the most common, and AB the least common. The *A* and *B* genes are codominant; that is, when the gene is present the antigen can be detected. The *O* gene is considered an amorph since its product cannot be detected. When either A or B antigens are present on red blood cells, the corresponding antibody or antibodies should not be present in the serum or plasma. In adults, when A or B or both are absent from the red blood cells, the corresponding naturally acquired antibody is present in the serum. This reciprocal relationship between antigens on the red blood cells and antibodies in the serum is known as Landsteiner's law. Other ABO phenotypes do exist, but these are quite rare. Further, the A blood type can be subdivided, based on strength of antigen expression, with A_1 red blood cells having the most A antigen.

Currently 45 antigens are assigned to the Rh blood group system, although D is the most important. Red blood cells that carry D are called Rh-positive; red blood cells lacking D are called Rh-negative. Other important Rh antigens are C, c, E, and *e*. Rh antigen expression is controlled by two adjacent homologous structural genes on chromosome 1 that are inherited as a pair or haplotype. The *RhD* gene encodes D antigen and is absent on both chromosomes of most Rh-negative subjects. The *RhCE* gene encodes CE protein. Nucleotide substitutions account for amino acid differences at two positions on the CE protein, and result in the Cc and Ee polymorphisms.

Biological role. The function of blood group antigens has been increasingly apparent. Single-pass proteins such as the LU and XG proteins are thought to serve as adhesion molecules that interact with integrins on the surface of white blood cells. Multipass proteins such as band 3, which carries the DI system antigens, are involved in the transportation of ions through the red blood cell membrane bilipid layer. Some blood group antigens are essential to the integrity of the red blood cell membrane, for their absence results in abnormal surface shape; for example, absence of KEL protein leads to the formation of acanthocytes, and absence of RH protein results in stomatocytosis and hemolytic anemia. Many membrane structures serve as receptors for bacteria and other microorganisms. For example, the FY or Duffy protein is the receptor on red blood cells for invasion by *Plasmodium vivax*, the cause of benign tertian malaria. Particularly significant is the fact that Fy(a-b-) phenotype is virtually nonexistent among Caucasians but has an incidence of around 70% among African-Americans. Presumably, the Fy(a-b-) phenotype evolved as a selective advantage in areas where *P. vivax* is endemic. Similarly, the S-s-U-red blood cell phenotype in the MNS blood group system affords protection against *P. falciparum*, or malignant tertian malaria. Yet other blood group antigens can be altered in disease states; A, B, and H antigens are sometimes weakened in leukemia or may be modified by bacterial enzymes in patients with septicemia. *See* BLOOD; IMMUNOLOGY. [W.J.J.]

Blood vessels Tubular channels for blood transport, of which there are three principal types: arteries, capillaries, and veins. Only the larger arteries and veins in the body bear distinct names. Arteries carry blood away from the heart through a system of successively smaller vessels. Capillaries are the smallest but most extensive blood vessels, forming a network everywhere in the body tissues. Veins carry blood from the capillary beds back to the heart through increasingly larger vessels. In certain locations blood vessels are modified for particular functions, as the sinusoids of the liver and the spleen and the choroid plexuses of the brain ventricles. *See* CAPILLARY (ANATOMY); LYMPHATIC SYSTEM. [W.J.B.]

Blowout coil A coil that produces a magnetic field in an electrical switching device for the purpose of lengthening and extinguishing an electric arc formed as the contacts of the switching device part to interrupt the current. The magnetic field produced by the coil is approximately perpendicular to the arc. The interaction between the arc and current and the magnetic field produces a force driving the arc in the direction perpendicular to both the magnetic flux and the arc current (see illustration). [T.H.L.]



Relation of directions of current, magnetic flux, and movement of arc in a blowout coil.

Blowpipe In glass blowing, a long straight tube on which molten glass is gathered and worked, partly by blowing into the tube. The blowpipe is spun to shape the glass object further by centrifugal force, or by a tool, in which case the blowpipe acts as a spindle for turning.

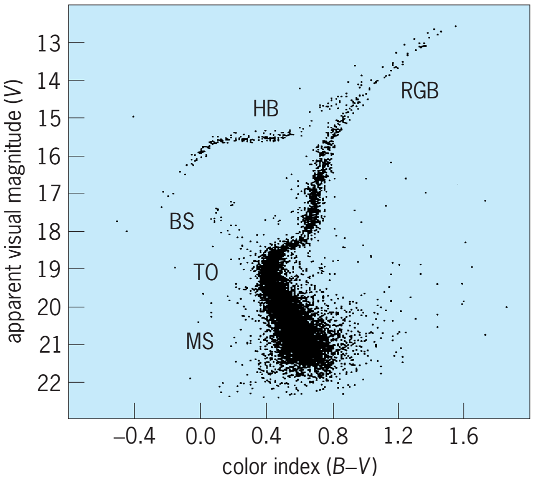
In analytical chemistry, a blowpipe is a small, tapered, and frequently curved tube that directs a jet, usually of air, into a flame to concentrate the flame onto an unknown substance.

Coloration of the flame and other characteristic reactions in the reducing and in the oxidizing portions of the flame created by the blowpipe aid in identifying the substance. Such a blow-pipe may be blown directly by the analyst, from a bellows, or from a pressurized line. [F.H.R.]

Blue straggler star A star that is a member of a stellar association and is located at an unusual position on the association's color-magnitude diagram, above the turnoff from the main sequence. *See* COLOR INDEX; HERTZSPRUNG-RUSSELL DIAGRAM.

The blue stragglers were discovered by A. Sandage in 1953 in the galactic globular cluster M3 (see illustration). They are located below the horizontal branch and above the turnoff from the main sequence. They form a new sequence extending from the extrapolation of the main sequence to higher luminosities on the left to the red giant branch on the right. While the majority of the cluster members fall rather precisely on the expected isochrones for the approximately 15×10^9-year age of the cluster, the 50 or so blue stragglers in M3 are located on much younger isochrones. More than 1000 objects of this type have been found so far in every known type of stellar association, including dwarf spheroidal galaxies. *See* GALAXY, EXTERNAL.

The simplest explanation of the phenomenon is that the blue stragglers are younger than the rest of the cluster members, perhaps because of a recent burst of star formation. This delayed-formation scenario is possible in young open clusters and some dwarf spheroidal galaxies. However, there is no evidence at all for recent star formation episodes in the galactic globular clusters. For these systems, the scenario for the origin of blue stragglers favored by most astronomers in the field involves the merging of two low-mass stars to form a relatively unevolved more massive star. Two possibilities in this context have been discussed: merging of stars in a preexisting binary system by mass transfer, and



Color-magnitude diagram [apparent visual magnitude *(V)* versus color index *(B-V)*] of 10,637 stars in the galactic globular cluster M3 (NGC 5272). The important evolutionary stages are marked by MS (main sequence), TO (turn-off), RGB (red giant branch), HB (horizontal branch), and BS (blue stragglers). (*After R. Buonanno et al., High precision photometry of 10,000 stars in M3, Mem. Soc. Astron. It., 57:391–393, 1986*)

formation of a relatively unevolved massive star by direct collision of two stars. Both of these mechanisms are likely to occur simultaneously in globular clusters, giving rise to two different types of blue stragglers. The collisional stragglers should have been formed in the dense core where the stellar density, and thus the chance of a collision, is the highest, while the binary stragglers depend sensitively only on the number of primordial binaries and could be located anywhere in the cluster. *See* Binary star; Star cluster; Stellar evolution. [F.P.]

Blueberry Several species of the genus *Vaccinium*, plant order Ericales, ranging from low-growing, almost prostrate plants to vigorous shrubs reaching a height of 12–15 ft (3.7–4.6 m). The fruit, a berry, is usually black and covered with bluish bloom, generally occurring in clusters, and has numerous small seeds, a characteristic that distinguishes the blueberry from the huckleberry, which has 10 rather large, gritty seeds. Although there are blueberry species on other continents, all cultivated varieties in the United States are American in origin.

The dryland blueberry (*V. ashei*) is adapted to relatively dry soils and has been brought under cultivation in Florida and Georgia. In the Northeast the lowbush blueberry (*V. lamarckii*) grows wild over thousands of acres of dry hillsides, where it is harvested commercially, especially in Maine, but also in other New England states, Michigan, Minnesota, and a few others. In the Northwest fruit of the evergreen blueberry (*V. ovatum*) is harvested in the wild, and large tonnages of the leafy twigs are shipped for use as florists' greens. The highbush blueberry, represented by *V. australe* and *V. corymbosum*, provides most of the cultivated plants. The highbush blueberry is found in swampy land, usually on hummocks.

The fruit is sold fresh, canned, and frozen. The blueberry is becoming increasingly popular in home gardens, although its cultural requirements are rather exacting. For garden culture, mulching with sawdust or other organic matter is desirable because the roots are shallow. *See* Ericales. [J.H.Cl.]

Bluefish A predatory and voracious species of fish that ranges throughout the tropical and temperate seas of the world, except for the eastern and central Pacific areas. A single species, *Pomatomus saltatrix*, makes up the family Pomatomidae. This fish, also known as the skipjack, is bluish gray with an average length of 3 ft (0.9 m) and weight of about 5 lb (2.3 kg). The mouth is large with sharp, strong teeth. The bluefish form schools and migrate north along the Atlantic coast, following schools of smaller fish upon which they prey. The bluefish continue to kill and destroy their prey even after feeding. About June they reach the New England coast, where the young can be found in estuaries and bays. *See* Perciformes. [C.B.C.]

Bluegrass Grass of genus *Poa* (also called meadowgrass), of the family Graminae (Poaceae). About 50 species are natural to the United States, and 4 are of economic importance: Kentucky bluegrass (*P. pratensis*), used in lawns and pasture; Canada bluegrass (*P. compressa*), used for erosion control; roughstalk bluegrass (*P. trivialis*), adapted for turf in cool wet shade; and annual bluegrass (*P. annua*), a weed of cool moist sites. Kentucky bluegrass was introduced from Europe to Illinois by French missionaries, and spread rapidly throughout the Midwest, thriving where mean July temperatures are below 68°F (20°C). *See* Grass crops.

Kentucky bluegrass (Junegrass) provides nutritious spring pasture, but tends to semidormancy and sparse pasture in summer. Replaced by other grasses for pasture, it is now valued as grass for lawns in temperate North America. Bluegrass lawn turf is planted during fall or spring from sod or seed. Seed is sown at about 2 lb/1000 ft^2 (1 kilogram/are). In fertile soil, plants spread by rhizomes to form a dense sod, favoring a soil of pH 5.8–6.8, good levels of phosphorus and nitrogen, and a mowing of not lower than 2 in. (5 cm) with a sharp blade. Fertilizer needs depend on soil, length of growing season, and whether clippings are removed or left so nutrients are recycled. Irrigation is needed in regions of low rainfall or during periods of drought. [J.H.Ma.]

Blueschist Metamorphic rock formed at high pressure and low temperature, commonly above 5 kilobars (500 megapascals) and below 750°F (400°C). Metamorphic rocks of the relatively uncommon blueschist facies contain assemblages of minerals that record these high pressures and low temperatures. The name "blueschist" derives from the fact that at this metamorphic grade, rocks of ordinary basaltic composition are often bluish because they contain the sodium-bearing blue amphiboles glaucophane or crossite rather than the calcium-bearing green or black amphiboles actinolite or hornblende, which are developed in the more common greenschist- or amphibolite-facies metamorphism.

Blueschist metamorphic rocks are found almost exclusively in the young mountain belts of the circum-Pacific and Alpine-Himalayan chains. The rocks are usually metamorphosed oceanic sediments and basaltic oceanic crust. Previously continental rocks rarely exhibit blueschist metamorphism. The tectonic mechanism for blueschist metamorphism must move the rocks to depths of more than 6 to 12 mi (10 to 20 km) while maintaining relatively cool temperatures (390–750°F or 200–400°C). These temperatures are much cooler than for continental crust at those depths. For example, surface geothermal gradients of the order of 30°C per kilometer are common in continental crust and in thick sedimentary basins. In contrast, a steady-state surface gradient of about 44 to 58°F per mile (15 to 20°C per kilometer) would be required for typical blueschist metamorphism. Heat flow measurements above long-lived subduction zones, together with thermal models, suggest that the conditions of blueschist metamorphism exist today above subduction zones just landward of deep-sea trenches. This tectonic setting at the time of blueschist metamorphism is independently inferred for a number of metamorphic terranes.

What is not well understood is how the blueschist metamorphic rocks return to the surface; clearly the mechanism is not simple uplift and erosion of 12–18 mi (20–30 km) of the Earth's crust. Blueschist metamorphic rocks are usually in immediate fault contact with much less metamorphosed or unmetamorphosed sediments, indicating they have been tectonically displaced relative to their surroundings since metamorphism. *See* Metamorphic rocks; Metamorphism. [J.Sup.]

Bluestem grass The common generic name often applied to the genera *Andropogon, Dichanthium, Bothriochloa*, and *Schizachyrium* in the grass tribe Andropogoneae. They are adapted to environments with high light intensities and high temperatures during the growing season. The bluestems are medium to tall, warm-season, perennial grasses. The two most important forage species are big bluestem (*A. gerardi*) and little bluestem (*S. scoparius*).

Big bluestem is a tall (usually 3 to 6 ft or 1 to 2 m), deep-rooted grass with strong rhizomes; it occurs throughout the continental United States (except in the extreme western states), in southern Canada, and in northern Mexico. One of the most palatable of all grasses when it is actively growing, its nutritional value declines sharply with maturity. Because of its high palatability and tall growth habit, big bluestem has been reduced or eliminated by heavy grazing over much of its range.

Little bluestem is a medium-height bunchgrass (usually 1 to 2 ft or 30 to 60 cm, but taller in the south) which occurs in the same geographic area as big bluestem but extends farther north in the prairie provinces of Canada to the southern Yukon. It is an excellent grass for grazing and hay when actively growing, but nutritional value declines rapidly with maturity. This is the grass that provides the major aspect of the Flint Hills of Kansas and the Osage Hills of Oklahoma. *See* CYPERALES. [J.K.L.]

Bluetongue An arthropod-borne disease of ruminant species. Its geographic distribution is dependent upon a susceptible ruminant population and climatic conditions that favor breeding of the primary vector, a mosquito (*Culicoides* species).

Bluetongue virus is the prototype of the genus *Orbivirus* (family Reoviridae). The viral genome exists as 10 segments of the double-stranded ribonucleic acid (RNA) that encode for seven structural and three nonstructural proteins. The viral particle has a double capsid, with the outer coat (morphologically poorly defined) being composed of two proteins. Twenty-four serotypes of bluetongue virus have been defined, and their distribution throughout the world is varied. *See* ANIMAL VIRUS.

While multiple ruminant species can become infected, only sheep and deer typically display clinical bluetongue disease. Severity of the disease is dependent upon multiple factors, including virus strain, animal breed, and environmental conditions. Upon infection by a gnat bite, the virus apparently replicates in the local lymphatic system prior to the viral particles moving into the blood (viremia). Viral replication occurs in the endothelial cells of small vessels, resulting in narrowing of the vessel, release of proteinaceous material into the surrounding tissues, and possibly hemorrhage, with the respiratory tract, mucous membranes, cardiac and skeletal musculature, and skin being most affected. Animals experiencing acute clinical symptoms typically die from pneumonia or pulmonary failure; hemorrhage at the base of the pulmonary artery indicates the presence of a vascular lesion.

Control of bluetongue disease requires the application of vaccines and modulation of the farm environment. While bluetongue virus vaccines are available, efficacy is often incomplete and variable, in part because of the multiplicity of serotypes active throughout the world and limited cross-serotype protection. Furthermore, use of polyvalent (multiple-serotype) vaccines in the United States has been discouraged because of potential genetic reassortment between vaccine viruses and wild-type viruses, a process that could possibly lead to pathogenic variants. Relative to environment, elimination of vector breeding sites can also facilitate control of virus transmission. With the multiplicity of serotypes typically active in an endemic area, and the minimal cross-serotype protection observed, administration of vaccine in the face of an outbreak may be of limited value. *See* VACCINATION. [J.L.Sto.]

Boat propulsion The action of propelling a boat through water. A boat machinery plant consists principally of a propulsion engine, propulsor (propeller or jet pump), and drive-line components. The engines are almost exclusively of the familiar internal combustion types: gasoline, diesel, or gas turbine. The gasoline engine has traditionally dominated the pleasure-boat field, while the diesel is favored for commercial and military craft. The gas turbine is comparatively rare and is found only in applications where high power from machinery of small weight and volume is essential.

Auxiliary items, such as bilge pumps, domestic water pumps and heaters, and electric generators and switchboards typically are found in the machinery plants of the larger boats. The generator (or alternator) is often driven by a belt from the propulsion engine, as in automotive practice, but is sometimes driven by a separate engine.

The marine gasoline engine appears in inboard and out-board forms. The outboard engine is a unit assembly of engine, propeller, and vertical drive shaft that is usually clamped to the boat transom. It is traditionally the power plant for the smallest motor boats, or an auxiliary for rowboats and sailboats. The inboard form is almost exclusively adapted from one of the mass-produced automotive engines. Inboard engines are compact, light, lower in first cost than any competitor, and familiar to untrained users, and so they predominate among pleasure boats and the smaller fishing boats.

The diesel engine is generally higher in first cost than the gasoline engine and is somewhat heavier for the same power, but it consumes less fuel. Fuel savings make the diesel attractive if the engine is to be used more than a few hundred hours a year or if the boat must have a long cruising range. Its principal market is thus in commercial and military craft, but some of the more compact models are used in pleasure craft.

The gas turbine engine is comparatively light and compact, making it attractive for high-speed, high-power boats. Its disadvantages are high first cost, high fuel consumption, and large exhaust and intake ducts. The last factor is due to its high rate of air consumption; the need for large volumes of air also makes it difficult, in a small vessel, to keep spray from being drawn into the engine, with consequent fouling and corrosion. *See* DIESEL ENGINE; GAS TURBINE; INTERNAL COMBUSTION ENGINE; MARINE ENGINE; MARINE MACHINERY. [J.B.W.]

Bog Nutrient-poor, acid peatlands with a vegetation in which peat mosses (*Sphagnum* spp.), ericaceous dwarf shrubs, and to a lesser extent, various sedges (Cyperaceae) play a prominent role. The terms muskeg, moor, heath, and moss are used locally to indicate these sites. *See* MUSKEG.

Bogs are most abundant in the Northern Hemisphere, especially in a broad belt including the northern part of the deciduous forest zone and the central and southern parts of the boreal forest zone. Farther south, and in drier climates farther inland, they become sporadic and restricted to specialized habitats. To the north, peatlands controlled by mineral soil water (aapa mires) replace them as the dominant wetlands.

Bogs are much less extensive in the Southern Hemisphere because there is little land in cold temperate latitudes. In these Southern Hemisphere peatlands, *Sphagnum* is much less important, and Epacridaceae and Restionaceae replace the Ericaceae and Cyperaceae of the Northern Hemisphere.

Bogs have a fibric, poorly decomposed peat consisting primarily of the remains of *Sphagnum*. Peat accumulation is the result of an excess of production over decomposition. Obviously, the very presence of bogs shows that production exceeded decay over the entire period of bog formation. However, in any given bog present production can exceed, equal, or be less than decomposition, depending on whether it is actively developing, in equilibrium, or eroding. In most bogs, production and decomposition appear to be in equilibrium at present.

Slow decay rather than high productivity causes the accumulation of peat. Decomposition of organic matter in peat bogs is slow due to the high water table, which causes the absence of oxygen in most of the peat mass, and to the low fertility of the peat. Bogs, in contrast to other peatlands, can accumulate organic matter far above the groundwater table.

Bogs show large geographic differences in floristic composition, surface morphology, and development. Blanket bogs, plateau bogs, domed bogs, and flat bogs represent a series of bog types with decreasing climatic humidity. Concentric patterns of pools and strings (peat dams) become more common and better developed northward. Continental bogs are often forest-covered, whereas oceanic bogs are dominated by dwarf shrub heaths and sedge lawns, with forests restricted to the bog slope if the climate is not too severe.

Bogs have long been used as a source of fuel. In Ireland and other parts of western Europe, the harvesting of peat for domestic fuel and reclamation for agriculture and forestry have affected most of the peatlands, and few undisturbed bogs are left. Other uses are for horticultural peat, air layering in greenhouses, litter for poultry and livestock, and various chemical and pharmaceutical purposes. Mechanical extraction of peat for horticultural purposes has affected large bog areas worldwide. *See* BIOMASS; SWAMP, MARSH, AND BOG. [A.W.H.D.]

Bohrium A chemical element, symbol Bh, atomic number 107. Bohrium was synthesized and identified in 1981 by using the Universal Linear Accelerator (UNILAC) of the Gesellschaft für Schwerionenforschung (GSI) at Darmstadt, West Germany, by a team led by P. Armbruster and G. Müzenberg. The reaction used to produce the element was proposed and applied in 1976 by Y. T. Oganessian and colleagues at Dubna Laboratories in Russia. A ^{209}Bi target was bombarded by a beam of ^{54}Cr projectiles.

The best technique to identify a new isotope is its genetic correlation to known isotopes through a radioactive decay chain. These decay chains are generally interrupted by spontaneous fission. In order to apply decay chain analysis, those isotopes that are most stable against spontaneous fission should be produced, that is, isotopes with odd numbers of protons and neutrons. Not only does the fission barrier govern the spontaneous fission of a species produced, but also, in the deexcitation of the virgin nucleus, fission competing with neutron emission determines the final production probability. To keep the fission losses small, a nucleus should be produced with the minimum excitation energy possible. In this regard, reactions using relatively symmetric collision partners and strongly bound closed-shell nuclei, such as ^{209}Bi and ^{208}Pb as targets and ^{48}Ca and ^{50}Ti as projectiles, are advantageous.

Six decay chains were found in the Darmstadt experiment. All the decays can be attributed to ^{262}Bh, an odd nucleus produced in a one-neutron reaction. The isotope ^{262}Bh undergoes alpha-particle decay (10.38 MeV) with a half-life of about 5 ms.

Experiments at Dubna, performed in 1983 using the 157-in. (400-cm) cyclotron, established the production of ^{262}Bh in the reaction ^{209}Bi ^{54}Cr. *See* NUCLEAR FISSION; NUCLEAR REACTION; PERIODIC TABLE; RADIOACTIVITY; TRANSURANIUM ELEMENTS. [P.Ar.]

Boiler A pressurized system in which water is vaporized to steam, the desired end product, by heat transferred from a source of higher temperature, usually the products of combustion from burning fuels. Steam thus generated may be used directly as a heating medium, or as the working fluid in a prime mover to convert thermal energy to mechanical work, which in turn may be converted to electrical energy. Although other fluids are sometimes used for these purposes, water is by far the most common because of its economy and suitable thermodynamic characteristics.

The physical sizes of boilers range from small portable or shop-assembled units to installations comparable to a multistory 200-ft-high (60-m) building equipped, typically, with a furnace which can burn coal at a rate of 6 tons/min (90 kg/s). Boilers operate at positive pressures and offer the hazardous potential of explosions. Pressure parts must be strong enough to withstand the generated steam pressure and must be maintained at acceptable temperatures, by transfer of heat to the fluid, to prevent loss of strength from overheating or destructive oxidation of the construction materials.

The overall functioning of steam-generating equipment is governed by thermodynamic properties of the working fluid. By the simple addition of heat to water in a closed vessel, vapor is formed which has greater specific volume than the liquid, and can develop an increase of pressure to the critical value of 3208 psia (22.1 megapascals absolute pressure). If the generated steam is discharged at a controlled rate, commensurate with the rate of heat addition, the pressure in the vessel can be maintained at any desired value, and thus be held within the limits of safety of the construction. *See* STEAM.

Addition of heat to steam, after its generation, is accompanied by increase of temperature above the saturation value. The higher heat content, or enthalpy, of superheated steam permits it to develop a higher percentage of useful work by expansion through the prime mover, with a resultant gain in efficiency of the power-generating cycle. *See* SUPERHEATER.

If the steam-generating system is maintained at pressures above the critical, by means of a high-pressure feedwater pump, water is converted to a vapor phase of high density equal to that of the water, without the formation of bubbles. Further heat addition causes superheating, with corresponding increase in temperature and enthalpy. The most advanced developments in steam-generating equipment have led to units operating above critical pressure, for example, 3600–5000 psi (25–34 MPa). Superheated steam temperature has advanced from 500 ± °F (260 ± °C) to the present practical limits of 1050–1100°F (566–593°C). *See* MARINE ENGINEERING; NUCLEAR POWER; STEAM-GENERATING UNIT. [T.Ba.]

Boiler economizer A component of a steam-generating unit that absorbs heat from the products of combustion after they have passed through the steam-generating and super-heating sections. The name, accepted through common usage, is indicative of savings in the fuel required to generate steam.

An economizer is a forced-flow, once-through, convection heat-transfer device to which feedwater is supplied at a pressure above that in the steam-generating section and at a rate corresponding to the steam output of the unit. The economizer is in effect a feedwater heater, receiving water from the boiler feed pump and delivering it at a higher temperature to the steam generator or boiler. Economizers are used instead of additional steam-generating surface because the feedwater, and consequently the heat-receiving surface, is at a temperature below that corresponding to the saturated steam temperature; thus, the economizer further lowers the flue gas temperature for additional heat recovery. *See* BOILER FEEDWATER; THERMODYNAMIC CYCLE.

Generally, steel tubes, or steel tubes fitted with externally extended surface, are used for the heat-absorbing section of the economizer; usually, the economizer is coordinated with the steam- generating section and placed within the setting of the unit. *See* AIR HEATER; BOILER; STEAM-GENERATING UNIT. [G.W.K.]

Boiler feedwater Water supplied to a boiler unit for the generation of steam. Feedwater should be virtually free of impurities that are harmful to the boiler and its associated system. Generally, natural waters are unsuitable for direct use as feedwater because of their contamination by contact with the earth, the atmosphere, or other sources of pollution. These contaminants can be removed or altered by chemical treatment and other means to provide satisfactory feedwater. *See* RAW WATER; WATER TREATMENT. [G.W.K.]

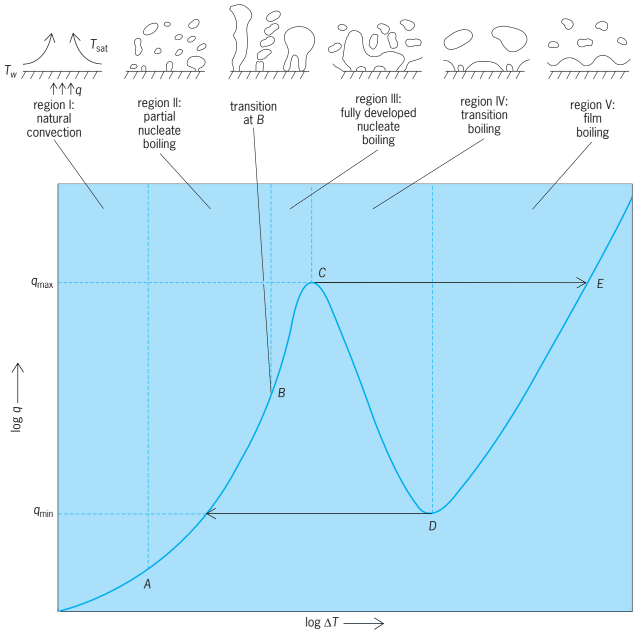
Boiler feedwater regulation Addition of water to a steam-generating unit at a rate commensurate with the removal of steam from the unit. The addition of water to a boiler requires a feedwater pump or some other device that will develop a pressure higher than that of the steam generated. Means also are required to control the rate at which water is added. *See* Boiler.

Variations of water level in the steam unit usually are due to changes in the rate of steam generation because such changes affect the steam output and the volume of the steam below the water level. Changes in water level can be compensated by use of automatic control which, primarily, regulates the rate of feedwater flow to be equal to the rate of steam output, as determined by metering equipment; the control then readjusts the rate of feedwater flow to maintain the water level within the prescribed normal range. *See* Boiler feedwater. [G.W.K.]

Boiling A process in which a liquid phase is converted into a vapor phase. The energy for phase change is generally supplied by the surface on which boiling occurs. Boiling differs from evaporation at predetermined vapor/gas-liquid interfaces because it also involves creation of these interfaces at discrete sites on the heated surface. Boiling is an extremely efficient process for heat removal and is utilized in various energy-conversion and heat-exchange systems and in the cooling of high-energy density components. *See* Boiler; Evaporation; Heat exchanger; Heat transfer.

Boiling is classified into pool and forced-flow. Pool boiling refers to boiling under natural convection conditions, whereas in forced-flow boiling the liquid flow over the heater surface is imposed by external means. Flow boiling is subdivided into external and internal. In external-flow boiling, liquid flow occurs over heated surfaces, whereas internal-flow boiling refers to flow inside tubes. Heat fluxes of 2×10^8 W/m^2, or three times the heat flux at the surface of the Sun, have been obtained in flow boiling. *See* Convection (heat).

Pool boiling. The illustration, a qualitative pool boiling curve, shows the dependence of the wall heat flux q on the wall superheat ΔT (the difference between the wall temperature and the liquid's saturation temperature). The plotted curve is for a horizontal surface underlying a pool of liquid at its saturation temperature (the boiling point at a given pressure). *See* Boiling point.



Typical boiling curve, showing qualitatively the dependence of the wall heat flux q on the wall superheat ΔT. Schematic drawings show the boiling process in regions I–V, and transition points *A–E*.

Several heat transfer regimes can be identified on the boiling curve: single-phase natural convection, partial nucleate boiling, fully developed nucleate boiling, transition boiling, and film boiling.

Forced-flow boiling. Forced flow, both external and internal, greatly changes the boiling curve in the illustration. The heat flux is increased by forced convection at temperatures below boiling inception, and after that the nucleate boiling region is extended upward until a flow-enhanced higher maximum flux (corresponding to point *C*) is achieved. Forced flow boiling in tubes is used in many applications, including steam generators, nuclear reactors, and cooling of electronic components. *See* Steam-generating unit. [V.K.D.]

Boiling point The boiling point of a liquid is the temperature at which the liquid and vapor phases are in equilibrium with each other at a specified pressure. Therefore, the boiling point is the temperature at which the vapor pressure of the liquid is equal to the applied pressure on the liquid. The boiling point at a pressure of 1 atmosphere is called the normal boiling point.

For a pure substance at a particular pressure P, the stable phase is the vapor phase at temperatures immediately above the boiling point and is the liquid phase at temperatures immediately below the boiling point. The liquid-vapor equilibrium line on the phase diagram of a pure substance gives the boiling point as a function of pressure. Alternatively, this line gives the vapor pressure of the liquid as a function of temperature. The vapor pressure of water is 1 atm (101.325 kilopascals) at 100°C (212°F), the normal boiling point of water. The vapor pressure of water is 3.2 kPa (0.031 atm) at 25°C (77°F), so the boiling point of water at 3.2 kPa is 25°C. The liquid-vapor equilibrium line on the phase diagram of a pure substance begins at the triple point (where solid, liquid, and vapor coexist in equilibrium) and ends at the critical point, where the densities of the liquid and vapor phases have become equal. For pressures below the triple-point pressure or above the critical-point pressure, the boiling point is meaningless. Carbon dioxide has a triple-point pressure of 5.11 atm (518 kPa), so carbon dioxide has no normal boiling point. *See* Triple point.

The normal boiling point is high for liquids with strong intermolecular attractions and low for liquids with weak intermolecular attractions. Helium has the lowest normal boiling point, 4.2 K (−268.9°C). Some other normal boiling points are 111.1 K (−162°C) for CH_4, 450°C (842°F) for n-$C_{30}H_{62}$, 1465°C (2669°F) for NaCl, and 5555°C (10031°F) for tungsten.

The rate of change of the boiling-point absolute temperature T_b of a pure substance with pressure is given by the equation below. $\Delta H_{\text{vap,m}}$ is the molar enthalpy (heat) of vaporization, and $\Delta V_{\text{vap,m}}$ is the molar volume change on vaporization.

$$\frac{dT_b}{dP} = \frac{T_b \Delta V_{\text{vap,m}}}{\Delta H_{\text{vap,m}}}$$

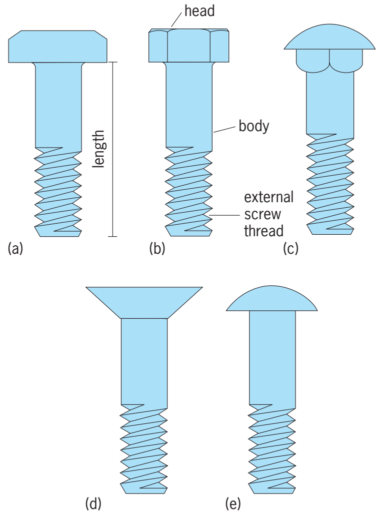
The quantity $\Delta H_{\text{vap,m}}/T_b$ is $\Delta S_{\text{vap,m}}$, the molar entropy of vaporization. The molar entropy of vaporization at the normal boiling point (nbp) is given approximately by Trouton's rule: $\Delta S_{\text{vap,m,nbp}} \approx 87$ J/mol K (21 cal/mol K). Trouton's rule fails for highly polar liquids (especially hydrogen-bonded liquids). It also fails for liquids boiling at very low or very high temperatures, because the molar volume of the vapor changes with temperature and the entropy of a gas depends on its volume.

When a pure liquid is boiled at fixed pressure, the temperature remains constant until all the liquid has vaporized. When a solution is boiled at fixed pressure, the composition of the vapor usually differs from that of the liquid, and the change in liquid composition during boiling changes the boiling point. Thus the boiling process occurs over a range of temperatures for a solution. An exception is an azeotrope, which is a solution that boils entirely at a constant temperature because the vapor in equilibrium with the solution has the same composition as the solution. In fractional distillation, the variation of boiling point with composition is used to separate liquid mixtures into their components. *See* AZEOTROPIC MIXTURE; DISTILLATION. [I.N.L.]

Bolometer A device for detecting and measuring small amounts of thermal radiation. The bolometer is a simple electric circuit, the essential element of which is a slab of material with an electrical property, most often resistance, that changes with temperature. Typical operation involves absorption of radiant energy by the slab, producing a rise in the slab's temperature and thereby a change in its resistance. The electric circuit converts the resistance change to a voltage change, which then can be amplified and observed by various, usually conventional, instruments.

Although bolometers are useful in studying a variety of systems where detection of small amounts of heat is important, their primary application remains as the instrument of choice for measuring weak radiation signals in the infrared and far infrared, that is, at wavelengths from about 1 to 2000 micrometers, from stars and interstellar material. *See* BARRETTER; INFRARED RADIATION; RADIOMETRY; THERMISTOR. [W.E.K.]

Bolt A cylindrical fastener with an integral head on one end and an external screw thread on the other end designed to be inserted through holes in assembled parts and to mate with an internally threaded block, called a nut, which is turned to tighten or loosen the bolt. Tensioning the fastener by turning the nut differentiates a bolt from a screw, which is tightened by turning its head. *See* BOLTED JOINT; NUT (ENGINEERING).



Examples of bolts inserted through clearance holes: (*a*) square bolt; (*b*) hex bolt; (*c*) round-head square-neck bolt for connecting wood to metal; (*d*) countersunk bolt; and (*e*) round-head bolt.

Bolts are generally manufactured from metals, but bolts made of other materials, such as nylon, are commercially available. The properties of some bolting metals are modified by heat treatment and other means to increase yield strength. Bolt heads have various shapes to suit different applications (see illustration). Hexagon-headed bolts (hex bolts) are available in two head widths for the same body diameter—regular hex bolts and heavy hex bolts, which have wider heads. The heavy-series bolts are normally supplied with heavy nuts that are wider and thicker than regular nuts.

Various types of bolts may be used for automobile, machinery, appliance, farm implement, and structural connections. For example, low-carbon-steel unfinished bolts with hex heads are used in machinery, and with square heads for structural steel connections. Heat-treated medium-carbon-steel finished hex-head bolts are high-strength bolts used for connections in structures as well as machinery. However, there are two kinds of high-strength bolts made specifically for structural steel connections, both kinds are heavy hex structural bolts (dimensions differ slightly from those of heavy hex screws). Other kinds of bolts are medium-carbon-steel or atmospheric-corrosion-resistant-alloy-steel, quenched and tempered bolts; and alloy-steel or atmospheric-corrosion-resistant-alloy-steel, quenched and tempered bolts. *See* SCREW FASTENER; WASHER. [C.Bi.]

Bolted joint The assembly of two or more parts by a threaded bolt and nut or by a screw that passes through one member and threads into another. A bolted joint can be disassembled more readily than welded or riveted joints.

Structural members, such as I beams, H beams, angles, and plates, may be joined by bolting. When properly tightened, such joints are as strong and reliable as riveted ones. For joints of this type, high-strength alloy-steel bolts and nuts tightened with impact wrenches are generally used. No locking feature is necessary for properly selected and tightened bolts.

The strength of a bolted assembly depends to a great extent on the initial loading and stress placed on the bolt by the assembly torque. Devices such as torque wrenches are used to determine tension as a function of the torque applied to the assembly of nut and bolt or cap screw and machine part despite the uncertain coefficient of friction between nut, bolt, and assembled members. A better measure is to gage the elongation of the bolt as the tightening torque is applied. Bolt and nut assemblies often include special lock washers to prevent accidental loosening of the fastening by vibration. *See* SCREW FASTENER; STRUCTURAL CONNECTIONS; WELDED JOINT. [L.S.L.]

Boltzmann constant A constant occurring in practically all statistical formulas and having a numerical value of 1.3807×10^{-23} joule/K. It is represented by the letter k. If the temperature T is measured from absolute zero, the quantity kT has the dimensions of an energy and is usually called the thermal energy. At 300 K (room temperature) $kT = 0.0259$ electronvolt.

The value of the Boltzmann constant may be determined from the ideal gas law. For 1 mole of an ideal gas Eq. (1*a*) holds, where

$$PV = RT \tag{1a}$$

$$PV = NkT \tag{1b}$$

P is the pressure, V the volume, and R the universal gas constant. The value of R, 8.31 J/K mole, may be obtained from equation-of-state data. Statistical mechanics yields for the gas law Eq. (1*b*). Here N, the number of molecules in 1 mole, is called Avogadro's number and is equal to 6.02×10^{23} molecules/mole. Hence, comparing Eqs. (1*a*) and (1*b*), one obtains Eq. (2).

$$k = R/N = 1.3807 \times 10^{-23}\text{J/K} \tag{2}$$

Almost any relation derived on the basis of the partition function or the Bose-Einstein, Fermi-Dirac, or Boltzmann distribution contains the Boltzmann constant. *See* BOLTZMANN STATISTICS; BOSE-EINSTEIN STATISTICS; FERMI-DIRAC STATISTICS; KINETIC THEORY OF MATTER; STATISTICAL MECHANICS. [M.Dr.]

Boltzmann statistics To describe a system consisting of a large number of particles in a physically useful manner, recourse must be had to so-called statistical procedures. If the mechanical laws operating in the system are those of classical mechanics, and if the system is sufficiently dilute, the resulting statistical treatment is referred to as Boltzmann or classical statistics. (Dilute in this instance means that the total volume available is much larger than the proper volume of the particles.) A gas is a typical example: The molecules interacting according to the laws of classical mechanics are the constituents of the system, and the pressure, temperature, and other parameters are the overall entites which determine the macroscopic behavior of the gas. In a case of this kind it is neither possible nor desirable to solve the complicated equations of motion of the molecules; one is not interested in the position and velocity of every molecule at any time. The purpose of the statistical description is to extract from the mechanical description just those features relevant for the determination of the macroscopic properties and to omit others.

The basic notion in the statistical description is that of a distribution function. Suppose a system of N molecules is contained in a volume V. The molecules are moving around, colliding with the walls and with each other. Construct the following geometrical representation of the mechanical system. Introduce a six-dimensional space (usually called the μ space), three of its coordinate axes being the spatial coordinates of the vessel x, y, z, and the other three indicating cartesian velocity components v_x, v_y, v_z. A molecule at a given time, having a specified position and velocity, may be represented by a point in this six-dimensional space. The state of the gas, a system of N molecules, may be represented by a cloud of N points in this space. In the course of time, this cloud of N points moves through the μ space.

Note that the μ space is actually finite; the coordinates x, y, z of the molecules' position are bounded by the finite size of the container, and the velocities are bounded by the total energy of the system. Imagine now that the space is divided into a large number of small cells, of sizes $w_1, \ldots, w_i, \ldots$. A certain specification of the state of the gas is obtained if, at a given time t, the numbers $n_1(t), \ldots, n_i(t), \ldots$ of molecules in the cells $1, \ldots, i, \ldots$ are given. To apply statistical methods, one must choose the cells such that on the one hand a cell size w is small compared to the macroscopic dimensions of the system, while on the other hand w must be large enough to allow a large number of molecules in one cell. If the cells are thus chosen, the numbers $n_i(t)$, the occupation numbers, will be slowly changing functions of time. The distribution functions $f_i(t)$ are defined by Eq. (1).

$$n_i(t) = f_i(t) w_i \tag{1}$$

The distribution function f_i describes the state of the gas, and f_i of course varies from cell to cell. Since a cell i is characterized by a given velocity range and position range, and since for appropriately chosen cells f should vary smoothly from cell to cell, f is often considered as a continuous function of the variables x, y, z, vx, vy, vz. The cell size w then can be written as $dxdydzdv_xdv_ydv_z$.

Since a cell i determines both a position and a velocity range, one may associate an energy ϵ_i with a cell. This is the energy a single molecule possesses when it has a representative point in cell i. This assumes that, apart from instantaneous collisions, molecules exert no forces on each other. If this were not the case, the energy of a molecule would be determined by the positions of all other molecules.

Most of the physically interesting quantities follow from a knowledge of the distribution function; the main problem in Boltzmann statistics is to find out what this function is. It is clear that $n_i(t)$ changes in the course of time for three reasons: (1) Molecules located at the position of cell i change their positions and hence move out of cell i; (2) molecules under the influence of outside forces change their velocities and again leave the cell i; and (3) collisions between the molecules will generally cause a (discontinuous) change of the occupation numbers of the cells. Whereas the effect of (1) and (2) on the distribution function follows directly from the mechanics of the system, a separate assumption is needed to obtain the effect of collisions on the distribution function. This assumption, the collision-number assumption, asserts that the number of collisions per unit time, of type $(i, j) \rightarrow (k, l)$ [molecules from cells i and j collide to produce molecules of different velocities which belong to cells k and l], called A_{ij}^{kl}, is given by Eq. (2). Here a_{ij}^{kl} depends on the collision

$$A_{ij}^{kl} = n_i n_j a_{ij}^{kl} \tag{2}$$

configuration and on the size and kind of the molecules but not on the occupation numbers. Gains and losses of the molecules in, say, cell i can now be observed. If the three factors causing gains and losses are combined, the Boltzmann transport equation, written as Eq. (3), is obtained. Here $\Delta_x f_i$ is the gradient of

$$\frac{\partial f_i}{\partial t} + (\mathbf{v}_i \cdot \Delta_x f_i) + (\mathbf{X}_i \cdot \Delta_v f_i) = \sum_{j,k,l} a_{ij}^{kl} w_j (f_k f_l - f_i f_j) \tag{3}$$

f with respect to the positions, $\Delta_v f_i$ refers similarly to the velocities, and $\mathbf{X}_i$ is the outside force per unit mass at cell i. This nonlinear equation determines the temporal evolution of the distribution function. Exact solutions are difficult to obtain. Yet Eq. (3) forms the basis for the kinetic discussion of most transport processes. There is one remarkable general consequence, which follows from Eq. (3). If one defines $H(t)$ as in Eq. (4), one finds by straight manipulation from Eqs. (3) and (4) that Eqs. (5)

$$H(t) = \sum_i n_i \operatorname{In} f_i \tag{4}$$

$$\frac{dH}{dt} \cdots 0 \; \frac{dH}{dt} = 0 \quad \text{if } f_i f_i = f_k f_i \tag{5}$$

hold. Hence H is a function which in the course of time always decreases. This result is known as the H theorem. The special distribution which is characterized by Eq. (6) has the property

$$f_i f_i = f_k f_l \tag{6}$$

that collisions do not change the distribution in the course of time; it is an equilibrium or stationary distribution.

The form of the equilibrium distribution may be determined from Eq. (6), with the help of conservation laws. For a gas which as a whole is at rest, it may be shown that the only solution to functional Eq. (6) is given by Eqs. (7*a*) or (7*b*). Here A and

$$f_i = Ae^{-\text{ß}\epsilon_i} \tag{7a}$$

$$f(\mathbf{x}, \mathbf{v}) = Ae^{(-1/2)\text{ß}mv^2 - \text{ß}U} \tag{7b}$$

ß are parameters, not determined by Eq. (6), and U is the potential energy at the point x, y, z. Equations (7*a*) and (7*b*) are the Maxwell-Boltzmann distribution. Actually A and ß can be determined from the fact that the number of particles and the energy of the system are specified.

The indiscriminate use of the collision-number assumption leads, via the H theorem, to paradoxical results. The basic conflict stems from the irreversible results that appear to emerge as a consequence of a large number of reversible fundamental processes. A careful treatment of the explicit and hidden probability assumptions is the key to the understanding of the apparent conflict. The equilibrium distribution may be thought of as the most probable state of a system. If a system is not in equilibrium, it will most likely (but not certainly) go there; if it is in equilibrium, it will most likely (but not certainly) stay there. By using such probability statements, it may be shown that the paradoxes and conflicts may indeed be removed. A consequence of the probabilistic character of statistics is that the entities computed also possess this characteristic. For example, one cannot really speak definitively of the number of molecules hitting a section of the wall per second, but only about the probability that a given number will hit the wall, or about the average number hitting. In the same vein, the amount of momentum transferred to a unit area of the wall by the molecules per second (this, in fact, is precisely the pressure) is also to be understood as an average. This in particular means that the pressure is a fluctuating entity. The fluctuations in pressure may be demonstrated by observing the motion of a mirror, suspended by a fiber, in a gas. On the average, as many gas molecules will hit the back as the front of the mirror, so that the average displacement will indeed be zero. However, it is easy to imagine a situation where more momentum is transferred in one direction than in another, resulting in a deflection of the mirror. From the knowledge of the distribution function the probabilities for such occurrences may indeed be computed; the calculated and observed behavior agree very well. This clearly demonstrates the essentially statistical character of the pressure. *See* BROWNIAN MOVEMENT; BOLTZMANN TRANSPORT EQUATION; KINETIC THEORY OF MATTER; QUANTUM STATISTICS; STATISTICAL MECHANICS. [M.Dr.]

Boltzmann transport equation An equation which is used to study the nonequilibrium behavior of a collection of particles. In a state of equilibrium a gas of particles has uniform composition and constant temperature and density. If the gas is subjected to a temperature difference or disturbed by externally applied electric, magnetic, or mechanical forces, it will be set in motion and the temperature, density, and composition may become functions of position and time; in other words, the gas moves out of equilibrium. The Boltzmann equation applies to a quantity known as the distribution function, which describes this nonequilibrium state mathematically and specifies how quickly and in what manner the state of the gas changes when the disturbing forces are varied. *See* KINETIC THEORY OF MATTER.

Equation (1) is the Boltzmann transport equation shown below,

$$\frac{\partial f}{\partial t} = \left(\frac{\partial f}{\partial t}\right)_{\text{force}} + \left(\frac{\partial t}{\partial t}\right)_{\text{diff}} + \left(\frac{\partial f}{\partial t}\right)_{\text{coll}} \qquad (1)$$

where f is the unknown distribution function which, in its most general form, depends on a position vector $\mathbf{r}$, a velocity vector $\mathbf{v}$, and the time t. The quantity $\partial f/\partial t$ on the left side of Eq. (1) is the rate of change of f at fixed values of $\mathbf{r}$ and $\mathbf{v}$. The equation expresses this rate of change as the sum of three contributions: first, $(\partial f/\partial t)_{\text{force}}$ arises when the velocities of the particles change with time as a result of external driving forces; second, $(\partial f/\partial t)_{\text{diff}}$ is the effect of the diffusion of the particles from one region in space to the other; and third, $(\partial f/\partial t)_{\text{coll}}$ is the effect of the collisions of the particles with each other or with other kinds of particles.

The distribution function carries information about the positions and velocities of the particles at any time. The probable number of particles N at the time t within the spatial element $dxdydz$ located at (x, y, z) and with velocities in the element $dv_x dv_y dv_z$ at the point (v_x, v_y, v_z) is given by Eq. (2) or, in vector notation, by Eq. (3). It is assumed that the particles are identical;

$$N = f(x, y, z, v_x, v_y, v_z, t)dxdydzdv_x dv_y dv_z \qquad (2)$$

$$N = f(\mathbf{r}, \mathbf{v}, t)d^3r\,d^3v \qquad (3)$$

a different distribution function must be used for each species if several kinds of particles are present.

The Boltzmann equation is irreversible in time in the sense that if $f(\mathbf{r}, \mathbf{v}, t)$ is a solution, then $f(\mathbf{r}, -\mathbf{v}, -t)$ is not a solution. Thus if an isolated system is initially not in equilibrium, it approaches equilibrium as time advances; the time-reversed performance, in which the system departs farther from equilibrium, does not occur. This is paradoxical because actual physical systems are reversible in time when looked at on an atomic scale. From a mathematical point of view it is puzzling that one can begin with the exact equations of motion, reversible in time, and by making reasonable approximations arrive at the irreversible Boltzmann equation. The resolution of this paradox lies in the statistical nature of the Boltzmann equation. It does not describe the behavior of a single system, but the average behavior of a large number of systems.

The Boltzmann equation can be used to calculate the electronic transport properties of metals and semiconductors. For example, if an electric field is applied to a solid, one must solve the Boltzmann equation for the distribution function of the electrons. If the electric field is constant, the distribution function is also constant and is displaced in velocity space in such a way that fewer electrons are moving in the direction of the field than in the opposite direction. This corresponds to a current flow in the direction of the field. *See* FREE-ELECTRON THEORY OF METALS.

With the Boltzmann equation one can also calculate the heat current flowing in a solid as the result of a temperature difference, the constant of proportionality between the heat current per unit area and the temperature gradient being the thermal conductivity. In still more generality, both an electric field and a temperature gradient can be applied. The resulting equations describe thermoelectric phenomena, such as the Peltier and Seebeck effects. Finally, if a constant magnetic field is also applied, it is found that the electrical conductivity usually decreases with increasing magnetic field, a behavior known as magnetoresistance. These equations also describe the Hall effect, as well as more complex thermomagnetic phenomena, such as the Ettingshausen and Nernst effects. *See* CONDUCTION (HEAT); GALVANOMAGNETIC EFFECTS; MAGNETORESISTANCE; THERMOELECTRICITY.

Nonequilibrium properties of atomic or molecular gases such as viscosity, thermal conduction, and diffusion have been treated with the Boltzmann equation. Although many useful results, such as the independence of the viscosity of a gas on pressure, can be obtained by simple approximate methods, the Boltzmann equation must be used in order to obtain quantitatively correct results. *See* DIFFUSION; VISCOSITY.

If one proceeds from a neutral gas to a charged gas or plasma, with the electrons partially removed from the atoms, a number of new phenomena appear. As a consequence of the long-range Coulomb forces between the charges, the plasma can exhibit oscillations in which the free electrons move back and forth with respect to the relatively stationary heavy positive ions at the characteristic frequency known as the plasma frequency. A plasma reflects an electromagnetic wave at a frequency lower than the plasma frequency, but transmits the wave at a higher frequency. This fact explains many characteristics of long-distance radio transmission, made possible by reflection of radio waves by the ionosphere, a low-density plasma. *See* PLASMA (PHYSICS).

If a magnetic field is applied to the plasma, its motion can become complex. In an Alfvén wave, which propagates in the direction of the magnetic field, the magnetic field lines oscillate like stretched strings, while waves that propagate in a direction perpendicular to the magnetic field have quite different properties. The outstanding problem in the attainment of a controlled thermonuclear reaction is to design a magnetic field configuration that can contain an extremely hot plasma long enough to allow nuclear reactions to take place. Plasmas in association with magnetic fields also occur in many astronomical phenomena. *See* MAGNETOHYDRODYNAMICS.

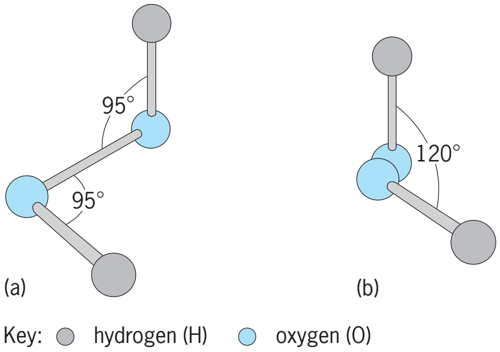
Many properties of plasmas can be calculated by studying the motion of individual particles in electric and magnetic fields, or by using hydrodynamic equations or the Vlasov equation, together with Maxwell's equations. However, subtle properties of plasmas, such as diffusion processes and the damping of waves, can best be understood by starting with the Boltzmann equation or the closely related Fokker-Planck equation. *See* MAXWELL'S EQUATIONS. [R.F.]

Bond angle and distance The angle between two bonds sharing a common atom is known as the bond angle. The distance between the nuclei of bonded atoms is known as bond distance. The geometry of a molecule can be characterized by bond angles and distances. The angle between two bonds sharing a common atom through a third bond is known as the torsional or dihedral angle (see illustration).

Certain pairs of atoms in a molecule are held together at distances of about 0.075–0.3 nanometer, with energies of about 150–1000 kilojoules/mol, because of a balance between electrostatic attraction and repulsion among the electrons and nuclei, subject to the electron distributions allowed by quantum mechanics. Such interactions are called chemical bonds.

Bond angles and distances are important because they determine the shape and size of a molecule and therefore affect many physical properties of a substance. The shape of a molecule influences its charge distribution, often determining whether a molecule is polar or nonpolar; polar molecules exhibit stronger intermolecular attraction and thus have higher boiling points. Molecular shapes also influence the packing density of molecules in solids and liquids.

Bond angles and distances depend on the identity of the atoms bonded together and the type of chemical bonding involved. For example, carbon-hydrogen bonds are remarkably similar in length in a wide range of compounds. Bonds vary in length



Bond angle versus torsional angle. (*a*) Two O—O—H bond angles in hydrogen peroxide (H_2O_2). (*b*) The same molecule when viewed along the O—O bond, revealing the torsional angle, that is, the angle between the two O—H bonds.

depending on the bond multiplicity: they are shorter for a triple bond than for a single bond. Single bonds vary in length slightly, depending on whether they are adjacent to multiple bonds. Bond angles vary considerably from molecule to molecule; the variation in bond angles and distances depends primarily on the electronic structures of the molecules.

The bond lengths and angles of an electronically excited molecule usually differ from the ground-state values. For example, carbon dioxide is linear in its ground state but is bent in its lowest excited state; that is, the O—C—O angle is 180° in the ground state but is 122 ± 2° in the first excited state. The C═O bond distance is 0.116 nm in the ground state but is 0.125 nm in the first excited state. [B.A.Ga.]

Bone The hard connective tissue that, together with cartilage, forms the skeleton of humans and other vertebrates. It is made of calcium phosphate crystals arranged on a protein scaffold. Bone performs a variety of functions: it has a structural and mechanical role; it protects vital organs; it provides a site for the production of blood cells; it serves as a reserve of calcium. *See* CONNECTIVE TISSUE; SKELETAL SYSTEM.

There are two types of bone in the skeleton: the flat bones (for example, the bones of the skull and ribs) and the long bones (for example, the femur and the bones of the hand and feet). Both types are characterized by an outer layer of dense, compact bone, known as cortical bone, and an inner spongy bone material made up of thin trabeculae, known as cancellous bone. Cortical bone consists of layers of bone (lamellae) in an orderly concentric cylindrical arrangement around tiny Haversian canals. These interconnecting canals carry the blood vessels, lymph vessels, and nerves through the bone and communicate with the periosteum and the marrow cavity. The periosteum is a thin membrane covering the outer surface of bone and consisting of layers of cells that participate in the remodeling and repair of bone. The cancellous bone is in contact with the bone marrow, in which much of the production of blood cells takes place. The interface between the cancellous bone and the marrow is called the endosteum, and it is largely at this site that bone is removed in response to a need for increased calcium elsewhere in the body.

Bone is formed by the laying down of an osteoid matrix by osteoblasts, the bone-forming cells, and the mineralization of the osteoid by the development and deposition of crystals of calcium phosphate (in the form of hydroxyapatite) within it. It is the mineral, organized in a regular pattern on a collagen scaffold, that gives bone its stiffness. Osteoid contains largely fibers of type I collagen and lesser amounts of numerous noncollagenous proteins. Although the role of these proteins in bone is not well understood, it is thought that their particular combination in bone gives this tissue the unique ability to mineralize. It is clear that these proteins interact with each other and that collagen and several of the noncollagenous proteins can bind to specialized receptors on the surface of bone cells. This binding is important for the adhesion of the cells to the bone matrix, and also delivers behavioral signals to the cells. *See* APATITE; COLLAGEN.

The primary cell types in bone are those that result in its formation and maintenance (osteoblasts and osteocytes) and those that are responsible for its removal (osteoclasts). Osteoblasts form from the differentiation of multipotential stromal cells that reside in the periosteum and the bone marrow. Under the appropriate stimuli, these primitive stromal cells mature to bone-forming cells at targeted sites in the skeleton. Under different stimuli, they are also capable of developing into adipocytes (fat cells), muscle cells, and chondrocytes (cartilage cells). Osteocytes, which are osteoblasts that become incorporated within the bone tissue itself, are the most numerous cell type in bone. They reside in spaces (lacunae) within the mineralized bone, forming numerous extensions through tiny channels (cannaliculi) in the bone that connect with other osteocytes and with the cells on the endosteal surface. Osteocytes are therefore ideally placed to sense stresses and loads placed on the bone and to convey this information to the osteoblasts on the bone surface, thus enabling bone to adapt to altered mechanical loading by the formation of new bone. Osteocytes are also thought to be the cells that detect and direct the repair of microscopic damage that frequently occurs in the bone matrix due to wear and tear. Failure to repair the cracks and microfractures that occur in bone, or when this microdamage accumulates at a rate exceeding its repair, can cause the structural failure of the bone, such as in stress fractures. A large number of molecules that regulate the formation and function of osteoblastic cells have been identified. Circulating hormones, such as insulin, growth hormone, and insulinlike growth factors, combine with growth factors within the bone itself, such as transforming growth factor beta (TGFβ) and bone morphogenetic proteins (BMPs), to influence the differentiation of osteoblasts.

Osteoclasts are typically large, multinucleated cells, rich in the intracellular machinery required for bone resorption. This is accomplished when the cells form a tight sealing zone by attachment of the cell membrane against the bone matrix, creating a bone-resorbing compartment. Into this space, the cell secretes acid to dissolve the bone mineral, and enzymes to digest the collagen and other proteins in the bone matrix. The removal of bone by osteoclasts is necessary to enable the repair of microscopic damage and changes in bone shape during growth and tooth eruption. Osteoclast-mediated bone resorption is also the mechanism for releasing calcium stored in bone for the maintenance of calcium levels in the blood. Most agents that promote bone resorption act on osteoblastic cells, which in turn convey signals to osteoclast precursors to differentiate into mature osteoclasts. These agents include the active form of vitamin D, parathyroid hormone, interleukin-1, interleukin-6, and interleukin-11, and prostaglandins such as prostaglandin E_2. Differentiation to fully functional osteoclasts also requires close contact between osteoclast precursors and osteoblastic cells. This is due to a molecule called osteoclast differentiation factor (ODF) which is located on the surface of osteoblasts, binds to receptors on the surface of osteoclast precursor cells, and induces their progression to osteoclasts.

Flat bones and long bones are formed by different embryological means. Formation of flat bones occurs by intramembranous ossification, in which primitive mesenchymal cells differentiate directly into osteoblasts and produce bony trabeculae within a periosteal membrane. The initial nature of this bone is relatively disorganized and is termed woven bone. Later, this woven bone is remodeled and replaced by the much stronger mature lamella bone, consisting of layers of calcified matrix arranged in orderly fashion. Long bones are formed by intracartilaginous development in which the future bone begins as cartilage. The cartilage template is gradually replaced by bone in an orderly sequence of events starting at the center of the growing bone. Cartilage remains at the ends of long bones during growth, forming a structure at each end termed the growth plate. Cartilage cells (chondrocytes) that arise in the growth plates proliferate and add to the length of the bone. This occurs during a complex series of events, with expansion both away from and toward the center of the bone. When the bone achieves its final length in maturity, expansion from the growth plate ceases. Cartilage persists at the ends of the long bones in a specific form called articular cartilage, which provides the smooth bearing surfaces for the joints.

Bone is a dynamic tissue and is constantly being remodeled by the actions of osteoclasts and osteoblasts. After bone removal, the osteoclasts either move on to new resorption sites or die; this is followed by a reversal phase where osteoblasts are attracted to the resorption site. It is thought that growth factors that are sequestered in an inactive form in the bone matrix are released and activated by the osteoclast activity and that these in turn promote fresh osteoid production by the recruited osteoblasts. The new osteoid eventually calcifies, and in this way the bone is formed and replaced in layers (lamellae), which are the result of these repeated cycles. In growing bone, the activities of bone cells is skewed toward a net increase in bone. However, in healthy mature bone there is an equilibrium between bone resorption and bone formation. When the equilibrium between these two cell types breaks down, skeletal pathology results.

The most common bone disease is osteoporosis, in which there is a net loss of bone due to osteoclastic bone resorption that is not completely matched by new bone formation. The best-understood cause of osteoporosis is that which occurs in women due to the loss of circulating estrogen after menopause. Another cause of osteoporotic bone loss is seen in disuse osteoporosis. Just as bone can respond to increased loading with the production of additional bone, bone is also dependent on regular loading for its maintenance. Significant bone loss can occur during prolonged bed rest or, for example, in paraplegia and quadriplegia. Likewise, an unloading of the skeleton (due to a lack of gravitational pull) in space flight results in severe bone loss in astronauts unless the effects of gravity are simulated by special exercises and devices. *See* OSTEOPOROSIS.

Many metabolic and genetic diseases can affect the amount and quality of bone. Metabolic diseases such as diabetes, kidney disease, oversecretion of parathyroid hormone by the parathyroid glands, anorexia nervosa, and vitamin D-dependent rickets may cause osteopenias (the reduction in bone volume and bone structural quality). Immunosuppressive therapy in organ transplant patients can lead to reduced bone mass, as can tumors of bone and other sites. Tumors can produce substances that cause the activation of osteoclastic bone resorption. In the genetically based disease osteogenesis imperfecta, mutations in the gene for type I collagen result in the production of reduced amounts of collagen or altered collagen molecules by osteoblasts. Other common diseases of the skeleton are diseases of the joints, such as rheumatoid arthritis and osteoarthritis. *See* ARTHRITIS; CALCIUM METABOLISM; THYROID GLAND. [D.M.Fi.]

Bonsai The construction of a mature, very dwarfed tree in a relatively small container. Although bonsai is formally an esoteric branch of horticulture, it is firmly based in the social, historical, and cultural ethic of Oriental peoples and its introduction to Western cultures is a development of the twentieth century; indeed, Westerners had not even seen bonsai plants prior to the early decades of this century. At the fundamental level, the word bonsai means merely "plant in a pot," and its origin can be traced back to China's Chou dynasty (900–250 B.C.), when emperors built miniaturized gardens in which soil, rocks, and plants from each province were installed as dwarfed representations of the lands held by the central government.

To a large extent, the technology of bonsai is derived from classical horticultural procedures which are the product of long tradition firmed up with considerations of many areas of plant physiology and ecology. There are, however, some techniques which are unique to bonsai. To maintain shape, not only must growth be controlled, but the branching patterns must be planned. This is done by selective pruning and by pinching out of terminal buds to release axillary buds from apical dominance. Root prunings, done at intervals as short as 2 or 3 months in some species, promote the development of a tight root ball with large numbers of young lateral roots whose ability to take up water and minerals is great. Branch and stem position is controlled by selective pruning and by the wiring techniques developed by the Japanese in the eighteenth century. Weighting or tying is used for the same reasons. [R.M.K.]

Book manufacture A series of professional operations including editing, designing, typography, platemaking, printing, and binding to transform a manuscript and its related illustrations into book form.

Books follow a distinctive technique in assembling and binding pages in sequential order and in fitting and sealing the pages into a separate cover. Those designed for relatively permanent usage are sealed into rigid or semirigid covers (called edition, case, or hardback binding), and those designed for less permanent usage are sealed into paper covers (called soft or paperback binding).

The basic cell of a book's construction is called a signature or section and is composed of multiples of 4 pages. The folding of signatures printed on a web press is integrated with the printing units. In sheet-fed printing, folding is separate from presswork and is performed on special machines located in a book bindery.

Folding a sheet of paper once produces 4 pages, and each additional fold doubles the number of pages. A sheet folded three times yields a 16-page signature, the first page being the lowest numbered (a page number is called a folio). All right-hand pages are odd numbered, and left-hand pages are even numbered. A book of 160 pages has ten 16-page signatures, the first being folioed 1–16 and the last 145–160.

Signatures, assembled in sequence, are mechanically held together along one folded edge, called the binding edge or spine, by continuous thread sewing through the fold of each signature; or by thread stitching through the side of the book from front to back; or by wire stapling; or by cutting off the binding-edge folds and applying a coating of strong flexible adhesive, sometimes adding an additional locking device of wide mesh textiles or stretch papers.

Purely decorative features include colorful bits of textiles added to the head and tail of the spine (called headbands) and tinted or gilded edges. One spectacular technical breakthrough was the mechanical gilding of book edges; for centuries this had been a closely guarded handicraft process.

The book cover serves to protect the pages against disintegration, to announce the title of the book, and to stimulate the visual interest of the prospective buyer. The degree of usage and permanency influences the selection of raw materials for a book cover (as in reference sets and text and library books), and visual appeal is influenced by the book's price and marketability. Permanent-type covers are made on special equipment in which the cover material and pulp-boards are assembled and joined with special adhesives. In embellishing the cover, the designer has numerous choices of special equipment and processes, such as flat ink, pigment or metal-foil stampings, embossing, silk-screening, and multicolor printing.

Preceding the final assembly of the book into its cover (called "casing in"), strong 4-page front and back end-sheets and one or more kinds of hinges (of textiles or paper) have been applied to strengthen the interlocking between book and cover (called "lining up"). The book also has acquired a concave and convex edge and a pair of ridges or joints along the binding edge (called "backing"). These features are added by special equipment and are specifically engineered to securely lock the book into its cover and to transmit the strains of opening the book throughout the entire body instead of only to the first and last pages.

For shelf display, a book is often wrapped in a colorful, eye-catching jacket (called dust wrapper), or in a transparent synthetic if the cover is highly decorative.

Books reach their markets packaged in many different ways. Single copies are packaged and mailed directly to the consumer; sets are assembled into cartons, one set per carton; textbooks and other single titles are bulk-cartoned or skid-packed and shipped to central warehouses. *See* PRINTING. [E.J.T.]

Boolean algebra A branch of mathematics that was first developed systematically, because of its applications to logic, by the English mathematician George Boole, around 1850. Closely related are its applications to sets and probability. Boolean algebra also underlies the theory of relations. A modern engineering application is to computer circuit design. *See* DIGITAL COMPUTER.

Most basic is the use of Boolean algebra to describe combinations of the subsets of a given set I of elements; its basic operations are those of taking the intersection or common part $S \cap T$ of two such subsets S and T, their union or sum $S \cup T$, and the complement S' of any one such subset S. These operations satisfy many laws, including those shown in Eqs. (1), (2), and (3).

$$\begin{gathered} S \cap T = S \qquad S \cap T = T \cap S \\ S \cap (T \cap U) = (S \cap T) \cap U \end{gathered} \tag{1}$$

$$\begin{gathered} S \cup S = S \cup T = T \cup]\, S \\ S \cup (T \cup U) = (S \cup T) \cup U \end{gathered} \tag{2}$$

$$\begin{gathered} S \cap (T \cup U) = (S \cap T) \cup (S \cap U) \\ S \cup (T \cap]\, U) = (S \cup T) \cap (S \cup U) \end{gathered} \tag{3}$$

If O denotes the empty set, and I is the set of all elements being considered, then the laws set forth in Eqs. (4) are also

$$\begin{gathered} O \cap S = O \quad O \cup S = S \quad I \cup S = S = S \\ I \cup S = I \quad S \cap S' = O \quad S \cup S' = I \end{gathered} \tag{4}$$

fundamental. Since these laws are fundamentals, all other algebraic laws of subset combination can be deduced from them.

In applying Boolean algebra to logic, Boole observed that combinations of properties under the common logical connectives and, or, and not also satisfy the laws specified above. These laws also hold for propositions or assertions, when combined by the same logical connectives. *See* LOGIC CIRCUITS.

Boole stressed the analogies between Boolean algebra and ordinary algebra. If $S \cap T$ is regarded as playing the role of st in ordinary algebra, $S \cup T$ that of $s + t$, O of 0, I of 1, and S' as corresponding to $1 - s$, the laws listed above illustrate many such analogies. However, as first clearly shown by Marshall Stone, the proper analogy is somewhat different. Specifically, the proper Boolean analog of $s + t$ is $(S' \cap T) \cup (S \cap T')$, so that the ordinary analog of $S \cup T$ is $s + t - st$. Using Stone's analogy, Boolean algebra refers to Boolean rings in which $s^2 = s$, a condition implying $s + s = 0$. *See* RING THEORY; SET THEORY.

In 1941 M. H. A. Newman developed a remarkable generalization which included Boolean algebras and Boolean rings. This generalization is based on the laws shown in Eqs. (5) and (6). From these assumptions, the idempotent, commutative, and associative laws (1) and (2) can be deduced.

$$a(b + c) = ab + ac(a + b)c = ac + bc \tag{5}$$

$$\begin{gathered} a1 = 1 \quad a + 0 = 0 + a = a \quad aa' = 0 \\ a + a' = 1 \end{gathered} \tag{6}$$

Such studies lead naturally to the concept of an abstract Boolean algebra, defined as a collection of symbols combined by operations satisfying the identities listed in formulas (1) to (4). Ordinarily, the phrase Boolean algebra refers to such an abstract Boolean algebra.

The class of finite (abstract) Boolean algebras is easily described. Each such algebra has, for some nonnegative integer n, exactly $2n$ elements and is algebraically equivalent (isomorphic) to the algebra of all subsets of the set of numbers $1, \dots, n$, under the operations of intersection, union, and complement.

The theory of infinite Boolean algebras is much deeper; it indirectly involves the whole theory of sets. One important result is Stone's representation theorem. Let a field of sets be defined as any family of subsets of a given set I, which contains with any two sets S and T their intersection $S \cap T$, union $S \cup T$, and complements S', T'. Considered abstractly, any such field of sets obviously defines a Boolean algebra. Stone's theorem asserts that, conversely, any finite or infinite abstract Boolean algebra is isomorphic to a suitable field of sets. His proof is based on the concepts of ideal and prime ideal, concepts which have been intensively studied for their own sake. [G.Bi.]

Boötes The Bear Driver, in astronomy, a northern and summer constellation. Boötes is one of the earliest recorded constellations. Arcturus, an orange, first-magnitude navigational star, dominates the constellation. Five prominent stars in this constellation form a pentagon, shaped much like an elongated kite, with Arcturus at the junction of the tail. Boötes is conventionally pictured as a driver of the Bear (Ursa Major) nearby. In a more recent version he is seen seated, smoking a pipe, his feet dangling and with one hand holding the leash of the Hunting Dogs (Canes Venatici). *See* CONSTELLATION. [C.-S.Y.]

Boracite A borate mineral with chemical composition $Mg_3B_7O_{13}Cl$. It occurs in Germany, England, and the United States, usually in bedded sedimentary deposits of anhydrite, gypsum, and halite, and in potash deposits of oceanic type. The chemical composition of natural boracites varies, with Fe^{2+} or Mn^{2+} replacing part of the Mg^{2+} to yield ferroan boracite or manganoan boracite. *See* BORATE MINERALS.

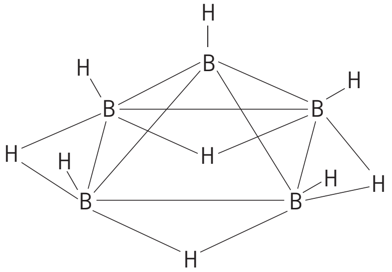
The hardness is $7–7^{1/2}$ on Mohs scale, and specific gravity is 2.91–2.97 for colorless crystals and 2.97–3.10 for green and ferroan types. Luster is vitreous, inclining toward adamantine. Boracite is colorless to white, inclining to gray, yellow, and green, and rarely pink (manganoan); its streak is white; and it is transparent to translucent. It is strongly piezoelectric and pyroelectric and does not cleave. [C.L.Ch.]

Borane One of a class of binary compounds of boron and hydrogen, often referred to as boron hydrides. The term borane is sometimes used to denote substances which may be considered to be derivatives of the boron-hydrogen compounds, such as boron trichloride (BCl_3), and diiododecaborane ($B_{10}H_{12}I_2$).

The simplest borane is diborane (B_2H_6); other boranes of increasingly higher molecular weight are known, one of the least volatile of which is an apparently polymeric solid of composition $(BH)_x$. Certain boranes, such as BH_3, and B_3H_7, are not known as such, but can be prepared in the form of adducts with electron-donor molecules.

The most spectacular projected large-scale use of the boranes and their derivatives is in the field of high-energy fuels for jet planes and rockets. The thermal decomposition of diborane (6) [B_2H_6] has been used to produce coatings of pure elementary boron for neutron-detecting devices and for applications requiring hard, corrosion-resistant surfaces. Boranes can also be used as vulcanizing agents for natural and synthetic rubbers, and are especially effective in the preparation of silicone rubbers.

The molecular structures possessed by the boranes are exhibited by no other class of substances. Because of the lack of sufficient electrons for the formation of the requisite number of covalent bonds, normal covalently bonded structures of the hydrocarbon type are not possible. The boranes are sometimes referred to as electron-deficient substances. In no case are the simple chain and ring configurations of carbon chemistry encountered in the more complex boranes. Instead, the boron atoms are situated at the corners of polyhedrons. An example of such a structure is that of pentaborane (9) [B_5H_9], as follows:



Boron nomenclature uses a prefix to designate the number of boron atoms in the molecule and a numeral suffix in parentheses to indicate the number of hydrogen atoms.

As a class, the boranes are quite reactive substances and are generally decomposed, at times explosively, on contact with air. Their reactivities with air and water decrease with increasing molecular weight. Because boranes react readily with air, laboratory investigations are almost invariably carried out in all-glass vacuum apparatus or in inert-atmosphere dry boxes. With the possible exception of decaborane (14) [$B_{10}H_{14}$], the known boranes are not indefinitely stable at room temperature. They decompose more or less rapidly to yield elementary hydrogen and boranes richer in boron.

The known derivatives of the boranes (other than BH_3) are relatively few in number. Several halo, alkyl, and amino boranes have been reported but, in general, these have not been extensively characterized. *See* BORON; CARBORANE; METAL HYDRIDES. [T.W.]

Borate minerals A large group of minerals in which boron is chemically bonded to oxygen. Boron is a fairly rare element. However, because of its chemical character, it is very susceptible to fractionation in earth processes and can become concentrated to a degree not found in other elements of similar abundance. Boron is symbolized B, carries atomic number 5, and has the ground-state electronic structure $[He]2s^22p^1$. The very high ionization potentials for boron mean that the total energy required to produce the B^{3+} ion is greater than the compensating structure energy of the resulting ionic solid, and hence bond formation involves covalent (rather than ionic) mechanisms. However, boron has only three electrons to contribute to covalent bonding involving four orbitals, (s, p_x, p_y, p_z). This results in boron being a strong electron-pair acceptor (that is, a strong Lewis acid) with a very high affinity for oxygen. The structural chemistry of boron and silicon (Si), when associated with oxygen (O), is quite similar. The BO_3, BO_4, and SiO_4 groups have a marked tendency to polymerize in the solid state, and this aspect of their behavior gives rise to the structural complexity of both groups. However, subtle differences in chemical bonding do give rise to differences in the character of this polymerization, particularly when water is also involved. These differences result in the very different properties of the resultant minerals and their very different behavior in earth processes. *See* BORON.

Boron has an estimated primitive-mantle abundance of 0.6 part per million and a crustal abundance of 15 ppm. Despite this low abundance, fractionation in crustal processes results in concentration of boron to the extent that it forms an extensive array of minerals in which it is an essential constituent, and very complex deposits of borate minerals. Major concentrations of borate minerals occur in continental evaporite deposits (common in the desert regions of California and Nevada). Borate minerals are often very soluble in aqueous environments. In areas of internal drainage, saline lakes are formed, and continued evaporation leads to accumulation of large deposits of borate minerals. Borates may also occur in marine evaporites. Isolated-cluster borates are characteristic of metamorphosed boron-rich sediments and skarns. Most borosilicate minerals are characteristic of granitic-pegmatite environments, either as a pegmatite phase or as a constituent of their exocontact zone. In particular, tourmaline is the most widespread of the mixed-anion borate minerals, occurring in a wide variety of igneous, hydrothermal, and metamorphic rocks. *See* SALINE EVAPORITES; ORE AND MINERAL DEPOSITS; PEGMATITE.

Despite its low crustal abundance, fractionation of boron in crustal processes leads to formation of deposits of borate minerals from which boron and (borates) can be easily extracted in large quantities. The easy availability and unique chemical properties result in boron being a major industrial material. It is widely used in soaps and washing powders. Boron combines well with silicon and other elements to form a wide variety of special-property glasses and ceramics; it also alloys with a variety of metals, producing lightweight alloys for specialty uses. Boron compounds usually have very low density; hence borates in particular are used as lightweight fillers in medicines, and also are used as insulation. The fibrous nature of some borate minerals results in their use in textile-grade fibers and lightweight fiber-strengthened materials. The mineral borax is used as a water softener and as a cleaning flux in welding and soldering. Boric acid has long been used as an antiseptic and a drying agent. Boron is also important as a constituent of inflammatory materials in fireworks and rocket fuel. Some mixed-anion borate minerals are used as gemstones. Tourmaline is of particular importance in this respect, forming pink (rubellite), blue-green (Paraiba tourmaline), green (chrome tourmaline), and pink + green (watermelon tourmaline) from a wide variety of localities. Kornerupine and sinhalite are also used as gemstones but are far less common. *See* BORON; TOURMALINE. [F.C.Ha.]

Bordetella A genus of gram-negative bacteria which are coccobacilli and obligate aerobes, and fail to ferment carbohydrates. These bacteria are respiratory pathogens. *Bordetella pertussis*, *B. parapertussis*, and *B. bronchiseptica* share greater than 90% of their deoxyribonucleic acid (DNA) sequences and would not warrant separate species designations except that the distinctions are useful for clinical purposes. *Bordetella pertussis* is an obligate human pathogen and is the causative agent of whooping cough (pertussis). *Bordetella parapertussis* causes a milder form of disease in humans and also causes respiratory infections in sheep. *Bordetella bronchiseptica* has the broadest host range, causing disease in many mammalian species, but kennel cough in dogs and atrophic rhinitis, in which infected piglets develop deformed nasal passages, have the biggest economic impact. *Bordetella avium* is more distantly related to the other species. A pathogen of birds, it is of major economic importance to the poultry industry.

Infection by all four species is characterized by bacterial adherence to the ciliated cells that line the windpipe (trachea), *B. pertussis* releases massive amounts of peptidoglycan, causing an exaggerated immune response that is ultimately deleterious, resulting in self-induced death of the ciliated cells. *Bordetella* also produces protein toxins. The best-characterized is pertussis toxin, made only by *B. pertussis*. This toxin interferes with the mechanisms used by host cells to communicate with one another.

Bordetella pertussis is spread by coughing and has no environmental reservoir other than infected humans. Culturing the organism is difficult. Erythromycin is the antibiotic used most frequently to treat whooping cough. Unfortunately, antibiotic treatment improves the patient's condition only if given early, when the disease is most difficult to diagnose, and does not help after whooping has begun. This is consistent with the concept that the early symptoms of the disease result from bacterial damage to the respiratory tract and the later symptoms are due to toxins released by the bacteria. Antibiotics can eradicate the microorganisms but cannot reverse the effects of toxins, which can cause damage far from the site of bacterial growth.

Vaccines have been developed for whooping cough and kennel cough. Multicomponent pertussis vaccines consisting of inactivated pertussis toxin and various combinations of filamentous hemagglutinin, pertactin, and fimbriae are now replacing the older whole-cell vaccines consisting of killed bacteria, which were suspected but not proven to cause rare but serious side effects. Vaccination programs have greatly reduced the incidence of whooping cough in affluent nations, but worldwide nearly half a million deaths occur each year, most of which are vaccine-preventable. *See* ANTIBIOTIC; MEDICAL BACTERIOLOGY. [A.We.]

Boring bivalves A variety of marine bivalve mollusks which penetrate solid substrata. They represent seven families and vary in the extent to which they are specialized, in the type of substrata they utilize, and in their method of boring.

Unlike other bivalves which use their shells as abrasive "tools," date mussels (*Lithophaga*, Mytilidae) penetrate calcareous rocks, corals, and shells by chemical means, possibly a weak carbonic acid. Larvae of *Botula* (another small, elongate mytilid), which settle in crevices of soft rock, corals, or wood, abrade their way into the substrate by continued movement of their shells and siphons. *Rupellaria* and *Petricola* (Petricolidae) are nonspecialized borers in peat, firm mud, and soft rock. *Platyodon* (Myidae), closely related to the soft-shelled clam, press their valves against the walls of the burrow by engorging the mantle and then abrade the soft rock by continued movement of their unspecialized valves. *Gastrochaena* and *Spengleria* (Gastrochaenidae) are specialized for boring by having a closed mantle cavity, a large pedal gape, and a truncate foot, allowing them to press the foot and shell against the burrow wall. The Pholadacea (Pholadidae and Teredinidae) are worldwide in distribution. The family Pholadidae (common name: piddocks) is composed of 17 genera, of which 5 are restricted to wood. All species of Teredinidae are obligate wood, nut, or plant-stem borers. The major difference between these two families is the presence of accessory plates in the pholads and pallets in the teredinids. *See* MOLLUSCA; SHIPWORM. [R.D.T.]

Boring sponges Sponges that excavate galleries in mollusk shells, corals, limestone, and other calcareous matter. Boring sponges are known in three families of the class Demospongiae; they are also called burrowing sponges. All species of the family Clionidae, order Hadromerida, excavate burrows in calcium carbonate substrata, as do some species of the genera *Anthosigmella* and *Spheciospongia* (family Spirastrellidae, order Hadromerida) and all species of *Siphonodictyon* (family Adociidae, order Haplosclerida).

Water currents are maintained through the tissues of these boring sponges exactly as in other Demospongiae. They do not obtain food from their hosts when the calcareous matter into which they burrow happens to be the shell or skeleton of a living organism. Instead, boring sponges feed on bacteria, flagellates, and other kinds of particulate organic matter. The burrowing process is similar in all genera and involves the excavation of numerous minute particles of calcium carbonate (20–70 micrometers in diameter) that pass out by way of the exhalant canals and oscula. In coral reef environments, up to 30–40% of fine sediment particles may be derived from the activities of burrowing sponges in low-energy environments; lesser proportions (5–22%) characterize sediments in high-energy environments.

Clionids are regarded as a nuisance in oyster beds because their excavations weaken the shells of these mollusks and thus hinder processing in canning factories. Boring sponges are also economically important when they attack limestone breakwaters.

Clionid boring sponges are found in all seas, chiefly in tidal and shallow waters. A few species reach a depth of at most 3000 ft (1000 m). Their excavations are known in fossil mollusk shells at least as far back as the Devonian Period. Burrowing species of the genera *Anthosigmella*, *Spheciospongia*, and *Siphonodictyon* are found on coral reefs at depths of more than 200 ft (60 m). *See* DEMOSPONGIAE. [W.D.H.]

Bornite A sulfide of composition Cu_5FeS_4, specific gravity 5.07, and hardness 3 (Mohs scale), commonly occurring as a primary mineral in many copper ore deposits. Crystals are rare; bornite is usually massive or granular. The metallic and brassy color of a fresh surface rapidly tarnishes upon exposure to air to a characteristic iridescent purple, giving rise to the name "peacock ore." Though of lesser importance as an ore than chalcocite or chalcopyrite, masses of bornite have been mined in Chile, Peru, Bolivia, and Mexico and in the United States in Arizona and Montana. *See* CHALCOCITE; CHALCOPYRITE; COPPER. [B.J.Wu.]

Boron A chemical element, B, atomic number 5, atomic weight 10.811, in group III of the periodic table. It has three valence electrons and is nonmetallic in behavior. It is classified as a metalloid and is the only nonmetallic element which has fewer than four electrons in its outer shell. The free element is prepared in crystalline or amorphous form. The crystalline form is an extremely hard, brittle solid. It is of jet-black to silvery-gray color with a metallic luster. One form of crystalline boron is bright red. The amorphous form is less dense than the crystalline and is a dark-brown to black powder. In the naturally occurring compounds, boron exists as a mixture of two stable isotopes with atomic weights of 10 and 11. *See* PERIODIC TABLE.

Many properties of boron have not been sufficiently established experimentally as a result of the questionable purity of some sources of boron, as well as of the variations in the methods and temperatures of preparation. A summary of the physical properties is shown in the table.

Physical properties of boron

Property	Temp., °C	Value
Density		
Crystalline	25–27	2.31 g/cm^3
Amorphous	25–27	2.3 g/cm^3
Mohs hardness		
Crystalline		9.3
Melting point		2100°C
Boiling point		2500°C
Resistivity	25	1.7×10^{-6} ohm-cm
Coefficient of thermal expansion	20–750	8.3×10^{-6} cm/°C
Heat of combustion	25	302.0 ± 3.4 kcal/mole
Entropy		
Crystalline	25	1.403 cal/(mole)(deg)
Amorphous	25	1.564 cal/(mole)(deg)
Heat capacity		
Gas	25	4.97 cal/(mole)(deg)
Crystalline	25	2.65 cal/(mole)(deg)
Amorphous	25	2.86 cal/(mole)(deg)

Boron and boron compounds have numerous uses in many fields, although elemental boron is employed chiefly in the metal industry. Its extreme reactivity at high temperatures, particularly with oxygen and nitrogen, makes it a suitable metallurgical degasifying agent. It is used to refine the grain of aluminum castings and to facilitate the heat treatment of malleable iron. Boron considerably increases the high-temperature strength characteristics of alloy steels. Elemental boron is used in the atomic reactor and in high-temperature technologies. The physical properties that make boron attractive as a construction material in missile and rocket technology are its low density, extreme hardness, high melting point, and remarkable tensile strength in filament form. When boron fibers are used in an epoxy (or other plastic) carrier material or matrix, the resulting composite is stronger and stiffer than steel and 25% lighter than aluminum. Refined borax, $Na_2B_4O_7 \cdot 10H_2O$, is an important ingredient of a variety of detergents, soaps, water-softening compounds, laundry starches, adhesives, toilet preparations, cosmetics, talcum powder, and glazed paper. It is also used in fireproofing, disinfecting of fruit and lumber, weed control, and insecticides, as well as in the manufacture of leather, paper, and plastics.

Boron makes up 0.001% of the Earth's crust. It is never found in the uncombined or elementary state in nature. Besides being present to the extent of a few parts per million in sea water, it occurs as a trace element in most soils and is an essential constituent of several rock-forming silicate minerals, such as tourmaline and datolite. The presence of boron in extremely small amounts seems to be necessary in nearly all forms of plant life, but in larger concentrations, it becomes quite toxic to vegetation. Only in a very limited number of localities are high concentrations of boron or large deposits of boron minerals to be found in nature; the more important of these seem to be primarily of volcanic origin. *See* BORATE MINERALS. [F.H.M./V.V.L.]

Borrelia A genus of spirochetes that have a unique genome composed of a linear chromosome and numerous linear and circular plasmids. Borreliae are motile, helical organisms with 4–30 uneven, irregular coils, and are 5–25 micrometers long and 0.2–0.5 μm wide. All borreliae are arthropod-borne. Of the 24 recognized species, 21 cause relapsing fever and similar diseases in human and rodent hosts; two are responsible for infections in ruminants and horses; and the remaining one, for borreliosis in birds. *See* BACTERIA.

The borreliae of human relapsing fevers are transmitted by the body louse or by a large variety of soft-shelled ticks of the genus *Ornithodoros*. The species *B. burgdorferi*, the etiologic agent of Lyme disease and related disorders, is transmitted by ticks of the genus *Ixodes*. *Borrelia anserina*, which causes spirochetosis in chickens and other birds, is propagated by ticks of the genus *Argas*. Various species of ixodid ticks are responsible for transmitting *B. theileri* among cattle, horses, and sheep. *Borrelia coriaceae*, isolated from *O. coriaceus*, is the putative cause of epizootic bovine abortion in the western United States. *See* RELAPSING FEVER.

Polyacrylamide gel electrophoresis of spirochetes has shown that the outer surface of the microorganisms contains numerous variable lipoproteins of which at least two are abundant. The antigenic variability is well known for the relapsing fever borreliae. A switch in the major outer-surface proteins leads to recurrent spirochetemias. Tetracyclines, penicillins, and doxycycline are the most effective antibiotics for treatment of spirochetes. Two vaccines consisting of recombinant *B. burgdorferi* have been evaluated in subjects of risk for Lyme disease. Both proved safe and effective in the prevention of this disease. *See* ANTIBIOTIC; MEDICAL BACTERIOLOGY. [W.Bu.; P.Ro.]

Bose-Einstein condensation When a gas of bosonic particles is cooled below a critical temperature, it condenses into a Bose-Einstein condensate. The condensate consists of a macroscopic number of particles, which are all in the ground state of the system. Bose-Einstein condensation is a phase transition, which does not depend on the specific interactions between particles. It is based on the indistinguishability and wave nature of particles, both of which are at the heart of quantum mechanics.

Basic phenomenon in ideal gas. In a simplified picture, particles in a gas may be regarded as quantum-mechanical wavepackets which have a spatial extent on the order of a thermal de Broglie wavelength, given by Eq. (1), where T is the

$$\lambda_{\mathrm{dB}} = \left(\frac{2\pi^2\hbar^2}{mk_B T}\right)^{1/2} \qquad (1)$$

temperature, m the mass of the particle, k_B is the Boltzmann constant, and $\hbar$ is Planck's constant divided by 2π. The wavelength λ_{dB} can be regarded as the position uncertainty associated with the thermal momentum distribution of the particles. At high temperature, λ_{dB} is small, and the probability of finding two particles within this distance of each other is extremely low. Therefore, the indistinguishability of particles is not important, and a classical description applies (namely, Boltzmann statistics). When the gas is cooled to the point where λ_{dB} is comparable to the distance between particles, the individual wavepackets start to overlap and the indistinguishability of particles becomes crucial—an identity crisis can be said to occur. For fermions, the Pauli exclusion principle prevents two particles from occupying the same quantum state; whereas for bosons, quantum statistics (in this case, Bose-Einstein statistics) dramatically increases the probability of finding several particles in the same quantum state. The system undergoes a phase transition and forms a Bose-Einstein condensate, where a macroscopic number of particles occupy the lowest-energy quantum state (Fig. 1). *See* BOLTZMANN STATISTICS; EXCLUSION PRINCIPLE; PHASE TRANSITIONS; QUANTUM MECHANICS.

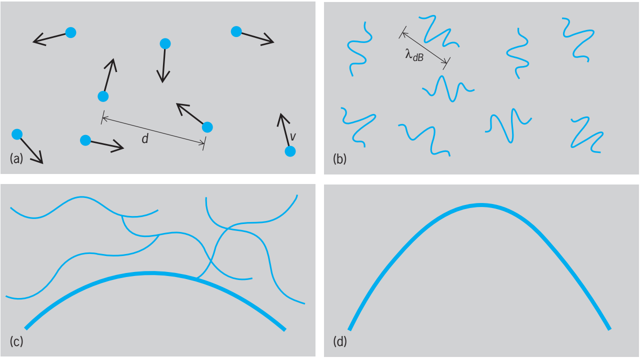


Fig. 1. Criterion for Bose-Einstein condensation in a gas of weakly interacting particles. (*a*) Gas at high temperature, treated as a system of billiard balls, with thermal velocity v and density d^{-3}, where d is the distance between particles. (*b*) Simplified quantum description of gas at low temperature, in which the particles are regarded as wave packets with a spatial extent of the order of the de Broglie wavelength, λ_{dB}. (*c*) Gas at the transition temperature for Bose-Einstein condensation, when λ_{dB} becomes comparable to d. The wave packets overlap and a Bose-Einstein condensate forms (in the case of bosonic particles). (*d*) Pure Bose condensate (giant matter wave), which remains as the temperature approaches absolute zero and the thermal cloud disappears. (*After D. S. Durfee and W. S. Ketterle, Experimental studies of Bose-Einstein condensation, Opt. Express, 2:299–313, Optical Society of America, 1998*)

Bose-Einstein condensation can be described intuitively in the following way: When the quantum-mechanical wave functions of bosonic particles spatially overlap, the matter waves start to oscillate in concert. A coherent matter wave forms that comprises all particles in the ground state of the system. This transition from disordered to coherent matter waves can be compared to the step from incoherent light to laser light. Indeed, atom lasers based on Bose-Einstein condensation have been realized. *See* COHERENCE; LASER.

Experimental techniques. The phenomenon of Bose-Einstein condensation is responsible for the superfluidity of helium and for the superconductivity of an electron gas, which involves Bose-condensed electron pairs. However, these phenomena happen at high density, and their understanding requires a detailed treatment of the interactions. *See* SUPERCONDUCTIVITY; SUPERFLUIDITY.

The quest to realize Bose-Einstein condensation in a dilute weakly interacting gas focused on atomic gases. At ultralow temperatures, all atomic gases liquefy or solidify in thermal equilibrium. Keeping the gas at sufficiently low density can prevent this from occurring. Typical number densities of atoms between 10^{12} and 10^{15} cm^{3} imply transition temperatures for Bose-Einstein condensation in the nanokelvin or microkelvin regime.

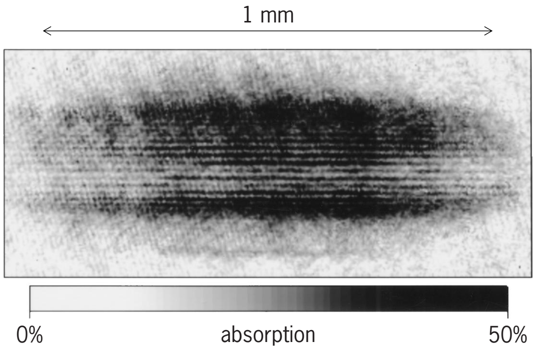

Fig. 2. **Interference pattern of two expanding condensates, demonstrating the coherence of Bose-Einstein condensates. This absorption image was observed after a 40-millisecond time of flight. Interference fringes have a spacing of 15 μm. (*After D. S. Durfee and W. S. Ketterle, Experimental studies of Bose-Einstein condensation, Opt. Express, 2:299–313, Optical Society of America, 1998*)**

The realization of Bose-Einstein condensation in atomic gases required techniques to cool gases to such low temperatures, and atom traps to confine the gases at the required density and keep them away from the much warmer walls of the vacuum chamber. The experiments on alkali vapors (lithium, rubidium, and sodium) use several laser-cooling techniques as precooling, then hold the atoms in a magnetic trap and cool them further by forced evaporative cooling. For atomic hydrogen, the laser-cooling step is replaced by cryogenic cooling.

Macroscopic wave function. In superconductors and liquid helium, the existence of coherence and of a macroscopic wave function is impressively demonstrated through the Josephson effect. In the dilute atomic gases, the coherence has been demonstrated even more directly by interfering two Bose condensates (Fig. 2). The interference fringes typically have a spacing of 15 μm, a huge length for matter waves. (In contrast, the matter wavelength of atoms at room temperature is only 0.05 nm, less than the size of the atoms.) [W.Ket.]

Bose-Einstein statistics

Bose-Einstein statistics The statistical description of quantum mechanical systems in which there is no restriction on the way in which particles can be distributed over the individual energy levels. This description applies when the system has a symmetric wave function. This in turn has to be the case when the particles described are of integer spin.

Suppose one describes a system by giving the number of particles *ni* in an energy state ϵ_i, where the n_i are called occupation numbers and the index *i* labels the various states. The energy level ϵ_i, is of finite width, being really a range of energies comprising, say, g_i, individual (nondegenerate) quantum levels. If any arrangement of particles over individual energy levels is allowed, one obtains for the probability of a specific distribution Eq. (1*a*). In Boltzmann statistics, this same probability would be written as Eq. (1*b*). *See* BOLTZMANN STATISTICS.

$$W = \prod_i \frac{(n_i + g_i - 1)!}{n_i!(g_i - 1)!} \qquad (1a)$$

$$W = \prod_i \frac{g_i^{n_i}}{n_i!} \qquad (1b)$$

The equilibrium state is defined as the most probable state of the system. To obtain it, one must maximize Eq. (1*a*) under the conditions given by Eqs. (2*a*) and (2*b*), which express the

$$\sum n_i i = N \qquad (2a)$$

$$\sum \epsilon_i n_i = E \qquad (2b)$$

fact that the total number of particles N and the total energy E are fixed. One finds for the most probable distribution that Eq. (3) holds. Here, A and ß are parameters to be determined

$$ni = \frac{gi}{\frac{1}{A}e^{\text{ß}\epsilon_i} + 1} \qquad (3)$$

from Eqs. (2*a*) and (2*b*); actually, $\text{ß} = 1/kT$, where k is the Boltzmann constant and T is the absolute temperature.

An interesting and important result emerges when Eq. (3) is applied to a gas of photons, that is, a large number of photons in an enclosure. (Since photons have integer spin, this is legitimate.) The formula for the energy density (energy per unit volume) in a given frequency range is found to be the celebrated Planck radiation formula for blackbody radiation. Thus, black-body radiation must be considered as a photon gas, with the photons satisfying Bose-Einstein statistics. *See* HEAT RADIATION.

If an ideal Bose gas, consisting of a fixed number of material particles, is compressed beyond a certain point, some of the particles will condense in a zero state, where they do not contribute to the density or the pressure. If the volume is decreased, this curious condensation phenomenon results, yielding the zero state which has the paradoxical properties of not contributing to the pressure, volume, or density. There is now considerable evidence that many of the superfluid properties exhibited by liquid helium are in fact manifestations of an Einstein condensation. *See* FERMI-DIRAC STATISTICS; QUANTUM STATISTICS; STATISTICAL MECHANICS. [M.Dr.]

Botanical gardens A garden for the culture of plants collected chiefly for scientific and educational purposes. Such a garden is more properly called a botanical institution, in which the outdoor garden is but one portion of an organization including the greenhouse, the herbarium, the library, and the research laboratory. *See* HERBARIUM.

It was only in modern Europe, after the foundation of the great medieval universities, that botanical gardens for educational purposes began to be established in connection with the schools. The oldest gardens are those in Padua (established 1533) and at Pisa (1543). The botanical garden of the University of Leiden was begun in 1587, and the first greenhouse is said to have been constructed there in 1599. The Royal Botanical Gardens at Kew, England, were officially opened in 1841. This institution came to be known as the botanical capital of the world.

The first of the great tropical gardens was founded at Calcutta in 1787. The original name, Royal Botanic Garden, was changed in 1947 to Indian Botanic Garden. Another great tropical garden, the Jardin Botanico of Rio de Janeiro, was founded in 1808. The great tropical botanical garden of Buitenzorg (Bogor), Java, which originated in 1817, has an area of 205 acres (83 hectares) with an additional 150 acres (61 hectares) in the Mountain Garden.

The first great garden of the United States was founded by Henry Shaw at St. Louis in 1859, and is now known as the Missouri Botanical Garden. The New York Botanical Garden was chartered in 1891 and the Brooklyn Botanic Garden in 1910. The Jardin Botanique of Montreal, the leading garden of Canada, was opened in 1936. *See* ARBORETUM. [E.L.C.]

Botany That branch of biological science which embraces the study of plants and plant life. Botanical studies may range from microscopic observations of the smallest and obscurest plants to the study of the trees of the forest. One botanist may be interested mainly in the relationships among plants and in their geographic distribution, whereas another may be primarily concerned with structure or with the study of the life processes taking place in plants.

Botany may be divided by subject matter into several specialties, such as plant anatomy, plant chemistry, plant cytology, plant ecology (including autecology and synecology), plant embryology, plant genetics, plant morphology, plant physiology, plant taxonomy, ethnobotany, and paleobotany. It may also be divided according to the group of plants being studied; for example, agostology, the study of grasses; algology (phycology), the study of algae; bryology, the study of mosses; mycology, the study of fungi; and pteridology, the study of ferns. Bacteriology and virology are also parts of botany in a broad sense. Furthermore, a number of agricultural subjects have botany as their foundation. Among these are agronomy, floriculture, forestry, horticulture, landscape architecture, and plant breeding. *See* AGRICULTURE; AGRONOMY; BACTERIOLOGY; CELL BIOLOGY; ECOLOGY; FLORICULTURE; GENETICS; LANDSCAPE ARCHITECTURE; PALEOBOTANY; PLANT ANATOMY; PLANT GROWTH; PLANT MORPHOGENESIS; PLANT PATHOLOGY; PLANT PHYSIOLOGY; PLANT TAXONOMY. [A.Cr.]

Botulism An illness produced by the exotoxin of *Clostridium botulinum* and occasionally other clostridia, and characterized by paralysis and other neurological abnormalities. There are seven principal toxin types involved (A–G); only types A, B, E, and F have been implicated in human disease. Types C and D produce illness in birds and mammals. Strains of *C. barati* and *C. butyricum* have been found to produce toxins E and F and have been implicated in infant botulism. *See* VIRULENCE.

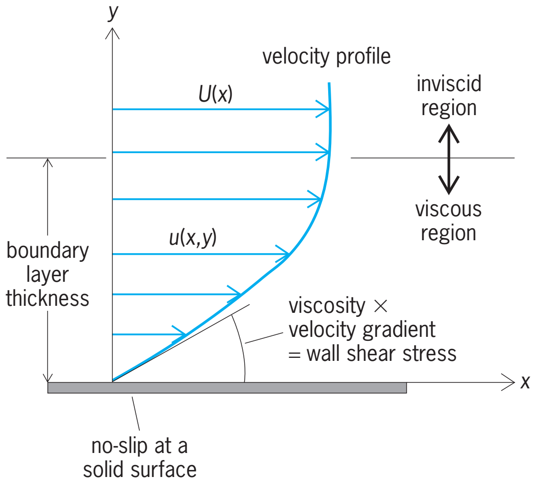
The three clinical forms of botulism are classic botulism, infant botulism, and wound botulism. Classic botulism is typically due to ingestion of preformed toxin, infant botulism involves ingestion of *C. botulinum* spores with subsequent germination and toxin production in the gastrointestinal tract, and wound botulism involves production of toxin by the organism's infecting or colonizing a wound. The incubation period is from a few hours to more than a week (but usually 1–2 days), depending primarily on the amount of toxin ingested or absorbed.

There is classically acute onset of bilateral cranial nerve impairment and subsequent symmetrical descending paralysis or weakness. Commonly noted are dysphagia (difficulty in swallowing), dry mouth, diplopia (double vision), dysarthria (a neuromuscular disorder affecting speech), and blurred vision. Nausea, vomiting, and fatigue are common as well. Ileus (impaired intestinal motility) and constipation are much more typical than diarrhea; there may also be urinary retention and dry mucous membranes. Central nervous system function and sensation remain intact, and fever does not occur in the absence of complications. Fever may even be absent in wound botulism. *See* TOXIN.

In food-borne botulism, home-canned or home-processed foods (particularly vegetables) are commonly implicated, with commercially canned foods involved infrequently. Outbreaks usually involve only one or two people, but may affect dozens. In infant botulism, honey and corn syrup have been implicated as vehicles. Therapy involves measures to rid the body of unabsorbed toxin, neutralization of unfixed toxin by antitoxin, and adequate intensive care support. *See* FOOD POISONING; POISON. [S.M.F.]

Boundary-layer flow That portion of a fluid flow, near a solid surface, where shear stresses are significant and the inviscid-flow assumption may not be used. All solid surfaces interact with a viscous fluid flow because of the no-slip condition, a physical requirement that the fluid and solid have equal velocities at their interface. Thus a fluid flow is retarded by a fixed solid surface, and a finite, slow-moving boundary layer is formed. A requirement for the boundary layer to be thin is that the Reynolds number of the body be large, 10^3 or more. Under these conditions the flow outside the boundary layer is essentially inviscid and plays the role of a driving mechanism for the layer. *See* REYNOLDS NUMBER.

A typical low-speed or laminar boundary layer is shown in the illustration. Such a display of the streamwise flow vector variation near the wall is called a velocity profile. The no-slip condition requires that $u(x, 0) = 0$, as shown, where u is the velocity of flow in the boundary layer. The velocity rises monotonically with distance y from the wall, finally merging smoothly with the outer (inviscid) stream velocity $U(x)$. At any point in the boundary layer, the fluid shear stress τ is proportional to the local velocity gradient, assuming a newtonian fluid. The value of the shear stress at the wall is most important, since it relates not only to the drag of the body but often also to its heat transfer. At the edge of the boundary layer, τ approaches zero asymptotically. There is no exact spot where $\tau = 0$; therefore the thickness δ of a boundary layer is usually defined arbitrarily as the point where $u = 0.99U$. *See* LAMINAR FLOW.



Typical laminar boundary-layer velocity profile.

When a flow enters a duct or confined region, boundary layers immediately begin to grow on the duct walls. An inviscid core accelerates down the duct center, but soon vanishes as the boundary layers meet and fill the duct with viscous flow. Constrained by the duct walls into a no-growth condition, the velocity profile settles into a fully developed shape which is independent of the streamwise coordinate. The pressure drops linearly downstream, balanced by the mean wall-shear stress. This is a classic and simple case of boundary-layer flow which is well documented by both theory and experiment.

A classic incompressible boundary-layer flow is a uniform stream at velocity U, moving past a sharp flat plate parallel to the stream. In the Reynolds number range 1×10^3 to 5×10^5, the flow is laminar and orderly, with no superimposed fluctuations. The boundary-layer thickness δ grows monotonically with x, and the shape of the velocity profile is independent of x when normalized. The profiles are said to be similar, and they are called Blasius profiles.

The Blasius flat-plate flow results in closed-form algebraic formulas for such parameters as wall-shear stress and boundary-layer thickness as well as for temperature and heat-transfer parameters. These results are useful in estimating viscous effects in flow past thin bodies such as airfoils, turbine blades, and heat-exchanger plates.

The flat plate is very distinctive in that it causes no change in outer-stream velocity U. Most body shapes immersed in a stream flow, such as cylinders, airfoils, or ships, induce a variable outer stream $U(x)$ near the surface. If U increases with x, which means that pressure decreases with x, the boundary layer is said to be in a favorable gradient and remains thin and attached to the surface. If, however, velocity falls and pressure rises with x, the pressure gradient is unfavorable or adverse. The low-velocity fluid near the wall is strongly decelerated by the rising pressure, and the wall-shear stress drops off to zero. Downstream of this zero-shear or separation point, there is backflow and the wall shear is upstream. The boundary layer thickens markedly to conserve mass, and the outer stream separates from the body, leaving a broad, low-pressure wake downstream. Flow separation may be predicted by boundary-layer theory, but the theory is not able to estimate the wake properties accurately.

In most immersed-body flows, the separation and wake occur on the rear or lee side of the body, with higher pressure and no separation on the front. The body thus experiences a large downstream pressure force called pressure drag. This happens to all blunt bodies such as spheres and cylinders and also to airfoils and turbomachinery blades if their angle of attack with respect to the oncoming stream is too large. The airfoil or blade is said to be stalled, and its performance suffers.

All laminar boundary layers, if they grow thick enough and have sufficient velocity, become unstable. Slight disturbances, whether naturally occurring or imposed artificially, tend to grow in amplitude, at least in a certain frequency and wavelength range. The growth begins as a selective group of two-dimensional periodic disturbances, called Tollmien-Schlichting waves, which become three-dimensional and nonlinear downstream and eventually burst into the strong random fluctuations called turbulence. The critical parameter is the Reynolds number. The process of change from laminar to turbulent flow is called transition.

The turbulent flow regime is characterized by random, three-dimensional fluctuations superimposed upon time-mean fluid properties, including velocity, pressure, and temperature. The fluctuations are typically 3–6% of the mean values and range in size over three orders of magnitude, from microscale movements to large eddies of size comparable to the boundary-layer thickness. They are readily measured by modern instruments such as hot wires and laser-Doppler velocimeters. *See* ANEMOMETER.

The effect of superimposing a wide spectrum of eddies on a viscous flow is to greatly increase mixing and transport of mass, momentum, and heat across the flow. Turbulent boundary layers are thicker than laminar layers and have higher heat transfer and friction. The turbulent mean-velocity profile is rather flat, with a steep gradient at the wall. The edge of the boundary layer is a ragged, fluctuating interface which separates the nonturbulent outer flow from large turbulent eddies in the layer. The thickness of such a layer is defined only in the time mean, and a probe placed in the outer half of the layer would show intermittently turbulent and nonturbulent flow.

As the stream velocity U becomes larger, its kinetic energy, $U^2/2$, becomes comparable to stream enthalpy, c_pT, where c_p is the specific heat at constant pressure and T is the absolute temperature. Changes in temperature and density begin to be important, and the flow can no longer be considered incompressible. Liquids flow at very small Mach numbers, and compressible flows are primarily gas flows. *See* GAS; MACH NUMBER.

In a flow with supersonic stream velocity, the no-slip condition is still valid, and much of the boundary-layer flow near the wall is at low speed or subsonic. The fluid enters the boundary layer and loses much of its kinetic energy, of which a small part is conducted away although most is converted into thermal energy. Thus the near-wall region of a highly compressible boundary layer is very hot, even if the wall is cold and is drawing heat away. The basic difference between low and high speed is the conversion of kinetic energy into higher temperatures across the entire boundary layer.

In a low-speed (incompressible) boundary layer, a cold wall simply means that the wall temperature is less than the free-stream temperature. The heat flow is from high toward lower temperature, that is, into the wall. For a low-speed insulated wall, the boundary-layer temperature is uniform. For a high-speed flow, however, an insulated wall has a high surface temperature because of the viscous dissipation energy exchange in the layer.

Except for the added complexity of having to consider fluid pressure, temperature, and density as coupled variables, compressible boundary layers have similar characteristics to their low-speed counterparts. They undergo transition from laminar to turbulent flow but typically at somewhat higher Reynolds numbers. Compressible layers tend to be somewhat thicker than incompressible boundary layers, with proportionally smaller wall-shear stresses. They tend to resist flow separation slightly better than incompressible flows.

In a supersonic outer stream, shock waves can always occur. Shocks may form in the boundary layer because of obstacles in the layer or downstream, or they may be formed elsewhere and impinge upon a boundary. In either case, the pressure rises sharply behind the shock, an adverse gradient, and this tends to cause early transition to turbulence and early flow separation. Special care must be taken to design aerodynamic surfaces to accommodate or avoid shockwave formation in transonic and supersonic flows. *See* COMPRESSIBLE FLOW.

As boundary layers move downstream, they tend to grow naturally and undergo transition to turbulence. Boundary layers encountering rising pressure undergo flow separation. Both phenomena can be controlled at least partially. Airfoils and hydrofoils can be shaped to delay adverse pressure gradients and thus move separation downstream. Proper shaping can also delay transition. Wall suction removes the low-momentum fluid and delays both transition and separation. Wall blowing into the boundary layer, from downward-facing slots, delays separation but not transition. Changing the wall temperature to hotter for liquids and colder for gases delays transition. Practical systems have been designed for boundary-layer control, but they are often expensive and mechanically complex. *See* AIRFOIL; FLUID-FLOW PRINCIPLES; STREAMLINING; VISCOSITY. [F.M.Wh.]

Bovine virus diarrhea A viral disease of cattle. The bovine viral diarrhea virus is common worldwide, infects cattle of all ages, and causes a variety of disease processes. In addition to cattle, the virus infects most even-toed ungulates, including sheep, swine, goats, deer, bison, llama, and antelope. *See* ANIMAL VIRUS.

The mature virion is spherical and 40–60 nanometers in diameter. It is composed of a spherical core that is surrounded by a lipid envelope. The viral genome consists of a single strand of positive-sense ribonucleic acid (RNA) about 12,300 nucleotides in length. Although all bovine viral diarrhea viruses are related serologically, variation is common among viral isolates in nucleotide sequence, antigenic sites on viral proteins, and biologic properties expressed in vitro or in vivo.

Cattle infected with bovine viral diarrhea virus usually develop a clinically mild, acute disease that is characterized by fever, low white blood cell count, mild depression, and transient loss of appetite. A clinically severe, acute disease occurs in cattle infected with some viruses. The clinical signs of severe disease include prolonged fever, pronounced depression, rapid respiration, ulceration of the mouth, esophagus, and intestines, hemorrhaging, diarrhea, dehydration, and death. The virus replicates in lymphoid cells and may suppress their immune function, potentially lowering resistance of the host to other infectious agents. Adverse effects on the fetus are common following infection of pregnant cattle with bovine viral diarrhea virus. Embryonic resorption, abortion, stillbirth, and congenital anomalies may result when the virus crosses the placenta and infects the fetus. A clinically severe disease, termed mucosal disease, occurs only in persistently infected cattle. The signs of mucosal disease are fever, low white blood cell count, diarrhea that is often bloody, mucosal ulcerations of the alimentary tract, inappetence, and death.

Oral or nasal exposure with virus is the primary mode of transmission of acute disease. Persistently infected cattle are important in viral transmission because they shed large quantities of virus in their saliva and nasal secretions. Contact with other cattle undergoing an acute infection is another important method of viral transmission. Biting insects and artificial insemination with semen contaminated with virus have been reported to transmit the virus. Because wild ruminants may be infected with bovine viral diarrhea virus, there is a possibility that disease may spread from farm to farm with movement of wildlife.

Treatment for bovine virus diarrhea primarily is based on supportive care. Prevention of disease can be achieved through use of vaccination. The vaccines usually are given first when calves are about 6 months of age. Vaccination is often repeated at regular intervals during the life of the animal. Identification and elimination of persistently infected cattle also is important for control of viral spread and for prevention of disease. [S.R.Bo.]

Boyle's law A law of gases which states that at constant temperature the volume of a gas varies inversely with its pressure. This law, formulated by Robert Boyle (1627–1691), can also be stated thus: The product of the volume of a gas times the pressure exerted on it is a constant at a fixed temperature. The relation is approximately true for most gases, but is not followed at high pressure. The phenomenon was discovered independently by Edme Mariotte about 1650 and is known in Europe as Mariotte's law. *See* GAS; KINETIC THEORY OF MATTER. [F.H.R.]

Brachiopoda A phylum of solitary, exclusively marine, coelomate, bivalved animals, with both valves symmetrical about a median longitudinal plane. They are typically attached to the substrate by a posteriorly located fleshy stalk or pedicle. Anteriorly, a relatively large mantle cavity is always developed between the valves, and the filamentous feeding organ, or lophophore, is suspended in it, projecting forward from the anterior body wall (see illustration).

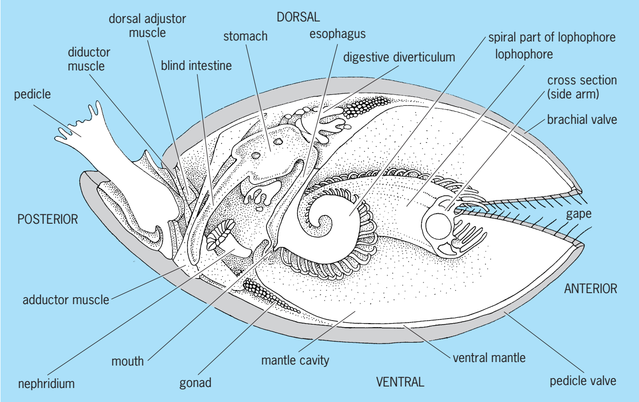
There are two clearly defined groups within the phylum, a division that is particularly marked if only Recent animals are considered. These two groups are regarded as classes; several names have been given to them, but Inarticulata and Articulata are the most widely used and are based on one of the most readily observed differences between them, the presence or absence of articulation between the two valves of the shell. Among the Articulata the valves are typically hinged together by a pair of teeth with complementary sockets in the opposing valve; these hinge teeth are lacking in the Inarticulata, whose valves are held together only by the soft tissue of the living animal. The phylum is currently classified into the following groups:

Class Inarticulata
  Order: Lingulida
    Acrotretida
    Obolellida
    Paterinida
Class Incertae Sedis
  Order Kutorginida

Class Articulata
  Order: Orthida
    Strophomenida
    Pentamerida
    Rhynchonellida
    Spiriferida
    Terebratulida

The pedicle is the only organ protruding outside the valves, while the remainder of the animal is enclosed in the space between them. This space is divided into two unequal parts, a smaller posteriorly located body cavity and an anterior mantle cavity. The two mantles approach each other and ultimately fuse along the posterior margin of articulate brachiopods; in contrast, the mantles are invariably discrete in the inarticulates and are separated by a strip of body wall.

The body cavity contains the musculature; the alimentary canal; the nephridia, which are paired excretory organs also functioning as gonoducts; the reproductive organs; and primitive circulatory and nervous systems. Except for the openings through the nephridia, the body cavity is enclosed, but the mantle cavity communicates freely with the sea when the valves are opened. The lophophore is suspended from the anterior body wall within the mantle cavity and is always symmetrically disposed about the median plane. The lophophore consists of a variably disposed, ciliated, filament-bearing tube, with the ciliary beat producing an ordered flow of water within the cavity, flowing across the filaments. The latter trap food particles which are carried along a groove in the lophophore to the medially situated mouth.



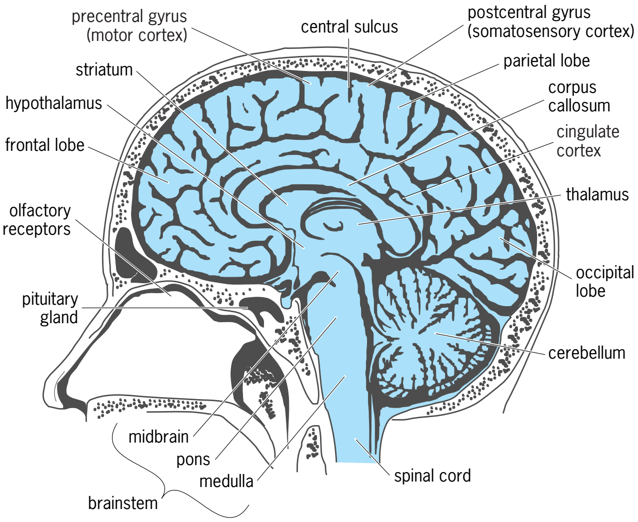
The principal organs of a brachiopod as typified by *Terebratulina.* (*After R. C. Moore, ed., Treatise on Invertebrate Paleontology, pt. H, Geological Society of America, Inc., and University of Kansas Press, 1965*)

All modern brachiopods are marine, and there is little doubt from the fossil record that brachiopods have always been confined to the sea. Recent brachiopods occur most commonly beneath the relatively shallow waters of the continental shelves, which seems to have been the most favored environment, but the bathymetric range of the phylum is large. A few modern species live intertidally and, at the other extreme, a limited number have been dredged from depths of over 16,000 ft (5000 m).

The majority of brachiopods form part of the sessile benthos and are attached by their pedicle during postlarval life. *Glottidia* and *Lingula* are exceptional in being infaunal and making burrows. A commoner modification involves loss of the pedicle, either complete suppression or atrophy early in the life history of the individual. Such forms either lie free on the sea floor, are attached by cementation of part or all of the pedicle valve, or are anchored by spines. The geographic distribution and geological setting of some fossil species suggest that they may have been epiplanktonic, attached to floating weed, but such a mode of life is unknown in modern faunas. *See* INARTICULATA. [A.J.R.]

Bradyodonti An order, perhaps composite in nature, of Paleozoic cartilaginous fishes (Chondrichthyes), presumably derived from primitive sharks. They are mainly represented by dentitions, which appear to have been adapted to the eating of mollusks and other shelled invertebrates; the body (seldom preserved) appears to have been broad and flattened, with large pectoral fins, as in the later skates and rays of similar habits. The first bradyodonts appeared at the end of the Devonian; they flourished during the Carboniferous, but declined and vanished by the end of the Permian, concomitantly with a reduction in the invertebrate fauna at that time. There are four families: Cochliodontidae, Petalodontidae, Psammodontidae, and Copodontidae. *See* CHIMAERIFORMES; CHONDRICHTHYES; ELASMOBRANCHII. [A.S.R.]

Brain A collection of specialized cells (neurons) in the head that regulates behavior as well as sensory and motor functions. The three main parts of the brain in vertebrates are the cerebrum, the cerebellum, and the brainstem that connects them with each other and with the spinal cord (see illustration). The two cerebral hemispheres are separated by a midline fissure that is bridged by a massive bundle of axons running in both directions, the corpus callosum. Each hemisphere has a core of groups of neurons (the basal ganglia); an outer shell of neurons in layers (the cerebral cortex); and massive bundles of axons for communication within the cerebrum and with the rest of the brain. These bundles are called white matter because of the waxy myelin sheaths surrounding the axons. *See* NEURON.



Midsagittal (midline, medial) section through the human brain. (*After C. R. Noback, The Human Nervous System, 4th ed., McGraw-Hill, 1991*)

The basal ganglia comprises three main groups. (1) The thalamus receives axons from all sensory systems and transmits information to the cortex. It also receives feedback from cortical neurons during sensory processing. (2) The striatum, comprising bundles of axons cutting through the groups of neurons, also has two-way communication with the cortex and assists in the organization of body movement. (3) The hypothalamus receives orders from the cortex and organizes the chemical systems that support body movement. One output channel is hormonal, and controls the pituitary gland (hypophysis) which in turn controls the endocrine system. The other channel is neural, comprising axons coursing through the brainstem and spinal cord to the motor neurons of the autonomic nervous system, which regulates the heart, blood vessels, lungs, gastrointestinal tract, sex organs, and skin. The autonomic and endocrine systems are largely self regulating, but they are subject to control by the cortex through the hypothalamus. *See* AUTONOMIC NERVOUS SYSTEM; ENDOCRINE SYSTEM (VERTEBRATE); NEUROBIOLOGY.

The cortex is also called gray matter because it contains the axons, cell bodies, and dendrites of neurons but there is very little myelin. An index of the capacity of a brain is cortical surface area. In higher mammals, the cortical surface increases more rapidly than the volume during fetal development; as a result the surface folds, taking the form of convexities (gyri) and fissures (sulci) that vary in their details from one brain to another. However, they are sufficiently reliable to serve as landmarks on the cerebral hemisphere that it can be subdivided into lobes. Four lobes make up the shell of each hemisphere, namely the frontal, parietal, temporal, and occipital lobes. Each lobe contains a motor or sensory map (an orderly arrangement of cortical neurons associated with muscles and sensory receptors on the body surface). The central sulcus delimits the frontal and parietal lobes. The precentral gyrus contains the motor cortex whose neurons transmit signals to motor neurons in the brainstem and spinal cord which control the muscles in the feet, legs, trunk, arms, face, and tongue of the opposite side of the body. The number of neurons for each section is determined by the fineness of control, not the size of the muscle; for example, the lips and tongue have larger areas than the trunk. Within the postcentral gyrus is the primary somatosensory cortex. Sensory receptors in the skin, muscles, and joints send messages to the somatosensory cortical cells through relays in the spinal cord and the thalamus to a map of the opposite side of the body in parallel to the map in the motor cortex. The lateral fissure separates the temporal lobe from the parietal and frontal lobes. The cortex on the inferior border of the fissure receives input relayed through the thalamus from the ears to the primary auditory cortex. The occipital lobe receives thalamic input from the eyes and functions as the primary visual cortex.

In humans, the association cortex surrounds the primary sensory and motor areas that make up a small fraction of each lobe. The occipital lobe has many specialized areas for recognizing visual patterns of color, motion, and texture. The parietal cortex has areas that support perception of the body and its surrounding personal space. Its operation is manifested by the phenomenon of phantom limb, in which the perception of a missing limb persists for an amputee. Conversely, individuals with damage to these areas suffer from sensory neglect. The temporal cortex contains areas that provide recognition of faces and of rhythmic patterns, including those of speech, dance, and music. The frontal cortex provides the neural capabilities for constructing patterns of motor behavior and social behavior. It was the rapid enlargement of the frontal and temporal lobes in human evolution over the past half million years that supported the transcendence of humans over other species. This is where the capacity to create works of art, and also to anticipate pain and death, is located. Insight and foresight are both lost with bilateral frontal lobe damage, leading to reduced experience of anxiety, asocial behavior, and a disregard of consequences of actions.

A small part of frontal lobe output goes directly to motor neurons in the brainstem and spinal cord for fine control of motor activities, such as search movements by the eyes, head, and fingers, but most goes either to the striatum from which it is relayed to the thalamus and then back to the cortex, or to the brainstem from which it is sent to the cerebellum and then through the thalamus back to the cortex. In the cerebellum, the cortical messages are integrated with sensory input predominantly from the muscles, tendons, and joints, but also from the eyes and inner ears (for balance) to provide split-second timing for rapid and complex movements. The cerebellum also has a cortex and a core of nuclei to relay input and output. Their connections, along with those in the cerebral cortex, are subject to modification with learning in the formation of a working memory (the basis for learned skills). *See* MEMORY; MOTOR SYSTEMS.

The cerebellum and striatum do not set goals, initiate movements, store temporal sequences of sensory input, or provide orientation to the spatial environment. These functions are performed by parts of the cortex and striatum deep in the brain that constitute another loop, the limbic system. Its main site of entry is the entorhinal cortex, which receives input from all of the sensory cortices, including the olfactory system. The input from all the sensory cortices is combined and sent to the hippocampus, where it is integrated over time. Hippocampal output returns to the entorhinal cortex, which distributes the integrated sensory information to all of the sensory cortices, updates them, and prepares them to receive new sensory input. This new information also reaches the hypothalamus and part of the striatum (the amygdaloid nucleus) for regulating emotional behavior. Bilateral damage to the temporal lobe including the hippocampus results in loss of short-term memory. Damage to the amygdaloid nucleus can cause serious emotional impairment. The Papez circuit is formed by transmission from the hippocampus to the hypothalamus by the fornix, then to the thalamus, parietal lobe, and entorhinal cortex. The limbic system generates and issues goal-directed motor commands, with corollary discharge to the sensory systems that prepares them for the changes in sensory input caused by motor activity (for example, when one speaks and hears oneself, as distinct from another).

Each hemisphere has its own limbic, Papez, cortico-thalamic, cortico-striatal, and cortico-cerebellar loops, together with sensory and motor connections. When isolated by surgically severing the callosum, each hemisphere functions independently, as though two conscious persons occupied the same skull, but with differing levels of skills in abstract reasoning and language. The right brain (spatial)-left brain (linguistic) cognitive differences are largely due to preeminent development of the speech areas in the left hemisphere in most right- and left-handed persons. Injury to Broca's area (located in the frontal lobe) and Wernicke's area (located in the temporal lobe) leads to loss of the ability, respectively, to speak (motor aphasia) or to understand speech (sensory aphasia). Studies of blood flow show that brain activity during intellectual pursuits is scattered broadly over the four lobes in both hemispheres. *See* APHASIA; CENTRAL NERVOUS SYSTEM; HEMISPHERIC LATERALITY. [W.J.F.]

Brake A machine element for applying a force to a moving surface to slow it down or bring it to rest in a controlled manner. In doing so, it converts the kinetic energy of motion into heat which is dissipated into the atmosphere. Brakes are used in motor vehicles, trains, airplanes, elevators, and other machines. Most brakes are of a friction type in which a fixed surface is brought into contact with a moving part that is to be slowed or stopped.

Friction brakes are classified according to the kind of friction element employed and the means of applying the friction forces. *See* FRICTION.

The single-block is the simplest form of brake. It consists of a short block fitted to the contour of a wheel or drum and pressed against its surface by means of a lever on a fulcrum, as widely used on railroad cars. The block may have the contour lined with friction-brake material, which gives long wear and a high coefficient of friction. The fulcrum may be located with respect to the lever in a manner to aid or retard the braking torque of the block. The lever may be operated manually or by a remotely controlled force (Fig. 1*a*).

In double-block brakes, two single-blocks brake in symmetrical opposition, where the operating force on the end of one lever is the reaction of the other, make up a double-block brake (Fig. 1*b*). External thrust loads are balanced on the rim of the rotating wheel.

An external-shoe brake operates in the same manner as the block brake, and the designation indicates the application of externally contracting elements. In this brake the shoes are appreciably longer, extending over a greater portion of the drum (Fig. 1*c*). This construction allows more combinations for special applications than the simple shoe, although assumptions of uniform pressure and concentrated forces are no longer possible. In particular, it is used on elevator installations for locking the hoisting sheave by means of a heavy spring when the electric current is off and the elevator is at rest. *See* ELEVATOR.

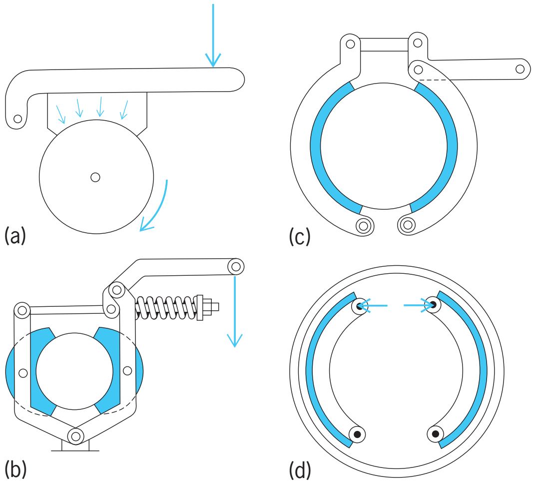


Fig. 1. Brakes. (*a*) Single-block brake. The block is fixed to the operating lever; force in the direction of the top arrow applies the brake. *(b)* Double-block brake. The blocks are pivoted on their levers; force in the direction of the arrow releases the brake. (*c*) External shoe brake. Shoes are lined with friction material. (*d*) Internal shoe brake with lining.

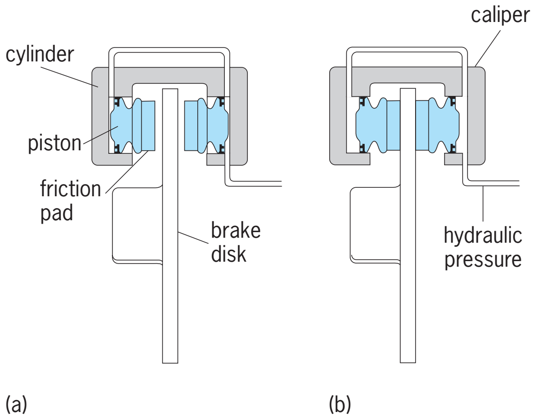

Fig. 2. Caliper disk brake. (*a*) Friction pads on either side of a disk that is free to rotate. (*b*) Brake applied, hydraulic pressure forces the pistons toward the disk to stop its rotation and hold it stationary. (*Automotive & Technical Writing, Charlottesville, Virginia*)

An internal shoe brake has several advantages over an external shoe. Because the internal shoe works on the inner surface of the drum, it is protected from water and grit (Fig. 1*d*). It may be designed in a more compact package, is easily activated, and is effective for drives with rotations in both directions. The internal shoe is used in the automotive drum brake, with hydraulic piston actuation. *See* AUTOMOTIVE BRAKE.

Hoists, excavating machinery, and hydraulic clutch-controlled transmissions have band brakes. They operate on the same principle as flat belts on pulleys. In the simplest band brake, one end of the belt is fastened near the drum surface, and the other end is then pulled over the drum in the direction of rotation so that a lever on a fulcrum may apply tension to the belt.

Disk brakes have long been used on hoisting and similar apparatus. Because more energy is absorbed in prolonged braking than in clutch startup, additional heat dissipation must be provided in equivalent disk brakes. Disk brakes are used for the wheels of aircraft, where segmented rotary elements are pressed against stationary plates by hydraulic pistons. Flexibility, self-alignment, and rapid cooling are inherent in this design. Another application is the bicycle coaster brake.

The caliper disk brake (Fig. 2) is widely used on automotive vehicles. It consists of a rotating disk which can be gripped between two friction pads. The caliper disk brake is hydraulically operated, and the pads cover between one-sixth and one-ninth of the swept area of the disk. *See* AUTOMOTIVE BRAKE.

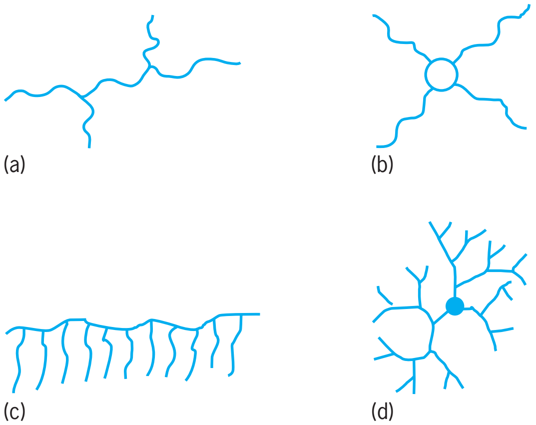
Railway brakes are normally applied air brakes; if the air coupling to a car is broken, the brakes are applied automatically. To apply the brakes, the brake operator releases the compressed air that is restraining the brakes by means of a diaphragm and linkage. Over-the-road trucks and buses use air brakes. Another form of air brake consists of an annular air tube surrounding a jointed brake lining that extends completely around the outside of a brake drum. Air pressure expands the tube, pressing the lining against the drum. [D.L.An.]

Branch circuit The portion of an electrical wiring system that extends beyond the final, automatic overcurrent protective device (circuit breaker or fuse), which is recognized by the National Electrical Code for use as a branch-circuit overcurrent protector, and that terminates at the utilization device (such as a lighting fixture, motor, or heater). Thermal cutouts, motor overload devices, and fuses in luminaires or plug connections are not approved for branch-circuit protection and do not establish the point of origin of a branch circuit.

Branch circuits serving more than one outlet or load are limited by the National Electrical Code to three types:

1. Circuits of 15 or 20 A may serve lights and appliances; the rating of one portable appliance may not exceed 80% of the circuit capacity; the total rating of fixed appliances may not exceed 50% of circuit capacity if lights or portable appliances are also supplied.
2. Circuits of 30 A may serve fixed lighting units with heavy-duty lampholders in other than dwellings or appliances in any occupancy.
3. Circuits of 40 or 50 A may serve fixed lighting with heavy-duty lampholders in other than dwellings, fixed cooking appliances, or infrared heating units. [B.J.McP.; J.F.McP.]

Branched polymer A polymer chain having branch points that connect three or more chain segments. Examples of branched polymers include long chains having occasional and usually short branches comprising the same repeat units as the main chain (nominally termed a branched polymer); long chains having occasional branches comprising repeat units different from those of the main chain (termed graft copolymers); main chains having one long branch per repeat unit (referred to as comb polymers); and small core molecules with branches radiating from the core (star polymers). Starburst or dendritic polymers are a special class of star polymer in which the branches are multifunctional, leading to further branching with polymer growth. Star, comb, and starburst polymers (see illustration), especially the last, represent interesting molecular structures that may lead to unusual supramolecular structures (for example, micelles and liposomes) that mimic the functions of complex biomolecules. *See* Biopolymer; Polymer; Polymerization. [G.E.W.]



Examples of branched polymers. (*a*) Branched polymer (if arms are of composition similar to backbone) or graft polymer (if compositions are different). (*b*) Star polymer. (*c*) Comb polymer. (*d*) Dendritic polymer.

Branchiopoda A class of crustaceans. The Conchostraca consist of two groups which, although superficially similar, differ in so many fundamental features that they have been placed in separate orders, Laevicaudata and Spinicaudata. *See* Laevicaudata; Spinicaudata.

Living members of the Branchiopoda range from less than 0.5 mm (0.02 in.) to (exceptionally) 100 mm (4 in.) in length. Form is exceedingly diverse. The trunk may be abbreviated and of probably as few as 5 segments (although segmentation is sometimes obscure) or elongate and of more than 40 segments. Trunk limbs range from 5 to about 70 pairs. A carapace is often present, either as a dorsal shield or as a bivalved structure; anostracans lack a carapace.

Most species are microphagous. Microphagous forms collect their food either by direct scraping from surfaces, which may or may not be followed by filtration, or by abstracting suspended particles by the use of complicated filtering devices.

Reproductive habits are diverse. Parthenogenesis is widespread, and the production of highly resistant resting eggs that can withstand freezing and drying and retain their viability for several years is highly characteristic. Almost all species live in fresh water, but a few are marine and some frequent highly saline situations. Branchiopods have a worldwide distribution. *See* Crustacea. [G.Fr.]

Branchiura A subclass of the Crustacea known as the fish lice. They are ectoparasites of fresh-water and marine fish. *Argulus* is a common genus. They are a small homogeneous group, less than 100 species, with worldwide distribution, and very much alike in appearance. The disklike head and thorax (cephalothorax) is strongly flattened and bears a small unsegmented abdomen bilobed at its distal end. Larger species may exceed 1 in. (25 mm) in length.

The appendages, all on the cephalothorax, consist of two pairs of antennae, the mouthparts which are one pair of mandibles and two pairs of maxillae, and four pairs of swimming legs. The wafer-thin cephalothorax with its appendages appressed to the underside permits fish lice to flatten themselves against a fish's skin. The resulting highly streamlined contour serves to minimize the considerable force of frictional drag found in a dense medium like water.

Other adaptations for holding fast to a mucus-covered swimming fish include numerous spinules and strategically placed hooks on the underside of the body and utilization of specialized portions of the body as suction cups. Despite these elaborate specializations, fish lice never lose the ability to abandon a host and swim. At least some of this activity is associated with mating and spawning.

Branchiurans feed on tissue fluids, especially blood. The mouth, located at the end of a movable proboscis, is applied to the host's skin and the rasping mandibles make the necessary wound. Fish lice usually are no threat to fish populations. In restricted areas such as hatchery ponds, however, an infestation can increase to levels that bring about high fish mortality. Treatment may require such drastic measures as drainage and cleaning before restocking can be successful. *See* Crustacea. [A.Fl.]

Brass An alloy of copper and zinc. In manufacture, lump zinc is added to molten copper, and the mixture is poured into either castings ready for use or into billets for further working by rolling, extruding, forging, or similar process. Brasses containing 75–85% copper are red-gold and malleable; those containing 60–70% are yellow and also malleable; and those containing 50% or less copper are white, brittle, and not malleable. Alpha brass contains up to 36% zinc; beta brass contains nearly equal proportions of copper and zinc. Specific brasses are designated as follows: gilding (95% copper: 5% zinc), red (85:15), low (80:20), and admiralty (70:29, with balance of tin). Naval brass is 59–62% copper with about 1% tin, less than that of lead and iron, and the remainder zinc. The nickel silvers contain 55–70% copper and the balance nickel. Leaded brass is used for castings.

Brass stains in moist air; however, the oxide so formed is sufficiently continuous and adherent to retard further oxidation. When brass is required to remain bright, it is either washed in nitric acid and then coated with clear lacquer, or it is regularly polished and waxed.

Brass is widely used in cartridge cases, plumbing fixtures, valves and pipes, screws, clocks, and musical instruments. *See* Alloy; Copper alloys; Zinc. [F.H.R.]

Brayton cycle A thermodynamic cycle (also variously called the Joule or complete expansion diesel cycle) consisting of two constant-pressure (isobaric) processes interspersed with two reversible adiabatic (isentropic) processes.

The thermal efficiency for a given gas, air, is solely a function of the ratio of compression. This is also the case with the Otto cycle. For the diesel cycle with incomplete expansion, the thermal efficiency is lower.

The Brayton cycle, with its high inherent thermal efficiency, requires the maximum volume of gas flow for a given power output. The Otto and diesel cycles require much lower gas flow rates, but have the disadvantage of higher peak pressures and temperatures. These conflicting elements led to many designs, all attempting to achieve practical compromises. With the development of fluid acceleration devices for the compression and expansion of gases, the Brayton cycle found mechanisms which could economically handle the large volumes of working fluid. This is perfected in the gas turbine power plant. *See* GAS TURBINE; THERMODYNAMIC CYCLE. [T.Ba.]

Brazil nut A large broad-leafed evergreen tree, *Bertholettia excelsa*, that grows wild in the forests of the Amazon valley of Brazil and Bolivia. The fruit is a spherical capsule weighing 2–4 lb (1–2 kg) which, when mature, consists of an outer hard indehiscent husk enclosing an inner hard-shelled container or pod filled with about 20 rather triangular seeds or nuts.

Although there are a few plantations in Brazil, almost the entire production is gathered from wild trees. The nuts are mostly exported to Europe, Canada, and the United States. About one-fourth of the crop is shelled in Brazil before export.

Brazil nuts have a high oil and protein content and require careful handling and refrigeration to prevent spoilage. The nuts are used in confectionery, baked goods, and nut mixtures. *See* LECYTHIDALES. [L.H.MacD.]

Brazing A method of joining metals, and other materials, by applying heat and a brazing filler metal. The filler metals used have melting temperatures above 840°F (450°C), but below the melting temperature of the metals or materials being joined. They flow by capillary action into the gap between the base metals or materials and join them by creating a metallurgical bond between them, at the molecular level. The process is similar to soldering, but differs in that the filler metal is of greater strength and has a higher melting temperature.

When properly designed, a brazed joint will yield a very high degree of serviceability under concentrated stress, vibration, and temperature loads. It can be said that in a properly designed brazement, any failure will occur in the base metal, not in the joint. There are many design variables to be considered. First among them is the mechanical configuration of the parts to be joined, and the joint area itself. All brazements can be categorized as having one of two basic joint designs: the lap joint or the butt joint. Others are adaptations of these two.

Design considerations should include the informed selection of the base and filler metals. In addition to the basic mechanical requirements, the base metals used in the brazement must retain the integrity of their physical properties throughout the heat of the brazing cycle. No universal filler metal that will satisfy all design requirements is possible, but there are many types available, ranging from pure metals such as copper, gold, or silver to complex alloys of aluminum, gold, nickel, magnesium, cobalt, silver, and palladium.

There are 11 basic brazing processes. In torch brazing, heat is applied by flame, from some type of torch, directly to the base metal. A mineral flux is normally used. The brazing filler metal may be preplaced in the joint, or face-fed into the joint. In induction brazing, brazing temperatures are developed in the parts to be brazed by placing them in or near a source of high-frequency ac electricity. Flux and preplaced filler metals are normally employed. Resistance brazing employs electrodes, which are arranged so that the joint forms a part of an electric circuit. Heat is developed by the resistance of the parts to the flow of the electric current. In dip brazing, the brazing filler metal is preplaced in or at the joint, and the assembly is immersed in a bath of molten salt or flux until the brazing temperature is achieved. In a variation of this process, the assembly is prefluxed and dipped into a bath of molten brazing filler metal. Infrared brazing is a process in which high-intensity quartz lamps are directed on the metals to be joined.

Furnace brazing is a widely used technique, especially useful where the parts to be brazed are machined or formed to their final dimensions, or constitute a complex assembly that has already been lightly joined or fixtured. The atmosphere within a brazing furnace is usually controlled, which permits a great deal of flexibility. An important advantage is that potential distortion of metal, created by heating and cooling, can be predicted and controlled and thereby minimized or eliminated. Also the capacity for automation is facilitated in the furnace brazing process.

Diffusion brazing, unlike furnace brazing, is defined not by the method of heating but rather by the degree of mutual fillermetal solution and diffusion with the base metal resulting from the temperature used and the time interval at heat. In diffusion brazing, temperature, time, in some cases pressure, and selection of base and filler materials are so controlled that the filler metal is partially or totally diffused into the base metal. The joint properties then closely approach those of the base metal.

Other, less used processes include arc brazing, block brazing, flow brazing, and twin carbon arc brazing. [R.L.P.]

Breadboarding Assembling an electronic circuit in the most convenient manner on a board or other flat surface, without regard for final locations of components, to prove the feasibility of the circuit and to facilitate changes when necessary. Standard breadboards for experimental work are made with mounting holes and terminals closely spaced at regular intervals, so that parts can be mounted and connected without drilling additional holes.

Printed-circuit boards having similar patterns of punched holes, with various combinations of holes connected together by printed wiring on each side, are often used for breadboarding when the final version is to be a printed circuit. *See* PRINTED CIRCUIT. [J.Mar.]

Breadfruit The multiple fruit of an Indo-Malaysian tree, *Artocarpus altilis*, of the mulberry family (Moraceae), now cultivated in tropical lowlands around the world. The fruits vary considerably in size and are often borne in small clusters. Breadfruit is a wholesome food for both humans and animals, although it has a high carbohydrate content. It is eaten fresh or baked, boiled, roasted, fried, or ground up and made into bread. There are many varieties, both with and without seeds. [E.L.C.]

Breakdown potential The potential difference at which an electrically stressed gas is transformed from an insulator to a conductor. In an electrically stressed gas, as the voltage is increased, the free electrons present in the gas gain energy from the electric field. When the applied voltage is increased to such a level that an appreciable number of these electrons are energetically capable of ionizing the gas, the gas makes the transition from an insulator to a conductor; that is, it breaks down. The potential difference at which this transition occurs is known as the breakdown potential for the particular gaseous medium.

The breakdown potential depends on the nature, number density, and temperature of the gas; on the material, state, and geometry of the electrodes; on the type of voltage applied (steady, alternating, impulsive); and on the degree of preexisting ionization. Areas of surface roughness at the electrodes (especially the cathode) or the presence of conducting particles in the gas greatly reduces the breakdown potential because at such points the electric field is significantly enhanced, increasing the electron energies and thus gas ionization. The breakdown voltage varies considerably from one gaseous medium to another; it is very low for the rare gases, and very high for polyatomic, especially electronegative, gases such as sulfur hexafluoride (SF_6).

The transition of a gas from an insulator to a conductor under an imposed electrical potential occurs in times ranging from milliseconds to nanoseconds, depending on the form of the applied field and the gas density. This transition depends on the behavior of electrons, ions, and photons in the gas, especially the processes which produce or deplete free electrons. Knowledge of these processes often allows prediction of the breakdown voltage of gases and the tailoring of gas mixtures which can withstand high electrical potentials for practical uses. *See* ELECTRICAL BREAKDOWN; ELECTRICAL CONDUCTION IN GASES.

The systematic development of gaseous dielectrics with high dielectric strength (that is, high breakdown potential) is most significant for high-voltage technology, which has a multiplicity of gas insulation needs. Dielectric gases are widely used as insulating media in high-voltage transmission lines, circuit breakers, transformers, substations, high-voltage research apparatus, and other electrical equipment. *See* CIRCUIT BREAKER; DIELECTRIC MATERIALS; TRANSMISSION LINES. [L.G.C.]

Breast The human mammary gland, usually well developed in the adult female but rudimentary in the male. Each adult female breast contains 15–20 separate, branching glands that radiate from the nipple. During lactation their secretions are discharged through separate openings at the base of the nipple.

In the female, hormonal changes in adolescence cause enlargement of breast tissue, but much of this is connective tissue although some glandular buds form. With the advent of full menstruation ovarian estrogenic hormones influence breast development. If pregnancy ensues, the glandular tissue reaches full development and full lactation begins shortly after birth. After cessation of lactation the breasts regress considerably and once again reflect cyclic regulation. *See* LACTATION. [W.J.B.]

Breast disorders may result from congenital or developmental abnormalities, inflammations, hormonal imbalances, and, most important, from tumor formation.

Congenital defects are usually unimportant except for their psychic or cosmetic implications. Supernumerary nipples and breasts or accessory breast tissue are common examples.

Inflammations are not encountered frequently and usually result from a staphylococcal or streptococcal invasion incurred during lactation. A special form of inflammation may result from fat necrosis. Although any age is susceptible, older women show a slightly higher incidence of fat necrosis, the commonest cause of which is injury from trauma. *See* STAPHYLOCOCCUS; STREPTOCOCCUS; SYPHILIS; TUBERCULOSIS.

Hormonal imbalances are believed to be responsible for the variants of the commonest nontumorous breast disorder of women, cystic hyperplasia. The changes are thought to result from exaggeration or distortion of the normal cyclic alterations induced during the menstrual interval. Although a wide range of clinical and pathologic variation is commonplace, three major types or tendencies prevail. The first, called fibrosis or mastodynia, is marked by an increase of connective tissue in the breast, without a proportionate increase in glandular epithelium. The second, cystic disease, is characterized by an increase in the glandular and connective tissues in local areas, with a tendency toward formation of cysts varying in size. The third major type is adenosis, in which glandular hyperplasia is predominant. Each major form of cystic hyperplasia has its own clinical characteristics, ages of highest incidence, and distribution. Each is important because the breast masses which occur require differentiation from benign and malignant tumors. These lesions also have been found to predispose to the subsequent development of carcinoma.

Breast cancer is the most significant lesion of the female breast, accounting for 25,000–30,000 deaths in the United States each year. It rarely occurs before the age of 25, but its incidence increases each year thereafter, with a sharper climb noted about the time of menopause. Early breast cancer may appear as a small, firm mass which is nontender and freely movable. Diagnosis at this time carries a more favorable prognosis than later, when immobility, nipple retraction, lymph node involvement, and other signs of extension or spread are noted. Paget's disease of the nipple is a special form of breast cancer, in which there are early skin changes about the nipple. *See* CANCER (MEDICINE); HORMONE; ONCOLOGY. [E.G.St./N.K.M.]

Breast disorders Benign and malignant lesions of the human mammary glands. Benign breast disorders are often symptomatic and bothersome but do not have malignant potential. Malignant disorders have the potential to grow locally in the breast and spread through the bloodstream to other parts of the body.

Physiologic changes. The breast is an organ that changes in response to fluctuations in hormone levels. Physiologic changes in the breast are often confused with disease. Fibrocystic disease, chronic cystic mastitis, and mammary dysplasia are terms that have been used to describe cyclical pain, tenderness, and lumpiness in the breast. These terms are imprecise and represent the normal physiologic responses to hormonal changes in the body rather than distinct clinical entities. Cyclic breast pain can occur in response to estrogens endogenous in premenopausal women or supplemental in postmenopausal women. Diffuse, palpable irregularities or lumps in the breast are also associated with this cyclical pain. Unlike malignant masses, however, these irregularities fluctuate in size and tenderness with the menstrual cycle, and are better described as physiologic nodularity of the breast. *See* MENOPAUSE.

Benign disorders. Common benign disorders include breast masses, cysts, gynecomastia, nipple discharge, and breast infections. Breast masses or dominant lumps are different from lumpiness; they are persistent over time and are palpably distinct from the surrounding breast tissue. They can develop in any age group and should be carefully evaluated. Mammography and ultrasound can help to determine the character of the mass, depending on the age of the patient.

Dominant lumps include fibroadenomas, gross cysts, pseudolumps, and cancer. Fibroadenomas may occur in any age group but are most commonly seen in young women. They are benign tumors consisting of smooth, rounded masses that are easily palpable in the breast. The cause is unknown; however, there is evidence to support the presence of an imbalance in circulating hormone levels that might be responsible for tumor growth. Breast cysts may be difficult to identify by physical examination or mammography, but can be distinguished from solid masses by using ultrasound imaging. Treatment of a cyst involves draining it with a small needle and syringe. If the cyst completely disappears, no further treatments are required. However, if the cyst remains or recurs or the cyst fluid is bloody, further examinations are required to rule out an underlying carcinoma. *See* MAMMOGRAPHY.

Gynecomastia, a benign enlargement of the male breast which can occur at any age and in one or both breasts, is a physiologic response to hormones, drugs, or an underlying medical condition. Nipple discharge does not always indicate a pathologic process; the character of the discharge is significant. A watery bilateral discharge from multiple ducts is usually normal. A milky discharge (galactorrhea) is often physiologic but sometimes can be associated with a tumor of the pituitary gland, which secretes prolactin. Unilateral, and especially spontaneous, nipple discharge generally signifies underlying pathology. Bloody nipple discharge is of most concern. About 80% of the time, however, the underlying cause is a benign papilloma within a duct. Breast infections are a common problem seen in both lactating and nonlactating individuals. *See* LACTATION.

Proliferative breast disorders include ductal and lobular hyperplasias. It is thought that some of these disorders might represent precancerous changes since they signal an increased risk for the development of breast cancer. Women who have hyperplasia without atypical cell changes have a mildly elevated risk for the subsequent development of breast cancer when they are compared with the general population. Women with atypical hyperplasia have a risk of developing breast cancer 4.4 times that of women without identifiable risk factors. This lesion is seen in only about 4–10% of breast biopsies. It does not characteristically form lumps or show up on mammography. Other benign neoplasms of the breast include adenomas, intraductal papillomas, adenosis, and radial sclerosing lesions.

Precancer. Ductal carcinoma is a precancer. It does not have the ability to disseminate throughout the body but can progress to an invasive carcinoma if left untreated. Once discovered, this lesion can be treated with breast conservation surgery, that is, excision of the tumor with a margin of normal tissue, with or without radiation, or with total mastectomy. Lobular carcinoma, however, is a misnomer since it is not a premalignant lesion but a marker for subsequent cancer. Women with lobular carcinoma who subsequently develop cancer do so in either breast with a relative risk 5.7 times that of the general population. Treatment options include close observation with physical examination and mammography, or bilateral mastectomies.

Cancer. Breast cancer is the most common cancer in women and is the second leading cause of cancer deaths among all American women, particularly in the fifth and sixth decades of life. Almost 80% of invasive carcinomas of the breast are of ductal origin; the remainder are lobular carcinomas or other special histologic types. Invasive ductal carcinomas can be subtyped if they have one or more characteristics of a specific histologic type, including tubular, medullary, papillary, or mucinous differentiation. When a large part of the tumor is differentiated into one of these subtypes, they generally carry a more favorable prognosis.

There are no significant differences in the rates of local recurrence and survival when breast conservation surgery is combined with radiation therapy to the breast as compared with total mastectomy. Removal of axillary lymph nodes continues to be an important tool in the staging and prognosis of invasive carcinomas of the breast. If axillary lymph node metastases are detected, systemic therapy is indicated to decrease the incidence of distant metastses, and will usually decrease the risk of mortality by one-third. Combination chemotherapy is generally recommended for premenopausal women, and its use has been extended to healthy postmenopausal women. Hormonal therapy is used to treat postmenopausal women with axillary lymph node metastases and hormone receptor positive tumors. Tamoxifen (an antiestrogen) is a hormonal agent which has been shown to decrease the risk of recurrence and the development of second primary tumors in postmenopausal women. *See* CANCER (MEDICINE); CHEMOTHERAPY.

Thirty percent of all women with negative lymph nodes will have developed micrometastases at the time of diagnosis and will eventually die of breast cancer. Chemotherapy or hormone therapy is therefore often recommended even for women with negative nodes. The use of chemotherapy or hormone therapy in women without axillary lymph node metastases is determined by multiple factors. The most important determinant is tumor size. Women with tumors greater than 2 cm (0.8 in.) in diameter, with negative axillary nodes, should receive systemic therapy. For individuals without axillary lymph node metastases and tumors less than 1 cm (0.4 in.) in diameter, the probability of relapse 10 years after diagnosis is less than 10%. Therefore, systemic chemotherapy is generally not recommended in this group.

Screening. Breast cancer screening is the most effective way of detecting breast cancer in its early stages. Screenings involve self-examination of the breast, physical examination, and mammography. The guidelines for when these examinations should be administered depend on the individual's age. A mammogram is the most reliable screening test for the early detection of breast cancer; mammograms are recommended every 2–3 years from age 40 to 50 and annually after age 50. As the density of the breast parenchyma changes with increasing age, mammography is better able to detect abnormalities within the breast. [K.K.H; S.M.L.]

Breccia A clastic rock composed of angular gravel-size fragments; the consolidated equivalent of rubble. The designation gravel-size refers to a mean particle diameter greater than 0.08 in. (2 mm), which means that 50% or more of the particles (by volume) are this size or larger. Various classifications specify different values for the degree of angularity. One system specifies angular or subangular fragments (roundness ≤ 0.25), whereas another restricts the term breccia to aggregates with angular fragments (roundness ≤ 0.10). *See* GRAVEL.

Sedimentary breccias, also known as sharpstone conglomerates, are significant because the angularity of their fragments indicates either proximity to the source or transportation by a mechanism that does not cause significant rounding of the fragments. Examples of the first condition are talus breccia formed at the base of a scarp, and reef breccia deposited adjacent to a reef margin. Transport mechanisms that can preserve the angularity of clasts over significant distances include debris flows, slumps, and glacial transport, although rounded fragments may also be carried. All of these mechanisms incorporate a large proportion of fine sediment in the transporting medium, which effectively cushions interparticle collisions and inhibits rounding. *See* CONGLOMERATE; REEF; SEDIMENTOLOGY.

Intraformational or intraclastic breccias are an important class of sedimentary breccias. They are formed by the breakup and incorporation of sediment aggregates from within the same formation, which requires either early cementation (for example, the formation of nodules or duricrusts) or uncemented aggregates sufficiently cohesive to be transported a short distance without disaggregation. Thus, uncemented aggregates are basically limited to sediments that are rich in clay or clay-size carbonates (calcilutites). The mechanisms for formation of intraformational breccias include bank slumping or desiccation fracturing of mud in river or tidal channels, and erosion and incorporation of mud blocks in mass flows such as slumps or turbidity currents. *See* SEDIMENTARY ROCKS.

Igneous breccias are mainly of pyroclastic origin but may also form as intrusive breccias by forceful intrusion of magma. In the latter case the operative agent is fluid pressure; in the former it is the explosive escape of gas from solidifying viscous lava. These rocks, termed pyroclastic or volcanic breccias, are distinct from agglomerates, which accumulate mainly as lava bombs solidified during flight and which are commonly rounded. *See* PYROCLASTIC ROCKS.

Cataclastic breccias result from the fracture of rocks by tectonic or gravitational stresses. However, since many tectonic processes are at least partly gravitational, the two processes can be considered together. Tectonic breccias include fault and fold breccias, the latter formed by fracturing of brittle layers within incompetent plastic strata during folding. In one classification, landslide and slump breccias are included in the gravitational category, but here they are considered to be sedimentary, commonly intraformational. Solution or collapse breccias are a type of nontectonic gravitational breccia. They result from the creation by groundwater solution of unsupported rock masses which collapse under their own weight to form breccia. [B.Rus.]

Breeding (animal) The application of genetic principles to improving heredity for economically important traits in domestic animals. Examples are improvement of milk production in dairy cattle, meatiness in pigs, feed requirements or growth rate in beef cattle, and egg production in chickens. Selection permits the best parents to leave more offspring in the next generation than do poor parents.

Selection is the primary tool for generating directed genetic changes in animals. It may be concentrated on one characteristic, may be directed independently on several traits, or may be conducted on an index or total score which includes information on several traits. In general, the third method is preferable when several important heritable traits need attention. In practice, selection is likely to be a mixture of the second and third methods.

Heritability, the fraction of the total variation in a trait that is due to additive genetic differences, is a key parameter in making decisions in selection. Most traits are strongly to moderately influenced by environmental or managemental differences. Therefore, managing animals to equalize environmental influences on them, or statistically adjusting for environmental differences among animals, is necessary to accurately choose those with the best inheritance for various traits.

The improvement achieved by selection is directly related to the accuracy with which the breeding values of the subjects can be recognized. Accuracy, in turn, depends upon the heritabilities of the traits and upon whether they can be measured directly upon the subjects for selection (mass selection), upon their parents (pedigree selection), upon their brothers and sisters (family selection), or upon their progeny (progeny testing). For traits of medium heritability, the following sources of information are about equally accurate for predicting breeding values of subjects: (1) one record measured on the subject; (2) one record on each ancestor for three previous generations; (3) one record each on five brothers or sisters where there is no environmental correlation between family members; and (4) one record each on five progeny having no environmental correlations, each from a different mate.

Propagation of improved animal stocks is achieved primarily with purebred strains descended from imported or locally developed groups or breeds of animals which have been selected and interbred for a long enough period to be reasonably uniform for certain trademark characteristics, such as coat color. Because the number of breeding animals is finite and because breeders tend to prefer certain bloodlines and sires, some inbreeding occurs within the pure breeds, but this has not limited productivity in most of these breeds. Crossbreeding makes use of the genetic phenomenon of heterosis. Heterosis is improved performance of crossbred progeny, exceeding that of the average performance of their parents. Most commercial pigs, sheep, and beef cattle are produced by crossbreeding. *See* GENETICS.

Advances in a variety of technologies have application for improvement of domestic animals, including quantitative genetics, reproductive physiology, and molecular genetics. Quantitative geneticists use statistical and genetic information to improve domestic animals. Typically a statistical procedure is used to rank animals based on their estimated breeding values for traits of economic importance. The statistical procedures used allow ranking animals across herds or flocks, provided the animals in different herds or flocks have relatives in common. The primary contribution of reproductive physiology to genetic improvement is to reduce the generation interval. If genetic improvement is increasing at the same rate per generation, more generations can be produced for a fixed time, and thus more gain per unit of time. The most important development was artificial insemination, which allows extensive use of superior males. Another development was embryo transplantation, which allows more extensive use of females. Cloning is a relatively new technique, by which whole and healthy animals have been produced that have the same DNA as the animal from which the cells were taken.

Due to advances in molecular genetics, knowledge is increasing regarding the location of genes on chromosomes and the distance between the genes. In domestic animals, polymorphisms (changes in the order of the four bases) that are discovered in the DNA may be associated with economic traits. When the polymorphisms are associated with or code for economic traits, they are called quantitative trait loci (QTL). When a few or several quantitative trait loci are known that control a portion of the variability in a trait, increasing the frequencies of favorable alleles can enhance the accuracy of selection and augment production. Another use of molecular genetics is to detect the genes that code for genetically predetermined diseases. An example is the bovine leukocyte deficiency gene, which does not allow white blood cells to migrate out of the blood supply into the tissues to fight infection. The calves perish at a young age. Screening all sires that enter artificial breeding organizations and not using sires that transmit the defect has effectively controlled this condition. [A.E.Fr.]

Breeding (plant) The application of genetic principles to improve cultivated plants. New varieties of cultivated plants can result only from genetic reorganization that gives rise to improvements over the existing varieties in particular characteristics or in combinations of characteristics. Thus, plant breeding can be regarded as a branch of applied genetics, but it also makes use of the knowledge and techniques of many aspects of plant science, especially physiology and pathology. Related disciplines, like biochemistry and entomology, are also important, and the application of mathematical statistics in the design and analysis of experiments is essential. *See* GENETICS.

The cornerstone of all plant breeding is selection, or the picking out of plants with the best combinations of agricultural and quality characteristics from populations of plants with a variety of genetic constitutions. Seeds from the selected plants are used to produce the next generation, from which a further cycle of selection may be carried out if there are still differences. Conventional breeding is divided into three categories on the basis of ways in which the species are propagated. First come the species that set seeds by self-pollination; that is, fertilization usually follows the germination of pollen on the stigmas of the same plant on which it was produced. The second category of species sets seeds by cross-pollination; that is, fertilization usually follows the germination of pollen on the stigmas of different plants from those on which it was produced. The third category comprises the species that are asexually propagated; that is, the commercial crop results from planting vegetative parts or by grafting. The procedures used in breeding differ according to the pattern of propagation of the species. Several innovative techniques have been explored to enhance the scope, speed, and efficiency of producing new, superior cultivars. Advances have been made in extending conventional sexual crossing procedures by laboratory culture of plant organs and tissues and by somatic hybridization through protoplast fusion.

The essential attribute of self-pollinating crop species, such as wheat, barley, oats, and many edible legumes, is that, once they are genetically pure, varieties can be maintained without change for many generations. When improvement of an existing variety is desired, it is necessary to produce genetic variation among which selection can be practiced. This is achieved by artificially hybridizing between parental varieties that may contrast with each other in possessing different desirable attributes. This system is known as pedigree breeding, and it is the method most commonly employed, and can be varied in several ways.

Another form of breeding often employed with self-pollinating species involves backcrossing. This is used when an existing variety is broadly satisfactory but lacks one useful and simply inherited trait that is to be found in some other variety. Hybrids are made between the two varieties, and the first hybrid generation is crossed, or backcrossed, with the broadly satisfactory variety which is known as the recurrent parent. Backcrossing has been exceedingly useful in practice and has been extensively employed in adding resistance to diseases, such as rust, smut, or mildew, to established and acceptable varieties of oats, wheat, and barley.

Natural populations of cross-pollinating species are characterized by extreme genetic diversity. No seed parent is true-breeding, first because it was itself derived from a fertilization in which genetically different parents participated, and second because of the genetic diversity of the pollen it will have received. In dealing with cultivated plants with this breeding structure, the essential concern in seed production is to employ systems in which hybrid vigor is exploited, the range of variation in the crop is diminished, and only parents likely to give rise to superior offspring are retained.

Plant breeders have made use either of inbreeding followed by hybridization or of some form of recurrent selection. During inbreeding programs normally cross-pollinated species, such as corn, are compelled to self-pollinate by artificial means. Inbreeding is continued for a number of generations until genetically pure, true-breeding, and uniform inbred lines are produced. During the production of the inbred lines, rigorous selection is practiced for general vigor and yield and disease resistance, as well as for other important characteristics. To estimate the value of inbred lines as the parents of hybrids, it is necessary to make tests of their combining ability. The test that is used depends upon the crop and on the ease with which controlled cross-pollination can be effected.

Breeding procedures designated as recurrent selection are coming into limited use with open-pollinated species. In theory, this method visualizes a controlled approach to homozygosity, with selection and evaluation in each cycle to permit the desired stepwise changes in gene frequency. Experimental evaluation of the procedure indicates that it has real possibilities. Four types of recurrent selection have been suggested: on the basis of phenotype, for general combining ability, for specific combining ability, and reciprocal selection. The methods are similar in the procedures involved, but vary in the type of tester parent chosen, and therefore in the efficiency with which different types of gene action (additive and nonadditive) are measured.

Varieties of asexually propagated crops consist of large assemblages of genetically identical plants, and there are only two ways of introducing new and improved varieties: by sexual reproduction and by the isolation of somatic mutations. (A very few asexually propagated crop species are sexually sterile, like the banana, but the majority have some sexual fertility.) The latter method has often been used successfully with decorative plants, such as chrysanthemum, and new forms of potato have occasionally arisen in this way. When sexual reproduction is used, hybrids are produced on a large scale between existing varieties; the small number that have useful arrays of characters are propagated vegetatively until sufficient numbers can be planted to allow agronomic evaluation. [R.Ri.]

Cell technologies have been used to extend the range and efficiency of asexual plant propagation. For example, plant cell culture involves the regeneration of entire mature plants from single cells or tissues excised from a source plant and cultured in a nutrient medium. In micropropagation and cloning, tissues are excised from root, stem, petiole, or seedling and induced to regenerate plantlets. All regenerants from tissues of one source plant constitute a clone. Microspore or anther culture is the generation of plants from individual cells with but one set of chromosomes, haploid cells, as occurs in the development of pollen. Microspores are isolated from anthers and cultured on nutrient media, or entire anthers are cultured in this manner. Doubling of chromosomes that may occur spontaneously or can be induced by treatment with colchicine leads to the formation of homozygous dihaploid plants. *See* PLANT PROPAGATION; POLLEN; TISSUE CULTURE.

Breeding for new, improved varieties of crop plants is most often based on cross-pollination and hybrid production. Such breeding is limited to compatible plants, and compatibility lessens with increasing distance in the relationship between plants. Breeding would benefit from access to traits inherent in sexually noncompatible plants. Biotechnological techniques such as in vitro fertilization and embryo rescue (the excision and culture of embryos on nutrient media) have been employed to overcome incompatibility barriers, as have somatic hybridization and DNA technologies. Somatic hybridization involves enzymatic removal of walls from cells of leaves and seedlings to furnish individual naked cells, that is, protoplasts, which can then be fused to produce hybrids. Similarity of membrane structure throughout the plant kingdom permits the fusion of distantly related protoplasts. Cell fusion may lead to nuclear fusion, resulting in amphi-diploid somatic hybrid cells. Fusion products of closely related yet sexually incompatible plants have been grown to flowering plants; the most famous example is the potato + tomato hybrid = pomato (*Solanum tuberosum* + *Lycopersicon esculentum*). DNA technologies enable the isolation of desirable genes from bacteria, plants, and animals (genes that confer herbicide resistance or tolerance to environmental stress, or encode enzymes and proteins of value to the processing industry) and the insertion of such genes into cells and tissues of target plants by direct or indirect uptake has led to the genetic transformation of plant cells. The regeneration of transformed plant cells and tissues results in new and novel genotypes (transgenic plants). Contrary to hybrids obtained by cross-pollination, such plants are different from their parent by only one or two single, defined traits. [F.Co.]

Bremsstrahlung In a narrow sense, the electromagnetic radiation emitted by electrons when they pass through matter. Charged particles radiate when accelerated, and in this case the electric fields of the atomic nuclei provide the force which accelerates the electrons. The continuous spectrum of x-rays from an x-ray tube is that of the bremsstrahlung; in addition, there is a characteristic x-ray spectrum due to excitation of the target atoms by the incident electron beam. The major energy loss of high-energy (relativistic) electrons (energy greater than about 10 MeV, depending somewhat upon material) occurs from the emission of bremsstrahlung, and this is the major source of gamma rays in a high-energy cosmic-ray shower. *See* COSMIC RAYS; ELECTROMAGNETIC RADIATION.

In a broader sense, bremsstrahlung is the radiation emitted when any charged particle is accelerated by any force. To a great extent, as a source of photons in the ultraviolet and soft x-ray region for the investigation of atomic structure (particularly in solids), bremsstrahlung from x-ray tubes has been replaced by synchrotron radiation. Synchrotron radiation is an analog to bremsstrahlung, differing in that the force which accelerates the electron is a macroscopic (large-scale) magnetic field. [C.G.]

Brick A construction material usually made of clay and extruded or molded as a rectangular block. Three types of clay are used in the manufacture of bricks: surface clay, fire clay, and shale. Adobe brick is a sun-dried molded mix of clay, straw, and water, manufactured mainly in Mexico and some southern regions of the United States. *See* CLAY.

The first step in manufacture is crushing the clay. The clay is then ground, mixed with water, and shaped. Then the bricks are fired in a kiln at approximately 2000°F (1093°C). Substances in the clay such as ferrous, magnesium, and calcium oxides impart color to the bricks during the firing process. The color may be uniform throughout the bricks, or the bricks may be manufactured with a coated face. The latter are classified as glazed, claycoat, or engobe.

The most commonly used brick product is known as facing brick. Decorative bricks molded in special shapes are used to form certain architectural details such as water tables, arches, copings, and corners. [M.Gu.]

Bridge A structure built to provide ready passage over natural or artificial obstacles, or under another passageway. Bridges serve highways, railways, canals, aqueducts, utility pipelines, and pedestrian walkways. In many jurisdictions, bridges are defined as those structures spanning an arbitrary minimum distance, generally about 10–20 ft (3–6 m); shorter structures are classified as culverts or tunnels. In addition, natural formations eroded into bridgelike form are often called bridges. This article covers only bridges providing conventional transportation passageways.

Bridges generally are considered to be composed of three separate parts: substructure, superstructure, and deck. The substructure or foundation of a bridge consists of the piers and abutments which carry the superimposed load of the superstructure to the underlying soil or rock. The superstructure is that portion of a bridge or trestle lying above the piers and abutments. The deck or flooring is supported on the bridge superstructure; it carries and is in direct contact with the traffic for which passage is provided.

Bridges are classified in several ways. Thus, according to the use they serve, they may be termed railway, highway, canal, aqueduct, utility pipeline, or pedestrian bridges. If they are classified by the materials of which they are constructed (principally the superstructure), they are called steel, concrete, timber, stone, or aluminum bridges. Deck bridges carry the deck on the very top of the superstructure. Through bridges carry the deck within the superstructure. The type of structural action is denoted by the application of terms such as truss, arch, suspension, stringer or girder, stayed-girder, composite construction, hybrid girder, continuous, cantilever, or orthotropic (steel deck plate).

The two most general classifications are the fixed and the movable. In the former, the horizontal and vertical alignment of the bridge are permanent; in the latter, either the horizontal or vertical alignment is such that it can be readily changed to permit the passage beneath the bridge of traffic. Movable bridges are sometimes called drawbridges in an anachronistic reference to an obsolete type of movable bridge spanning the moats of castles.

A singular type of bridge is the floating or pontoon bridge, which can be a movable bridge if it is designed so that a portion of it can be moved to permit the passage of water traffic.

The term trestle is used to describe a series of short spans supported by braced towers, and the term viaduct is used to describe a high structure of short spans, often of arch construction.

Fixed bridges. This type of construction is selected when the vertical clearance provided beneath the bridge exceeds the clearance required by the traffic it spans. For very short spans, construction may be a solid slab or a number of beams; for longer spans, the choice may be girders or trusses. Still longer spans may dictate the use of arch construction, and if the spans are even longer, stayed-girder bridges are used. Suspension bridges are used for the longest spans.

Beam bridges consist of a series of beams, usually of rolled steel, supporting the roadway directly on their top flanges. The beams are placed parallel to traffic and extend from abutment to abutment. Plate-girder bridges are used for longer spans than can be practically traversed with a beam bridge. In its simplest form, the plate girder consists of two flange plates welded to a web plate, the whole having the shape of an I. Box-girder bridges have steel girders fabricated by welding four plates into a box section. A conventional floor beam and stringer can be used on box-girder bridges, but the more economical arrangement is to widen the top flange plate of the box so that it serves as the deck. When this is done, the plate is stiffened to desired rigidity by closely spaced bar stiffeners or by corrugated or honeycomb-type plates. These stiffened decks, which double as the top flange of the box girders, are termed orthotropic. The wearing surface on such bridges is usually a relatively thin layer of asphalt.

Truss bridges, consisting of members vertically arranged in a triangular pattern, can be used when the crossing is too long to be spanned economically by simple plate girders. Where there is sufficient clearance underneath the bridge, the deck bridge is more economical than the through bridge because the trusses can be placed closer together, reducing the span of the floor beams.

The continuous bridge is a structure supported at three or more points and capable of resisting bending and shearing forces at all sections throughout its length. The bending forces in the center of the span are reduced by the bending forces acting oppositely at the piers. Trusses, plate girders, and box girders can be made continuous. The advantages of a continuous bridge over a simple-span bridge (that is, one that does not extend beyond its two supports) are economy of material, convenience of erection (without need for falsework), and increased rigidity under traffic. The disadvantages are its sensitivity to relative change in the levels of supporting piers, the difficulty of constructing the bridge to make it function as it is supposed to, and the occurrence of large movements at one location due to thermal changes.

The cantilever bridge consists of two spans projecting toward each other and joined at their ends by a suspended simple span. The projecting spans are known as cantilever arms, and these, plus the suspended span, constitute the main span. The cantilever arms also extend back to shore, and the section from shore to the piers offshore is termed the anchor span. Trusses, plate girders, and box girders can be built as cantilever bridges. The chief advantages of the cantilever design are the saving in material and ease of erection of the main span. The cable-stayed bridge, a modification of the cantilever bridge which has come into modern use, resembles a suspension bridge. It consists of girders or trusses cantilevering both ways from a central tower and supported by inclined cables attached to the tower at the top or sometimes at several levels.

The suspension bridge is a structure consisting of either a roadway or a truss suspended from two cables which pass over two towers and are anchored by backstays to a firm foundation. If the roadway is attached directly to the cables by suspenders, the structure lacks rigidity, with the result that wind loads and moving live loads distort the cables and produce a wave motion on the roadway. When the roadway is supported by a truss which is hung from the cable, the structure is called a stiffened suspension bridge. The stiffening truss distributes the concentrated live loads over a considerable length of the cable.

Since the development of the prestressing method, bridges of almost every type are being constructed of concrete. Prior to the advent of prestressing, these bridges were of three types: (1) arches, which were built in either short or long spans; (2) slab bridges of quite short spans, which were simply reinforced concrete slabs extending from abutment to abutment; and (3) deck girder bridges, consisting of concrete slabs built integrally with a series of concrete girders placed parallel to traffic. The advent of prestressed concrete greatly extended the utility and economy of concrete for bridges, particularly by making the hollow box-girder type practicable. *See* PRESTRESSED CONCRETE.

Movable bridges. Modern movable bridges are either bascule, vertical lift, or swing; with few exceptions, they span waterways. They are said to be closed when set for the traffic they carry, and open when set to permit traffic to pass through the waterway they cross. Bascule and swing bridges provide unlimited vertical clearance in the open position. The vertical clearance of a lift bridge is limited by its design.

The bascule bridge consists primarily of a cantilever span, which may be either a truss or a plate girder, extending across the channel. Bascule bridges rotate about a horizontal axis parallel with the waterway. The portion of the bridge on the land side of the axis, carrying a counterweight to ease the mechanical effort of moving the bridge, drops downward, while the forward part of the leaf opens up over the channel much like the action of a playground seesaw. Bascule bridges may be either single-leaf, where rotation of the entire leaf over the waterway is about one axis on one side of the waterway, or double-leaf, where the leaves over the waterway rotate about two axes on opposite sides of the waterway.

The vertical-lift bridge has a span similar to that of a fixed bridge and is lifted by steel ropes running over large sheaves at the tops of its towers to the counterweights, which fall as the lift span rises and rise as it falls. If the bridge is operated by machinery on each tower, it is known as a tower drive. If it is driven by machinery located on the lift span, it is known as a span drive.

Swing bridges revolve about a vertical axis on a pier, called the pivot pier, in the waterway. There are three general classes of swing bridges: the rim-bearing, the center-bearing, and the combined rim-bearing and center-bearing. Rim-bearing bridges are supported on circular girder drums on rollers, center-bearing on a single large bearing at the center of rotation.

Substructure. Bridge substructure consists of those elements that support the trusses, girders, stringers, floor beams, and decks of the bridge superstructure. Piers and abutments are the primary bridge substructure elements. Other types of substructure, such as skewbacks for arch bridges, pile bents for trestles, and various forms of support wall, are also commonly used for specific applications. [E.R.H.; H.W.F.; R.W.Ch.; B.H.]

Degradation. Many factors can cause bridges to degrade and become structurally deficient and in need of repair. Two environmental factors that cause significant damage to primarily concrete components in bridges are excessive changes in temperature and freeze-thaw cycles in the presence of moisture. Steel structures are vulnerable to corrosion, especially in prolonged moisture environments. Use of deicing salts on concrete pavements and bridge decks produces chemical reactions that accelerate the corrosion of reinforcing steel. A significant cause of bridge damage is vehicular impact and fatigue from repeated truck loads. Special loads, such as seismic, wind, and snow, also may produce dramatic degradation of bridge structures. *See* Earthquake; Mechanical vibration.

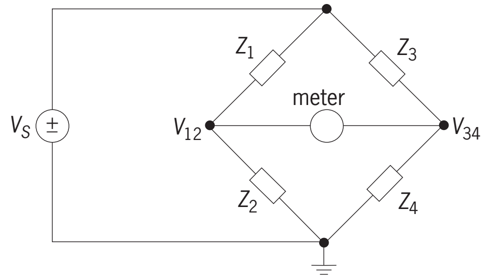
Strengthening techniques. The strengthening of concrete bridges is generally achieved by replacing the damaged material, incorporating additional structural members, as in external prestressing, or increasing the size and capacity of existing members.

Repair techniques. Numerous repair techniques have evolved for concrete members in both bridges and buildings for replacing damaged concrete, repairing cracks, and repairing corroded reinforced steel bars. Steel bridges are most often strengthened by the addition of new steel members or smaller elements. Steel welding and bolting are well-developed techniques for steel connections. Thus, strengthening of steel bridges is perhaps more defined than for the concrete bridges. Techniques for repairing steel bridge elements include flame straightening, hot mechanical straightening, cold mechanical straightening, welding, bolting, partial replacement and complete replacement. [J.M.Pl.; O.He.; A.Pug.]

Bridge circuit A circuit composed of a source and four impedances that is used in the measurement of a wide range of physical quantities. The bridge circuit is useful in measuring impedances (resistors, capacitors, and inductors) and in converting signals from transducers to related voltage or current signals. *See* Capacitor; Inductor; Resistor; Transducer.

The bridge impedances Z_1, Z_2, Z_3, Z_4, shown in the illustration may be single impedances (resistor, capacitor, or inductor), combinations of impedances, or a transducer with varying impedance. For example, strain gages are resistive transducers whose resistance changes when they are deformed.

Bridge circuits are often used with transducers to convert physical quantities (temperature, displacement, pressure) to electrical quantities (voltage and current). High-accuracy voltmeters and ammeters are relatively inexpensive, and the voltage form of a signal is usually most convenient for information display, control decisions, and data storage. Another important advantage of the bridge circuit is that it provides greater measurement sensitivity than the transducer.



Bridge circuit with source and impedances.

The bridge circuit is balanced when the output read by the meter is zero. In this condition the voltages on both sides of the meter are identical. The bridge is used in two forms. The null adjustment method requires adjustment of a calibrated impedance to balance it. In this case the meter is usually a highly sensitive current-measuring galvanometer. The null adjustment method is often used to measure impedances, with the output read from a dial attached to the adjustable impedance. The deflection method requires on accurate meter in the bridge to measure the deviation from the balance condition. The deviation is proportional to the quantity being measured.

There are many special forms of the bridge circuit. When all of the impedances are resistive, it is commonly called a Wheatstone bridge. Other common forms use a current source in place of the voltage source, a sinusoidal source in place of a constant (dc) source, or branch impedances which are specific combinations of single passive impedances. The bridge circuit is also used in a variety of electrical applications varying from oscillators to instrumentation amplifier circuits for extremely accurate measurements. *See* Instrumentation amplifier; Oscillator; Wheatstone bridge. [K.D.P.]

Brillouin zone In the propagation of any type of wave motion through a crystal lattice, the frequency is a periodic function of wave vector $\mathbf{k}$. This function may be complicated by being multivalued; that is, it may have more than one branch. Discontinuities may also occur. In order to simplify the treatment of wave motion in a crystal, a zone in $\mathbf{k}$-space is defined which forms the fundamental periodic region, such that the frequency or energy for a $\mathbf{k}$ outside this region may be determined from one of those in it. This region is known as the Brillouin zone (sometimes called the first or the central Brillouin zone). It is usually possible to restrict attention to $\mathbf{k}$ values inside the zone. Discontinuities occur only on the boundaries. If the zone is repeated indefinitely, all $\mathbf{k}$-space will be filled. Sometimes it is also convenient to define larger figures with similar properties which are combinations of the first zone and portions of those formed by replication. These are referred to as higher Brillouin zones.

The central Brillouin zone for a particular solid type is a solid which has the same volume as the primitive unit cell in reciprocal space, that is, the space of the reciprocal lattice vectors, and is of such a shape as to be invariant under as many as possible of the symmetry operations of the crystal. *See* Crystallography. [J.C.]

Brittleness That characteristic of a material that is manifested by sudden or abrupt failure without appreciable prior ductile or plastic deformation. A brittle fracture occurs on a cleavage plane which has a crystalline appearance at failure because each crystal tends to fracture on a single plane. On the other hand, a shear fracture has a fibrous appearance because of the sliding of the fracture surfaces over each other. Brittle failures are caused by high tensile stresses, high carbon content, rapid rate of loading, and the presence of notches. Materials such as glass, cast iron, and concrete are examples of brittle materials. [J.B.S.]

Broccoli A cool-season biennial crucifer, *Brassica oleracea* var. *italica*, of Mediterranean origin, belonging to the plant order Papaverales. Broccoli is grown for its thick branching lower stalks which terminate in clusters of loose green flower buds. Stalks and buds are cooked as a vegetable or may be processed in either canned or frozen form. California and Texas are important broccoli-producing states. *See* Papaverales. [H.J.C.]

Bromegrass A common name designating a number of grasses found in the North Temperate Zone that produce highly palatable and nutritious forage. Of these, smooth bromegrass (*Bromus inermis*) is the most important. Although first widely used in the eastern Great Plains and western Corn Belt regions, improved strains are now grown extensively for hay and rotation pastures north of the Mason-Dixon line, from the Plains to the Atlantic. Smooth bromegrass is a long-lived perennial, spreads by underground creeping stems, and is fairly deep rooted and drought-tolerant. Top growth is used for hay or pasture. Regional strains are available for Canada and the northern two-thirds of the United States. *See* CYPERALES. [H.B.S.]

Bromeliales An order of flowering plants, division Magnoliophyta (Angiospermae) in the subclass Zingiberidae of the class Liliopsida (monocotyledons). It consists of the single family Bromeliaceae, with about 45 genera and 2000 species, occurring chiefly in tropical and subtropical America. They are firm-leaved, terrestrial xerophytes, or very often epiphytes, with six stamens and regular or somewhat irregular flowers that usually have septal nectaries and an inferior ovary. Spanish moss (*Tillandsia*) and the cultivated pineapple (*Ananas*) are familiar members of the Bromeliales, and many others attract attention as houseplants. *See* LILIOPSIDA; MAGNOLIOPHYTA. [A.Cr.; T.M.Ba.]

Bromine A chemical element, Br, atomic number 35, atomic weight 79.909, which normally exists as Br_2, a dark-red, low-boiling but high-density liquid of intensely irritating odor. This is the only nonmetallic element that is liquid at normal temperature and pressure. Bromine is very reactive chemically; one of the halogen group of elements, it has properties intermediate between those of chlorine and iodine. *See* HALOGEN ELEMENTS; PERIODIC TABLE.

The most stable valence states of bromine in its salts are -1 and $+5$, although $+1$, $+3$, and $+7$ are known. Within wide limits of temperature and pressure, molecules of the liquid and vapor are diatomic, Br_2, with a formula weight of 159.818. There are two stable isotopes (^{79}Br and ^{81}Br) that occur naturally in nearly equal proportion, so that the atomic weight is 79.909. A number of radioisotopes are also known.

The solubility of bromine in water at 20°C (68°F) is 3.38 g/100 g (3.38 oz/100 oz) solution, but its solubility is increased tremendously in the presence of its salts and in hydrobromic acid. The ability of this inorganic element to dissolve in organic solvents is of considerable importance in its reactions. The table summarizes the physical properties of bromine.

Although it is estimated that from 10^{15} to 10^{16} tons of bromine are contained in the Earth's crust, the element is widely distributed and found only in low concentrations in the form of its salts. The bulk of the recoverable bromine, however, is found in the hydrosphere. Sea water contains an average of 65 parts per million (ppm) of bromine. The other major sources of bromine in the United States are underground brines and salt lakes, with commercial production in Michigan, Arkansas, and California.

While many inorganic bromides have found industrial use, the organic bromides have even wider application. Because of the ease of reaction of bromine with organic compounds and the ease of its subsequent removal or replacement, organic bromides have been much studied and used as chemical intermediates. In addition, any of the bromine reactions are so clean-cut that they can be used for the study of reaction mechanisms without complication of side reactions. The ability of bromine to add into unusual places on organic molecules has added to its value as a research tool.

Bromine and its compounds have found acceptance as disinfection and sanitizing agents in swimming pools and potable water. Certain bromine-containing compounds are safer to use than the analogous chlorine compounds due to certain persistent residuals found in the chlorine-containing materials. Other bromine chemicals are used as a working fluid in gages, as hydraulic fluids, as chemical intermediates in the manufacture of organic dyes, in storage batteries, and in explosion-suppressant and fire-extinguishing systems. Bromine compounds, because of their density, also find use in the gradation of coal and other minerals where separations are effected by density gradients. The versatility of bromine compounds is illustrated by the commercial use of over 100 compounds that contain bromine.

Physical properties of bromine

Property	Value
Flash point	None
Fire point	None
Freezing point, °C	−7.27
Density, 20°C	3.1226
Pounds per gallon, 25°C	25.8
Boiling point, 760 mm Hg, °C	58.8
Refractive index, 20°C	1.6083
Latent heat of fusion, cal/g	15.8
Latent heat of vaporization, cal/g, bp	44.9
Vapor density, g/liter, standard conditions (0°C, 1 atm)	7.139
Viscosity, centistokes, 20°C	0.314
Surface tension, dynes/cm, 20°C	49.5
30°C	47.3
40°C	45.2
Dielectric constant, 10^5 freq, 25°C	3.33
Compressibility, vapors, 25°C	0.998

Thermodynamic data, cal/(mole K)

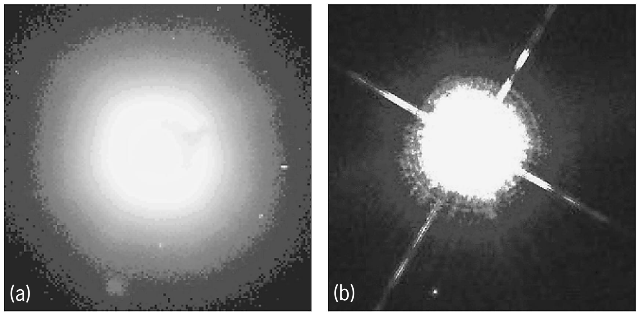
	T,K	*Entropy*	*Heat capacity*
Solid	265.9	24.786	14.732
Liquid	265.9	34.290	18.579

Bromine is almost instantaneously injurious to the skin, and it is difficult to remove quickly enough to prevent a painful burn that heals slowly. Bromine vapor is extremely toxic, but its odor gives good warning; it is difficult to remain in an area of sufficient concentration to be permanently damaging. Bromine can be handled safely, but the recommendations of the manufacturers should be respected. [R.C.S.]

Bronze Usually an alloy of copper and tin. Bronze is used in bearings, bushings, gears, valves, and other fittings both for water and steam.

The properties of bronze depend on its composition and working. Lead, zinc, silver, and other metals are added for special-purpose bronzes. Tin bronze, including statuary bronze, contains 2–20% tin; bell metal 15–25%; and speculum metal up to 33%. Gun metal contains 8–10% tin plus 2–4% zinc. Phosphor bronze is tin bronze hardened and strengthened with traces of phosphorus; it is used for fine tubing, wire springs, and machine parts. Lead bronze may contain up to 30% lead; it is used for cast parts such as low-pressure valves and fittings. Manganese bronze with 0.5–5% manganese plus other metals, but often no tin, has high strength. Aluminum bronze also contains no tin; its mechanical properties are superior to those of tin bronze, but it is difficult to cast. Silicon bronze, with up to 3% silicon, casts well and can be worked hot or cold by rolling, forging, and similar methods. Beryllium bronze (also called beryllium copper) has about 2% beryllium and no tin. The alloy is hard and strong and can be further hardened and strengthened by precipitation hardening; it is one of the few copper alloys that responds to heat treatment, approaching three times the strength of structural steel. *See* ALLOY; COPPER; TIN. [F.H.R.]

Brown dwarf A starlike body whose mass is too small to sustain nuclear fusion reactions in its core. All stars, including the Sun, shine because they engage in nuclear fusion in their hot and dense cores. In the early 1960s, S. S. Kumar noted that, if they existed, stars with mass less than 8% that of the Sun would not have the high temperatures in their cores necessary to sustain nuclear fusion reactions. These objects, called



Images of the cool brown dwarf Gliese 229B. In each image, the bright primary star is at the center and the brown dwarf is the faint object near the bottom center. (*a*) Discovery image, taken with the Palomar 60-in. (1.5-m) telescope and an instrument designed to reduce the substantial glare of the nearby star. (*b*) Hubble Space Telescope image.

brown dwarfs, would not truly be normal stars because their lack of nuclear fusion would inhibit their ability to shine. Indeed, these brown dwarfs would grow dimmer as they aged. At even lower masses are the planets, such as Earth and Jupiter (which is approximately 0.1% the mass of the Sun). *See* PLANET; STAR; STELLAR EVOLUTION.

Calculations by several research groups have established that the lowest-mass star (8% the mass of the Sun) will shine with a luminosity of about 10^{-4} times the luminosity of the Sun. (Luminosity here means the energy emitted per unit of time.) While young brown dwarfs can have luminosities larger than this value, they eventually cool to much smaller ranges of brilliance. These calculations also show that all brown dwarfs have essentially the same radius, about 10% that of the Sun. This is also approximately the radius of Jupiter. *See* RED DWARF STAR.

Because young brown dwarfs are hot and even more luminous than the oldest, lowest-mass stars, they are very difficult to distinguish from such stars. However, an important diagnostic exists. The fragile element lithium is transmuted in stars by high-temperature fusion reactions that are absent in most brown dwarfs' cores. This suggests that although the youngest brown dwarfs might look identical to low-mass stars they will exhibit signs of lithium, which stars will not.

Two searches for brown dwarfs in the Pleiades, which is one of the youngest nearby star clusters, were undertaken in 1995. Sensitive spectroscopic observations with the Keck Telescope in Hawaii revealed for the first time the telltale features of lithium in three low-luminosity objects. Since these discoveries, many more brown dwarfs have been identified in the Pleiades, other star clusters, and in interstellar space. The majority of these brown dwarfs have been found due to improved astronomical imaging and spectroscopy technology, in particular, large-scale surveys of the sky in infrared wavelengths. *See* ASTRONOMICAL SPECTROSCOPY; INFRARED ASTRONOMY; PLEIADES; TELESCOPE.

In 1995, Tadashi Nakajima and coworkers at the Palomar Observatory, California Institute of Technology, discovered an object in orbit around the nearby star Gliese 229, located only 17 light-years (1.0×10^{14} mi or 1.6×10^{14} km) from the Sun (see illustration). With a luminosity of 6×10^{-6} that of the Sun, this was the first unambiguous discovery of an old brown dwarf, one that had absolutely no similarity to any star. Dozens of other stars of this type have now been identified. [B.R.O.; S.R.K.]

Brownian movement The irregular motion of a body arising from the thermal motion of the molecules of the material in which the body is immersed. Such a body will of course suffer many collisions with the molecules, which will impart energy and momentum to it. Because, however, there will be fluctuations in the magnitude and direction of the average momentum transferred, the motion of the body will appear irregular and erratic.

In principle, this motion exists for any foreign body suspended in gases, liquids, or solids. To observe it, one needs first of all a macroscopically visible body; however, the mass of the body cannot be too large. For a large mass, the velocity becomes small. *See* KINETIC THEORY OF MATTER. [M.Dr.]

Brucellosis An infectious, zoonotic disease of various animals and humans caused by *Brucella* species. Each species tends to preferentially infect a particular animal, but several types can infect humans. *Brucella melitensis* (preferentially infects goats and sheep), *B. suis* (infects pigs), and *B. abortus* (infects cattle) are the most common causes of human brucellosis. *Brucella melitensis* is the most virulent for humans, followed by *B. suis* and *B. abortus*. *Brucella canis* and *B. ovis*, which infect dogs and sheep respectively, rarely infect humans. Although brucellosis is found all over the world, in many countries the disease has been eradicated. The brucellae are small, gram-negative coccobacilli which are defined as facultative intracellular parasites since they are able to replicate within specialized cells of the host.

In animals the brucellae often localize in the reproductive tract, mammary gland, and lymph node. They have a particular affinity for the pregnant uterus, leading to abortion and reduced milk production with resultant economic loss to the farmer. Wildlife, including elk, feral pigs, bison, and reindeer, can become infected and can spread the disease to domestic livestock.

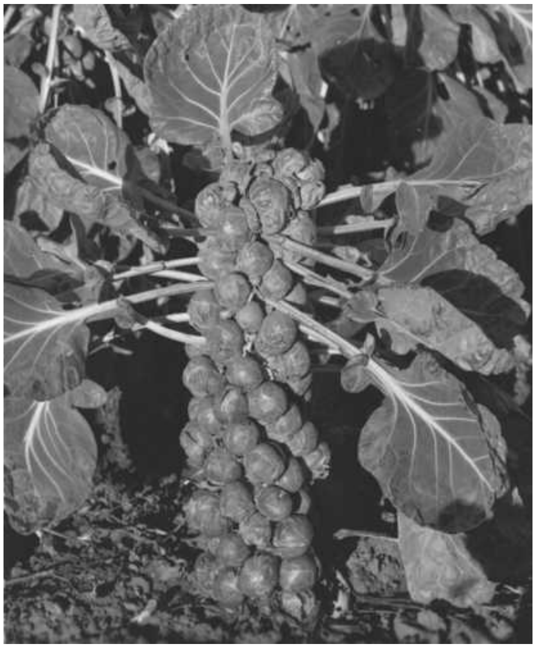
Brucellosis in humans is characterized by undulant fever, cold sweats, chills, muscular pain, and severe weakness. Some individuals may have recurrent bouts of the disease in which a variety of organs may be affected, sometimes resulting in death. The disease can be contracted by consuming unpasteurized milk or cheese, or via the introduction of organisms through small skin lesions or as an aerosol through the conjunctiva and the respiratory system. Treatment with tetracycline and other antibiotics is most successful if started early after symptoms occur. Development of the disease can be prevented if treatment is initiated immediately after contact with potentially infected material.

At present there are no effective vaccines for humans. The disease can be eliminated only by eradicating it in animals. A major source of brucellosis in humans is the consumption of *B. melitensis*–infected milk and cheese from goats. Incidence can be reduced by pasteurizing milk. Animals can be vaccinated to increase their immunity against brucellosis and therefore reduce abortions and disease transmission. *See* EPIDEMIOLOGY; MEDICAL BACTERIOLOGY. [W.W.Sp.]

Brucite A magnesium hydroxide mineral, $Mg(OH)_2$, crystallizing in the trigonal system. It is a member of the important $Cd(OH)_2$ structure type, consisting of hexagonal close-packed oxygen atoms with alternate octahedral layers occupied by Mg. The "brucite layer"'is an important structural component in the clay, mica, and chlorite mineral groups. Brucite occurs as tabular crystals and as elongated fibers (as the variety nemalite), hardness $2^1/_2$ (Mohs scale), color white to greenish, and specific gravity 2.4. Fe^{2+} and Mn^{2+} commonly substitute for Mg^{2+}.

Brucite often occurs in a low-temperature vein paragenesis, usually with serpentine and accessory magnesite. It is also derived by the action of water on periclase, MgO, which results from the thermal metamorphism of dolomites and limestones. Carbonate rocks rich in periclase and brucite are called predazzites. *See* DOLOMITE; MAGNESITE; SERPENTINE. [P.B.M.]

Brussels sprouts A cool-season biennial crucifer (*Brassica oleracea* var. *gemmifera*), which is of northern European origin and belongs to the plant order Capparales. The plant is grown for its small headlike buds formed in the axils of the leaves along the plant stem (see illustration). These buds are eaten as a cooked vegetable. Popular varieties (cultivars) are Half Dwarf



Brussels sprouts (*Brassica oleracea* var. *gemmifera*), Jade Cross. (*Joseph Harris Co., Rochester, New York*)

and Catskill; however, hybrid varieties are increasingly planted. California and New York are important producing states. *See* Capparales. [H.J.C.]

Bryales An order of the subclass Bryidae. With 11 families and perhaps 44 genera, it is defined in terms of terminal inflorescences, with rare exceptions, and perfect, double peri-stomes which are papillose on the outer surface. The capsules are generally inclined and more or less pear-shaped. Erect capsules are associated with reduced peristomes.

These mosses often grow in disturbed places. They are perennial and grow in tufts, with stems erect and simple or forked and often densely covered with rhizoids. The leaves are generally bordered by elongate cells and often toothed. The midrib often ends in a hairpoint. The sporophytes are nearly always terminal. The setae are generally elongate, and the operculate capsules are usually symmetric but generally inclined to pendulous and commonly pyriform owing to the development of a sizable neck. The peristome is normally double, with a well-developed endostome. *See* Bryidae; Bryophyta; Bryopsida. [H.Cr.]

Bryidae A subclass of the class Bryopsida. Most genera of true mosses (Bryopsida) belong in the 16 orders of the Bryidae. The most characteristic feature is the peristome consisting of one or two series of teeth, derived from parts of cells rather than whole cells, as in the Tetraphididae, Dawsoniidae, and Polytrichidae. (The Buxbaumiidae have some resemblance in peristome structure to Bryidae.) The stems may be erect and merely forked, or prostrate and freely branched, with sporophytes produced terminally or laterally, respectively. The leaves are inserted in many rows, though sometimes flattened together and appearing two-ranked, but only rarely actually in two rows. The costa may be single or double, sometimes very short, and rarely lacking. The setae are generally present and elongate. The capsules dehisce by means of an operculum except in a few genera that show extreme reduction. *See* Archidiidae; Bryophyta; Bryopsida; Bryoxiphiales; Dawsoniidae; Dicranales; Encalyptales; Fissidentales; Funariales; Grimmiales; Hookeriales; Hypnales; Isobryales; Mitteniales; Orthotrichales; Polytrichidae; Pottiales; Seligeriales; Splachnales. [H.Cr.]

Bryophyta A division that consists of some 23,000 species of small and relatively simple plants commonly known as mosses, granite mosses, peat mosses, liverworts, and hornworts (see illustration). The bryophytes display a distinct alternation of sexual and asexual generations; the sexual gametophyte, with a haploid chromosome number, is the more diversified. The sporebearing, diploid sporophyte is reduced in size and structure, attached to the gametophyte, and partially or almost completely dependent on it.

The gametophytes may consist of leafy stems or flat thalli. They have no roots but are anchored to the substrate by hairlike rhizoids. Vascular tissue is at best poorly differentiated, with no lignification of cells. Growth results from the divisions of single cells (rather than meristematic tissues) located at stem tips or in notches at the margins of thalli. The sex organs are multicellular and have a jacket of sterile cells surrounding either the single egg produced in flask-shaped archegonia or the vast number of sperms produced in globose to cylindric, stalked antheridia. The sperms swim by means of two flagella. The sporophyte commonly consists of a capsule that produces a large number of spores, a stalklike seta, and a swollen foot anchored in the gametophyte. The spores, nearly always single-celled, are dispersed in the air, except in the case of a small number of aquatics. They germinate directly or produce a juvenile stage called a protonema. *See* Reproduction (plant).

Moss plant, *Polytrichum juniperinum* (*General Biological Supply House*).

The division can be divided into five classes: Sphagnopsida (peat mosses), Andreaeopsida (granite mosses), Bryopsida (true mosses), Hepaticopsida (liverworts), and Anthocerotopsida (hornworts). The mosses have radially organized leafy gametophytes that develop from a protonema and have multicellular rhizoids with slanted crosswalls. The liverworts and hornworts are mostly flat and dorsiventrally organized and have no protonematal stage; the rhizoids are unicellular. Though obviously related, as evidenced by similar sex organs and attachment of a simplified sporophyte to a more complex and independent gametophyte, the classes differ greatly in structural detail. *See* Andreaeopsida; Anthocerotopsida; Bryopsida; Hepaticopsida; Plant Kingdom; Sphagnopsida. [H.Cr.]

Bryopsida The largest class of the division Bryophyta, the true mosses. Members of the class are best characterized by operculate capsules and a peristome that aids in the dispersal of spores, and are generally perennial. The class consists of about 14,000 species distributed in six subclasses based primarily on the structure and developmental history of the sporophyte and especially the peristome. The orders and families are likewise based primarily on stable sporophytic details, whereas genera and species are most often differentiated in terms of gametophytic features.

The filamentous, freely branched protonema of Bryopsida gametophytes produces an abundance of leafy plants which may be erect, simple or sparsely forked, and growing in tufts and producing archegonia at the stem tips; or, alternatively, plants may be prostrate, freely branched, growing in intertangled mats, and producing archegonia laterally. In large, erect-growing plants, the stems may have a central strand of vascular tissues similar to xylem and phloem but without lignification. In smaller plants, the vascular tissue is reduced or lacking. The rhizoids are multicellular, with slanted crosswalls. The inflorescences are usually enveloped in differentiated leaves, and the sex organs, of superficial origin, are often mingled with paraphyses, especially in the male inflorescence. The archegonia are flask-shaped; the antheridia are banana-shaped and stalked. *See* PHLOEM; XYLEM.

The long-lived sporophytes are abundantly green until maturity and largely self-supporting. They consist of foot and capsule, usually also a seta. The capsules dehisce by means of a lidlike operculum, or rarely irregularly by rupture. The capsule wall is usually spongy, especially in the neck portion below the spore sac. Stomata are usually present, especially in the neck or at the junction of capsule and seta. The spore sac is derived from the endothecium. The calyptra may be mitrate (conic and lobed) or cucullate (slit up one side and hoodlike). The chromosome numbers are exceedingly diverse; polyploidy is common, both within species and among related ones. *See* ARCHIDIIDAE; BRYIDAE; BRYOPHYTA; BUXBAUMIIDAE; DAWSONIIDAE; POLYTRICHIDAE; TETRAPHIDIDAE. [H.Cr.]

Bryopsidales An order of the green algae (Chlorophyceae), also called Caulerpales, Codiales, or Siphonales, in which the plant body (thallus) is a coenocytic filament (tube or siphon). The order comprises six families with about 24 genera. The filaments may be discrete with free or laterally coherent branches, or organized into a dense plexus exhibiting distinctive morphological features. Septa, which are generally infrequent and incomplete, are formed by centripetal deposition of wall material. A large, continuous central vacuole restricts the cytoplasm to a thin layer just beneath the wall. The cytoplasm contains innumerable nuclei, discoid plastids, and other organelles. Vegetative reproduction is common, usually by rhizomes or fragments. Reproductive cells may be formed in unmodified or slightly modified portions of the filament or in special organs. *See* ALGAE; CHLOROPHYCEAE. [P.C.Si.; R.L.Moe]

Bryoxiphiales An order of the class Bryopsida in the subclass Bryidae. The order consists of a single genus and species, *Bryoxiphium norvegicum*, the sword moss. This order is characterized by a swordlike appearance owing to leaves overlapping in two rows. The shiny, rigid leaves are keeled and conduplicate-folded. The apex is long-awned at the stem tip and progressively shorter-pointed downward. The midrib bears at back a low ridge of one to four rows of cells. The leaf cells are smooth and subquadrate within, longer and narrower toward the margins. The plants are dioecious with terminal archegonia. *See* BRYIDAE; BRYOPHYTA; BRYOPSIDA. [H.Cr.]

Bryozoa A phylum of sessile aquatic invertebrates (also called Polyzoa) which form colonies of zooids. Each zooid, in its basic form, has a lophophore of ciliated tentacles situated distally on an introvert, a looped gut with the mouth inside the lophophore and the anus outside, a coelomic body cavity, and (commonly) a protective exoskeleton. The colonies are variable in size and habit. Some are known as lace corals and others as sea mats, but the only general name is bryozoans (sea mosses).

The colony may be minute, of not more than a single feeding zooid and its immediate buds, or substantial, forming masses 3 ft (1 m) in circumference, festoons 1.6 ft (0.5 m) in length, or patches 2.7 ft^2 (0.25 m^2) in area. Commonly the colonies form incrustations not more than a few square centimeters in area, small twiggy bushes up to about 1.2 in. (3 cm) in height, or soft masses up to about 0.3 ft (0.1 m) in the largest dimension. In many colonies much of the bulk consists of the zooid exoskeletons which may persist long after the death of the organism and account for the abundance of fossilized bryozoan remains.

Many bryozoans display polymorphism, having certain zooids adapted in particular ways to perform specialized functions, such as protection, cleaning the surface, anchoring the colony, or sheltering the embryo. The evolution of nonfeeding polymorphs is dependent upon some form of intercommunication between zooids.

Bryozoa is the name of a phylum for which Ectoprocta is generally regarded as a synonym, these names being used by zoologists according to personal preference. Entoprocta (synonym Callyssozoa) is likewise regarded as an independent phylum. A minority regard Ectoprocta and Entoprocta as subphyla within the Bryozoa, while others maintain Ectoprocta and Entoprocta as phyla but link them under Bryozoa as a name of convenience. *See* ENTOPROCTA.

The phylum contains some 20,000 described species, one-fifth of them living. These are distributed among three classes and a somewhat variable number of orders:

- Phylum Bryozoa
  - Class Phylactolaemata
    - Order Plumatellida
  - Class Gymnolaemata
    - Order Ctenostomata
      - Suborder Cheilostomata
  - Class Stenolaemata
    - Order Cyclostomata
      - Suborder Cystoporata (extinct)
      - Suborder Trepostomata
      - Suborder Cryptostomata
      - Suborder Hederellida

See GYMNOLAEMATA; PHYLACTOLAEMATA; STENOLAEMATA.

Fresh-water bryozoans are present on submerged tree roots and aquatic plants in most lakes, ponds, and rivers, especially in clear water of alkaline pH. Most other bryozoans are marine, although some gymnolaemates inhabit brackish water. They are common in the sea, ranging from the middle shore to a depth of over 26,000 ft (8000 m), and are maximally abundant in waters of the continental shelf. Most attach to firm substrata, so that their distribution is primarily determined by the availability of support. Mud is unfavorable and so is sand unless well provided with stone, dead shells, hydroids, or large foraminiferans.

Colony form in bryozoans is to some extent related to habitat. Encrusting and bushy flexible species are adapted to wave exposure; brittle twiglike and foliaceous species are found deeper; some erect branching species tolerate sediment deposition. One group of tiny discoid species lives on sand in warm seas, and in one genus the colonies are so small that they live actually among the sand grains; a few species live anchored in mud. A number of stolonate ctenostomes bore into the substance of mollusk shells; other species are associated only with hermit crabs, and a few are commensal with shrimps or polychaete worms.

Bryozoans have few serious predators. Nudibranch mollusks and pycnogonids (sea spiders) specialize in feeding on zooids but are rarely destructive of entire colonies. Loxosomatids (Entoprocta) and a hydroid (*Zanclea*) are common commensals.

Life spans vary. Small algal dwellers complete their life cycle in a few months. Many species survive a year but have two overlapping generations; others are perennial, with one known to survive for 12 years.

Bryozoans may be a nuisance in colonizing ship hulls and the insides of water pipes, and one species has caused severe dermatitis in fishers. Recently some delicate kinds have been used in costume jewelry, and green-dyed clumps of dried *Bugula* are often sold as "everlasting plants." [J.S.R.]

Fossil Bryozoa have a long geological history, from early in the Ordovician Period [500 million years ago (Ma)] to the Recent. Individual fossils range in size from a few millimeters to several meters in maximum dimension. Various encrusting or erect growth forms are common, though some were free-living. Representatives of the marine orders that secreted calcareous skeletons (Cryptostomata, Cyclostomata, Cystoporata, Trepostomata, and Cheilostomata) commonly are abundant in sedimentary rocks formed where benthic organisms flourished. Skeletons generally are calcite, though some are aragonite or mixed calcite and aragonite. Ctenostomata have nonmineralized skeletons, so they have been preserved only as excavations or borings in marine shells or on the undersides of other organisms that overgrew them. The fresh-water Phylactolaemata have gelatinous skeletons, but their tough statoblasts (dormant reproductive bodies) have been reported from sediments as old as the Jurassic (at least 150 Ma). During the Ordovician, Carboniferous, and Permian periods, bryozoans were important parts of many fossil reefs, reef flanks, and other carbonate buildups in shallow (less than 100 m depth) tropical waters. Bryozoans commonly dominate and may reach very high diversities in post-Paleozoic cool-temperate carbonate deposits, indicating a shift in primary environment after the Paleozoic.

Although colonies of many bryozoan species are large, the individual skeletons of each zooid (unit of the colony) range from less than 0.1 to about 1 mm in diameter. The smaller diameters are typical for cross sections of elongate tubes that characterize zooids in stenolaemate bryozoans, and the larger diameters are typical for the more equidimensional zooids of cheilostomes. Identification is based on numerous external and, for most stenolaemates, internal features that require study with a microscope. Features of the colonial skeletons (zoaria) as well as the morphology of the individual zooidal skeletons (zooecia) are used to classify bryozoans. Many fossil bryozoans had only one type of zooid (autozooids), which apparently could feed and carry out all other necessary biological functions of the colony. Others were polymorphic, with various types of specialized zooids supplementing the autozooids. Number, types, and morphology of polymorphs is important in classification. Other characters important in classification of fossil bryozoans are wall structure, reproductive chambers, general growth habit or specific shape of colonies, and for some, surface topography of the colony. [F.K.McK.]

Buckeye A genus, *Aesculus*, of deciduous trees or shrubs belonging to the plant order Sapindales, buckeyes grow in North America, southeast Europe, and eastern Asia to India. The distinctive features are opposite, palmately compound leaves and a large fruit having a firm outer coat and containing usually one large seed with a conspicuous hilum.

The Ohio buckeye (*A. glabra*) is found mainly in the Ohio valley and in the southern Appalachians. It can be recognized by the glabrous winter buds, prickly fruits, and compound leaves having five leaflets. Another important species, the yellow buckeye (*A. octandra*), is native in the Central states, has five leaflets and smooth buds, but differs in its smooth, larger fruit. The horse chestnut (*A. hippocastanum*), which usually has seven leaflets and resinous buds, is a native of the Balkan Peninsula. It is planted throughout the United States and is a beautiful ornamental tree bearing cone-shaped flower clusters in early summer.

The seeds of all species contain a bitter and narcotic principle. The wood of the native tree species is used for furniture, boxes, crates, baskets, and artificial legs. *See* SAPINDALES. [A.H.G./K.P.D.]

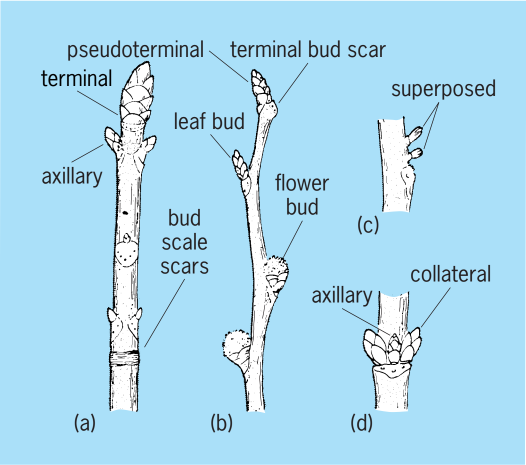
Buckwheat A herbaceous, erect annual, the dry seed or grain of which is used as a source of food and feed. It is not a true cereal and is one of the very few plants, other than those of the Gramineae family, used for their starchy seed, which is processed as a meal or flour. Buckwheat belongs to the Polygonaceae family, which also includes the common weeds dock, sorrel, knotweed, bindweed, smartweed, and climbing false buckwheat. Species of buckwheat that have been commercially grown are *Fagopyrum sagittatum* (*F. esculentum*), *F. emarginatum*, and *F. tataricum*. *See* POLYGONALES.

The plant grows to a height of 2–5 ft (0.6–1.5 m), with many broad heart-shaped leaves. It produces a single main stem which usually bears several branches, and is grooved, succulent, and smooth except for nodes. Buckwheat is an indeterminate species in response to photoperiod, and produces flowers and fruits (so-called seeds) until the beginning of frost. *See* PHOTOPERIODISM. [H.G.M.]

The production of buckwheat flour requires cleaning, grinding, and fractionation in a manner similar to that used for wheat flour. Whole groats, splits, and farina are obtained by selective sieving and may be utilized as breakfast cereals and porridges or as thickening agents. When milled as flour, buckwheat will yield 60–75% extraction. The flour is typically more coarse and more highly colored than wheat flour. Buckwheat middlings, which include the layer immediately below the hull and the germ, provide valuable animal feed stock. In the United States, buckwheat flour is used primarily in pancake mix formulations, blended with wheat, corn, rice, or oat flour. *See* CEREAL; FOOD MANUFACTURING; GRAIN CROPS. [M.A.U.]

Bud An embryonic shoot containing the growing stem tip surrounded by young leaves or flowers or both, and the whole frequently enclosed by special protective leaves, the bud scales.

The bud at the apex of the stem is called a terminal bud (illus. *a*). Any bud that develops on the side of a stem is a lateral bud. The lateral bud borne in the axil (angle between base of leaf and stem) of a leaf is the axillary bud (illus. *a* and *d*). It develops concurrently with the leaf which subtends it, but usually such buds do not unfold and grow rapidly until the next season. Because of the inhibitory influence of the apical or other buds, many axillary buds never develop actively or may not do so for many years. These are known as latent or dormant buds. Above or beside the axillary buds, some plants regularly produce additional buds called accessory, or supernumerary, buds. Accessory buds which occur above the axillary bud are called superposed buds (illus. *c*), and those beside it collateral buds (illus. *d*). Under certain conditions, such as removal of terminal and axillary buds, other buds may arise at almost any point on the stem, or even on roots or leaves. Such buds are known as adventitious buds. *See* PLANT GROWTH.



Bud positions. (*a*) Terminal and axillary (buckeye). (*b*) Pseudoterminal (elm). (*c*) Superposed (butternut). (*d*) Collateral (red maple).

Buds that give rise to flowers only are termed flower buds, or in some cases, fruit buds. If a bud grows into a leafy shoot, it is called a leaf bud, or more accurately, a branch bud. A bud which contains both young leaves and flowers is called a mixed bud.

Buds of herbaceous plants and of some woody plants are covered by rudimentary foliage leaves only. Such buds are called naked buds. In most woody plants, however, the buds are covered with modified protective leaves in the form of scales. These buds are called scaly buds or winter buds. In the different species of plants, the bud scales differ markedly. They may be covered with hairs or with water-repellent secretions of resin, gum, or wax. Ordinarily when a bud opens, the scales fall off, leaving characteristic markings on the stem (bud scale scars). *See* Leaf. [N.A.]

Buffalo The name for members of the family Bovidae in the mammalian order Artiodactyla. The buffalo is an Old World species and resembles the oxen in general appearance. The North American bison is often called a buffalo, but is not related to the true buffalo.

The Asiatic buffalo (*Bubalus bubalis*), known as the Indian or water buffalo and also as the carabao, is found as a domestic animal in the Balkans, Asia Minor, and Egypt. These buffalo exist in the wild state in southern Asia and Borneo, where they are considered to be ferocious and dangerous. Water buffalo are stocky, heavy-built animals. They have very short hair and short, splayed horns. Like all buffalo, they have a liking for marshes, where they wallow and become caked with mud that affords protection against insects.

Two other Asiatic species related to, but smaller than, the water buffalo are the tamarau (*Anoa mindorensis*), which is indigenous to the Philippines, and the still smaller anoa (*A. depressicornis*), or wild dwarf buffalo, found in the Celebes.

The African buffalo, classed in the genus *Syncerus*, was very numerous until the turn of the century, when the infectious disease rinderpest caused many deaths. They are still abundant though widely hunted. There are several varieties of African buffalo, and it is thought that all may be subspecies of *S. caffer*, the Cape buffalo. They live in the open country of central, eastern, and southern Africa. Except for its size, this animal is difficult to distinguish from the rare dwarf or forest buffalo (*S. caffer nanus*). It lives in marshy, forested areas of western Africa, where it is known as the bush cow. *See* Artiodactyla; Bison. [C.B.C.]

Buffers (chemistry) A solution selected or prepared to minimize changes in hydrogen ion concentration which would otherwise tend to occur as a result of a chemical reaction. In general, chemical buffers are systems which, once constituted, tend to resist further change due to external influences. Thus it is possible, for example, to make buffers resistant to changes in temperature, pressure, volume, redox potential, or acidity. The commonest buffer in chemical solution systems is the acid-base buffer.

Chemical reactions known or suspected to be dependent on the acidity of the solution, as well as on other variables, are frequently studied by measurements in comixture with an appropriate buffer. For example, it may be desirable to investigate how the rate of a chemical reaction depends upon the hydrogen ion activity (pH). This is accomplished by measurements in several buffer systems, each of which provides a nearly constant, different pH. Alternatively, it may be desirable to measure the effects of other variables on a pH-sensitive system, by stabilizing the pH at a convenient value with a particular buffer. *See* pH.

Buffer action depends upon the fact that, if two or more reactions coexist in a solution, then the chemical potential of any species is common to all reactions in which it takes part, and may be defined by specification of the chemical potentials of all other species in any one of the reactions. To be effective, a buffer must be able to respond to an increase as well as a decrease of the species to be buffered. In order to do so, it is necessary that the proton transfer step of the buffer be reversible with respect to the species involved, in the reaction to be buffered. In aqueous solution the proton transfer between most acids, their conjugate bases, and water, is so rapid and reversible that the dominant direct source of protons for a chemical reaction is H_3O^+, the hydronium ion.

Buffers are particularly effective in water, because of the unusual properties of water as a solvent. Its high dielectric constant tends to promote the existence of formally charged ions (ionization). Because it has both an acidic (H) and a basic (O) group, it may form bonds with ionic species leading to an organized sheath of solvent surrounding an ion (solvation). Water also tends to self-ionize to form its own conjugate acidbase system. *See* Acid and base; Acid-base indicator; Ionic equilibrium; Solvation. [A.M.H.]

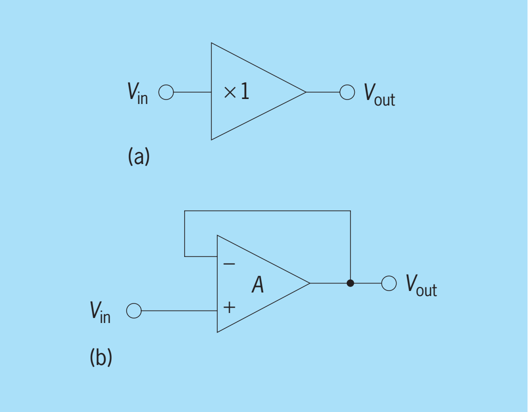
Buffers (electronics) Electronic circuits whose primary function is to connect a high-impedance source to a low-impedance load without significant attenuation or distortion of the signal. Thus, the output voltage of a buffer replicates the input voltage without loading the source. An ideal voltage buffer is an amplifier with the following properties: unity gain, $A_B = 1$; zero output impedance, $Z_{\text{out}} = 0$; and infinite input impedance, $Z_{\text{in}} = \infty$. For example, if the voltage from a high-impedance source, say a strain-gage sensor with 100 kΩ output resistance, must be processed by further circuitry with an input impedance of, say, 500 Ω, the signal will be attenuated to only $500/100{,}500 \approx 0.5\%$ of the sensor voltage if the two circuits are directly connected, whereas the full strain-gage voltage will be available if a buffer is used.

Buffers are generally applied in analog systems to minimize loss of signal strength due to excessive loading of output nodes (illus. *a*). Two kinds of circuits are frequently used: the operational-amplifier-based buffer and the transistor follower.

The operational-amplifier-based buffer circuit (illus. *b*) is based on an operational amplifier (op amp) with unity-gain feedback. The open-loop gain, $A(s)$, of the operational amplifier should be very high. To form the buffer, the amplifier is placed in a feedback loop. The buffer gain, $A_B(s)$, is then given by Eq. (1). Here, $s = j\omega$

$$A_B(s) = \frac{V_{\text{out}}}{V_{\text{in}}} = \frac{A(s)}{1 + A(s)} \qquad (1)$$

is the Laplace transform variable, $j = -1$; $\omega = 2\pi f$ is the radian frequency in radians per second (rad/s); and f is the frequency in hertz (Hz). The magnitude of A_B is approximately equal to unity, that is, $|A_B|$ approaches 1, if $|A|$ becomes very large. A common



Buffer circuit. (*a*) Circuit schematic symbol. (*b*) Operational-amplifier-based circuit.

representation of the frequency dependence of the operational-amplifier gain is given by Eq. (2), where ω_t is the operational

$$A(s) = \frac{\omega_t}{s} \qquad (2)$$

amplifier's unity-gain frequency. By using this notation, Eq. (1) becomes Eq. (3), which shows that the buffer's bandwidth is

$$A_B = \frac{\omega_t}{s + \omega_t} \qquad (3)$$

approximately equal to the unity-gain frequency of the operational amplifier, typically 1 MHz or higher.

Under the assumption that the frequency of interest is much less than ω_t, it follows from Eq. (2) that the magnitude of the operational-amplifier gain, $A(s)$, is much greater than 1. In that case, it can be shown that, because of the feedback action, the buffer's input impedance is much larger than that of the operational amplifier itself [by a factor of $A(s)$]. Similarly, the buffer's output impedance is much smaller than that of the operational amplifier [again, by a factor of $A(s)$].

The very low output impedance of operational-amplifier-based buffers assures that a load impedance, $Z_L(s)$, does not affect the buffer's gain, A_B. Also, operational-amplifier-based buffers have no systematic offset. The high-impedance input node of a buffer may in practice have to be shielded to prevent random noise from coupling into the circuit. This shielding can be accomplished with a coaxial cable. To eliminate the capacitive loading of the source by the effective input capacitance of the cable, the shield can be driven with the output voltage of the buffer so that no voltage difference exists between the signal line and the shield. The driven shield is referred to as the guard. *See* AMPLIFIER; ELECTRICAL SHIELDING; ELECTROMAGNETIC COMPATIBILITY; OPERATIONAL AMPLIFIER.

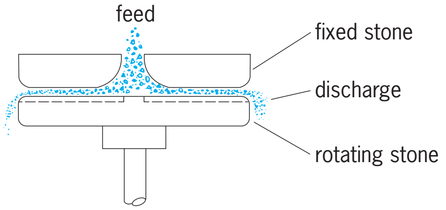
The bipolar junction transistor (BJT) emitter follower and the field-effect transistor (FET) source follower are very simple but effective buffer circuits. Both consist of a single transistor and a bias-current source; they are used in applications where power consumption and circuit area must be reduced to a minimum or where specifications are not too demanding.

The performance of a transistor follower circuit depends strongly on the source and load impedances, that is, on the surrounding circuitry. In fact, the transistors are so fast that the frequency response is usually determined by loading. In general, follower circuits exhibit a systematic direct-current (dc) offset equal to the base-to-emitter voltage, V_{BE}, in BJTs and equal to the gate-to-source voltage, V_{GS}, for FET. Only followers made with depletion-mode field-effect transistors can be biased with zero V_{GS} to avoid this offset. *See* EMITTER FOLLOWER; TRANSISTOR.

Buffer circuits should have small dc offset voltages (dc outputs when no input is applied), small bias currents (to minimize the effect of high-impedance sources), large linear signal swing (to minimize distortion), and high slew rate (to handle fast transitions of the applied signals).

Buffers should have a low-frequency gain of unity and wide bandwidth (to reproduce the applied signals faithfully), low phase margins (to prevent peaking and overshoots), and low equivalent input-referred noise (to have wide dynamic range). Field-effect-transistor input buffers exhibit the lowest noise for high-impedance signal sources. *See* ELECTRICAL NOISE; GAIN.
[R.Sc.]

Buhrstone mill A mill for grinding or pulverizing, in which a flat siliceous rock, generally of cellular quartz, rotates against a stationary stone of the same material. Grooves in the stones facilitate the movement of the material. Fineness of the product is controlled by the pressure between the stones and by the grinding speed. A finely ground product is achieved by slowly rotating the stone at a high pressure against the materials and its mate (see illustration). *See* CRUSHING AND PULVERIZING.
[G.W.K.]



In a Buhrstone mill, material is fed at the center of the fixed stone and moves toward outer edge of the stones where product is discharge.

Buildings Fixed permanent structures, more or less enclosed and designed to use as housing or shelter or to serve the needs of commerce and industry.

Building materials. Iron and steel building components are noncombustible, and their strength-to-weight ratio of steel is also good. Steel is equally strong in tension and compression and possesses excellent ductility, a highly desirable quality in building design. Contemporary applications of structural steel in building construction generally utilize rolled shapes in the form of wide flange and I beams, pipes and tubes, channels, angles, and plates. There are fabricated and erected into frameworks of beams, girders, and columns. Floors are usually concrete slabs cast of corrugated metal deck or on removable wood forms. *See* FLOOR CONSTRUCTION; STRUCTURAL STEEL.

Another important building material is concrete. The material is inherently weak in tension and must be reinforced by means of steel bars embedded in and bonded to the concrete matrix. This combination of nonhomogeneous materials, called reinforced concrete, is utilized in many areas of building construction, including foundations, walls, columns, beams, floors, and roofs. *See* COLUMN; CONCRETE; FOUNDATIONS; REINFORCED CONCRETE; ROOF CONSTRUCTION; WALL CONSTRUCTION.

In North America, where large softwood forests were plentiful, the milling of small-dimension lumber gave rise to the balloon frame house in the latter part of the nineteenth century. In this technique, closely spaced studs, joists, and rafters are fastened together with simple square cuts and nails. The balloon frame allowed relatively unskilled persons to erect simple frame houses. In the twentieth century, the balloon frame gave way to the platform frame, in which the studs were capped at each floor rather than running continuously for two stories.

Masonry is a widely used construction technique, and perhaps the oldest building material. The three most common masonry materials are stone (quarried from natural geologic formations), brick (manufactured from clay that is exposed to high temperature in kilns), and concrete masonry units (solid or hollow blocks manufactured from carefully controlled concrete mixes). These materials are used alone or in combination, with each unit separated from the adjacent one by a bed of mortar. *See* BRICK; MORTAR; STONE AND STONE PRODUCTS.

The strength of a masonry wall depends greatly on the quality of construction. Since quality varies widely, it is desirable to introduce a relatively large factor of safety into the design. Masonry has been used in structural supporting walls built as high as 20 stories. *See* MASONRY.

New materials include high-strength alloys of steel as well as products developed for space programs that have very high strength-to-weight ratios. Other desirable properties involve increased strength as well as resistance to corrosion, high temperature from fires, and fatigue. Plastics are used in many building applications. However, these materials require improvements in strength and stiffness, long-term dimensional stability, resistance to high temperature and the degrading effects of ultraviolet radiation, and ease in being fastened and connected. Composite materials have been developed for application in buildings, and include sandwich panels in which the surfaces are bonded to a core. Combinations of steel and concrete, masonry and steel reinforcement or prestress, timber and concrete, and timber and steel are in use. Other novel materials include high-performance fabric for roof coverings, structural adhesives, carbon fiber, and glass-fiber products.

Skyscrapers. Skyscrapers were developed at the end of the nineteenth and early in the twentieth century to maximize the economic return on parcels of land in urban environments. Earlier heavy-masonry-bearing-wall buildings had walls up to 6 ft (2 m) thick at their base to support as much as 16 stories of load. These walls occupied valuable space that could otherwise be rented to tenants. This drawback provided stimulus to the development of the skeleton steel frame, in which the thin exterior cladding does not participate in the support of the building but functions as a weather enclosure and a visual expression. These external skins (curtain walls) are often constructed of light aluminum or steel supports infilled with glass or metal panels. Curtain walls may also be fabricated of masonry veneer or precast concrete panels. They are designed to resist water and wind pressure and infiltration, and they are attached to the building frame for their primary support.

The major structural problem that must be considered in the design of skyscrapers is the ability of the frame to resist lateral wind loads. The building must be strong enough to resist the applied forces and stiff enough to limit the lateral displacement. The simplest method of providing lateral rigidity is to ensure that the joints between girders and columns remain rigid, that is, their geometry remains unchanged. Rigid frame design is still the most economical method of framing buildings up to 20 stories tall. *See* STRUCTURAL ANALYSIS.

As buildings became taller than 20 stories, diagonal braces were introduced between the top of one column and the bottom of an adjacent one to form a truss type of framework. The diagonals were found to be very efficient for buildings up to about 60 stories. *See* TRUSS.

Building services. In order for buildings to be fully functional, they must be able to provide adequate levels of comfort and service. There are many methods used to supply the services of heating and cooling. Heating may be provided by radiation, conduction, or convection. Electrical systems are installed throughout buildings to provide lighting as well as power to operate appliances and machinery. Signal systems for telephones, computers, and alarms are also commonly specified and built. Finally, there is plumbing service, which delivers hot and cold water and carries away wastewater as well as storm water into disposal systems such as sewers or septic systems. *See* AIR CONDITIONING; COMFORT HEATING; SEWAGE.

Building safety. Buildings are designed to resist loads due to their own weight, to environmental phenomena, and from the occupants' usage. The self-weight of a building, called dead load, is relatively easy to calculate if the composition and thickness of all of the materials are known. Included in the dead load are the building frame, walls, floors, roof, ceilings, partitions, finishes, and service equipment—that is, everything that is fixed and immovable. Environmentally applied loads include rain, which may cause ponding, and snow and ice.

Another significant load to which buildings are subjected is the force of earthquakes. Seismic loads, unlike most other loads except for wind, are dynamic in character rather than static. Engineers have devised a number of methods by which buildings can resist significant seismic loads. One is to design a maximum of energy absorption into the building by providing ductility in the frame and its connections. A second method involves an attempt to separate the superstructure of the building from ground-induced vibration—a method called base isolation. In this system, shock-absorbent material is inserted between the foundation and the superstructure to prevent vibrations from traveling up into the building. *See* EARTHQUAKE; SEISMIC RISK.

The danger of fire in buildings has several aspects. Of primary importance is the assurance that all occupants can exit safely and that firefighters can perform their work with minimal danger. The second consideration involves the protection of property, the building, and its contents. In the initial planning of a building, the location, number, and size of exits must be carefully considered in relation to the anticipated occupancy and the material of construction. Where it is not possible to provide sufficient access to exit doors at ground level, fire escapes (generally steel-bar platforms and stairs) are affixed to the sides of buildings.

Sophisticated fire detection systems can sense both smoke and heat. These sound audible alarms and directly contact municipal fire departments and building safety officers. In addition, the alarm may automatically shut down ventilation systems to prevent smoke from spreading, may cause elevators to return to the ground floor where they remain until the danger is passed, and may close fire doors and dampers to compartmentalize the spread of smoke or flames. Supplementing this passive detection are automatic sprinkler systems. *See* AUTOMATIC SPRINKLER SYSTEM; FIRE DETECTOR; FIRE TECHNOLOGY.

Building codes and environmental concerns. The process of building is often regulated by governmental authorities through the use of building codes that have the force of law. In the United States there is no national code; rather there are regional, state, or even city building codes. Codes establish classifications of buildings according to the proposed occupancy or use. Then, for any given type of construction (for example, wood, steel, or concrete), they establish minimum standards for exit and egress requirements, for height and area, and for fire resistance ratings. In addition, minimum loads are designated as well as requirements for natural light, ventilation, plumbing, and electrical servies. Local codes are written to regulate zoning, stipulating items such as building type, occupancy, size, height, setbacks from property lines, and historic considerations.

The process of building raises large numbers of environmental issues. In many cases the owner must prepare an official environmental impact statement that considers the potential effect of the proposed building on traffic, air quality, sun and shadow, wind patterns, archeology, wildlife, and wetlands, as well as demands on existing utilities and services.

One of the primary environmental concerns is energy conservation. In the initial design of a building, all systems are studied to obtain maximum efficiency. Heating and cooling are two of the largest consumers of energy, and a great deal of effort is directed toward minimizing energy consumption by techniques such as building orientation, sun shading, insulation, use of natural ventilation and outside air, recapture of waste heat, cogeneration (using waste heat to generate electricity), use of solar energy both actively and passively, and limiting heat generation from lighting. Efforts at reducing electric power consumption by designing more efficient lighting, power distribution, and machinery are also of high priority. Consumption of water and disposal of liquid and solid waste are additional concerns. *See* COGENERATION; HEAT INSULATION; SOLAR HEATING AND COOLING; VENTILATION.

[R.Sil.]

Bulk-handling machines A diversified group of materials-handling machines specialized in design and construction for handling unpackaged, divided materials.

Solid, free-flowing materials are said to be in bulk. The handling of these materials requires that the machinery both support their weight and confine them either to a desired path of travel for continuous conveyance or within a container for handling in discrete loads. Wet or sticky materials may also be handled successfully by some of the same machines used for bulk materials. Characteristics of materials that affect the selection of equipment for bulk handling include (1) the size of component particles, (2) flowability, (3) abrasiveness, (4) corrosiveness, (5) sensitivity to contamination, and (6) general conditions such as dampness, structure, or the presence of dust or noxious fumes.

Equipment that transports material continuously in a horizontal, inclined, or vertical direction in a predetermined path is a form of conveyor. The many different means used to convey bulk materials include gravity, belt, apron, bucket, skip hoist, flight or screw, dragline, vibrating or oscillating, and pneumatic conveyors. Wheel or roller conveyors cannot handle bulk materials.

Gravity chutes are the only unpowered conveyors used for bulk material. They permit only a downward movement of material.

Belt conveyors of many varieties move bulk materials. Fabric belt conveyors have essentially the same operating components as those used for package service; however, these components are constructed more ruggedly to stand up under the more rigorous conditions imposed by carrying coal, gravel, chemicals, and other similar heavy bulk materials. Belts may also be made of such materials as rubber, metal, or open wire. Their advantages include low power requirements, high capacities, simplicity, and dependable operation.

An apron conveyor is a form of belt conveyor, but differs in that the carrying surface is constructed of a series of metal aprons or pans pivotally linked together to make a continuous loop. This type of conveyor is suitable for handling large quantities of bulk material under severe service conditions. Apron conveyors are most suitable for heavy, abrasive, or lumpy materials.

Bucket conveyors are constructed of a series of buckets attached to one or two strands of chain or in some instances to a belt. These conveyors are most suitable for operating on a steep incline or vertical path, sometimes being referred to as elevating conveyors. This type of conveyor is most ideal for bulk materials such as sand or coal.

Flight conveyors employ the use of flights, or bars attached to single or double strands of chain. The bars drag or push the material within an enclosed duct or trough. These are frequently referred to as drag conveyors. This type of conveyor is commonly used for moving bulk material such as coal or metal chips from machine tools.

Spiral or screw conveyors rotate upon a single shaft to which are attached flights in the form of a helical screw. When the screw turns within a stationary trough or casing, the material advances. These conveyors are used primarily for bulk materials of fine and moderate sizes, and can move material on horizontal, inclined, or vertical planes.

Vibrating or oscillating conveyors employ the use of a pan or trough bed, attached to a vibrator or oscillating mechanism, designed to move forward slowly and draw back quickly. The inertia of the material keeps the load from being carried back so that it is automatically placed in a more advanced position on the carrying surface.

Pneumatic, or air, conveyors employ air as the propelling media to move materials. One implementation of this principle is the movement within an air duct of cylindrical carriers, into which are placed currency, mail, and small parts for movement from one point to discharge at one of several points by use of diverters. Pneumatic pipe conveyors are widely used in industry, where they move granular materials, fine to moderate size, in original bulk form without need of internal carriers.

Power cranes and shovels perform many operations moving bulk materials in discrete loads. When functioning as cranes and fitted with the many below-the-hook devices available, they are used on construction jobs and in and around industrial plants. Such fittings as magnets, buckets, grabs, skull-crackers, and pile drivers enable cranes to handle many products. The machines of the convertible, full-revolving type are mounted on crawlers, trucks, or wheels. Specialized front-end operating equipment is required for clamshell, dragline, lifting-crane, pile-driver, shovel, and hoe operations. Specialized equipment for mechanized pit mining has been developed. Power cranes, shovels, and scoops are actively engaged in strip mines, quarries, and other earth-moving operations. *See* ELEVATING MACHINES; INDUSTRIAL TRUCKS; MATERIALS-HANDLING EQUIPMENT; MONORAIL. [A.M.P.]

Buoy An anchored or moored floating object, other than a lightship, intended as an aid to navigation. Buoys are the most numerous of all engineered aids to navigation.

Buoys are intended to serve as daymarks. Some buoys, particularly those at turning points in channels, are provided with lights of distinctive characteristics for location and identification at night. Some buoys are equipped with apparatus for providing distinctive sounds at intervals so they can be used as aids to navigation in fog and darkness. Some buoys are equipped with radio beacons, and some have reflectors to make them more conspicuous to radar.

Over the years, a number of different buoyage systems have been developed in various parts of the world. In an effort to reduce the differences, the International Association of Lighthouse Authorities (IALA) recommended a uniform system that has been adopted by most European, African, and Asian nations.

This system, identified as IALA system A, has one feature that has not been acceptable to most nations in the Western Hemisphere and some Asian countries: the use of red buoys to port while entering a channel from seaward. These nations have adopted IALA system B, similar to system A but with the red buoys on the opposite side of the channel. [A.B.M.]

Buoyancy The resultant vertical force exerted on a body by a static fluid in which it is submerged or floating. The buoyant force F_B acts vertically upward, in opposition to the gravitational force that causes it. Its magnitude is equal to the weight of fluid displaced, and its line of action is through the centroid of the displaced volume, which is known as the center of buoyancy. *See* AEROSTATICS; HYDROSTATICS.

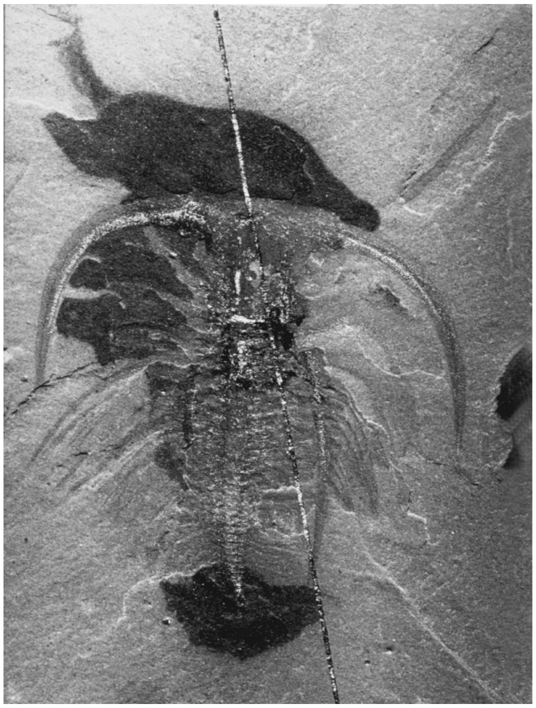
By weighing an object when it is suspended in two different fluids of known specific weight, the volume and weight of the solid may be determined. *See* ARCHIMEDES' PRINCIPLE.

Another form of buoyancy, called horizontal buoyancy, is experienced by models tested in wind or water tunnels. Horizontal buoyancy results from variations in static pressure along the test section, producing a drag in closed test sections and a thrust force in open sections. These extraneous forces must be subtracted from data as a boundary correction. Wind tunnel test sections usually diverge slightly in a downstream direction to provide some correction for horizontal buoyancy. *See* WATER TUNNEL; WIND TUNNEL.

A body floating on a static fluid has vertical stability. A small upward displacement decreases the volume of fluid displaced, hence decreasing the buoyant force and leaving an unbalanced force tending to return the body to its original position. Similarly, a small downward displacement results in a greater buoyant force, which causes an unbalanced upward force.

A body has rotational stability when a small angular displacement sets up a restoring couple that tends to return the body to its original position. When the center of gravity of the floating body is lower than its center of buoyancy, it will always have rotational stability. Many a floating body, such as a ship, has its center of gravity above its center of buoyancy. Whether such an object is rotationally stable depends upon the shape of the body. *See* SHIP DESIGN. [V.L.S.]

Burgess Shale Part of a clay and silt sequence that accumulated at the foot of a colossal "reef" during the Cambrian explosion, a dramatic evolutionary radiation of animals beginning about 545 million years ago. Although this explosion is most obvious from the geologically abrupt appearance of



***Marrella splendens*, a characteristic Burgess Shale arthropod. The head shield bears two prominent pairs of spinose extensions; also visible are various appendages that include walking legs and gills. The prominent dark areas appear to represent body contents that oozed into the newly deposited sediment. This indicates that some decay occurred before an unknown factor intervened. (*Copyright by Simon Conway Morris*)**

skeletons, the bulk of the radiation consisted of soft-bodied animals (see illustration). The Burgess Shale fauna, located near Field in southern British Columbia, is Middle Cambrian, approximately 520 million years old.

The Burgess Shale fauna is remarkably diverse, with about 120 genera. Its approximate composition is arthropods 37%, sponges 15%, brachiopods 4%, priapulids 5%, annelids 5%, chordates and hemichordates 5%, echinoderms 5%, cnidarians and ctenophores 2%, mollusks 3%, and "other fauna" 19%. Although arthropods are the most important group, the trilobites, normally dominant among Cambrian arthropods, are entirely overshadowed both in number of species and in absolute number of specimens by a remarkable variety of other arthropods with delicate exoskeletons. The priapulids, which today are a more or less relict group of marine worms, also show a wide diversity of anatomical form, as do the polychaete annelids. Only one species of polychaete annelids has a close parallel among the Recent assemblages.

The Burgess Shale has revealed many other aspects of the Cambrian explosion. First, a census of the collections reveals a marine ecology that is fundamentally unchanged to the present day. Predators, long thought to be insignificant in the Cambrian, are an important component. Second, groups with a minimal fossilization potential are preserved. One example is the gelatinous and delicate ctenophores, an important pelagic group in today's oceans but practically unknown as fossils. Third, although many of the species are a product of the Cambrian explosion, rare species are clear holdovers from the primitive Ediacaran faunas of late Precambrian age. Finally, some species are of particular evolutionary importance. Most significant is the worm *Pikaia*, which is interpreted as an early chordate, and as a predecessor of fish it lies near the beginning of the evolutionary path that ultimately leads to humans. *See* CAMBRIAN; FOSSIL; PALEONTOLOGY. [S.C.M.]

Burn An injury to tissues caused by heat, chemicals, electricity, or irradiation effects.

The commonest type of burn is that due to thermal injury, in which some portion of the body surface is exposed to either moist or dry heat of sufficient temperature to cause local and systemic reactions. Clinically, the extent of such a burn is often expressed as first degree, second degree, and so forth. Different systems of classification exist.

First-degree burns result in some redness and swelling of the injured part, without necrosis of any tissue or the formation of blisters. Healing is completed in a few days without scarring.

Second-degree burns show a variable destruction of parts of the epidermis so that blistering occurs. Healing by regeneration in such superficial burns does not necessitate skin grafting, unless secondary infections ensue; no scarring results.

Third-degree burns are marked by complete destruction of the epidermis of a region, including the necrosis of accessory skin structures like hair and sweat glands. A brownish-black eschar marks the destroyed tissue. This is sloughed off and that defect becomes filled with granulation tissue that later consolidates and changes to form a dense, thick scar. Complications may occur without adequate care, and grafting is not unusual, sometimes being required because of contracture of the scar tissue.

In fourth-degree burns, tissue is destroyed to the level of or below the deep fascia lying beneath the subcutaneous fat and connective tissue of the body. Muscle, bone, deeper nerves, and even organs may be injured or destroyed by this severe degree of burn. Healing is usually a slow, involved process, requiring much reparative and reconstructive work by surgical specialists.

Electrical burns result from the amount of heat incident to the flow of a certain amount of electricity through the resistance offered by tissues. From a practical standpoint, most of the resistance offered to the passage of an electric current is that of the skin and the interface between the skin and the external conductor. Therefore, most electrothermal injuries are limited to the skin and immediately subjacent tissues, although deep penetration may follow large voltages.

Most chemical burns result from the action of corrosive agents which destroy tissues at the point of contact. Exposure of the skin, eyes, and gastrointestinal tract are commonest. [E.G.St./N.K.M.]

Burrowing animals Some terrestrial and aquatic animals are capable of excavating holes in the ground (burrowing) for protection from adverse environmental conditions, as well as for storing food. Burrows vary from temporary structures of simple design (for example, the nesting burrows of some birds) to more permanent underground networks that may be inhabited for several generations (for example, rabbit warrens, badger sets, fox earths, and prairie dog burrows). They vary in structure from blind burrows with a single opening to extensive systems with several openings. Some animals (for example, some species of moles) live permanently underground, and their burrows have no obvious large openings to the surface. Burrows may be shared by a number of species, and abandoned burrows may be used by other species. Animals with limbs usually excavate their burrows by using their legs, but many burrowing animals are limbless and the mechanism of progression is not always obvious.

Worms, slugs, many insects, and many vertebrates live in burrows. Earthworms are important soil organisms because their burrows improve drainage and aeration, their feeding habits enhance leaf decomposition, and their droppings increase soil fertility. Earthworms burrow by contracting circular muscles in their body wall to push forward, and contracting the longitudinal muscles to widen the burrow. Termites (Isoptera) and ants (Hymenoptera) are social insects, most of which live underground. Termites are major consumers of vegetation in warm climates, and many construct extensive underground galleries extending from the mound located on the surface. Most ants are predators or scavengers, but leaf-cutter ants feed on a fungus that grows on the harvested pieces of leaf in carefully tended underground galleries.

Many marine animals, including flatfish, crabs, and shrimps, take temporary refuge or live more permanently in sand or mud by burying themselves just below the surface. Aquatic sand and mud pose several problems for burrowing animals. First, the particles are usually tightly packed together, restricting movement and requiring these organisms to expend 10–1000 times as much energy to move a given distance compared to other forms of locomotion. Second, burrows readily collapse unless reinforced or consolidated. The wall of burrows may simply be consolidated with mucus, but some animals make a more permanent, substantial tube of particles stuck together with mucus. Finally, all burrowing animals must be able to create a current of water through the burrow so that they can breathe. Many animals also feed partly or wholly on particles carried in such currents. [H.D.J.]

Bursa A simple sac or cavity with smooth walls and containing a clear, slightly sticky fluid interposed between two moving surfaces of the body to reduce friction. Subcutaneous bursae are found where the skin stretches around the greater curvature of a joint, as in the elbow or knee, and considerable chafing may occur; they may be single or multiple sacs. These bursae may enlarge as a result of continuous excessive irritation, as in housemaid's knee or miner's elbow. *See* BURSITIS.

Synovial bursae are small closed sacs of fibrous tissue continuous with the joint cavity of a diarthrosis. They are lined with a complex membrane that secretes a clear lubricating fluid, serving to reduce friction between the opposing surfaces of the articulation. *See* JOINT (ANATOMY).

Bursae may exist in the form of elongated sheaths surrounding tendons or ligaments, where these moving bands are in contact with another structure, such as a bone, muscle, or another tendon or ligament. Tendon sheaths are especially common where tendons bend around the ends of two bones at an articulation. *See* MUSCULAR SYSTEM; SKELETAL SYSTEM. [W.J.B.]

Bursitis Any inflammation of a bursa. Bursae are synovial pouches, positioned to minimize friction between moving parts of the body. Bursitis most often occurs near the shoulder, hip, elbow, or knee. *See* BURSA; JOINT (ANATOMY).

Inflammatory changes in bursae produce acute or chronic swelling, an increase in the fluid content, and variable degrees of pain and tenderness. Acute bursitis may be septic (caused by microorganisms) or nonseptic. Nonseptic bursitis can be further subdivided into idiopathic (of unknown cause), traumatic, and crystal-induced bursitis. Septic bursitis may result from direct penetration by microorganisms through medical instrumentation or trauma; rarely, microorganisms may reach bursae through the blood. Most cases of bursitis are nonseptic; they may result from trauma or physical stress. In chronic bursitis, the wall of the bursa becomes thickened, shaggy, and irregular, with calcium deposits commonly being present.

The treatment depends on whether the bursitis is septic or nonseptic. Septic bursitis is most commonly due to *Staphylococcus aureus* and requires prompt administration of appropriate antibiotics and repeated drainage of fluid containing pus. Nonseptic bursitis can be treated conservatively by withdrawal of fluid and administration of nonsteroidal, anti-inflammatory drugs. Crystal-induced nonseptic bursitis is most frequently due to gout and usually responds well to drug therapy. Avoidance of trauma can help to prevent occupation-related cases of bursitis. Most cases of bursitis have a favorable prognosis. *See* CONNECTIVE TISSUE; GOUT. [R.P.S.]

Bus A motor vehicle for mass transit, built in various capacities and sizes, designed for carrying from 10 to 60 passengers or more on school, local, intercity, or interstate routes. A commercial bus usually operates on a regular schedule and travels a fixed route, and each passenger pays a fare. In general, a bus has a long body with the passengers sitting on benches or seats. A double-deck bus has two separate passenger compartments, one above the other. The articulated bus has two connected passenger compartments that bend at their connecting point as the bus turns.

Most commercial buses have diesel engines, air conditioning, air suspension, and automatic transmission. Restroom facilities are usually included in buses for long-distance service. Basic bus design retains many passenger car and truck components. Gross weight is kept at a minimum for economic operation and for maximum utilization of space for entry, aisle, and exit areas. Seating and safety devices must comply with federal regulations. Heavy frames perform the same functions as those in other commercial vehicles for load-bearing capacity, rigidity, and resistance to impact. [D.L.An.]

Bus-bar An aluminum or copper conductor supported by insulators that interconnects the loads and the sources of electric power in an electric power system. A typical application is the interconnection of the incoming and outgoing transmission lines and transformers at an electrical substation. Bus-bars also interconnect the generator and the main transformers in a power plant. In an industrial plant such as an aluminum smelter, large bus-bars supply several tens of thousands of amperes to the electrolytic process. *See* ELECTRIC POWER SUBSTATION.

The major types are (1) rigid bus-bars, used at low, medium, and high voltage; (2) strain bus-bars, used mainly for high voltage; (3) insulated-phase bus-bars, used at medium voltage; and (4) sulfur hexafluoride (SF_6)-insulated bus-bars, used in medium- and high-voltage systems. The rigid bus-bar is an aluminum or copper bar, which is supported by porcelain insulators. The strain bus-bar is a flexible, stranded conductor which is strung between substation metal structures and held by suspension-type insulators. The insulated-phase bus-bar is a rigid bar supported by insulators and covered by a grounded metal shield. The main advantage of this system is the elimination of short circuits between adjacent phases. The sulfur hexafluoride-insulated bus-bar is a rigid aluminum tube, supported by insulators and installed in a larger metal tube, which is filled with high-pressure sulfur hexafluoride gas. *See* CONDUCTOR (ELECTRICITY); ELECTRICAL INSULATION; WIRING. [G.G.K.]

Bushing A removable metal lining, usually in the form of a bearing to carry a shaft. Generally a bushing is a small bearing in the form of a cylinder and is made of soft metal or graphite-filled sintered material. Bushings are also used as cylindrical liners for holes to preserve the dimensional requirements, such as in the guide bearings in jigs and fixtures for drilling holes in machine parts. [J.J.R.]

Butter A food product made by churning cream. Butter is a water-in-fat emulsion. Cream is a fat-in-water emulsion. Cream consists of discrete fat globules, 6–16 micrometers in size, suspended in skim milk. Fat globules have a membrane or coating consisting of natural emulsifiers, lipoproteins, fat-soluble vitamins, cholesterol, and some other materials in lesser concentrations. The membrane provides stability for the globule and protects it from attack by lipase enzymes. *See* EMULSION; MILK.

Butter manufacturers first pasteurize the cream. This heat treatment destroys bacteria, inactivates enzymes, and gives the cream a cooked or heated flavor. *See* PASTEURIZATION.

Following pasteurization, rapid cooling promotes fat crystals on the exterior and liquid fat on the interior of the fat globules. If the cream were churned after this step, the loss of fat to the buttermilk would be high. Thus, a tempering step is used in which the cream is held at about 50°F (10°C) to allow rearrangement of the fat crystals. Then, liquid fat is on the outside of the globules to allow rapid aggregation during churning.

Continuous churns produce as much as 15,000 lb (6800 kg) of butter per hour; they convert cream to butter in a few minutes. With the batch churn, about 45 min is needed to produce butter, and then at least 30 min to standardize the composition and get water dispersed in tiny droplets.

In the continuous churn the entering pasteurized and tempered cream is agitated vigorously by beater bars. This causes stripping of the fat globule membrane and aggregation of the fat globules into chunks 0.2–0.4 in. (0.5–1 cm) in diameter. At this point the emulsion has been inverted. The slope of the continuous churn allows the buttermilk to drain out the rear of the churn and the butter granules to continue through the churn barrel. The next flow-through position continues the kneading process to produce butter with finely dispersed droplets of moisture. If composition or color adjustment is required, it is done in this step; also, a salt solution is added to give the finished butter 1.2–1.5% salt. As the butter continues through the last step, more kneading is done with finer bars to complete the blending process and provide for fat crystallization that will yield optimum spreadability in the finished butter.

Butter in the package has a composition close to 80.0% milk fat, 1.2–1.5% salt, 17.5–17.8% water, and 1% milk solids. If butter is salt-free, the moisture and fat contents are adjusted to a slightly higher value to compensate. [R.Bra.]

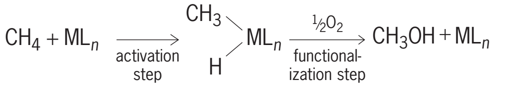
Buxbaumiidae A subclass of the class Bryopsida, the true mosses. It consists of a single family with four genera. The Buxbaumiidae is very distinctive in every way and most significantly in the structure of the peristome. The plants are small and occur especially on soil. The gametophyte is greatly reduced (*Buxbaumia*), with no stem and few leaves that are readily disappearing, or better developed with well-formed leaves having a single costa and short cells. The sporophytes are terminal. The capsules are disproportionately large and immersed or elevated on a seta (*Buxbaumia*). They are strongly inclined and asymmetric, tapered to a small mouth from a broad base. The operculum is small and conic. *See* BRYOPHYTA; BRYOPSIDA. [H.Cr.]

Bytownite A member of the plagioclase feldspar solid-solution series with a composition ranging from $Ab_{30}An_{70}$ to $Ab_{10}An_{90}$ ($Ab = NaAlSi_3O_8$ and $An = CaAl_2Si_2O_8$). Bytownite is very abundant in basic igneous rocks where it is the first plagioclase to crystallize under plutonic conditions; it forms the cores of zoned plagioclase phenocrysts in basaltic volcanics, and it sometimes occurs in anorthosites. *See* FELDSPAR. [L.Gr.]

C

C—H activation The cleavage of carbon-hydrogen bonds in organic compounds, leading to subsequent functionalization to introduce useful chemical groups. For example, petroleum and natural gas, important energy resources for the modern world, are both alkanes, C_nH_{2n+2}, with many C—H bonds. One problem is to convert these alkanes to useful alcohols, $C_nH_{2n+1}OH$. This is particularly difficult because of the lack of reactivity of alkanes as indicated by their older name, paraffins (from Latin, meaning low affinity). In C—H activation, metal catalysts are often used to mediate the hydrocarbon conversion reactions. *See* Alcohol; Alkane; Chemical bonding; Organic chemistry.

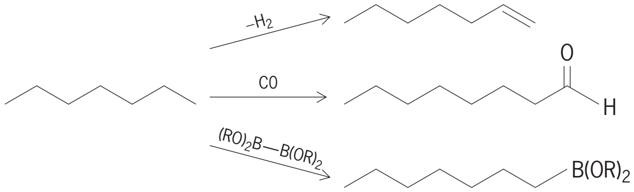
A variety of ML_n fragments, consisting of a metal M and its associated ligands L_n, are capable of reaction with an alkane to give C—H bond breaking as shown in the first step of reaction (1). In principle, it should be possible to follow this with a



$$\mathrm{CH_4 + ML}_n \xrightarrow[\text{activation step}]{} \genfrac{}{}{0pt}{}{\mathrm{CH_3}}{\mathrm{H}}\!>\!\mathrm{ML}_n \xrightarrow[\text{functional-ization step}]{\frac{1}{2}\mathrm{O_2}} \mathrm{CH_3OH + ML}_n \qquad (1)$$

second step to give the functionalized alkane, but this has proved difficult in practice. R. G. Bergman showed as early as 1982 that $(C_5Me_5)Ir(PMe_3)$, formed photochemically, is suitable for the first reaction, for example. *See* Coordination chemistry; Ligand.

Other cases are known where the first step of reaction (1) is followed by a functionalization reaction. H. Felkin, R. H. Crabtree, and A. S. Goldman showed reactions of this kind where the intermediate alkyl hydride decomposes to give alkene and free H_2 or, in the presence of a second alkene as sacrificial oxidant, alkene and hydrogenated sacrificial oxidant [reaction (2)].



(2)

Y. Saito and M. Tanaka showed that the intermediate alkyl hydride can be trapped by carbon monoxide (CO) to give aldehyde (RCHO) as final product, and J. F. Hartwig trapped the alkyl with diborane derivatives to give alkyl boronic esters [reaction (2)]. In all of these cases, C—H activation preferentially occurs at the least hindered C—H bond, leading to products that are quite different from those formed in radical and acid pathways where the most substituted and most hindered C—H bonds are most reactive. In each case, appropriate transition-metal compounds are present and catalyze the reactions. These reactions do not yet form the basis of any practical process, but produce terminally functionalized products (the most desirable type) rather than the mixtures commonly found in other reactions. [R.H.Cr.]

Cabbage A hardy, cool-season crucifer (*Brassica oleracea* var. *capitata*) of Mediterranean origin and belonging to the plant order Capparales. Cabbage is grown for its head of overlapping leaves (see illustration), which are generally eaten raw in salads, cooked fresh, or processed into sauerkraut. Because it normally produces seed the second year, cabbage is considered to be a biennial by most authorities. Others regard it a perennial because it will remain vegetative unless subjected to cold weather.

Cabbage (*Brassica oleracea* var. *capitata*), cultivar Golden Acre 84. (*Joseph Harris Co., Inc., Rochester, New York*)

Chinese cabbage is a related annual of Asiatic origin. Two species are grown in the United States, pe-tsai (*B. pekinensis*) and pakchoi (*B. chinensis*). *See* Oriental vegetables.

Cabbage varieties (cultivars) are generally classified according to season of maturity, leaf surface (smooth, savoyed, or wrinkled), head shape (flattened, round, or pointed), and color (green or red). Round, smooth-leaved, green heads are commonest. Varieties differ in their resistance to disease and in the tendency for heads to crack or split in the field.

Texas and Florida are important winter crop producing states; Georgia, Mississippi, and North Carolina produce large acreages in the spring; and New York, North Carolina, and Wisconsin are important for the summer and fall crops. New York and Wisconsin are the important kraut cabbage states. *See* Capparales. [H.J.C.]

Cable television system A system that receives and processes television signals from various sources and retransmits these signals through cables to subscribers' homes. The sources of the signals include broadcast transmissions, satellite-delivered programming, and local television studio productions. The facility that receives, processes, and retransmits the signals is called a headend.

Unlike broadcast television signals, which travel through free space, cable signals travel through coaxial cable or optical fiber, with different programs or channels traveling at different frequencies (much the same as frequency-division multiplex). In effect, the coaxial cable or optical fiber acts as a self-contained, closed, noninterfering frequency spectrum, created inside the cable by the reuse of the spectrum already in use for other purposes. *See* Multiplexing.

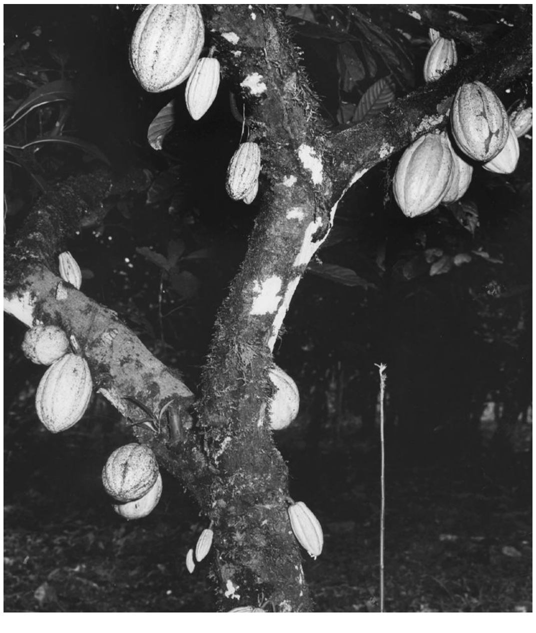
Cable television is made possible by the technology of coaxial and optical-fiber cable and is subject to the principles of transmission-line theory. The primary disadvantage of coaxial-cable distribution systems is their relatively high loss or attenuation regarding television signals at the frequencies normally used in cable television systems (50–550 MHz, extending up to 1 GHz in newer systems). Amplifiers are required to overcome this signal loss, and the farther the subscriber is from the cable headend the more amplifiers are needed. Noise and intermodulation distortions created by many cascaded amplifiers limit the practical length of any coaxial cable network. *See* Coaxial cable.

Optical fiber does not have the same high attenuation or loss characteristics as coaxial cable, and optical-fiber networks can therefore be built without amplifiers. Most cable systems that use optical fibers do so in a hybrid fashion. Optical fiber is connected from the headend to some localized node or terminating location. The subscriber is then connected to the optical-fiber node by short distances of coaxial cable. *See* Communication cables; Optical communications; Optical fibers.

The system design or architecture is known as a tree-and-branch design. The tree-and-branch architecture is the most efficient way to transmit a package of multiple channels of programming from a headend to all subscribers. *See* Closed-circuit television; Television. [R.D.Pi.]

Cacao *Theobroma cacao*, a small tropical tree (see illustration) that is cultivated for the almond-shaped seeds which are used to make chocolate. The species is native to the rainforest of the Amazon basin, and two regions of distribution in pre-Columbian times are recognized. The crop was first cultivated in Central America and northern South America, the varieties found there being known as Criollos. The second region comprises the Amazon and Orinoco basins, where the cacao populations are known as Amazonian Forastero. The second type is more commonly cultivated, particularly in Brazil, Ivory Coast, Ghana, and Nigeria.

The produce is generally exported in the form of dry beans. The farmers' production is purchased by dealers and exported by registered exporters or government marketing boards. Sales are effected through contracts or futures markets, principally in New York and London. The market distinguishes between bulk and fine cocoas. The latter have preferred flavor or other characteristics and receive a price premium. *See* Theales. [P.DeT.A.]



Cacao (*Theobroma cacao*). (*USDA*)

Cachexia The severe wasting syndrome that accompanies such diseases as cancer, infection, or parasitic infestation. The causes of cachexia are only partially understood. However, it is clear that most cachexia is caused by diminished consumption of nutrients rather than by a hypermetabolic state.

Anorexia, the proximal cause of this problem, is thought to be related to the expression of endogenous factors collectively termed cytokines, some of which have now been identified. For example, tumor necrosis factor, a protein (also known as cachectin), when administered to animals for a long period of time, causes a syndrome of cachexia indistinguishable from that produced by chronic disease. It is likely that other cytokines are also involved, and that together these agents cause wasting of such severity that it may lead to death in a wide variety of diseases. *See* Anorexia nervosa; Cytokine.

The cytokines that cause cachexia are produced mainly by cells of the immune system, especially macrophages. Synthesis is triggered by contact with molecules produced by microbial pathogens or tumor cells. Rational strategies for alleviation of cachexia include eradicating the underlying infection or tumor, blocking cytokine synthesis with agents that specifically interrupt the requisite signaling pathways, or inhibiting cytokine activity with specific antibodies or other antagonists. Oral or intravenous administration of nutrients is likely to be effective if the process has not advanced to a point at which utilization of nutrients is impaired. *See* Oncology. [B.Be.]

Cactus The common name for any member of the cactus family (Cactaceae). There are 120 genera with perhaps 1700 species, nearly all indigenous to America. The cacti are among the most extremely drought-resistant plants, and consequently they thrive in very arid regions. The group is characterized by a fleshy habit, presence of spines and bristles, and large, brightly colored, solitary flowers. There is a great variety of body shapes and patterns, and many of the species are grown as ornamentals or oddities. A few have edible fruits. The cochineal insect, which produces a valuable red dye, is cultivated chiefly on the cochineal cactus (*Nopalea coccinellifera*). The saguaro (*Cereus giganteus*) of Arizona and Sonora is the largest of the cacti, attaining a height of 70 ft (21 m). *See* Caryophyllales.

Cacti grow in many habitats, ranging from epiphytes living on trees in dense tropical forests to large, isolated plants in deserts. In all cases, various adaptations that lead to water conservation are apparent. For example, the stems of most cacti are massive and can store large amounts of water that sustain the plants during prolonged drought. Adaptations for water conservation also occur on a metabolic level. Cacti have a thick waxy cuticle on their stems, which acts as a waterproofing skin. Also, the pores (called stomata or stomates) in the cactus skin that are necessary for the uptake of carbon dioxide (CO_2) from the atmosphere tend to open only at night. Much less water (generally 80–90% less) is lost by transpiration during the nocturnal opening of stomata by cacti compared with the daytime stomatal opening of most other plants. The opening of stomata at night presents a problem for photosynthesis, which requires light. Specifically, photosynthesis uses atmospheric carbon dioxide and the energy of sunlight to form sugars in the chloroplasts of the chlorenchyma. During the night malic acid accumulates in the large vacuoles of cactus chlorenchyma cells; during the next daytime, when the stomata have closed, carbon dioxide is released from the accumulated acid within the stems of cacti. Carbon dioxide is then fixed into sugars via photosynthesis when sunlight is available as the energy source. This process, known as crassulacean acid metabolism (CAM) because it was first discovered in the plant family Crassulaceae, is crucial for the adaptation of cacti to the dry conditions characteristic of deserts. Its water-conserving attribute is also important in the increasing cultivation of cacti for their fruits and as fodder for livestock, particularly cattle. [P.D.St.; E.L.C.; P.S.N.; S.M.A.]

Cadmium A relatively rare chemical element, symbol Cd, atomic number 48, closely related to zinc, with which it is usually associated in nature. It is a silvery-white ductile metal with a faint bluish tinge. It is softer and more malleable than zinc, but slightly harder than tin. It has an atomic weight of 112.40 and a specific gravity of 8.65 at 20°C (68°F). Its melting point of 321°C (610°F) and boiling point of 765°C (1410°F) are lower than those of zinc. There are eight naturally occurring stable isotopes, and eleven artificial unstable radio isotopes have been reported. Cadmium is the middle member of group II (zinc, cadmium, and mercury) in the periodic table, and its chemical properties generally are intermediate between zinc and mercury. The cadmium ion is displaced by zinc metal in acidic sulfate solutions. Cadmium is bivalent in all its stable compounds, and its ion is colorless. *See* PERIODIC TABLE; TIN; ZINC.

Cadmium does not occur uncombined in nature, and the one true cadmium mineral, greenockite (cadmium sulfide), is not a commercial source of the metal. Almost all of the cadmium produced is obtained as a by-product of the smelting and refining of zinc ores, which usually contain 0.2–0.4% cadmium. The United States, Canada, Mexico, Australia, Belgium-Luxembourg, and the Republic of Korea are principal sources, although not all are producers.

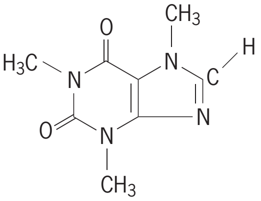
At one time an important commercial use of cadmium was as an electrodeposited coating on iron and steel for corrosion protection. Nickel-cadmium batteries are the second-largest application, with pigment and chemical uses third. Sizable amounts are used in low-melting-point alloys, similar to Wood's metal, and in automatic fire sprinklers, and relatively smaller uses are in brazing alloys, solders, and bearings. Cadmium compounds are used as stabilizers in plastics and the production of cadmium phosphors. Because of its great neutron-absorbing capacity, especially the isotope 113, cadmium is used in control rods and shielding for nuclear reactors. *See* ALLOY; CADMIUM METALLURGY. [W.H.]

Cadmium metallurgy Most cadmium occurs in solid solution in the zinc sulfide mineral called sphalerite. Although cadmium may be recovered from some lead and copper ores, it is associated with the zinc which is also found in these ores. Since cadmium is entirely a by-product metal, the supply available is closely aligned with zinc production, averaging about 0.4% of zinc production.

All cadmium recovery processes involve the dissolution of cadmium-bearing feed material, followed by various purification and cadmium displacement steps. Methods of processing can be grouped conveniently into two basic categories, electrolytic and electromotive. In the former case, cadmium is recovered by electrolyzing purified solutions; in the latter case, cadmium in the form of a metallic sponge is displaced from purified solutions by a less noble metal, zinc being used in every known commercial application, and the sponge is melted or distilled, or both.

Major end uses for cadmium are in corrosion-resistant plating and in cadmium compounds for use as pigments in paints, ceramics, and plastics. Cadmium is also used in alloys, plastic stabilizers, batteries, and television picture tube phosphors. In view of the changing world energy situation, uses for cadmium are anticipated in applications such as solar energy cells and energy storage systems. *See* CADMIUM. [R.E.L.]

Caffeine An alkaloid, formerly synthesized by methylation of theobromine isolated from cacao, but now recovered from the solvents used in the manufacture of decaffeinated coffee. Chemically, caffeine is 1,3,7-trimethylxanthine, and has the formula shown here. It is widely used in medicine as a stimulant for the central nervous system and as a diuretic. It occurs naturally in tea, coffee, and yerba maté, and small amounts are found in cola nuts and cacao. Caffeine crystallizes into long, white needlelike crystals that slowly lose their water of hydration to give a white solid that melts at 235–237.2°C (455–459.0°F). It sublimes without decomposition at lower temperatures. Caffeine has an intensely bitter taste, though it is neutral to litmus. *See* ALKALOID. [F.W.]



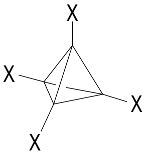
Cage hydrocarbon A compound that is composed of only carbon and hydrogen atoms and contains three or more rings arranged topologically so as to enclose a volume of space. In general, the "hole" within a cage hydrocarbon is too small to accommodate even a proton. The carbon frameworks of many cage hydrocarbons are quite rigid. Consequently, the geometric relationships between substituents on the cage are well defined. This quality makes these compounds exceptionally valuable for testing concepts concerning bonding, reactivity, structure-activity relationships, and structure-property relationships. *See* CHEMICAL BONDING.

The carbocyclic analogs of the platonic solids that are tenable are tetrahedrane (structure **1**, where $X = -H$), cubane (**2**), and dodecahedrane. *See* ALICYCLIC HYDROCARBON.

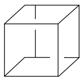
An unsubstituted prismane has the general formula of $(CH)_n$, and the carbon atoms are located at the corners of a regular prism. Prismane (**3**), cubane (**2**), pentaprismane, and hexaprismane are the simplest members of this family of cage hydrocarbons.

The monomer of the diamond carbon skeleton is adamantane (**4**, where $X = -H$).

Amantadine (**4**, where $X = -NH_2$) was developed commercially as the first orally active antiviral drug for the prevention of respiratory illness due to influenza A2-Asian viruses.

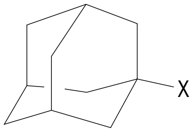


(1)

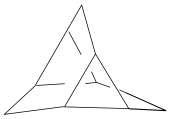


(2)

(3)



(4)



(5)

The other simple diamondoid hydrocarbons are diamantane and triamantane.

Organic chemists have prepared a wide variety of cage hydrocarbons that do not occur in nature. Among these compounds are triasterane (**5**), iceane or wurtzitane, and pagodane. [R.K.Mu.]

Caisson foundation A permanent substructure that, while being sunk into position, permits excavation to proceed inside and also provides protection for the workers against water pressure and collapse of soil. The term caisson covers a wide range of foundation structures. Caissons may be open, pneumatic, or floating type; deep or shallow; large or small; and of circular, square, or rectangular cross section. The walls may consist of timber, temporary or permanent steel shells, or thin or massive concrete. Large caissons are used as foundations for bridge piers, deep-water wharves, and other structures. Small caissons are used singly or in groups to carry such loads as building columns. Caissons are used where they provide the most feasible method of passing obstructions, where soil cannot otherwise be kept out of the bottom, or where cofferdams cannot be used. *See* Bridge; Pile foundation.

The bottom rim of the caisson is called the cutting edge (see illustration). The edge is sharp or narrow and is made of, or faced with, structural steel. The narrowness of the edge facilitates removal of ground under the shell and reduces the resistance of the soil to descent of the caisson.

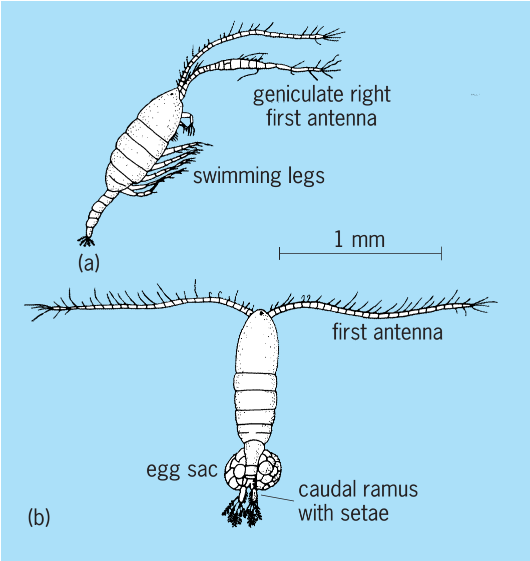
Underside of open caisson for Greater New Orleans bridge over Mississippi River. (*Dravo Corp.*)

An open caisson is a shaft open at both ends. It is used in dry ground or in moderate amounts of water. A pneumatic caisson is like a box or cylinder in shape; but the top is closed and thus compressed air can be forced inside to keep water and soil from entering the bottom of the shaft. A pneumatic caisson is used where the soil cannot be excavated through open shafts or where soil conditions are such that the upward pressure must be balanced. A floating or box caisson consists of an open box with sides and closed bottom, but no top. It is usually built on shore and floated to the site where it is weighted and lowered onto a bed previously prepared by divers. *See* Foundations. [R.D.Che.]

Calamine A term that may refer to either a zinc mineral, $Zn_4Si_2O_7(OH)_2 \cdot H_2O$, which is also known as hemimorphite, or to zinc oxide, ZnO, which is used in medicinal or pharmaceutical products and in cosmetics. *See* Hemimorphite. [E.E.W.]

Calanoida An order of Copepoda that includes the larger and more abundant of the pelagic species. Some authorities consider the Calanoida an order of the subclass Copepoda. In the food cycles of the sea these copepods are the most important group of marine animals because of their overwhelming numbers, ubiquitous distribution, and position at the base of the animal food chain. *See* Copepoda.

The anterior part of the body is cylindrical with five or six segments, and much broader than the posterior part. The first antennae are not for locomotion, but are stabilizers and sinking retarders, and also have an olfactory function. The second antennae and mandibular palps are biramous and create water currents for feeding and slow movement. The five pairs of swimming legs are biramous, but the last pair is sometimes reduced or absent in the female, and the male's right fifth leg may be modified for grasping the female (see illustration).



***Diaptomus*. (*a*) Lateral view of male. (*b*) Dorsal view of female.**

Nearly all calanoids are planktonic and, as a group, occur in all parts of the oceans from the surface to abyssal depths. The geographic and bathymetric ranges of many species are, however, restricted by the nature of water currents and the chemical and physical conditions of the water. In their southernmost range the northern species are found at greater depths. [H.C.Y.]

Calcarea A class of the phylum Porifera, including sponges with a skeleton composed of spicules of calcium carbonate. Calcarea vary from radially symmetrical vase-shaped species to colonies made up of a reticulum of thin tubes to irregular massive forms. Calcareous sponges are mostly of small size and inhabit the shallow waters of all seas, from tidal areas to depths of 600 ft (200 m), with a few species extending down to at least 12,000 ft (4000 m).

Primitive calcareous sponges with an ascon grade of construction consist of colonies of upright tubes with unfolded walls made up of an outer epidermis of pinacocytes and an inner lining of choanocytes. Between these layers of cells is a stratum of mesoglea containing amebocytes and spicules. Cells called porocytes, each perforated by a tubular canal, pierce the walls at intervals and allow water to enter the central cavity or spongocoel. Water leaves by way of a terminal osculum.

A somewhat more complicated structure is seen in calcareous sponges of the sycon grade of construction. Syconoid sponges are usually individual vase-shaped forms with a thick wall enclosing a large central spongocoel opening out through a terminal osculum. In the simplest forms the wall is pushed out at intervals into fingerlike projections, called radial canals, in which the choanocytes are localized. Water enters the radial canals directly through pores without the intervention of special inhalant canals. In most syconoid species, however, a dermal membrane made up of pinacocytes and mesenchyme forms a cortex of greater or less thickness which joins the outer ends of the radial canals. Pores or ostia pierce the dermis and open into inhalant canals which are simply the spaces between the radial canals in some cases.

The leuconoid grade of construction has probably evolved independently among the several lines of calcareous sponges. In those with a syconoid ancestry, the radial canals subdivide into many small flagellated chambers which arise as outpocketings of the radial canal wall. [W.D.H.]

Fossils clearly referable to the class Calcarea do not appear before the Carboniferous, later than any other class of sponges.

The dominant Calcarea preserved from the late Paleozoic (Carboniferous and Permian periods) are the Sphinctozoa. In the Permian probable Calcinea with the pharetronid type of skeleton first appear. Both the Sphinctozoa and the pharetronids become highly varied and abundant in the Permian and Triassic periods. Calcareous sponges remained fairly abundant in shallow water and reefy deposits until the end of the Cretaceous. After that time the Sphinctozoa became extinct and the pharetronids became gradually less abundant. *See* PORIFERA. [R.M.F.]

Calcichordates Primitive fossil members of the phylum Chordata with a calcite skeleton of echinoderm type. They occur in marine rocks of Cambrian to Pennsylvanian age (530–300 million years old) and, because of their skeletons, have traditionally been placed in the phylum Echinodermata. They are shown to be chordates, however, by many chordate anatomical features. Their calcite skeletons merely confirm an old view—that echinoderms and chordates are closely related. There are three main groups of calcichordates—the Soluta, the Corenuta, and the Mitrata. *See* CHORDATA; ECHINODERMATA. [R.P.S.J.]

Calcite A mineral composed of calcium carbonate ($CaCO_3$); one of the most common and widespread minerals in the Earth's crust. Calcite may be found in a great variety of sedimentary, metamorphic, and igneous rocks. It is also an important rock-forming mineral and is the sole major constituent in limestones, marbles, and many carbonatites. Calcite in such rocks is the main source of the world's quicklime and hydrated, or slaked, lime. It is also widely used as a metallurgical flux to a scavenge siliceous impurities by forming a slag in smelting furnaces. It provides the essential calcium oxide component in common glasses and cement. Limestones and marbles of lower purity may find uses as dimension stone, soil conditioners, industrial acid neutralizers, and aggregate in concrete and road building. Calcite in transparent well-formed crystals is used in certain optical instruments. *See* CRYSTAL OPTICS; GLASS; LIME (INDUSTRY); LIMESTONE; STONE AND STONE PRODUCTS.

When pure, calcite is either colorless or white, but impurities can introduce a wide variety of colors: blues, pinks, yellow-browns, greens, and grays have all been reported. Hardness is 3 on Mohs scale. The specific gravity of pure calcite is 2.7102 ± 0.0002 at 68°F (20°C). Calcite has a very low solubility in pure water (less than 0.001% at 77°F or 25°C), but the solubility increases considerably with CO_2 added, as in natural systems from the atmosphere, when more bicarbonate ions and carbonic acid are formed. The solubility is also increased by falling temperature and rising total pressure. Shallow warm seas are supersaturated with calcite, while enormous quantities of calcite are dissolved in the unsaturated deep oceans. *See* CALCIUM; CARBONATE MINERALS. [R.I.Ha.]

Calcium A chemical element, Ca, of atomic number 20, fifth among elements and third among metals in abundance in the Earth's crust, Calcium compounds make up 3.64% of the Earth's crust. The physical properties of calcium metal are given in the table. The metal is trimorphous and is harder than sodium, but softer than aluminum. Like beryllium and aluminum, but unlike the alkali metals, it will not cause burns on the skin. It is less reactive chemically than the alkali metals and the other alkaline-earth metals. *See* PERIODIC TABLE.

Occurrence of calcium is very widespread; it is found in every major land area of the world. This element is essential to plant and animal life, and is present in bones, teeth, eggshell, coral, and many soils. Calcium chloride is present in sea water to the extent of 0.15%. *See* CARBONATE MINERALS.

Calcium metal is prepared industrially by the electrolysis of molten calcium chloride. Calcium chloride is obtained either by treatment of a carbonate ore with hydrochloric acid or as a waste product from the Solvay carbonate process. The pure metal may be machined in a lathe, threaded, sawed, extruded, drawn into wire, pressed, and hammered into plates. *See* ELECTROMETALLURGY.

Properties of calcium metal

Property	Value
Atomic number	20
Atomic weight	40.08
Isotopes (stable)	40, 42, 43, 44, 46, 48
Atomic volume, cm^3/g-atom	25.9
Crystal form	Face-centered cubic
Valence	2+
Ionic radius, nm	0.099
Electron configuration	2882
Boiling point, °C	1487(?)
Melting point, °C	810(?)
Density, g/cm^3 at 20°C	1.55
Latent heat of vaporization at boiling point, kilojoules/g-atom	399

In air, calcium forms a thin film of oxide and nitride, which protects it from further attack. At elevated temperatures, it burns in air to form largely the nitride. The commercially produced metal reacts easily with water and acids, yielding hydrogen that contains noticeable amounts of ammonia and hydrocarbons as impurities.

The metal is employed as an alloying agent for aluminum-bearing metal, as an aid in removing bismuth from lead, and as a controller for graphitic carbon in cast iron. It is also used as a deoxidizer in the manufacture of many steels, as a reducing agent in preparation of such metals as chromium, thorium, zirconium, and uranium, and as a separating material for gaseous mixtures of nitrogen and argon.

Calcium oxide, CaO, is made by the thermal decomposition of carbonate minerals in tall kilns using a continuous-feed process. The oxide is used in high-intensity arc lights (lime-lights) because of its unusual spectral features and as an industrial dehydrating agent. The metallurgical industry makes wide use of the oxide during the reduction of ferrous alloys.

Calcium hydroxide, $Ca(OH)_2$, is used in many applications where hydroxide ion is needed. During the slaking process for producing calcium hydroxide, the volume of the slaked lime [$Ca(OH)_2$] produced expands to twice that of quicklime (CaO), and because of this, it can be used for the splitting of rock or wood. Slaked lime is an excellent absorbent for carbon dioxide to produce the very insoluble carbonate. *See* LIME (INDUSTRY).

Calcium silicide, CaSi, an electric-furnace product made from lime, silica, and a carbonaceous reducing agent, is useful as a steel deoxidizer. Calcium carbide, CaC_2, is produced by heating a mixture of lime and carbon to 5432°F (3000°C) in an electric furnace. The compound is an acetylide which yields acetylene upon hydrolysis. Acetylene is the starting material for a great number of chemicals important in the organic chemicals industry.

Pure calcium carbonate exists in two crystalline forms: calcite, the hexagonal form, which possesses the property of birefringence, and aragonite, the rhombohedral form. Naturally occurring carbonates are the most abundant of the calcium minerals. Iceland spar and calcite are essentially pure carbonate forms, whereas marble is a somewhat impure and much more compact variety which, because it may be given a high polish, is much in demand as a construction stone. Although calcium carbonate is quite insoluble in water, it has considerable solubility in water containing dissolved carbon dioxide, because in these solutions it dissolves to form the bicarbonate. This fact accounts for cave formation in which limestone deposits have been leached away by the acidic ground waters. *See* CARBONATE MINERALS.

The halides of calcium include the phosphorescent fluoride, which is the most widely distributed calcium compound and which has important applications in spectroscopy. Calcium chloride has in the anhydrous form important deliquescent properties which make it useful as an industrial drying agent and as a dust quieter on roads. Calcium chloride hypochlorite (bleaching powder) is produced industrially by passing chlorine into slaked lime, and has been used as a bleaching agent and a water purifier. *See* BLEACHING; CHLORINE.

Calcium sulfate dihydrate is the mineral gypsum. It constitutes the major portion of portland cement, and has been used to help reduce soil alkalinity. A hemihydrate of calcium sulfate, produced by heating gypsum at elevated temperatures, is sold under the commercial name plaster of paris. *See* PLASTER OF PARIS.

Calcium is an invariable constituent of all plants because it is essential for their growth. It is contained both as a structural constituent and as a physiological ion. Calcium is found in all animals in the soft tissues, in tissue fluid, and in the skeletal structures. The bones of vertebrates contain calcium as calcium fluoride, as calcium carbonate, and as calcium phosphate. *See* CALCIUM METABOLISM. [R.F.R.]

Calcium metabolism The calcium ion is essential to the normal function of all living cells. In the human, some 99% of total body calcium resides in the skeleton, and 1% is distributed in the soft tissues and extracellular fluids. The concentration of free calcium ions in the cytoplasm of resting cells and in the extracellular fluids is rigidly maintained, in keeping with the critical physiological importance of calcium to a wide variety of biological processes.

The calcium salts in bone provide structural integrity to the skeleton. They exist largely in the form of hydroxylapatite, a crystalline structure composed of calcium, phosphate, and hydroxyl ions. *See* BONE.

The total concentration of calcium in serum is approximately 10 milligrams per deciliter (2.5 millimoles per liter). Only about one-half of this concentration is represented by free calcium ions, the biologically important fraction, the remainder being bound to proteins and complexed to other ionic species. The concentration of free calcium ions in the extracellular fluids is involved in the maintenance of plasma membrane integrity and permeability, functions as a cofactor for certain clotting factors, and is of crucial importance to normal skeletal mineralization. *See* BLOOD; CELL MEMBRANES; CELL PERMEABILITY.

The concentration of calcium ions in the cytoplasm of resting cells is approximately 10^{-6} molar, only about one-thousandth that present in the extracellular fluids. The cytosolic calcium concentration is tightly regulated by calcium transport mechanisms in the plasma membrane, mitochondria, and microsomes. Calcium ions play various roles in cellular physiology, including coupling of excitation and contraction in skeletal and heart muscle, participation in nerve excitation, regulation of cellular secretion and ion transport, and regulation of the activities of cytosolic enzymes. *See* BIOPOTENTIALS AND IONIC CURRENTS.

At a systemic level, the metabolism of calcium and phosphate ions is intimately related. The two most important hormones that are responsible for regulating the extracellular concentration of these ions are parathyroid hormone and 1,25-dihydroxyvitamin D [1,25-$(OH)_2D$]. The secretion of parathyroid hormone is rigidly controlled by the extracellular concentration of calcium ions, and parathyroid hormone is responsible for the fine regulation of the serum calcium concentration on a minute-to-minute basis, by virtue of its effects on calcium mobilization from bone and the rate of calcium (and phosphate) excretion into the urine. 1,25-Dihydroxyvitamin D is primarily responsible for regulating the quantity of calcium absorbed in the small intestine, and it also participates with parathyroid hormone in the regulation of mineral mobilization from bone. The demonstration of prominent 1,25-$(OH)_2D$ effects requires hours rather than minutes, so that it may be more important to the long-term maintenance of systemic calcium balance than to the minute-to-minute regulation of the serum concentration of calcium ions. There are a large number of human disorders affecting the parathyroid glands and vitamin D metabolism. *See* PARATHYROID HORMONE; PHOSPHATE METABOLISM; VITAMIN D. [A.E.Bro.]

Calculators Desktop or, more often, portable electronic devices that are used to perform arithmetic, statistical, or other, more complex processing operations at the step-by-step direction of the user or by execution of a program (a stored sequence of processing operations) selected and initiated by the user. Models are offered with particular stored programs specialized to professional fields such as finance and science, and results are displayed in formats ranging from the still prevalent single line of alphanumeric characters to small viewing screens capable of graphical representations.

Calculator designs use either a customized integrated circuit or a microprocessor and a small number of peripheral integrated circuits to perform their operations. A customized integrated circuit will accept and interpret keystrokes made by the user, perform the requested operation, and generate signals to drive the display device, providing the user an indication of the processing result. Complex mathematical processing abilities are built into some calculator integrated circuits, and some accept plug-in memory modules that extend the available processing sequences. A single line of alphanumeric readout is usually coupled with a customized calculator integrated circuit. Microprocessor-based calculators are generally more complex, more flexible, more capable, and more costly. Some accept memory modules or programs selected from a library to meet the particular requirements of a application and downloaded to the unit. The peripheral integrated circuits effect interfacing of the microprocessor with data and program entry and display, readout, and printout devices. *See* MICROPROCESSOR. [W.W.Mo.]

Calculus The branch of mathematics dealing with two fundamental operations, differentiation and integration, which are carried out on functions. The subject, as traditionally developed in college textbooks, is partly an elementary development of the purely theoretical aspects of these operations and their interrelation, partly a development of rules and formulas for applying calculus to the standard functions which arise in algebra and trigonometry (with exponentials and logarithms included), and partly a collection of applications to problems of geometry, physics, chemistry, engineering, economics, and perhaps a few other subjects.

The fundamental concept of differential calculus is that of the derivative of a function of one variable. The classical physical prototype of this concept is that of instantaneous velocity, which is the derivative of distance as a function of time. The derivative also has a highly significant geometrical realization which depends upon the graphical representation of a function in rectangular coordinates (x, y). If y is a differentiable function of x, perhaps as x increases from x_1 to x_2, the graph of the function is a continuous curve with exactly one y for each x, and at each point the curve has a tangent line which is not parallel to the y axis. If ϕ is the angle, measured counterclockwise, from the positive x direction to the tangent (Fig. 1), then tan ϕ is equal to the derivative of y with respect to x. (This is on the supposition

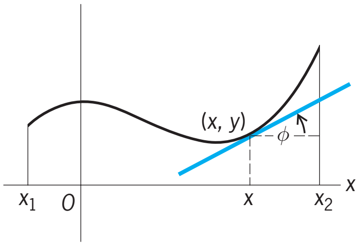


Fig. 1. Graphical representation of the derivative of *f*(*x*).

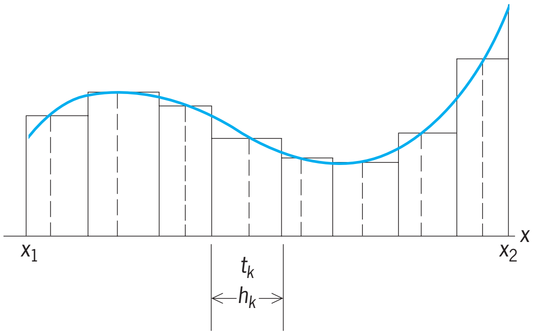

Fig. 2. The definite integral.

that the same unit of length is used along the two axes.) This tan ϕ is also called the slope of the curve.

The standard notation for the derivative of y with respect to x is dy/dx. If the functional notation $y = f(x)$ is used, the derivative is often denoted by $f'(x)$. *See* DIFFERENTIATION.

If f is a function defined on the finite interval from x_1 to x_2 inclusive, the definite integral of f from x_1 to x_2, denoted by

$$\int_{x_1}^{x_2} (x)\,dx$$

is defined by applying to f a rather intricate process which entails the consideration of what are called approximating sums. When the function f is subjected to certain restrictions, this process culminates in the determination of a number as the limit of the approximating sums, and this number is called the definite integral of f from x_1 to x_2. The integral is not defined unless the approximating sums do converge to a well-defined limit. A sufficient condition that this be so is that the function f be continuous.

There is a geometrical representation of the process of defining the definite integral, and it furnishes a plausible argument for the convergence of the approximating sums to a limit. Divide the interval from x_1 to x_2 into a finite number N of not necessarily equal parts. Let the lengths of these parts be h_1, $h_2, \ldots h_N$ and let t_k be the value of x in the kth part (Fig. 2). Then the expression

$$f(t_1)h_1 + f(t_2)h_2 + \ldots + f(t_N)h_N$$

is called an approximating sum. In Fig. 2, where the function is continuous and the function values are all positive, each term $f(t_k)h_k$ in the approximating sum is equal to the area of a certain shaded rectangle, and the whole sum is an approximation of the area between the graph of the function and x axis, from x_1 to x_2 inclusive. The limiting process is carried on by the increasing N and making the largest of the h_k's approach 0. It is then intuitively clear that the definite integral is the number which represents the exact area between the x axis and the graph. This geometrical interpretation of the integral is the basis of an important application of integral calculus, to the calculation of areas.

It would be tedious and difficult in practice to compute definite integrals by actually working out the limits of approximating sums. It is therefore fortunate that by purely mathematical reasoning it is possible to demonstrate a theorem which links derivatives and integrals and makes it possible, in many important instances, to compute definite integrals by an easier procedure. *See* INTEGRATION.

The two fundamental theorems of calculus are as follows:

1. For the calculation of

$$\int_{x_1}^{x_2} f(x)\,dx$$

find, if possible, a function F with continuous derivative F' such that $F'(x) = f(x)$ when $x_1 \leqq x \leqq x_2$. Then Eq. (1) can be written.

$$\int_{x_1}^{x_2} f(x)\,dx = F(x_2) - F(x_1) \qquad (1)$$

This is one of the two central theorems.

2. Suppose f is continuous, and consider the function F defined by Eq. (2).

$$F(x) = \int_{x_1}^{x_2} f(t)\,dt \qquad (2)$$

Then F has a derivative given by $F'(x) = f(x)$. [A.L.Ta.]

Calculus of variations

An extension of the part of differential calculus which deals with maxima and minima of functions of a single variable. The functions of the calculus of variations depend in an essential way upon infinitely many independent variables. Classically these functions are usually integrals whose integrand depends on a function whose specification by any finite number of parameters is impossible. For example, let C be a smooth bounded region of a space of m variables, x_1, $x_2, \ldots, x_m$, let y be any function of some smooth class on C and its boundary into real numbers or into n-tuples of real numbers and taking specified values on the boundary, and let $f(x, y, p)$ be a smooth function of $2m + 1$ variables $x_1, x_2, \ldots, x_m, y, p_1$, $p_2, \ldots, p_m$. Then the integral, shown below, is a function on

$$J = \int \cdots \int_C f(x, y, y_x)$$

the space of functions y to the real numbers, and this space of functions is infinite dimensional unless excessive restrictions are placed on it. Here y_x denotes the derivatives $\partial y/\partial x$.

The calculus of variations studies such functions and their maxima and minima. The limitation of the competing functions is made realistically, and with sufficient restrictions it is possible to arrive at a rewarding theory; these restrictions do not always include the fixed boundary conditions stated above.

Principal applications may be to physical systems involving flexible components or time-dependent orbits; equilibrium positions or orbits may be determined by minimizing energy or action integrals. The problems are of mathematical interest because of intrinsic difficulties (largely related to lack of topological compactness of bounded regions in spaces of infinitely many dimensions) and possibly because more progress with difficult nonlinear problems has been made here than elsewhere. *See* HAMILTON'S PRINCIPLE; LEAST-ACTION PRINCIPLE.

Much of the work on the calculus of variations is devoted to meticulous detail with regard to the number of derivatives assumed to be available for various functions, particularly the competitive admissible functions $y(x)$. If too many derivatives are assumed, minima may not exist; if too few are assumed, the solution might not be sufficiently smooth to be acceptable in the light of the original statement of the problem. In an attempt to use fewer derivatives, different approaches are used depending on the number of independent variables x. [C.M.T.]

Calculus of vectors

In its simplest form, a vector is a directed line segment. Physical quantities, such as velocity, acceleration, force, and displacement, are vector quantities, or simply vectors, because they can be represented by directed line segments. Vector analysis is a tool of the mathematical physicist, because many physical laws can be expressed in vector form.

Two vectors $\mathbf{a}$ and $\mathbf{b}$ are added according to the parallelogram law (Fig. 1). An equivalent definition is as follows: From the end point of $\mathbf{a}$, a vector is constructed parallel to $\mathbf{b}$, of the same magnitude and direction as $\mathbf{b}$. The vector from the origin of $\mathbf{a}$ to the end point of $\mathbf{b}$ yields the vector sum $\mathbf{s} = \mathbf{a} + \mathbf{b}$ (Fig. 2). Any number of vectors can be added by this rule.

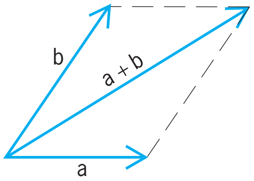

Fig. 1. Addition of two vectors.

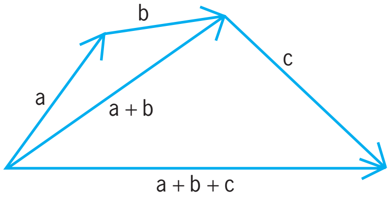

Fig. 2. Addition of three vectors.

Given a vector **a**, a class of vectors can be formed which are parallel to **a** but of different magnitudes. If x is a real number, the vector $x\mathbf{a}$ is defined to be parallel to **a** of magnitude $|x|$ times that of **a**. For $x < 0$, the two vectors **a** and $x\mathbf{a}$ have the same sense of direction, whereas for $x < 0$ the vector $x\mathbf{a}$ is in a reverse direction from that of **a**. The vector $-\mathbf{a}$ is the negative of the vector **a**, such that $\mathbf{a} + (-\mathbf{a}) = \mathbf{0}$, with **0** designated as the zero vector (a vector with zero magnitude). Subtraction of two vectors is defined by Eq. (1).

$$\mathbf{a} - \mathbf{b} = \mathbf{b} + (-\mathbf{b}) \qquad (1)$$

The cartesian coordinate frame of analytic geometry is very useful for yielding a description of a vector (Fig. 3). The unit vectors **i**, **j**, **k** lie parallel to the positive x, y, and z axes, respectively. Any vector can be written as a linear combination of **i**, **j**, **k**. From Fig. 3, it is noted that Eq. (2) holds. Furthermore, the

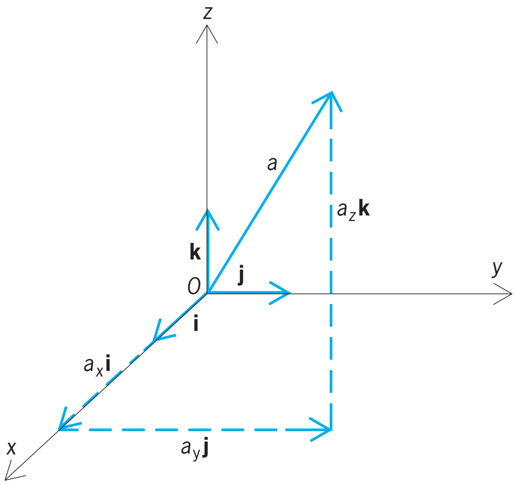

Fig. 3. Vectors in cartesian coordinate system.

$$\mathbf{a} = a_x\mathbf{i} + a_y\mathbf{j} + a_z\mathbf{k} \qquad (2)$$

scalars a_x, a_y, a_z are simply the projections of **a** on the x, y, and z axes, respectively, and are designated as the components of **a**. Thus, a_x is the x component of **a**, and so on. If the vector **b** is described by $\mathbf{b} = b_x\mathbf{i} + b_y\mathbf{j} + b_z\mathbf{d}$, then Eq. (3) holds.

$$\alpha\mathbf{a} + \beta\mathbf{b} = (\alpha a_x + \beta b_x)\mathbf{i} + (\alpha a_y + \beta Y_y)\mathbf{j} + (\alpha a_z + \beta b_z)\mathbf{k} \qquad (3)$$

From two vectors **a** and **b**, a scalar quantity is formed from the definition in Eq. (4), where θ is the angle between the two

$$\mathbf{a} \cdot \mathbf{b} = |\mathbf{a}| \cdot |\mathbf{b}| \cos\theta \qquad (4)$$

vectors when drawn from a common origin (Fig. 4).

In three-dimensional space, a vector can be formed from two vectors **a** and **b** in the following manner if they are non-parallel. Let **a** and **b** have a common origin defining a plane, and let **c** be that vector perpendicular to this plane of magnitude $|\mathbf{c}| = |\mathbf{a}|\,|\mathbf{b}| \sin\theta$. If **a** is rotated into **b** through the angle θ, a right-hand screw will advance in the direction of **c** (Fig. 5). Thus Eq. (5) can be written.

$$\mathbf{c} = \mathbf{a} \times \mathbf{b} = |\mathbf{a}|\,|\mathbf{b}| \sin\theta\, \mathbf{n} \qquad (5)$$

The distributive law can be shown to hold for the vector product so that Eq. (6) holds.

$$(\mathbf{a} + \mathbf{b}) \times (\mathbf{c} + \mathbf{d}) = \mathbf{a} \times \mathbf{c} + \mathbf{a} \times \mathbf{d} + \mathbf{b} \times \mathbf{c} + \mathbf{b} \times \mathbf{d} \qquad (6)$$

It follows from

$$\mathbf{i} \times \mathbf{i} = \mathbf{j} \times \mathbf{j} = \mathbf{k} \times \mathbf{k} = \mathbf{0}$$
$$\mathbf{i} \times \mathbf{c} = \mathbf{k}, \mathbf{j} \times \mathbf{k} = \mathbf{i}, \mathbf{k} \times \mathbf{i} = \mathbf{j}$$

that for

$$\mathbf{a} = a_x\mathbf{i} + a_y\mathbf{j} + a_z\mathbf{k} \qquad \mathbf{b} = b_x\mathbf{i} + b_y\mathbf{j} + b_z\mathbf{k}$$

Eq. (7) holds. The expression in Eq. (7) is to be expanded by the ordinary rules governing determinants.

$$\mathbf{a} \times \mathbf{b} = \begin{vmatrix} \mathbf{i} & \mathbf{j} & \mathbf{k} \\ a_x & a_y & a_z \\ b_x & b_y & b_z \end{vmatrix} \qquad (7)$$

It is easy to verify that a reflection of the space coordinates given by $x' = -x$, $y' = -y$, $z' = -z$, reverses the sign of the components of a vector. Under a space reflection, however, the components of the vector $\mathbf{a} \times \mathbf{b}$ do not change sign. This is seen from Eq. (7), for if a_x, a_y, a_z are replaced by $-a_x$, $-a_y$, $-a_z$, and if b_x, b_y, b_z are replaced by $-b_x$, $-b_y$, $-b_z$, the components of $\mathbf{a} \times \mathbf{b}$ remain invariant. Hence, $\mathbf{a} \times \mathbf{b}$ is not a true vector and therefore is given the title pseudovector. In electricity theory the magnetic field vector **B** is a pseudovector, whereas the electric field vector is a true vector provided the electric charge is a true scalar under a reflection of axes.

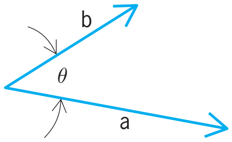

Fig. 4. Scalar product of two vectors.

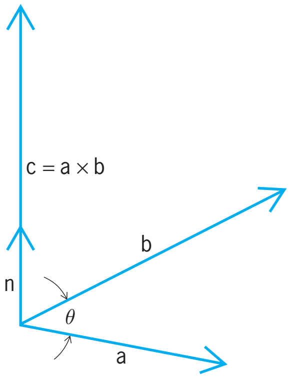

Fig. 5. Vector product of two vectors.

There are three differentiation processes that are of conceptual value in the study of vectors: the gradient of a scalar, the divergence of a vector, and the curl of a vector.

From the scalar $\phi(x, y, z)$, one can form the three partial derivatives $\partial\phi/\partial x$, $\partial\phi/\partial y$, $\partial\phi/\partial z$, from which the vector in Eq. (8) can

$$\left\{\begin{array}{c}\text{gradient of } \phi\\ \text{grad } \phi\\ \text{del } \phi \equiv \nabla\phi\end{array}\right\} = \frac{\partial}{\partial x}\mathbf{i} + \frac{\partial}{\partial y}\mathbf{j} + \frac{\partial}{\partial z}\mathbf{k} \qquad (8)$$

be formed. The vector, grad ϕ, has two important properties. Grad ϕ is a vector field normal to the surface $\phi(x, y, z) =$ constant at every point of the surface. Moreover, grad ϕ yields that unique direction such that ϕ increases at its greatest rate.

The del operator defined by Eq. (9) plays an important role in the development of the differential vector calculus. For the

$$\nabla = \mathbf{i}\frac{\partial}{\partial x} + \mathbf{j}\frac{\partial}{\partial y} + \mathbf{k}\frac{\partial}{\partial z} \qquad (9)$$

vector field of Eq. (10), the divergence of $\mathbf{v}$ is defined by Eq. (11). The divergence of a vector is a scalar.

$$\mathbf{v} = v_1(x, y, z)\,\mathbf{i} + v_2(x, y, z)\,\mathbf{j} + v_3(x, y, z)\,\mathbf{k} \qquad (10)$$

$$\operatorname{div}\mathbf{v} = \nabla\cdot\mathbf{v} = \frac{\partial v_1}{\partial x} + \frac{\partial v_2}{\partial y} + \frac{\partial v_3}{\partial z} \qquad (11)$$

By use of the del operator one obtains quite formally Eq. (12). The vector $\nabla \times \mathbf{v}$ is called the curl of $\mathbf{v}$ (curl $\mathbf{v}$). Under

$$\nabla\times\mathbf{v} = \begin{vmatrix} \mathbf{i} & \mathbf{j} & \mathbf{k} \\ \dfrac{\partial}{\partial x} & \dfrac{\partial}{\partial y} & \dfrac{\partial}{\partial z} \\ v_1 & v_2 & v_3 \end{vmatrix}$$

$$= \left(\frac{\partial v_3}{\partial y} - \frac{\partial v_2}{\partial z}\right)\mathbf{i} + \left(\frac{\partial v_1}{\partial z} - \frac{\partial v_3}{\partial x}\right)\mathbf{j} + \left(\frac{\partial v_2}{\partial z} - \frac{\partial v_1}{\partial y}\right)\mathbf{k} \qquad (12)$$

a reflection of space coordinates, $\partial v_3/\partial y \to \partial(-v_3)/\partial(-y) = \partial v_3/\partial y$, and so on, so that the curl of $\mathbf{v}$ is a pseudovector.

If a closed surface is decomposed into a large number of small surfaces, a vector field normal to the surface can be constructed, each normal element being represented by $d\sigma$. The magnitude of $d\sigma$ is the area of the surface element dS, $d\sigma = \mathbf{N}\,dS$.

If $\mathbf{f}$ is a vector field defined at every point of the surface, then notation (13) represents the total flux of $\mathbf{f}$ through the surface S.

$$\iint_S \mathbf{f}\cdot d\sigma \qquad (13)$$

The elements $\mathbf{d}\sigma$ point outward from the interior of S.

The divergence theorem of Gauss states that Eq. (14) is true,

$$\iint_S \mathbf{f}\cdot d\sigma = \iiint_R (\nabla\cdot\mathbf{f})\,d\tau \qquad (14)$$

where R is the region enclosed by S, $d\tau$ a volume element of R. *See* GAUSS' THEOREM.

The line integral of a vector field is described as follows: Let Γ be a space curve, and let $\mathbf{t}$ be the unit vector field tangent to Γ at every point of Γ in progressing from A to B, the initial and end points of the trajectory Γ.

The scalar integral in notation (15) is called the line integral

$$\int_A^B (\mathbf{f}\cdot\mathbf{t})\,ds \qquad (15)$$

of $\mathbf{f}$ along Γ, with arc length s measured along Γ. If $\mathbf{f}$ is a force field, notation (15) represents the work performed by the force field if a unit test particle is taken from A to B along Γ.

The value of the integral of notation (15) will generally depend on the path from A to B. However, if $\mathbf{f} = \nabla\phi$, then

$$\int_A^B (\mathbf{f}\cdot\mathbf{t})\,ds = \int_A^B \nabla\phi\cdot d\mathbf{r} = \int_A^B d\phi = \phi(B) - \phi(A)$$

and the line integral is independent of the path of integration.

The theorem of Stokes states that Eq. (16) holds, where Γ

$$\oint_\Gamma f\cdot dr = \iint_S (\nabla\times\mathbf{f})\cdot d\sigma \qquad (16)$$

is the boundary of the open surface S. *See* STOKES' THEOREM.

[H.La.]

Caldera A large volcanic collapse depression, typically circular to slightly elongate in shape, the dimensions of which are many times greater than any included vent. Calderas range from a few miles to 37 mi (60 km) in diameter. A caldera may resemble a volcanic crater in form, but differs genetically in that it is a collapse rather than a constructional feature. The topographic depression resulting from collapse is commonly widened by slumping of the sides along concentric faults, so that the topographic crater wall lies outside the caldera wall. As originally defined, the term caldron referred to volcanic subsidence structures, and caldera referred only to the topographic depression formed at the surface by collapse. However, the term caldera is now common as a synonym for caldron, denoting all features of collapse, both topographic and structural. *See* PETROLOGY.

Calderas occur primarily in three different volcanic settings, each of which affects their shape and evolution: basaltic shield cones, stratovolcanoes, and volcanic centers consisting of preexisting clusters of volcanoes. These last calderas, associated with broad, large-volume andesitic to rhyolitic ignimbrite sheets, are generally the largest and most impressive, and are those generally denoted by the term. Calderas have been formed throughout much of the Earth's history, ranging in age from Precambrian (greater than 1.4 billion years old) to Holocene (for example, Krakatau in Indonesia, which erupted in 1883). *See* RHYOLITE; VOLCANO.

In addition to Earth, large calderas occur on Mars, Venus, and Jupiter's moon Io. The presence of calderas on four solar system bodies indicates that the underlying mechanisms of shallow intrusion and caldera collapse are basic processes in planetary geology. *See* MAGMA.

Collapse occurs because of withdrawal of magma from an underlying chamber some 2.4–3.6 mi (4–6 km) beneath the surface, resulting in foundering of the roof into the chamber. Withdrawal of magma may occur either by relatively passive eruption of lavas, as in the case of calderas formed on basaltic shield cones, or by catastrophic eruption of pyroclastic material, as accompanies formation of the largest calderas.

Caldera-forming eruptions probably last only a few hours or days. Eruption of pyroclastic material begins as gases (predominantly water) that are dissolved in the magma come out of solution at shallow depths. Magma is explosively fragmented into particles ranging in size from micrometers to meters. An eruption column develops, rising several miles into the atmosphere. This first and most explosive phase of the eruption, known as the Plinian phase, covers the area around the vent with pumice. Caldera subsidence occurs during eruption. As caldera subsidence proceeds and eruption becomes less explosive, the Plinian eruption column collapses. This collapse produces hot, ground-hugging pyroclastic flows that can travel as far as 93 mi (150 km) outward from the vent at speeds of 330 ft/s (100 m/s). Successive collapses of the column produce multiple flow units with an aggregate thickness that may be several hundreds of feet thick near the caldera.

The floors of many of the largest calderas (typically those with diameters exceeding 6 mi or 10 km) have been domed upward, resulting in a central massif or resurgent dome. Resurgence results from the continued or renewed buoyant rise of magma after collapse.

Calderas typically contain or are associated with extensive hydrothermal systems, because of two factors: (1) the shallow magma chambers that underlie them provide a readily available source of heat: and (2) the floors of calderas may be extensively fractured, which, along with the main ring faults, allows meteoric water to penetrate deeply into the crust beneath calderas. Hydrothermal activity related to a caldera system can occur any time after magmas rise to shallow crustal levels, but it is dominant late in caldera evolution.

Many metals, including such base and precious metals as molybdenum, copper, lead, zinc, silver, gold, mercury, uranium, tungsten, and antimony, are mobile in hydrothermal circulation systems driven by the shallow intrusions which underlie and give rise to large calderas. Many economically important ore deposits in the western United States lie within calderas. *See* ORE AND MINERAL DEPOSITS. [W.S.Ba.]

Calendar A system that gives a name to each day. Ancient calendars were based on observations of phenomena such as the waxing and waning of the Moon, the change in seasons, or the movement of heavenly bodies. Modern calendars tend to be based solely on arithmetical rules, distanced from their motivation in nature.

Most calendars divide a year into an integral number of months and divide months into an integral number of days. However, these astronomical periods—day, month, and year—are incommensurate, so exactly how these time periods are coordinated and the accuracy with which they approximate their astronomical values are what differentiate one calendar from another. *See* DAY; EARTH ROTATION AND ORBITAL MOTION; MONTH; YEAR.

Dozens of calendars are still in use, in addition to the almost universally used Gregorian calendar. Many religious holidays and national events are determined by dates on these calendars. Solar calendars—including the Egyptian, Julian, Coptic, Ethiopic, Gregorian, and Persian—are based on the yearly solar cycle, whereas lunar calendars such as the Islamic and lunisolar calendars such as the Hebrew, Hindu, and Chinese take the monthly lunar cycle as the basic building block. Most solar calendars are divided into months, but these months are divorced from the lunar events; they are sometimes related to the movement of the Sun through the twelve signs of the zodiac.

Almost every calendar incorporates a notion of “leap” year to correct the cumulative error caused by approximating a year by an integral number of days and months. Solar calendars add a day every few years to keep up with the astronomical year.

The simplest naming convention would be to assign an integer to each day; fixing day 1 would determine the whole calendar. The Babylonians had such a day count, as did the Maya and the Hindus. Astronomers, especially those studying variable stars, use Julian day numbers to specify dates. The Julian period, introduced in 1583 by Joseph Justus Scaliger, was originally a counting of years in a cycle of 7980 years, starting from 4713 B.C.E. (before the common era; or B.C.); nineteenth-century astronomers adapted the system into a strict counting of days backward and forward from JD0 = noon on Monday, January 1, 4713 B.C.E. (Julian) = noon on Monday, November 24, −4713 (Gregorian). A fractional part of a Julian day gives the fraction of a day beyond noon. Computer scientists often use diurnal calendars as an intermediate device for converting from one calendar to another.

The Gregorian calendar, now in common use throughout the world, is based on a 12-month year that closely approximates the Earth’s solar cycle. This calendar was designed by a commission assembled by Pope Gregory XIII in the sixteenth century; the main author of the new system was the Naples astronomer Aloysius Lilius. This calendar is based on a 365-day common year divided into 12 months, and on 366 days in leap years, the extra day being added to the second month. A year is a leap year if it is divisible by 4 and is not a century year (multiple of 100) or if it is divisible by 400. For example, 1900 is not a leap year; 2000 is a leap year. The Gregorian calendar differs from its predecessor, the Julian calendar, only in that the Julian calendar did not include the century rule for leap years—all century years were leap years.

Since every fourth year on the Julian calendar was a leap year, a cycle of 4 years contained $(4 \times 365) + 1 = 1461$ days, giving an average length of year of 365.25 days. This is somewhat more than the mean length of the tropical year, and over the centuries the calendar slipped with respect to the seasons. By the sixteenth century, the date of the spring equinox had shifted from around March 21 to around March 11. Pope Gregory XIII instituted only a minor change in the calendar: century years not divisible by 400 would no longer be leap years. (He also improved the rules for Easter.) Thus, three out of four century years are common years, giving a cycle of 400 years containing $(400 \times 365) + 97 = 146{,}097$ days and an average year length of $146{,}097/400 = 365.2425$ days. He also corrected the accumulated 10-day error in the calendar by proclaiming that Thursday, October 4, 1582 C.E., the last date in the old-style (Julian) calendar, would be followed by Friday, October 15, 1582, the first day of the new-style (Gregorian) calendar. Catholic countries followed his rule, but Protestant countries resisted. Turkey did not switch to the Gregorian calendar until 1927.

The Islamic calendar is an example of a strictly lunar calendar, with no intercalation of months (unlike lunisolar calendars). Its independence of the solar cycle means that its months do not occur in fixed seasons but migrate through the solar year.

Lunisolar calendars invariably alternate 12- and 13-month years. The so-called Metonic cycle is based on the observation that 19 solar years contain almost exactly 235 lunar months. This correspondence, named after the Athenian astronomer Meton and known much earlier to ancient Babylonian and Chinese astronomers, makes a relatively simple and accurate fixed solar/lunar calendar feasible. The $235 = (12 \times 12) + (7 \times 13)$ months in the cycle are divided into 12 years of 12 months and 7 leap years of 13 months. The 7 leap years are evenly distributed within the 19-year cycle, with gaps of 1 or 2 years between them. The Metonic cycle is (currently) accurate to within 6.5 minutes a year and is still employed in the Hebrew calendar (instituted in 359 C.E.) and for the ecclesiastical calculation of Easter. [N.D.; E.M.Re.]

Calibration The process of determining the performance parameters of an artifact, instrument, or system by comparing it with measurement standards. Adjustment may be a part of a calibration, but not necessarily. A calibration assures that a device or system will produce results which meet or exceed some defined criteria with a specified degree of confidence.

Two important measurement concepts related to calibration are precision and accuracy. Precision refers to the minimum discernible change in the parameter being measured, while accuracy refers to the actual amount of error that exists in a calibration. All measurement processes used for calibration are subject to various sources of error. It is common practice to classify them as random or systematic errors. When a measurement is repeated many times, the results will exhibit random statistical fluctuations which may or may not be significant. Systematic errors are offsets from the true value of a parameter and, if they are known, corrections are generally applied, eliminating their effect on the calibration. If they are not known, they can have an adverse effect on the accuracy of the calibration. High-accuracy calibrations are usually accompanied by an analysis of the sources of error and a statement of the uncertainty of the calibration. Uncertainty indicates how much the accuracy of a calibration could be degraded as a result of the combined errors. *See* ANALYSIS OF VARIANCE; DISTRIBUTION (PROBABILITY); INSTRUMENT SCIENCE; PHYSICAL MEASUREMENT; PROBABILITY; PROBABILITY (PHYSICS); STATISTICS. [B.Br.]

Caliche A soil that is mineralogically an impure limestone. Such soils are also known as duricrust, kunkar, nari, kafkalla, Omdurman lime, croute, and race. Many soil profiles in semiarid climates (that is, those characterized by a rainfall of 4–20 in. or 10–50 cm per year) contain concentrations of calcium carbonate ($CaCO_3$). This calcium carbonate is not an original feature of the soils but has been added during soil formation either by direct precipitation in soil pores or by replacement of preexisting material. Fossil analogs of caliche, which are widely reported in ancient sedimentary sequences, are referred to as calcrete or cornstone. *See* LIMESTONE; SOIL.

The principal control on the formation of caliche is a hydrologic regime in which there is sufficient moisture to introduce calcium carbonate in solution to the soil but not enough to leach it through the system. As a result, calcium carbonate precipitates in the soil during periods of evaporation, and it will slowly increase in amount as long as the hydrologic setting remains stable. The source of the carbonate may be from the dissolution of adjacent limestones, from the hydrolysis of plagioclase and other silicates, or from carbonate loess.

Within the climatic constraints noted above, most caliche forms in river floodplains and near the surface of alluvial fans. In addition, caliche deposits may form within exposed marine and lacustrine limestones during periods of sea-level fall or lake desiccation. Caliche may also form at inert pediment (eroded rock) surfaces; in the geological record such surfaces will be seen as unconformities. In this context it is interesting that the first unconformity ever recognized as such, by James Hutton in 1787 on the Isle of Arran, western Scotland, is characterized by a development of caliche. *See* UNCONFORMITY.

The mineralogy of the host soil or rock in which a caliche develops may vary considerably; it is not essential for there to be any preexisting carbonate grains within the regolith. The most favorable medium is a clay-rich soil of limited permeability. Low permeability provides the residence time in the soil pores necessary for calcite to precipitate. *See* CALCITE; REGOLITH. [N.Do.]

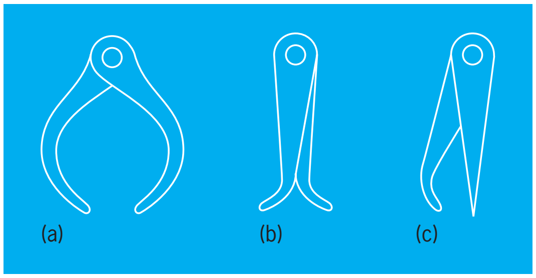
Caliciales An order of the Ascolichenes. This order is characterized by an unusual apothecium. The hymenial layer originates normally, but by the time the spores are mature, the asci and paraphyses have partially disintegrated into a mass of spores and hymenial tissues known as a mazaedium. Two families, Caliciaceae and Roesleriaceae, are so close that some species in either one may or may not lichenize symbiotic algae. The family Cypheliaceae is more typically crustose, with sessile apothecia and a more fully developed thallus. The Sphaerophoraceae are fruticose but the thallus is solid. The apothecia are open or enclosed in a spherical chamber at the tips of branches. The largest genus, *Sphaerophorus*, is widespread in boreal zones and mountains of both hemispheres. [M.E.H.]

Californium A chemical element, Cf, atomic number 98, the ninth member of the actinide series of elements. Its discovery and production have been based upon artificial nuclear transmutation of radioactive isotopes of lighter elements. All isotopes of californium are radioactive, with half-lives ranging from a minute to about 1000 years. Because of its nuclear instability, californium does not exist in the Earth's crust. *See* ACTINIDE ELEMENTS; BERKELIUM; PERIODIC TABLE; RADIOACTIVITY.

The chemical properties are similar to those observed for other 3+ actinide elements: a water-soluble nitrate, sulfate, chloride, and perchlorate. Californium is precipitated as the fluoride, oxalate, or hydroxide. Ion-exchange chromatography can be used for the isolation and identification of californium in the presence of other actinide elements. Californium metal is quite volatile and can be distilled at temperatures of the order of 1100–1200°C (2010–2190°F). It is chemically reactive and appears to exist in three different crystalline modifications between room temperature and its melting point, 900°C (1600°F).

The most easily produced isotope for many purposes is ^{252}Cf, which is obtained in gram quantities in nuclear reactors and has a half-life of 2.6 years. It decays partially by spontaneous fission, and has been very useful for the study of fission. It has also had an important influence on the development of counters and electronic systems with applications not only in nuclear physics but in medical research as well. *See* TRANSURANIUM ELEMENTS. [G.T.S.]

Caliper An instrument with two legs used for measuring linear dimensions. Calipers may be fixed, adjustable, or movable. Fixed calipers are used in routine inspection of standard products; adjustable calipers are used similarly but can be reset to slightly different dimensions if necessary. Movable calipers can be set to match the distance being measured. The legs may pivot about a rivet or screw in a firm-joint pair of calipers; they may pivot about a pin, being held against the pin by a spring and set in position by a knurled nut on a threaded rod; or the legs may slide either directly (caliper rule) or along a screw (micrometer caliper) relative to each other. *See* MICROMETER.



Some typical machinist's calipers. (*a*) Outside. (*b*) Inside. (*c*) Hermaphrodite. (*After R. J. Sweeney, Measurement Techniques in Mechanical Engineering, John Wiley and Sons, Inc., 1953*)

The legs may be shaped to facilitate measuring outside dimensions, inside dimensions, surface dimensions as between points on a plate, or from a surface into a hole as in a keyway (see illustration). *See* GAGE. [F.H.R.]

Callitrichales An order of flowering plants, division Magnoliophyta (Angiospermae), in the subclass Asteridae of the class Magnoliopsida (dicotyledons). The order consists of three small families with about 50 species, most of which are aquatics or small herbs of wet places, and have much reduced vascular systems. The flowers are small and solitary in the axils of leaves or bracts. The perianth is nearly or completely absent. The pistil consists of two carpels united to form a compound, unilocular or four-chambered ovary, or sometimes the pistil appears to be of a single carpel. The Callitrichales are placed in the Asteridae largely on the basis of their embryology and phytochemistry. The ovules are anatropous and tenuinucellular and have a single integument, and the plants generally produce iridoid substances. *See* ASTERIDAE; MAGNOLIOPHYTA; MAGNOLIOPSIDA; PLANT KINGDOM. [T.M.Ba.]

Calobryales An order of liverworts. They are characterized by prostrate, simple or branched, leafless stems and erect, leafy branches of a radial organization. The order consists of a single genus, *Calobryum*, and 12 species, most of them occupying restricted ranges in apparently relic areas indicative of an ancient origin and dispersal. The order is considered primitive in comparison with the Jungermanniales, in which the leafy axis tends to be prostrate and the underleaves reduced. The stems are thick and fleshy, with no differentiated outer layers. Rhizoids are lacking. The leaves may be small or lacking below, larger and more crowded above. They are three-ranked, with those of one rank sometimes more or less reduced. They are broad, unlobed, and entire. *See* BRYOPHYTA; JUNGERMANNIALES; JUNGERMANNIIDAE. [H.Cr.]

Calomel Mercury(I) chloride, Hg_2Cl_2, a covalent compound which is insoluble in water. The substance sublimes when heated. The formula weight is 472.086 and the specific gravity is 7.16 at 20°C (68°F). The material is a white, impalpable powder consisting of fine tetragonal crystals.

Calomel is used in preparing insecticides and medicines. It is well known in the laboratory as the constituent of the calomel reference electrodes which are commonly used in conjunction with a glass electrode to measure pH. *See* MERCURY (ELEMENT). [E.E.W.]

Calorimetry The measurement of the quantity of heat energy involved in processes such as chemical reactions, changes of state, and mixing of substances, or in the determination of heat capacities of substances. The unit of energy in the International System of Units is the joule. Another unit still being used is the calorie, defined as 4.184 joules.

A calorimeter is an apparatus for measuring the quantity of heat energy released or absorbed during a process. Since there are many processes that can be studied over a wide range of temperature and pressure, a large variety of calorimeters have been developed.

Nonisothermal calorimeters measure the temperature change that occurs during the process. An aneroid-type nonisothermal calorimeter is normally constructed of a material having a high thermal conductivity, such as copper, so that there is rapid temperature equilibration. It is isolated from its surroundings by a high vacuum to reduce heat leaks. This type of calorimeter can be used for determining the heat capacity of materials when measurements involve low temperatures. Aneroid-type nonisothermal calorimeters have also been developed for measuring the energy of combustion for small samples of rare materials.

With most nonisothermal calorimeters, it is necessary to relate the temperature rise to the quantity of energy released in the process. This is done by determining the calorimeter constant, which is the amount of energy required to increase the temperature of the calorimeter itself by 1°. This value can be determined by electrical calibration or by measurement on a well-defined test system. For example, in bomb calorimetry the calorimeter constant is often determined from the temperature rise which occurs when a known mass of a very pure standard sample of benzoic acid is burned.

Isothermal calorimeters make measurements at constant temperature. The simplest example is a calorimeter containing an outer annular space filled with a liquid in equilibrium with a crystalline solid at its melting point, arranged so that any volume change will displace mercury along a capillary tube. The Bunsen ice calorimeter operates at 0°C (32°F) with a mixture of ice and water. Changes as a result of the process being studied cause the ice to melt or the water to freeze, and the consequent volume change is determined by measurement of the movement of the mercury meniscus in the capillary tube. While these calorimeters can yield accurate results, they are limited to operation at the equilibrium temperature of the two-phase system. Other types of isothermal calorimeters use the addition of electrical energy to achieve exact balance of the heat absorption that occurs during an endothermic process.

All calorimeters consist of the calorimeter proper and a jacket or a bath, which is used to control the temperature of the calorimeter and the rate of heat leak to the environment. For temperatures not too far removed from room temperature, the jacket or bath contains liquid at a controlled temperature. For measurements at extreme temperatures, the jacket usually consists of a metal block containing a heater to control the temperature. With nonisothermal calorimeters, where the jacket is kept at a constant temperature, there will be some heat leak to the jacket when the temperature of the calorimeter changes. It is necessary to correct the temperature change observed to the value it would have been if there were no leak. This is achieved by measuring the temperature of the calorimeter for a time period both before and after the process and applying Newton's law of cooling. This correction can be avoided by using the technique of adiabatic calorimetry, where the temperature of the jacket is kept equal to the temperature of the calorimeter as a change occurs. This technique requires more elaborate temperature control, and its primary use is for accurate heat capacity measurements at low temperatures.

In calorimetric experiments it is necessary to measure temperature differences accurately; in some cases the temperature itself must be accurately known. Modern calorimeters use resistance thermometers to measure both temperatures and temperature differences, while thermocouples or thermistors are used to measure smaller temperature differences. *See* TEMPERATURE MEASUREMENT; THERMISTOR; THERMOCOUPLE; THERMOMETER.

Heat capacities of materials and heats of combustion are processes that are routinely measured with calorimeters. Calorimeters are also used to measure the heat involved in phase changes, for example, the change from a liquid to a solid (fusion) or from a liquid to a gas (vaporization). Calorimetry has also been applied to the measurement of heats of hydrogenation of unsaturated organic compounds, the heat of dissolution of a solid in a liquid, or the heat change on mixing two liquids. [K.M.M.]

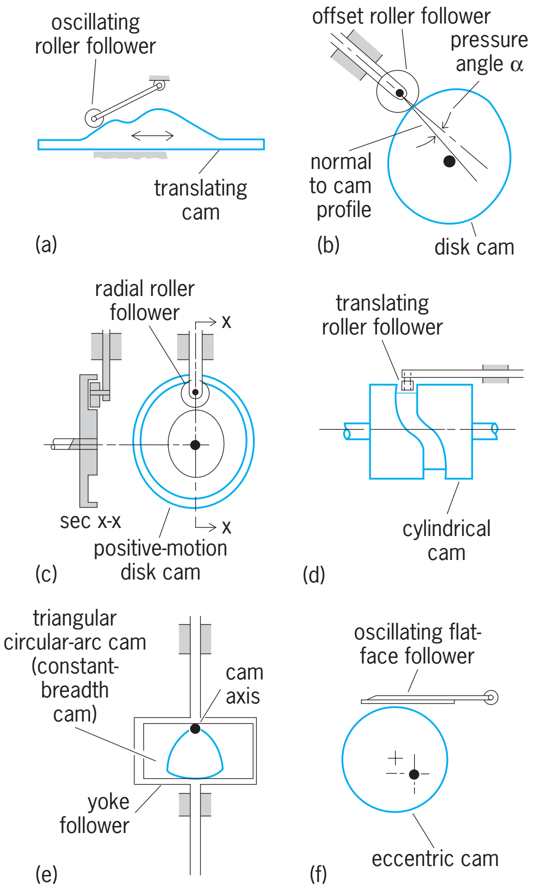
Calycerales An order of flowering plants, division Magnoliophyta (Angiospermae), in the subclass Asteridae of the class Magnoliopsida (dicotyledons). The order consists of a single family with about 60 species native to tropical America. The plants are herbs with alternate, simple leaves that do not have stipules. The flowers are borne in involucrate heads with centripetal flowering sequence. The calyx is reduced to small lobes or teeth, and the corolla consists of (4)5(6) fused lobes and is regular or somewhat irregular. The stamens are attached near the summit of the corrolla tube, and the filaments are more or less connate. The pistil consists of two united carpels, forming a compound, inferior ovary with a single, pendulous ovule. The order Calycerales is sometimes included within the Dipsacales, and the order has attracted attention because of the overall resemblance of the inflorescence to that of the Asteraceae. *See* ASTERALES; ASTERIDAE; DIPSACALES; MAGNOLIOPHYTA; MAGNOLIOPSIDA; PLANT KINGDOM. [T.M.Ba.]

Cam mechanism A mechanical linkage whose purpose is to produce, by means of a contoured cam surface, a prescribed motion of the output link of the linkage, called the follower. Cam and follower are a higher pair. *See* LINKAGE (MECHANISM).

A familiar application of a cam mechanism is in the opening and closing of valves in an automotive engine. The cam rotates with the cam shaft, usually at constant angular velocity, while the follower moves up and down as controlled by the cam surface. A cam is sometimes made in the form of a translating cam. Other cam mechanisms, employed in elementary mechanical analog computers, are simple memory devices, in which the position of the cam (input) determines the position of the follower (output or readout).

Although many requisite motions in machinery are accomplished by use of pin-jointed mechanisms, such as four-bar linkages, a cam mechanism frequently is the only practical solution to the problem of converting the available input, usually rotating or reciprocating, to a desired output, which may be an exceedingly complex motion. No other mechanism is as versatile and as straightforward in design. However, a cam may be difficult and costly to manufacture, and it is often noisy and susceptible to wear, fatigue, and vibration.

Cams are used in many machines. They are numerous in automatic packaging, shoemaking, typesetting machines, and the like, but are often found as well in machine tools, reciprocating



Classification of cams. (*a*) Translating. (*b*) Disk. (*c*) Positive motion. (*d*) Cylindrical. (*e*) With yoke follower. (*f*) With flat-face follower.

engines, and compressors. They are occasionally used in rotating machinery.

Cams are classified as translating, disk, plate, cylindrical, or drum (see illustration). The link having the contoured surface that prescribes the motion of the follower is called the cam. Cams are usually made of steel, often hardened to resist wear and, for high-speed application, precisely ground.

The output link, which is maintained in contact with the cam surface, is the follower. Followers are classified by their shape as roller, flat face, and spherical face. Followers are also described by the nature of their constraints, for example, radial, in which motion is reciprocating along a radius from the cam's axis of rotation; offset, in which motion is reciprocating along a line that does not intersect the axis of rotation (illus. *b*); and oscillating, or pivoted (illus. *a*). Three-dimensional cam-and-follower systems are coming into more frequent use, where the follower may travel over a lumpy surface. [D.P.Ad.]

Cambrian An interval of time in Earth history (Cambrian Period) and its rock record (Cambrian System). The Cambrian Period spanned about 60 million years and began with the first appearance of marine animals with mineralized (calcium carbonate, calcium phosphate) shells. The Cambrian System includes many different kinds of marine sandstones, shales, limestones, dolomites, and volcanics. Apart from the occurrence of an alkaline playa containing deposits of trona (hydrated basic sodium carbonate) in the Officer Basin of South Australia, there is very little provable record of nonmarine Cambrian environments. The best present estimates suggest that Cambrian time began about 545 million years ago (Ma) and ended at about 485 Ma. It is the longest of the Paleozoic periods and the fourth longest of the Phanerozoic periods.

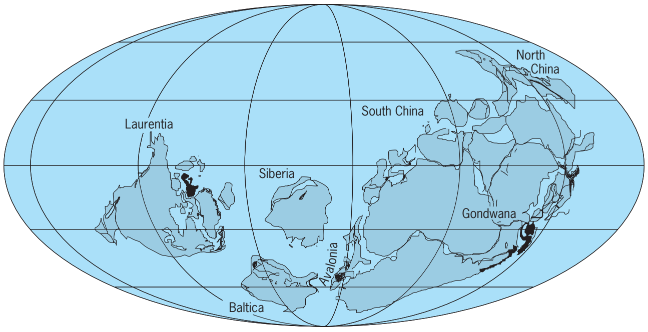
The Cambrian world can be resolved into at least four major continents that were quite different from those of today (see illustration). These were (1) Laurentia, which is essentially North America, minus a narrow belt along the eastern coast from eastern Newfoundland to southern New England that belonged to a separate microcontinent, Avalonia. This microcontinent, which also included present-day England, and another microcontinent now incorporated in South Carolina were originally marginal to Gondwana; (2) Baltica, consisting of present-day northern Europe north of France and west of the Ural Mountains but excluding most of Scotland and northern Ireland, which are fragments of Laurentia; (3) Gondwana, a giant continent whose present-day fragments are Africa, South America, India, Australia, Antarctica, parts of southern Europe, the Middle East, and Southeast Asia; and (4) Siberia, including much of the northeastern quarter of Asia. *See* CONTINENTAL MARGIN; CONTINENTS, EVOLUTION OF; PLATE TECTONICS.

For most practical purposes, rocks of Cambrian age are recognized by their content of distinctive fossils. On the basis of the successive changes in the evolutionary record of Cambrian life that have been worked out during the past century, the Cambrian System has been divided globally into three or four series, each of which has been further divided on each continent into stages, each stage consisting of several zones. Despite the amount of work already done, precise intercontinental correlation of series and stage boundaries, and of zones, is still difficult, especially in the Early Cambrian due to marked faunal provinciality. Refinement of intercontinental correlation of these ancient rocks is a topic of research.

The record preserved in rocks indicates that essentially all Cambrian plants and animals lived in the sea. The few places where terrestrial sediments have been preserved suggest that the land was barren of major plant life, and there are no known records of Cambrian insects or of terrestrial vertebrate animals of any kind.

The plant record consists entirely of algae, preserved either as carbonized impressions in marine black shales or as filamentous or blotchy microstructures within marine buildups of calcium carbonate, called stromatolites, produced by the actions of these organisms. Cambrian algal stromatolites were generally low domal structures, rarely more than a few meters high or wide, which were built up by the trapping or precipitation of calcium carbonate by one or more species of algae. Such structures, often composed of upwardly arched laminae, were common in regions of carbonate sedimentation in the shallow Cambrian seas. *See* STROMATOLITE.

The most abundant remains of organisms in Cambrian rocks are of trilobites. They are present in almost every fossiliferous Cambrian deposit and are the principal tools used to describe divisions of Cambrian time and to correlate Cambrian rocks. These marine arthropods ranged from a few millimeters to 20 in. (50 cm) in length, but most were less than 4 in. (10 cm) long. The



Reconstruction of the Lower Cambrian world. (*After W. S. McKerrow, C. R. Scotese, and M. D. Brasier, Early Cambrian continental reconstructions. J. Geol. Soc., 149:599–606, 1992*)

next most abundant Cambrian fossils are brachiopods. These bivalved animals were often gregarious and lived on the sediment surface or on the surfaces of other organisms. Limestones of Early Cambrian age may contain large reeflike structures formed by an association of algae and an extinct phylum of invertebrates called Archaeocyatha. The Cambrian record of mollusks and echinoderms is characterized by many strange-looking forms. Some lived for only short periods of time and left no clear descendants. Except for rare jellyfish impressions, the Coelenterata were thought to be unrepresented in Cambrian rocks. Corals have now been discovered in early Middle Cambrian rocks in Australia. However, like clams, they are not seen again as fossils until Middle Ordovician time, many tens of millions of years later. *See* Archaeocyatha; Brachiopoda; Coelenterata; Echinodermata; Mollusca; Trilobita.

Throughout Cambrian time, terrestrial landscapes were stark and barren. Life in the sea was primitive and struggling for existence. Only in post-Cambrian time did the shallow marine environment stabilize and marine life really flourish. Only then did vertebrates evolve and plants and animals invade the land. [A.R.P.; J.H.Sh.]

Camel The name given to two species of mammals which are members of the family Camelidae in the order Artiodactyla. These are the Bactrian camel (*Camelus bactrianus*) and the Arabian or dromedary camel (*C. dromedarius*). Both species are domesticated, but a few wild herds of Bactrian camels are still in existence in the Gobi desert. The legs of these animals are long and slender and terminate in two toes. The neck and head are elongate, and there is a cleft upper lip. The period of gestation is about 1 year and the female breeds every second year, producing one young (colt).

The Bactrian camel is stronger and more heavily built than the dromedary and is more suitable as a pack animal. There are two humps of fatty tissue, one over the shoulders and the other atop the hindquarters. This animal is economically important as it provides milk, meat, and leather for the nomads in central Asia.

The Arabian camel is taller than the Bactrian and has a single hump of fatty tissue, which can be used as a food reserve. There are two varieties of this species found in the desert. One is the baggage camel, used as a beast of burden. The other type is the more slightly built racing camel. The species is wellsuited to desert life with its broad feet adapted to walking on sand, its ability to close its nostrils completely, and its double row of interlocking eyelashes.

These two species have a most important physiological adaptation in their ability to conserve water. Camels do not store water but conserve it, since the body is well insulated by fur and has a temperature range of over 12°F (7°C) before it perspires sufficiently to prevent a further rise. The camel can lose over 40% of its body water without fear of dehydration. However, although able to survive for long periods without water, it may drink as much as 15 gal (57 liters) when water is available. *See* Artiodactyla. [C.B.C.]

Camel's hair A fine hair known to the American consumer chiefly in the form of high-quality coat fabrics. This texfile fiber is obtained from the two-humped Bactrian camel. Camel's-hair fabrics are ideal for comfort, particularly when used for overcoating, as they are especially warm and light in weight. Camel's hair is characterized by strength, luster, and smoothness. The best quality is expensive. It is often mixed with wool to improve the quality of the wool fabric. The price of such a mixed cloth is much less than that of a 100% camel's-hair fabric. *See* Camel; Natural fiber; Wool. [M.D.P.]

Cameo A type of carved gemstone in which the background is cut away to leave the subject in relief. Often cameos are cut from stones in which the coloring is layered, resulting in a figure of one color and a background of another. The term cameo, when used without qualification, is usually reserved for those cut from a gem mineral, although they are known also as stone cameos. The commonly encountered cameo cut from shell is properly called a shell cameo.

Most cameos are cut from onyx or agate, but many other varieties of quartz, such as tiger's-eye, bloodstone, sard, carnelian, and amethyst, are used; other materials used include beryl, malachite, hematite, labradorite, and moonstone. *See* Gem; Intaglio (gemology). [R.T.L.]

Camera A device for forming and recording images; the basic tool of photography. In its simplest form, a camera is a light-tight box in which an image is formed by a pinhole or lens at one end on a light-sensitive material at the opposite end. Most cameras contain an aperture and shutter for controlling the amount of light reaching the light-sensitive material (exposure). The receiving material, the film, is usually a plastic sheet or flexible strip coated with a photosensitive silver halide emulsion. It can also be an electronic device such as a charge-coupled device.

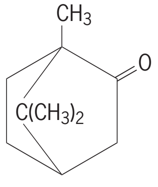
Cameras for still photography include box, point-and-shoot, view-and-press, roll film, 35-mm, instant-picture, stereo, underwater, and panoramic. Some categories overlap. Still video and digital cameras use electronic sensors instead of film, and store the image in solid-state memory or on magnetic media or optical disks. Motion picture or cine cameras record movement at regular intervals in a series of frames, which are projected on a screen to create an illusion of movement. Television and video cameras record movement electronically for broadcast and storage on magnetic media or optical disks. Camcorders are video cameras which contain both the image sensor and recording media in a single unit. *See* Photography. [L.R.Wh.]

Camerata An extinct subclass of stalked Crinoidea comprising about 210 Paleozoic genera ranging from the Lower Ordovician to the upper Permian. The calyx was composed of a rigid, boxlike structure of many small, polygonal plates. The lower arm plates (brachials) were solidly incorporated into the upper part of the calyx, and were separated by small interbrachial and interradial plates. The tegmen was rigid and roofed over the mouth and proximal food grooves. Advanced forms had a long, slender, solid anal tube with the anal opening at the tip. All but a few primitive Ordovician forms had biserial arms, and the arms bore pinnules.

Both dicyclic forms with infrabasal plates (order Diplobathrida; 50 genera) and monocyclic forms without infrabasals (order Monobathrida; 160 genera) are known. The former became extinct during middle Mississippian time, the latter persisted to the close of the Paleozoic Era and flourished during Mississippian time. The origin of the Camerata is obscure but presumably occurred during Cambrian or earliest Ordovician time. Camerates are not closely related to the other two large subclasses of Paleozoic crinoids, the flexibles and the inadunates. *See* Crinoidea; Echinodermata. [N.G.L.]

Campanulales An order of flowering plants, division Magnoliophyta in the subclass Asteridae of the class Magnoliopsida (dicotyledons). It consists of 7 families and about 2500 species. The order is distinguished in this subclass by its chiefly herbaceous habit, alternate leaves, inferior ovary, and stamens which are free from the corolla or attached at the base of the tube. About 2000 of the species belong to the single family Campanulaceae. Several familiar ornamentals, including the Canterbury bell (*Campanula medium*) and the cardinal flower (*Lobelia cardinalis*), belong to the Campanulaceae. *See* Asteridae; Magnoliophyta; Magnoliopsida; Ornamental plants; Plant kingdom. [A.Cr.; T.M.Ba.]

Camphor A bicyclic, saturated terpene ketone. It exists in the optically active dextro and levo forms, and as the racemic mixture of the two forms. All of these melt within a degree of 178°C (352°F). The principal form is *dextro*-camphor, which occurs in the wood and leaves of the camphor tree (*Cinnamomum camphora*). Camphor is also synthesized commercially on a large scale from pinene which yields mainly the racemic variety. The structural formula of the molecule is shown below.



Camphor has a characteristic odor; it crystallizes in thin plates and sublimes readily at ordinary temperatures.

Camphor has use in liniments and as a mild rubefacient, analgesic, and antipruritic. It has a local action on the gastrointestinal tract, producing a feeling of warmth and comfort in the stomach. It is also used in photographic film and as a plasticizer in the manufacture of plastics. *See* Ketone; Pine terpene; Terpene. [E.L.S.]

Camphor tree The plant *Cinnamomum camphora*, a member of the laurel family (Lauraceae) and a native of China, Japan, and Taiwan. The tree is dense-topped and has shiny, dark, evergreen leaves. All parts of the tree contain camphor, an essential oil which is obtained from the finely ground wood and leaves by distillation with steam. *See* Camphor; Magnoliales. [P.D.St./E.L.C.]

Camptostromatoidea A small class of primitive echinoderms (subphylum Echinozoa) known from the single species *Camptostroma roddyi* based on about 200 specimens from the Early Cambrian (*Bonnia-Olenellus* Zone) in southeastern Pennsylvania. *Camptostroma* was originally described as a hydrozoan or jellyfish, but it was recognized as an echinoderm and the new class Camptostromatoidea was set up for it. *Camptostroma* has been reinterpreted as an early edrioasteroid, and as a "stem echinoderm" ancestral to several other groups including edrioasteroids. Because of *Camptostroma's* puzzling morphology, different reconstructions of it have been made. Its unusual thecal plating is the main feature separating *Camptostroma* from later Edrioasteroidea, which it otherwise resembles, but this genus may also have been ancestral to other classes such as the Eocrinoidea. *See* Echinodermata; Echinozoa. [J.Sp.]

Canal An artificial open channel usually used to convey water or vessels from one point to another. Canals are generally classified according to use as irrigation, power, flood-control, drainage, or navigation canals or channels. All but the last type are regarded as water conveyance canals.

Canals may be lined or unlined. Linings may consist of plain or reinforced concrete, cement mortar, asphalt, brick, stone, buried synthetic membranes, or compacted earth materials. Linings serve to reduce water losses by seepage or percolation through pervious foundations or embankments and to lessen the cost of weed control. Concrete and other hard-surface linings also permit higher water velocities and, therefore, steeper gradients and smaller cross sections, which may reduce costs and the amount of right-of-way required.

Navigation canals are artificial inland waterways for boats, barges, or ships. A canalized river is one that has been made navigable by construction of one or more weirs or overflow dams to impound river flow, thereby providing navigable depths. Locks may be built in navigation canals and canalized rivers to enable vessels to move to higher or lower water levels. A lock is a chamber equipped with gates at both upstream and downstream ends. Water impounded in the chamber is used to raise or lower a vessel from one elevation to another. The lock chamber is filled and emptied by means of filling and emptying valves and a culvert system usually located in the walls and bottom of the lock. *See* Irrigation (agriculture); Transportation engineering; Water supply engineering. [C.E.; B.R.]

Cancer (constellation) The Crab, in astronomy, a winter constellation and the faintest of the zodiacal groups. Cancer, the fourth sign of the zodiac, is important because during early times it marked the northernmost limit of the ecliptic, when the zodiacal system was adopted. The Tropic of Cancer takes its name from this constellation. Four faint stars form a rough Y outline, which is suggestive of a crab. In the center of Cancer is a hazy object. This is a magnificent cluster of faint stars called Praesepe (the Beehive) or the Manger. *See* Constellation. [C.-S.Y.]

Cancer (medicine) The common name for a malignant neoplasm or tumor. Neoplasms are new growths and can be divided into benign and malignant types, although in some instances the distinction is unclear. The most important differentiating feature is that a malignant tumor will invade surrounding structures and metastasize (spread) to distant sites whereas a benign tumor will not. Other distinctions between benign and malignant growth include the following: malignancies but not benign types are composed of highly atypical cells; malignancies tend to show more rapid growth than benign neoplasms, and are composed, in part, of cells showing frequent mitotic activity; and malignant tumors tend to grow progressively without self-limitation. *See* Mitosis; Tumor.

Malignant neoplasms that arise from cells of mesenchymal origin (for example, bone muscle, connective tissue) are called sarcomas. Those that develop from epithelial cells and tissues (for example, skin, mucosal membranes, and glandular tissues) are termed carcinomas. Carcinomas usually metastasize initially by way of lymphatic channels, whereas sarcomas spread to distant organs through the bloodstream.

The cause of most types of human cancers is unknown. However, a number of factors are thought to be operative in the development of some malignant neoplasms. Genetic factors are thought to be causally related to some human malignancies such as lung cancer in that the incidence of cancer among persons with a positive family history of cancer may be three times as high as in those who do not have a family history. A number of different neoplasms are known to be genetically related and may be due to damage or changes in chromosome structure. Radiation in various forms is thought to be responsible for up to 3% of all cancers. In the United States the carcinogens in tobacco account for up to one-third of all cancer deaths in men and 5–10% in women. The increasing incidence and death rate from cancer of the lung in women is alarming, and is directly related to the increasing prevalence of cigarette smoking by women. Cigarette smoking and the heavy consumption of ethyl alcohol appear to act synergistically in the development of oral, esophageal, and gastric cancers. There are several carcinogens to which people are exposed occupationally that result in the development of cancer, although the mechanisms by which they cause neoplasms are sometimes poorly understood. For example, arsenic is associated with lung, skin, and liver cancer and asbestos causes mesotheliomas (cancer of the pleural, peritoneal, and pericardial cavities). Certain drugs and hormones have been found to cause certain types of neoplasms. Postmenopausal women taking estrogen hormones have a much higher incidence of endometrial cancer (cancer of the lining of the uterine cavity). The role of diet and nutrition in the development of malignant tumors is controversial and still under investigation. Some epidemiologic studies have shown that certain diets, such as those high in saturated fats, are associated with an increased incidence of certain types of neoplasm, such as colon cancer. The role of viruses in the development of human cancers is being studied. *See* Mutagens and carcinogens; Radiation biology; Tumor viruses.

It is generally accepted that the neoplastic condition is caused by alterations in genetic mechanisms involved in cellular differentiation. In malignant cells, normal cellular processes are bypassed due to the actions of a select group of genes called oncogenes which regulate cellular activities. A group of these highly conserved genes exist in normal cells and are called proto-oncogenes. These genes appear to be important in regulating cellular growth during embryonic development. It is thought that in carcinogenesis these proto-oncogenes become unmasked or changed during the breakage or translocation of chromosomes. These genes that were previously suppressed in the cell then become functional, and in some instances lead to the excessive production of growth factors which could be important in the neoplastic state. *See* ONCOGENES.

The physical changes that cancer produces in the body vary considerably, depending on the type of tumor, location, rate of growth, and whether it has metastasized. The American Cancer Society has widely publicized cancer's seven warning signals: (1) a change in bowel or bladder habits; (2) a sore that does not heal; (3) unusual bleeding or discharge; (4) a thickening or lump in the breast or elsewhere; (5) indigestion or difficulty in swallowing; (6) an obvious change in a wart or mole; and (7) a nagging cough or hoarseness. In current medical practice, most cancers are staged according to tumor size, metastases to lymph nodes, and distant metastases. This type of staging is useful in determining the most effective therapy and the prognosis.

The progression, or lack thereof, of a given cancer is highly variable and depends on the type of neoplasm and the response to treatment. Treatment modalities include surgery, chemotherapy, radiation therapy, hormonal manipulation, and immunotherapy. In general, each type of cancer is treated very specifically, and often a combination of the various modalities is used, for example, surgery preceded or followed by radiation therapy. The response to treatment depends on the type of tumor, its size, and whether it has spread. *See* CHEMOTHERAPY; IMMUNOTHERAPY; ONCOLOGY; RADIOGRAPHY. [S.P.H.]

Cancrinite A family of minerals, related to the scapolite family, characteristically occurring in basic rocks such as nepheline syenites and sodalite syenites. Cancrinite is hexagonal. Four-, six-, and twelve-membered aluminosilicate rings can be discerned in the structure. Large anions such as $[SO_4]^{2-}$ and $[CO_3]^{2-}$ occur in the hexagonal channels of the structure. Four members of the cancrinite family are cancrinite, vishnevite, hauyne, and afghanite. The cancrinite member is white, yellow, greenish, or reddish. It has perfect prismatic cleavage, hardness is 5–6 on Mohs scale, and the specific gravity is 2.45. Localities include the Fen area, southern Norway; the Kola Peninsula, Russia; Bancroft, Ontario, Canada; and Litchfield, Maine, U.S.A. *See* NEPHELINE SYENITE; SILICATE MINERALS. [P.B.M.]

Candlepower Luminous intensity expressed in candelas. The term refers only to the intensity in a particular direction and by itself does not give an indication of the total light emitted. The candlepower in a given direction from a light source is equal to the illumination in footcandles falling on a surface normal to that direction, multiplied by the square of the distance from the light source in feet. The candlepower is also equal to the illumination of metercandles (lux) multiplied by the square of the distance in meters.

The apparent candlepower is the candlepower of a point source which will produce the same illumination at a given distance as produced by a given light source.

The mean horizontal candlepower is the average candlepower of a light source in the horizontal plane passing through the luminous center of the light source.

The mean spherical candlepower is the average candlepower in all directions from a light source as a center. Since there is a total solid angle of 4π (steradians) emanating from a point, the mean spherical candlepower is equal to the total luminous flux (in lumens) of a light source divided by 4π (steradians). *See* LUMINOUS INTENSITY; PHOTOMETRY. [R.C.Pu.]

Canine distemper A fatal viral disease of dogs and other carnivores, with a worldwide distribution. Canine distemper virus has a wide host range; most terrestrial carnivores are susceptible to natural canine distemper virus infection. All animals in the families Canidae (such as dog, dingo, fox, coyote, wolf, jackal), Mustelidae (such as weasel, ferret, mink, skunk, badger, stoat, marten, otter), and Procyonidae (such as kinkajou, coati, bassariscus, raccoon, panda) may succumb to canine distemper virus infection. Members of other Carnivora families, including domestic cats and swine, may become subclinically infected. The virus has also been isolated from large cats (lions, tigers, leopards) that have died in zoological parks in North America, from wild lions in the Serengeti National Park (Tanzania), and from wild javelinas (collared peccaries). *See* CARNIVORA.

Canine distemper virus is classified as a morbillivirus within the Paramyxoviridae family, closely related to measles virus and rinderpest virus of cattle and the phocine (seal) and dolphin distemper virus. The virus is enveloped with a negative-sense ribonucleic acid and consists of six structural proteins: the nucleoprotein and two enzymes in the nucleocapsid, the membrane protein on the inside, and the hemagglutinating and fusion proteins on the outside of the lipoprotein envelope. *See* ANIMAL VIRUS; PARAMYXOVIRUS.

Canine distemper is enzootic worldwide. Aerosol transmission in respiratory secretions is the main route of transmission. Virus shedding begins approximately 7 days after the initial infection. Acutely infected dogs and other carnivores shed virus in all body excretions, regardless of whether they show clinical signs or not.

Great variations occur in the duration and severity of canine distemper, which may range from no visible signs to severe disease, often with central nervous system involvement, with approximately 50% mortality in dogs. The first fever 3–6 days after infection may pass unnoticed; the second peak (several days later and intermittent thereafter) is usually associated with nasal and ocular discharge, depression, and anorexia. A low lymphocyte count is always present during the early stages of infection. Gastrointestinal and respiratory signs may follow, often enhanced by secondary infection.

A specific antiviral drug having an effect on canine distemper virus in dogs is not presently available. Treatment of canine distemper, therefore, is nonspecific and supportive. Antibiotic therapy is recommended because of the common occurrence of secondary bacterial infections of the respiratory and alimentary tracts. Administration of fluids and electrolytes may be the most important therapy for canine distemper because diseased dogs with diarrhea are often dehydrated. [M.J.G.A.; B.A.S.]

Canine parvovirus infection Severe enteritis caused by a small nonenveloped single-stranded deoxyribonucleic acid (DNA) virus that is resistant to inactivation and remains infectious in the environment for 5–7 months. First observed in dogs in 1976, canine parvovirus may have originated by mutation of a closely related parvovirus of cats or wildlife. The original virus was designated as canine parvovirus, type 2 (CPV-2); however, since its discovery the virus has undergone two minor genetic alterations, designated CPV-2a and CPV-2b. These alterations may have enabled the virus to adapt to its new host, replicate, and spread more effectively. *See* ANIMAL VIRUS.

Canine parvovirus is transmitted between dogs by the fecaloral route. The incubation period is 3–7 days. Virus is first shed in the feces on day 3, and shedding continues for an additional 10 days. Chronically infected dogs that shed virus intermittently are rare. Most naturally occurring infections in dogs are subclinical or result in mild signs of the disease. Dogs with subclinical infections play an important role in the spread of the disease by shedding large amounts of virus into the environment. This shedding, along with the ability of the virus to persist in the environment, contributes to the endemicity of the disease. The development of disease following infection ranges from 20 to 90%, and mortality ranges 0 to 50%.

The goal of treatment is to support the animal until the infection runs its course. There are no specific antiviral therapies available. The intensity of treatment depends on the severity of signs. Dehydrated pups require intensive intravenous fluid therapy. Antimicrobial drugs are useful because of the risk of secondary bacterial infections, and antiemetic drugs help control vomiting and nausea. Good nursing care is essential. All food and water should be withheld until the pup is no longer vomiting, and the pup should be kept warm, clean, and dry. Because of the infectious nature of the disease, pups should be isolated from other dogs. [M.S.Co.]

Canonical transformations Transformations among the coordinates and momenta describing the state of a classical dynamical system which leave the canonical or Hamiltonian form of the equations of motion unchanged. *See* HAMILTON'S EQUATIONS OF MOTION; HAMILTON'S PRINCIPLE. [P.M.S.]

Cantaloupe In the United States the name applied to muskmelon cultivars belonging to *Cucumis melo* var. *reticulatus* of the family Cucurbitaceae. However, this is a misnomer, and the name cantaloupe should be restricted to cultivars of *C. melo* var. *cantalupensis*. The fruits of this group are rough and scaly, with deep vein tracts and a hard rind. Cultivars of the variety *cantalupensis* are grown in Europe and Asia, but seldom in the United States.

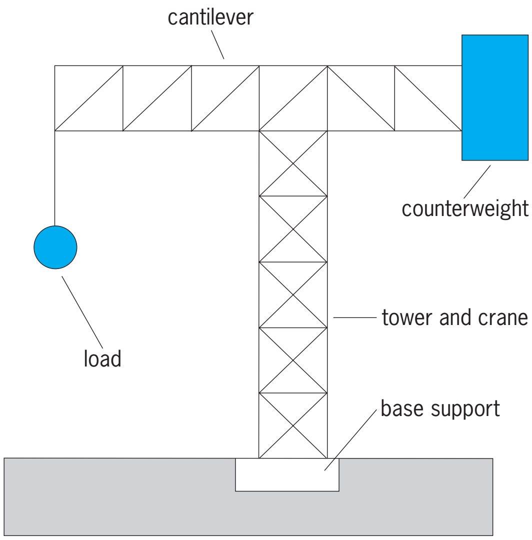
The fruits grown in the United States are round to oval; the surface is netted and has shallow vein tracts. At maturity the skin color changes from dark green or gray to light gray or yellow. The flesh is usually salmon-colored, but it may vary from green to deep salmon-orange. When mature the melon is sweet, averages 6–8% sugar, and has a distinct aroma and flavor. The flesh is high in potassium and vitamin C, and, when deep orange, rich in vitamin A. *See* MUSKMELON; VIOLALES. [O.A.L.]

Cantilever A linear structural member supported both transversely and rotationally at one end only; the other end of the member is free to deflect and rotate. Cantilevers are common throughout nature and engineered structures; examples are a bird's wing, an airplane wing, a roof overhang, and a balcony. *See* WING.

A horizontal cantilever must be counterbalanced at its one support against rotation. This requirement is simply achieved in the design of a playground seesaw, with its double-balanced cantilever. This principle of counterbalancing the cantilever is part of the basic design of a crane, such as a tower crane (see illustration). More commonly, horizontal cantilevers are resisted by being continuous with a backup span that is supported at both ends. This design is common for cantilever bridges; all swing bridges or drawbridges are cantilevers. *See* BRIDGE.

Vertical cantilevers primarily resist lateral wind loads and horizontal loads created by earthquakes. Common vertical cantilevers are chimneys, stacks, masts, flagpoles, lampposts, and railings or fences. All skyscrapers are vertical cantilevers. One common system to provide the strength to resist lateral loads acting on the skyscraper is the use of a truss (known as bracing). *See* BUILDINGS; SHEAR; TRUSS.

Some of the largest cantilevers are used in the roofs of airplane hangars. It has become common practice to include cantilevers in the design of theaters and stadiums, where an unobstructed view is desired; balconies and tiers are supported in the back and cantilevered out toward the stage or playing field so that the audience has column-free viewing. *See* BEAM; ROOF CONSTRUCTION. [I.P.L.]



Cantilever configuration in the form of a tower support crane.

Capacitance The ratio of the charge q on one of the plates of a capacitor (there being an equal and opposite charge on the other plate) to the potential difference v between the plates; that is, capacitance (formerly called capacity) is $C = q/v$.

In general, a capacitor, often called a condenser, consists of two metal plates insulated from each other by a dielectric. The capacitance of a capacitor depends on the geometry of the plates and the kind of dielectric used, since these factors determine the charge which can be put on the plates by a unit potential difference existing between the plates.

In an ideal capacitor, no conduction current flows between the plates. A real capacitor of good quality is the circuit equivalent of an ideal capacitor with a very high resistance in parallel or, in alternating-current (ac) circuits, of an ideal capacitor with a low resistance in series. *See* CAPACITOR; DIELECTRIC MATERIALS. [R.P.Wi.]

Capacitance measurement The measurement of the ratio of the charge induced on a conductor to the change in potential with respect to a neighboring conductor which induces the charge. In a multiconductor system there are capacitances between each pair of conductors. In general, these capacitances are functions of the total geometry, that is, the location of all of the conducting and dielectric bodies. When, as is usually true, only the capacitance between two conductors is of interest, the presence of other conductors is an undesirable complication. It is then customary to distinguish between two-terminal and three-terminal capacitors and capacitance measurements. In a two-terminal capacitor, either one of the conductors of primary interest surrounds the other (in which case the capacitance between them is independent of the location of other bodies except in the vicinity of the terminals); or the somewhat indefinite contributions of the other conductors to the capacitance of interest are accepted.

A three-terminal capacitor consists of two active electrodes surrounded by a third, or shield, conductor. The direct capacitance between the two active electrodes is the capacitance of interest, and, when shielded leads are used, it is independent of the location of all other conductors except the shield.

Every physically realizable capacitor has associated loss in the dielectric and in the metal electrodes. At a single frequency these are indistinguishable, and the capacitor may be represented by either a parallel or series combination of pure capacitance and pure resistance. The measurement of capacitance, then, in general involves the simultaneous measurement of, or allowance for, an associated resistive element. *See* PERMITTIVITY.

Most capacitance measurements involve simply a comparison of the capacitor to be measured with a capacitor of known value. Methods which permit comparison of essentially equal capacitors by simple substitution of one for the other at the same point in a circuit are frequently possible and almost always preferable.

Bridge comparison methods. When capacitors must be compared with high accuracy, bridge methods must be adopted. *See* BRIDGE CIRCUIT; WHEATSTONE BRIDGE.

Resistance-ratio bridges are Wheatstone-bridge configurations in which the potential division of the capacitor being measured and either a parallel combination of a standard loss-free capacitor C_s and a conductance G_s or a series combination of C_s and a resistor R_s is equated, when the detector is nulled, to the ratio of potentials across resistors R_1 and R_2. More commonly now, the reference potential division is that of a variable-ratio autotransformer known as an inductive voltage divider (IVD). *See* INDUCTIVE VOLTAGE DIVIDER.

The Schering bridge yields a measurement of the equivalent series-circuit representation of a capacitor.

The resistance-ratio and Schering bridges are useful for two-terminal capacitance measurements. Their use may be extended to three-terminal measurements and extended in accuracy and range by the introduction of shielding and the addition of the Wagner branch.

Time-constant methods. If a direct voltage is suddenly applied to the series combination of a resistor and an initially discharged capacitor, the charge and the voltage on the capacitor increase exponentially toward their full magnitudes with a time constant equal in seconds to the product of the resistance in ohms and the capacitance in farads. Similarly, when a charged capacitor is discharged through a resistor, the charge and the voltage decay with the same time constant. Various methods are available for the measurement of capacitance by measurement of the time constant of charge or discharge through a known resistor. *See* TIME CONSTANT.

In one such method the time required for the output voltage of an operational amplifier having a capacitor as a feedback component to increase to a value equal to the step-function input voltage applied through a resistor to its input is determined by an electronic voltage-comparison circuit and timer. With the assumption of ideal characteristics for the amplifier, such as infinite gain without feedback, infinite input impedance, and zero output impedance, the measured time interval is equal to the product of the values of the known resistance and the capacitance being measured. *See* OPERATIONAL AMPLIFIER.

[B.P.K.; F.R.Ko.; G.H.Ra.]

Capacitance multiplication The generation of a capacitance which is some multiple of that of an actual capacitor. Capacitance multiplication circuits have an input impedance which is capacitive and which is proportional to that of an actual capacitor appearing somewhere in the circuit. In most applications, capacitance multiplication circuits are used to generate an equivalent input capacitance which is much larger than that of the actual capacitor. One scenario where capacitance multiplication might prove useful is where a physical capacitor of a required capacitance may be too large, too expensive, or unavailable. A second is where the capacitor must be reasonably large and capable of handling bidirectional signals, thus precluding the direct use of widely available electrolytic capacitors and hence making practical the utilization of a much smaller nonelectrolytic capacitor in a capacitance multiplication circuit. *See* CAPACITANCE; CAPACITOR.

Capacitance multiplication circuits are often made from operational amplifiers and resistors along with the capacitor that is to be scaled, although transistors and other active devices can also be used. Capacitance multiplication circuits are closely related to classes of circuits termed generalized immittance converters and negative impedance converters. Generalized immittance converters are used to generate an equivalent input impedance that is proportional to products or quotients of specific impedances that appear in the circuit. Generalized immittance converters are often used for capacitance multiplication. Related applications of generalized immittance converters are synthetic inductance simulation and negative-resistance generation. Negative-impedance converters are also used for the generation of negative impedances. *See* ELECTRICAL IMPEDANCE; IMMITTANCE; INDUCTANCE; NEGATIVE-RESISTANCE CIRCUITS; OPERATIONAL AMPLIFIER.

[R.L.Ge.]

Capacitor An electrical device capable of storing electrical energy. In general, a capacitor consists of two metal plates insulated from each other by a dielectric. The capacitance of a capacitor depends primarily upon its shape and size and upon the relative permittivity ϵ_r of the medium between the plates. In vacuum, in air, and in most gases, ϵ_r ranges from one to several hundred. *See* CAPACITANCE; PERMITTIVITY.

One classification of capacitors comes from the physical state of their dielectrics, which may be gas (or vacuum), liquid, solid, or a combination of these. Each of these classifications may be subdivided according to the specific dielectric used. Capacitors may be further classified by their ability to be used in alternating-current (ac) or direct-current (dc) circuits with various current levels.

Capacitors are also classified as fixed, adjustable, or variable. The capacitance of fixed capacitors remains unchanged, except for small variations caused by temperature fluctuations. The capacitance of adjustable capacitors may be set at any one of several discrete values. The capacitance of variable capacitors may be adjusted continuously and set at any value between minimum and maximum limits fixed by construction. Trimmer capacitors are relatively small variable capacitors used in parallel with larger variable or fixed capacitors to permit exact adjustment of the capacitance of the parallel combination.

Made in both fixed and variable types, air, gas, and vacuum capacitors are constructed with flat parallel metallic plates (or cylindrical concentric metallic plates) with air, gas, or vacuum as the dielectric between plates. Alternate plates are connected, with one or both sets supported by means of a solid insulating material such as glass, quartz, ceramic, or plastic. Gas capacitors are similarly built but are enclosed in a leakproof case. Vacuum capacitors are of concentric-cylindrical construction and are enclosed in highly evacuated glass envelopes.

The purpose of a high vacuum, or a gas under pressure, is to increase the voltage breakdown value for a given plate spacing. For high-voltage applications, when increasing the spacing between plates is undesirable, the breakdown voltage of air capacitors may be increased by rounding the edges of the plates. Air, gas, and vacuum capacitors are used in high-frequency circuits. Fixed and variable air capacitors incorporating special design are used as standards in electrical measurements. *See* CAPACITANCE MEASUREMENT; ELECTRICAL UNITS AND STANDARDS.

Solid-dielectric capacitors use one of several dieletrics such as a ceramic, mica, glass, or plastic film. Alternate plates of metal, or metallic foil, are stacked with the dielectric, or the dielectric may be metal-plated on both sides.

A large capacitance-to-volume ratio and a low cost per microfarad of capacitance are chief advantages of electrolytic capacitors. These use aluminum or tantalum plates. A paste electrolyte is placed between the plates, and a dc forming voltage is applied. A current flows and by a process of electrolysis builds up a molecule-thin layer of oxide bubbles on the positive plate. This serves as the dieletric. The rest of the electrolyte and the other plate make up the negative electrode. Such a device is said to be polarized and must be connected in a circuit with the proper polarity. Polarized capacitors can be used only in circuits in which the dc component of voltage across the capacitors exceeds the crest value of the ac ripple.

Another type of electrolytic capacitor utilizes compressed tantalum powder and the baking of manganese oxide (MnO_2) as an electrolyte. Nonpolarized electrolytic capacitors can be constructed for use in ac circuits. In effect, they are two polarized capacitors placed in series with their polarities reversed.

Thick-film capacitors are made by means of successive screen-printing and firing processes in the fabrication of certain types of microcircuits used in electronic computers and other electronic systems. They are formed, together with their connecting conductors and associated thick-film resistors, upon a ceramic substrate. Their characteristics and the materials are similar to those of ceramic capacitors. *See* PRINTED CIRCUIT.

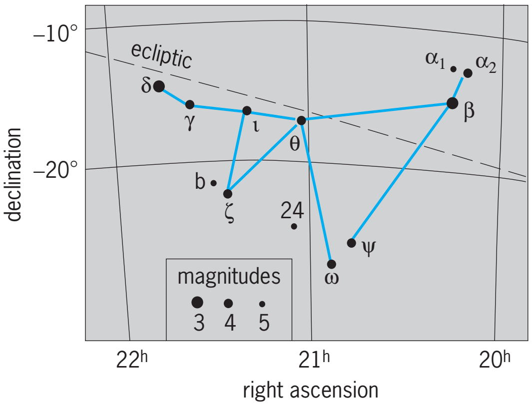
Thin-film dielectrics are deposited on ceramic and integrated-circuit substrates and then metallized with aluminum to form capacitive components. These are usually single-layer capacitors. The most common dielectrics are silicon nitride and silicon dioxide. *See* INTEGRATED CIRCUITS. [A.Mot.]

Capparales An order of flowering plants (Angiospermae) of approximately 15 families of dicotyledons with over 4000 species. In molecular phylogenetic classifications, it is placed near Malvales, Myrtales, and Sapindales. *See* MALVALES; MYRTALES; PLANT KINGDOM; SAPINDALES.

The mustard family, Brassicaceae (Cruciferae), with about 3000 species, and the caper family, Capparaceae, with about 800 species, form the core of the order. An additional 200 or so species are treated in 13 families, including Caricaceae (papaya), Limnanthaceae (meadowfoam), Resedaceae (mignonette), and Tropaeolaceae (garden nasturtium). The plants are diverse in vegetative habit and in floral and fruit morphology. However, they commonly possess myrosin cells, containing the enzyme myrosinase, and produce mustard oil glucosides (glucosinolates), the breakdown products of which are the pungent compounds of radish, wasabi, horseradish, and capers. Primitive members of the order have five-parted flowers, but the core families have four-parted flowers. Common vegetables such as broccoli, brussels sprouts, cabbage, kale, radish, rutabaga, turnip, and water cress belong to the Brassicaceae. Capparales are also important sources of seed oils and of several ornamental flowers. *See* BROCCOLI; BRUSSELS SPROUTS; CABBAGE; CAULIFLOWER; COLLARD; CRESS; HORSERADISH; KALE; KOHLRABI; MUSTARD; ORNAMENTAL PLANTS; RADISH; RAPE; RUTABAGA; TURNIP. [J.E.Ro.]

Caprellidea A common crustacean suborder in marine and estuarine environments, belonging to the superorder Peracarida, order Amphipoda. As peracarids, female Caprellidea have a ventral brood pouch and eggs develop directly (that is, there are no planktonic larvae); as amphipods, Caprellidea have the second and third thoracic appendages formed into enlarged subchelate claws (gnathopods). The abdomen and abdominal appendages of caprellideans are reduced; thus caprellideans are restricted to a clinging and crawling life-style. Almost all caprellideans use other organisms as substrata. Family distinctions within the Caprellidea are being reevaluated, but the classical divisions are the families Caprellidae and Cyamidae (whale lice). The ecology of both families is poorly understood. *See* AMPHIPODA; CRUSTACEA. [E.A.C.]

Capricornus The Sea Goat, in astronomy, an inconspicuous zodiacal constellation in the southern sky lying between Aquarius and Sagittarius. Capricornus is the tenth sign of the zodiac. The constellation has been described from the earliest times as a goat, or as a figure that is part goat with the tail of a fish (see illustration). The Tropic of Capricorn originates from this constellation, which marked the southern limit of the ecliptic in ancient times. *See* CONSTELLATION. [C.S.Y.]



Line pattern of constellation Capricornus. Grid lines represent coordinates of the sky. Apparent brightness, or magnitudes, of stars are shown by size of dots, which are graded by appropriate numbers as indicated.

Caprimulgiformes An order of crepuscular or mainly nocturnal birds collectively known as the goatsuckers. The group is apparently most closely related to the owls (Strigiformes) and is found worldwide, mainly in the tropics and warm temperate regions. Species breeding in the Arctic and cooler temperate regions are migratory. *See* STRIGIFORMES.

The order Caprimulgiformes is divided into the suborder Steatornithes, containing the single family Steatornithidae (oilbirds; 1 species), and the suborder Caprimulgi, including the families Podargidae (frogmouths; 13 species), Aegothelidae (owlet-frogmouths; 8 species), Nyctibiidae (potoos; 6 species), and Caprimulgidae (nightjars or goatsuckers; 77 species). The largest family, Caprimulgidae, is found worldwide; Steatornithidae are restricted to northern South America; Podargidae live in the Old World tropics from India to Australia; Aegothelidae are restricted to Australia and surrounding islands; and Nyctibiidae are found in the New World tropics.

The goatsuckers are primarily insectivorous, although the large frogmouths also feed on small vertebrates; the oilbird is unique in feeding on fruits, especially of palms. Goatsuckers have a huge, generally weak mouth with long, stout bristles surrounding it to make an effective trap for insects caught in flight. The wings are well developed, but the feet are weak and serve mainly for perching. The plumage is soft and fluffy, and is mottled and barred brown and gray, serving as a cryptic protective coloration. White patches may exist on the wings, tail, and throat, which are visible only in flight. Goatsuckers are solitary but may migrate in loose flocks (nighthawks). Most species are highly vocal, using the calls to attract mates and defend territories. The English names of a number of species, such as the whippoorwill and chuck-will's-widow, are based on their calls. Goatsuckers nest on the ground or in trees, laying one to five eggs. Young are downy and remain in the nest until they are able to fly. A few species are known to hibernate.

The oilbirds are colonial nesters, placing their nest of seeds and droppings on ledges deep in caves. Paired adults remain together throughout the year, roosting on their breeding ledge. Oilbirds have excellent night vision, but inside their often totally dark caves they find their way by using echolocation based on pulses of sound of about 7000 Hz which are audible to the human ear. *See* AVES; ECHOLOCATION. [W.J.B.]

Captorhinida A moderately coherent group of primitive reptiles constituting an order of the subclass Anapsida. Most members are characterized by a closed cheek (temporal) region. The order is divided into four suborders: Captorhinomorpha, Millerosauria, Procolophonia, and Pareiasauria. Except for the Procolophonia, which continue into the Late Triassic, Captorhinida are confined to the Permo-Carboniferous. They lived in lowlands, where they were associated with amphibians and synapsid reptiles. Some of the smaller animals of the Captorhinomorpha and the Millerosauria fed primarily on insects and small vertebrates, but the larger genera were exclusively herbivorous. Along with the caseid pelycosaurs, they were the dominant consumers of vegetation in the middle Permian ecosystems. *See* ANAPSIDA; REPTILIA; SYNAPSIDA. [E.C.O.]

Carat The unit of weight now used for all gemstones except pearls. It is also called the metric carat (m.c.). By international agreement, the carat weight is set at 200 milligrams. Pearls are weighed in grains, a unit of weight equal to 50 mg, or $^1/_4$ carat. The application of the term carat as a unit of weight must not be confused with the term karat used to indicate fineness or purity of the gold in which gems are mounted. *See* GEM. [R.T.L.]

Caraway An important spice from the fruits of the perennial herb *Carum carvi*, of the family Umbelliferae. A native of Europe and western Asia, it is now cultivated in many temperate areas of both hemispheres. The small, brown, slightly curved fruits are used in perfumery, cookery, confectionery, in medicine, and for flavoring beverages. *See* APIALES. [P.D.St./E.L.C.]

Carbohydrate A term applied to a group of substances which include the sugars, starches, and cellulose, along with many other related substances. This group of compounds plays a vitally important part in the lives of plants and animals, both as structural elements and in the maintenance of functional activity. Plants are unique in that they alone in nature have the power to synthesize carbohydrates from carbon dioxide and water in the presence of the green plant chlorophyll through the energy derived from sunlight, by the process of photosynthesis. This process is responsible not only for the existence of plants but for the maintenance of animal life as well, since animals obtain their entire food supply directly or indirectly from the carbohydrates of plants. *See* CARBOHYDRATE METABOLISM; PHOTOSYNTHESIS.

The term carbohydrate originated in the belief that naturally occurring compounds of this class, for example, D-glucose ($C_6H_{12}O_6$), sucrose ($C_{12}H_{22}O_{11}$), and cellulose $(C_6H_{10}O_5)_n$, could be represented formally as hydrates of carbon, that is, $C_x(H_2O)_y$. Later it became evident that this definition for carbohydrates was not a satisfactory one. New substances were discovered whose properties clearly indicated that they had the characteristics of sugars and belonged in the carbohydrate class, but which nevertheless showed a deviation from the required hydrogen-to-oxygen ratio. Examples of these are the important deoxy sugars, D-deoxyribose, L-fucose, and L-rhamnose, the uronic acids, and such compounds as ascorbic acid (vitamin C). The retention of the term carbohydrate is therefore a matter of convenience rather than of exact definition. A carbohydrate is usually defined as either a polyhydroxy aldehyde (aldose) or ketone (ketose), or as a substance which yields one of these compounds on hydrolysis. However, included within this class of compounds are substances also containing nitrogen and sulfur. *See* DEOXYRIBOSE; FRUCTOSE.

The properties of many carbohydrates differ enormously from one substance to another. The sugars, such as D-glucose or sucrose, are easily soluble, sweet-tasting, and crystalline; the starches are colloidal and paste-forming; and cellulose is completely insoluble. Yet chemical analysis shows that they have a common basis; the starches and cellulose may be degraded by different methods to the same crystalline sugar, D-glucose.

The carbohydrates usually are classified into three main groups according to complexity: monosaccharides, oligosaccharides, and polysaccharides. Monosaccharides are simple sugars that consist of a single carbohydrate unit which cannot be hydrolyzed into simpler substances. These are characterized, according to their length of carbon chain, as trioses ($C_3H_6O_3$), tetroses ($C_4H_8O_4$), pentoses ($C_5H_{10}O_5$), hexoses ($C_6H_{12}O_6$), heptoses ($C_7H_{14}O_7$), and so on. Oligosaccharides are compound sugars that are condensation products of two to five molecules of simple sugars and are subclassified into disaccharides, trisaccharides, tetrasaccharides, and pentasaccharides, according to the number of monosaccharide molecules yielded upon hydrolysis. Polysaccharides comprise a heterogeneous group of compounds which represent large aggregates of monosaccharide units, joined through glycosidic bonds. They are tasteless, nonreducing, amorphous substances that yield a large and indefinite number of monosaccharide units on hydrolysis. Their molecular weight is usually very high, and many of them, like starch or glycogen, have molecular weights of several million. They form colloidal solutions, but some polysaccharides, of which cellulose is an example, are completely insoluble in water. On account of their heterogeneity they are difficult to classify. *See* MONOSACCHARIDE; OLIGOSACCHARIDE; POLYSACCHARIDE.

The sugars are also classified into two general groups, the reducing and nonreducing. The reducing sugars are distinguished by the fact that because of their free, or potentially free, aldehyde or ketone groups they possess the property of readily reducing alkaline solutions of many metallic salts, such as those of copper, silver, bismuth, mercury, and iron. The most widely used reagent for this purpose is Fehling's solution. The reducing sugars constitute by far the larger group. The monosaccharides and many of their derivatives reduce Fehling's solution. Most of the disaccharides, including maltose, lactose, and the rarer sugars cellobiose, gentiobiose, melibiose, and turanose, are also reducing sugars. The best-known nonreducing sugar is the disaccharide sucrose. Among other nonreducing sugars are the disaccharide trehalose, the trisaccharides raffinose and melezitose, the tetrasaccharide stachyose, and the pentasaccharide verbascose.

The sugars consist of chains of carbon atoms which are united to one another at a tetrahedral angle of $109^\circ 28'$. A carbon atom to which are attached four different groups is called asymmetric. A sugar, or any other compound containing one or more asymmetric carbon atoms, possesses optical activity; that is, it rotates the plane of polarized light to the right or left. *See* OPTICAL ACTIVITY. [W.Z.H.]

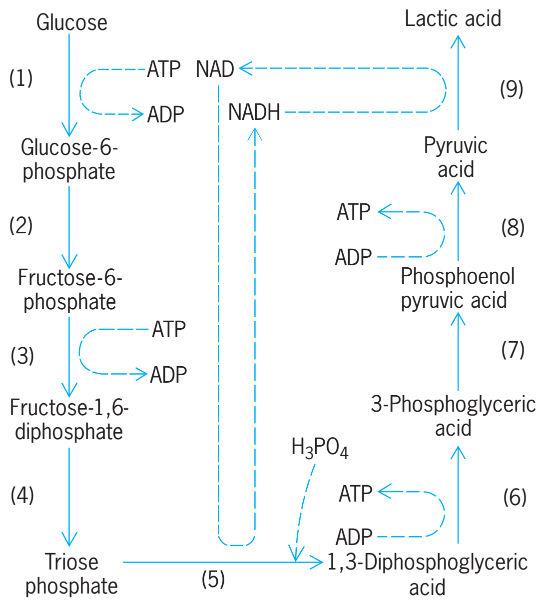
Carbohydrate metabolism Many aspects of biochemistry and physiology have to do with the breakdown and synthesis of simple sugars, oligosaccharides, and polysaccharides, and with the transport of sugars across cell membranes and tissues. The breakdown or dissimilation of simple sugars, particularly glucose, is one of the principal sources of energy for living organisms. The dissimilation may be anaerobic, as in fermentations, or aerobic, that is, respiratory. In both types of metabolism, the breakdown is accompanied by the formation of energy-rich bonds, chiefly the pyrophosphate bond of the coenzyme adenosine triphosphate (ATP), which serves as a coupling agent between different metabolic processes. In higher animals, glucose is the carbohydrate constituent of blood, which carries it to the tissues of the body. In higher plants, the disaccharide sucrose is often stored and transported by the tissues. Certain polysaccharides, especially starch and glycogen, are stored as endogenous food reserves in the cells of plants, animals, and microorganisms. Others, such as cellulose, chitin, and bacterial polysaccharides, serve as structural components of cell walls. As constituents of plant and animal tissues, various carbohydrates become available to those organisms which depend on other living or dead organisms for their source of nutrients. Hence, all naturally occurring carbohydrates can be dissimilated by some animals or microorganisms. *See* ADENOSINE TRIPHOSPHATE (ATP); CARBOHYDRATE; CELLULOSE; CHITIN; GLYCOGEN; STARCH.

Certain carbohydrates cannot be used as nutrients by humans. For example, cellulose cannot be digested by humans or other mammals and is a useful food only for those, such as the ruminants, that harbor cellulose-decomposing microorganisms in their digestive tracts. The principal dietary carbohydrates available to humans are the simple sugars glucose and fructose, the disaccharides sucrose and lactose, and the polysaccharides glycogen and starch. Lactose is the carbohydrate constituent of milk and hence one of the main sources of food during infancy. The disaccharides and polysaccharides that cannot be absorbed directly from the intestine are first digested and hydrolyzed by enzymes, glycosidases, secreted into the alimentary canal. *See* Fructose; Lactose.

The simple sugars reach the intestine or are produced there through the digestion of oligosaccharides. They are absorbed by the intestinal mucosa and transported across the tissue into the bloodstream. This process involves the accumulation of sugar against a concentration gradient and requires active metabolism of the mucosal tissue as a source of energy. The sugars are absorbed from the blood by the liver and are stored there as glycogen. The liver glycogen serves as a constant source of glucose in the bloodstream. The mechanisms of transport of sugars across cell membranes and tissues are not yet understood, but they appear to be highly specific for different sugars and to depend on enzymelike components of the cells.

The degradation of monosaccharides may follow one of several types of metabolic pathways. In the phosphorylative pathways, the sugar is first converted to a phosphate ester (phosphorylated) in a reaction with ATP. The phosphorylated sugar is then split into smaller units, either before or after oxidation. In the nonphosphorylative pathways, the sugar is usually oxidized to the corresponding aldonic acid. This may subsequently be broken down either with or without phosphorylation of the intermediate products. Among the principal intermediates in carbohydrate metabolism are glyceraldehyde-3-phosphate and pyruvic acid. The end products of metabolism depend on the organism and, to some extent, on the environmental conditions. Besides cell material the products may include carbon dioxide (CO_2), alcohols, organic acids, and hydrogen gas. In the so-called complete oxidations, CO_2 is the only excreted end product. In incomplete oxidations, characteristic of the vinegar bacteria and of certain fungi, oxidized end products such as gluconic, ketogluconic, citric, or fumaric acids may accumulate. Organic end products are invariably found in fermentations. The amount of biosynthesis and mechanical work that an organism can do at the expense of a given amount of sugar is many times greater in respiration than in fermentation. *See* Fermentation; Respiration.

The principal phosphorylative pathway involved in fermentations is known as the glycolytic, hexose diphosphate, or Embden-Meyerhof pathway (see illustration). This sequence of reactions is the basis of the lactic acid fermentation of mammalian muscle and of the alcoholic fermentation of yeast. For every molecule of glucose fermented through the glycolytic sequence, two molecules of ATP are used for phosphorylation, while four are produced. Thus, fermentation results in the net gain of two energy-rich phosphate bonds as ATP at the expense of inorganic phosphate esterified. The excess ATP is converted back to ADP and inorganic phosphate through coupled reactions useful to the organism, such as the mechanical work done by the contraction of muscle or biosynthetic reactions associated with growth. *See* Adenosine diphosphate (ADP); Nicotinamide adenine dinucleotide (NAD).



Glycolysis in lactic acid fermentation.

The oxidative or respiratory metabolism of sugars differs in several respects from fermentative dissimilation. First, the oxidative steps, that is, the reoxidation of NADH, are linked to the reduction of molecular oxygen. Second, the pyruvic acid produced through glycolytic or other mechanisms is further oxidized, usually to CO_2 and H_2O. Third, in most aerobic organisms, alternative pathways either supplement or completely replace the glycolytic sequence of reactions for the oxidation of sugars. Where pyruvic acid appears as a metabolic intermediate, it is generally oxidatively decarboxylated to yield CO_2 and the two-carbon acetyl fragment which combines with coenzyme A. The acetyl group is then further oxidized via the Krebs cycle. The principal alternative pathways by which sugars are dissimilated involve the oxidation of glucose-6-phosphate to the lactone of 6-phosphogluconic acid and are known as the hexose monophosphate pathways. *See* Citric acid cycle.

The metabolism of simple sugars other than glucose usually involves the conversion of the sugar to one of the intermediates of the phosphorylative pathways described for glucose metabolism. For example, fructose may be phosphorylated to fructose-6-phosphate, which can then be degraded via the glycolytic pathway or converted to glucose-6-phosphate and oxidized through the hexose monophosphate pathway.

The dissimilation and biosynthesis of the oligosaccharides are effected through the enzymatic cleavage or formation of glycosidic bonds between simple monosaccharide constituents of the complex carbohydrates. The principal types of enzyme which split or synthesize glycosidic bonds are the hydrolases or glycosidases, phosphorylases, and transglycosylases. The enzymes are generally highly specific with respect to the glycosidic portion, or moiety, and the type of linkage of the substrates which they attack. The essential function of all three types of enzymes is the transfer of the glycosyl moiety of the substrate to an appropriate glycosyl acceptor. The phosphorylases catalyze the reversible phosphorolysis of certain disaccharides, polysaccharides, and nucleosides by transferring the glycosyl moieties to inorganic phosphate. The breakdown of glycogen and starch by the enzymes known as amylophophorylases is an example of biologically important phosphorolytic reactions. [M.D.]

Carbon A chemical element, C, with an atomic number of 6 and an atomic weight of 12.01115. Carbon is unique in chemistry because it forms a vast number of compounds, larger than the sum total of all other elements combined. By far the largest group of these compounds are those composed of carbon and hydrogen. It has been estimated that there are at least 1,000,000 known organic compounds, and this number is increasing rapidly each year. Although the classification is not rigorous, carbon forms another series of compounds, classified as inorganic, comprising a much smaller number than the organic compounds. *See* ORGANIC CHEMISTRY; PERIODIC TABLE.

Elemental carbon exists in two well-defined crystalline allotropic forms, diamond and graphite. Other forms, which are poorly developed in crystallinity, are charcoal, coke, and carbon black. Chemically pure carbon is prepared by the thermal decomposition of sugar (sucrose) in the absence of air. The physical and chemical properties of carbon are dependent on the crystal structure of the element. The density varies from 2.25 g/cm^3 (1.30 oz/in.^{3}) for graphite to 3.51 g/cm^3 (2.03 oz/ in.^{3}) for diamond. For graphite, the melting point is 3500°C (6332°F) and the extrapolated boiling point is 4830°C (8726°F). Elemental carbon is a fairly inert substance. It is insoluble in water, dilute acids and bases, and organic solvents. At elevated temperatures, it combines with oxygen to form carbon monoxide or carbon dioxide. With hot oxidizing agents, such as nitric acid and potassium nitrate, mellitic acid, $C_6(CO_2H)_6$, is obtained. Of the halogens, only fluorine reacts with elemental carbon. A number of metals combine with the element at elevated temperatures to form carbides.

Carbon forms three gaseous compounds with oxygen: carbon monoxide, CO; carbon dioxide, CO_2; and carbon suboxide, C_3O_2. The first two oxides are the more important from an industrial standpoint. Carbon forms compounds with the halogens which have the general formula CX_4, where X is fluorine, chlorine, bromine, or iodine. At room temperature, carbon tetrafluoride is a gas, carbon tetrachloride is a liquid, and the other two compounds are solids. Mixed carbon tetrahalides are also known. Perhaps the most important of them is dichlorodifluoromethane, CCl_2F_2, commonly called Freon. *See* CARBON DIOXIDE; HALOGENATED HYDROCARBON.

Carbon and its compounds are found widely distributed in nature. It is estimated that carbon makes up 0.032% of the Earth's crust. Free carbon is found in large deposits as coal, an amorphous form of the element which contains additional complex carbon-hydrogen-nitrogen compounds. Pure crystalline carbon is found as graphite and as diamonds.

Extensive amounts of carbon are found in the form of its compounds. In the atmosphere, carbon is present in amounts of up to 0.03% by volume as carbon dioxide. Various minerals such as limestone, dolomite, marble, and chalk all contain carbon in the form of carbonate. All plant and animal life is composed of complex organic compounds containing carbon combined with hydrogen, oxygen, nitrogen, and other elements. The remains of past plant and animal life are found as deposits of petroleum, asphalt, and bitumen. Deposits of natural gas contain compounds that are composed of carbon and hydrogen. *See* CARBONATE MINERALS.

The free element has many uses, ranging from ornamental applications of the diamond in jewelry to the black-colored pigment of carbon black in automobile tires and printing inks. Another form of carbon, graphite, is used for high-temperature crucibles, arc-light and dry-cell electrodes, lead pencils, and as a lubricant. Charcoal, an amorphous form of carbon, is used as an absorbent for gases and as a decolorizing agent. *See* CARBON BLACK; CHARCOAL; DIAMOND; GRAPHITE.

The compounds of carbon find many uses. Carbon dioxide is used for the carbonation of beverages, for fire extinguishers, and in the solid state as a refrigerant. Carbon monoxide finds use as a reducing agent for many metallurgical processes. Carbon tetrachloride and carbon disulfide are important solvents for industrial uses. Freon is used in refrigeration devices. Calcium carbide is used to prepare acetylene, which is used for the welding and cutting of metals as well as for the preparation of other organic compounds. Other metal carbides find important uses as refractories and metal cutters. [E.E.W.]

Carbon black An amorphous form of carbon produced commercially by thermal or oxidative decomposition of hydrocarbons. It is used principally in rubber goods, pigments, and printer's ink. It is not an inert filler but enhances and reinforces various properties of rubber.

Manufacturing processes may be classed as contact, furnace, or thermal. In the channel (contact) process, natural gas is burned with insufficient air for complete combustion. The smoky flame from individual burners impinges on a cool channel iron, and carbon black deposited on the channel is removed by a scraper blade. In the furnace process, the hydrocarbon and air are fed into a reactor. Combustion of part of the hydrocarbon raises the temperature to 2000–3000°F (1100–1700°C), causing decomposition of the unburned hydrocarbon to carbon black. A water spray quickly cools the hot reaction products, and the finely divided black is recovered by cyclones and bag filters, In the thermal process, natural gas is decomposed to carbon and hydrogen by heated refractories. [C.J.He.]

Carbon dioxide A colorless, odorless, tasteless gas, formula CO_2, about 1.5 times as heavy as air. Under normal conditions, it is stable, inert, and nontoxic. The decay (slow oxidation) of all organic materials produces CO_2. Fresh air contains approximately 0.033% CO_2 by volume. In the respiratory action (breathing) of all animals and humans, CO_2 is exhaled.

Carbon dioxide gas may be liquefied or solidified. Solid CO_2 is known as dry ice. Carbon dioxide is obtained commercially from four sources: gas wells, fermentation, combustion of carbonaceous fuels, and as a by-product of chemical processing. Applications include use as a refrigerant, in either solid or liquid form, inerting medium, chemical reactant, neutralizing agent for alkalies, and pressurizing agent.

Most CO_2 is obtained as a by-product from steam-hydrocarbon reformers used in the production of ammonia, gasoline, and other chemicals; other sources include fermentation, deep gas wells, and direct production from carbonaceous fuels. Whatever the source, the crude CO_2 (containing at least 90% CO_2) is compressed in either two or three stages, cooled, purified, condensed to the liquid phase, and placed in insulated storage vessels. Carbon dioxide is distributed in three ways; in high-pressure uninsulated steel cylinders; as a low-pressure liquid in insulated truck trailers or rail tank cars; and as dry ice in insulated boxes, trucks, or boxcars. [J.S.L.]

Carbon-nitrogen-oxygen cycles A group of nuclear reactions that involve capture of protons by carbon, nitrogen, and oxygen nuclei. These cycles are believed to be the source of energy in main-sequence stars which are more massive than the Sun. Completion of any one of the cycles results in consumption of four protons, synthesis of one helium nucleus (^{4}He) and two neutrinos, and 26.73 MeV of energy. This energy E reflects the difference in mass m between the four protons and the helium nucleus and is equal to the mass difference times the square of the velocity of light c, as is known from Einstein's statement of mass-energy equivalence, $E = mc^2$. Because the nuclear fuel consumed in these processes is hydrogen, they are referred to as hydrogen burning by means of the carbon-nitrogen-oxygen (CNO) cycles. [G.R.C.]

Carbon star Any star whose spectrum shows a higher abundance of carbon than of oxygen. The carbon enhancements are easily recognizable from strong spectral absorption bands of carbon in molecular forms such as C_2, CN, and CH.

Most stars with masses between 0.6 and 5 times the mass of the Sun must pass through a carbon-star phase. Stars like the Sun, called dwarf stars, derive their energy from nuclear fusion of hydrogen to produce helium. As a star evolves and its core supply of hydrogen disappears, it can begin to burn helium into carbon, becoming a giant star. Asymptotic giant branch (AGB) stars are further evolved stars where nuclear burning of helium surrounds a dense carbon-oxygen core. The helium shell burning causes large temperature gradients and convection, which efficiently dredge up the processed, carbon-rich material toward the stellar surface. *See* NUCLEOSYNTHESIS.

Asymptotic giant branch carbon stars expel much of their carbon-rich envelopes as a wind. During a single year of its mass-losing phase, a carbon star may expel up to 10^{-5} of a solar mass, about 3 Earth masses, of carbon-rich material. This material may form cool envelopes of ejected circumstellar dust that dim and redden its appearance. The expelled stellar envelopes eventually mix with the surrounding interstellar environment, so that much of the carbon throughout the Milky Way Galaxy comes from mass-losing carbon stars.

Matter expelled from asymptotic giant branch stars in binary star systems may fall onto and enhance the carbon abundance of a dwarf companion star. Since dwarf carbon stars are much fainter, only a few are yet known. The long lifetimes of dwarfs, however, all but ensure that many more currently exist than do carbon giants. *See* BINARY STAR; DWARF STAR; GIANT STAR; STAR; STELLAR EVOLUTION. [P.J.G.]

Carbonate minerals Mineral species containing the carbonate ion as the fundamental anionic unit. The carbonate minerals can be classified as (1) anhydrous normal carbonates, (2) hydrated normal carbonates, (3) acid carbonates (bicarbonates), and (4) compound carbonates containing hydroxide, halide, or other anions in addition to the carbonate. *See* CARBONATE.

Most of the common carbonate minerals belong to group (1), and can be further classified according to their structures. The rhombohedral carbonates are typified by calcite, $CaCO_3$, and by dolomite, $CaMg(CO_3)_2$, The other structural type within this group is that of aragonite, which has orthorhombic symmetry. *See* ANKERITE; ARAGONITE; CALCITE; CERUSSITE; DOLOMITE; MAGNESITE; RHODOCHROSITE; SIDERITE; SMITHSONITE; STRONTIANITE; WITHERITE.

The minerals in groups (2) and (3) all decompose at relatively low temperatures and therefore occur only in sedimentary deposits (typically evaporites) and as low-temperature hydrothermal alteration products. The only common mineral in these groups is trona, $Na_3H(CO_3)_2 \cdot 2H_2O$. *See* SALINE EVAPORATE.

Similarly, the group (4) minerals are relatively rare and are characteristically low-temperature hydrothermal alteration products. The commonest members of this group are malachite, $Cu_2CO_3(OH)_2$, and azurite, $Cu_3(CO_3)_2(OH)_2$, which are often found in copper ore deposits. *See* AZURITE; MALACHITE.

Important occurrences of carbonates include ultrabasic igneous rocks such as carbonatites and serpentinites, and metamorphosed carbonate sediments, which may recrystallize to form marble. The major occurrences of carbonates, however, are in sedimentary deposits as limestone and dolomite rock. *See* DOLOMITE ROCK; LIMESTONE; MARBLE; SEDIMENTARY ROCKS. [A.M.G.]

Carbonatite An igneous rock in which carbonate minerals make up at least half the volume. Individual occurrences of carbonatite are not numerous (about 330 have been recognized) and generally are small, but they are widely distributed. Carbonatites are scientifically important because they reveal clues concerning the composition and thermal history of the Earth's mantle. *See* CARBONATE MINERALS.

The carbonate minerals that dominate the carbonatites are, in order of decreasing abundance, calcite, dolomite, ankerite, and rarely siderite and magnesite. Sodium- and potassium-rich carbonate minerals have been confirmed in igneous rocks at only one locality, the active volcano Oldoinyo Lengai in Tanzania. Noncarbonate minerals that typify carbonatites are apatite, magnetite, phlogopite or biotite, clinopyroxene, amphibole, monticellite, perovskite, and rarely olivine or melilite. Secondary minerals, produced by alteration of primary magmatic minerals, include barite, alkali feldspar, quartz, fluorite, hematite, rutile, pyrite, and chlorite. Minerals that are important in some carbonatites because they carry niobium, rare-earth elements, and other metals in concentrations high enough for profitable extraction are pyrochlore, bastnaesite, monazite, baddeleyite, and bornite.

Carbonatites, compared to the inferred composition of the Earth's mantle and to other igneous rocks, are greatly enriched in niobium, rare-earth elements, barium, strontium, phosphorus, and fluorine, and they are relatively depleted in silicon, aluminum, iron, magnesium, nickel, titanium, sodium, potassium, and chlorine. These extreme differences are attributed to strong fractionation between carbonate liquid on the one hand and silicate and oxide solid phases on the other during separation of the carbonate liquid from its source. Strontium and neodymium isotope ratios indicate that the sources of carbonatites are geologically old, inhomogeneous, and variably depleted in the radioactive parent elements rubidium and samarium.

Ultramafic xenoliths from lithospheric mantle commonly show textures and mineral assemblages that indicate modification of the original rock. This alteration typically results in strong enrichment in light rare-earth elements, uranium, thorium, and lead, but much less enrichment in titanium, zirconium, niobium, and strontium. These changes are commonly attributed to interaction of lithospheric mantle with an invading carbonate-rich magma. The wide geographic dispersal of these altered xenoliths suggests that carbonate-rich liquid has been more common in the upper mantle than the low abundance of carbonatites in the upper crust would suggest. According to the testimony of these samples, carbonatite magma, ascending through lithospheric mantle, commonly is trapped before it can invade the crust. In addition to the factors that can stop the rise of any magma (heat loss, increase of solidus temperature with decrease in pressure, decrease in density and increase in strength of wall rock), carbonatite magma can be halted by reaction with wall rock to form calcium and magnesium silicates plus carbon dioxide (CO_2), and by less oxidizing conditions to reduce carbonate to elemental carbon (graphite or diamond) or to methane. Both of these changes subtract dissolved CO_2 from the magma, causing crystallization. *See* EARTH INTERIOR.

Carbonatites are not restricted to a single tectonic regime. They occur in oceanic and continental crust and have formed in compressional fold belts and stable cratons as well as regions of crustal extension. Rather than indicating the stress field in the shallow crust in which they were emplaced, carbonatites are useful in modeling the long-term thermal and chemical development of the mantle. *See* IGNEOUS ROCKS.

Carbonatites yield a variety of mineral commodities, including phosphate, lime, niobium, rare-earth elements, anatase, fluorite, and copper. Agricultural phosphate for fertilizer is the most valuable single product from carbonatites; most is obtained from apatite in lateritic soils that have developed by tropical weathering of carbonatites, dissolving the carbonates and thereby concentrating the less soluble apatite. Lime for agriculture and for cement manufacture is obtained from carbonatites in regions where limestones are lacking. The carbonatites at Bayan Obo, China, and Mountain Pass, California, dominate the world suppliers of rare-earth elements, but many other carbonatites contain unexploited reserves. Tropical weathering at several carbonatites in Brazil has produced economically important concentrations of anatase (TiO_2) from decomposition of perovskite ($CaTiO_3$). [D.S.Ba.]

Carboniferous The fifth period of the Paleozoic Era. The Carboniferous Period spanned from about 355 million years to about 295 million years ago. The rocks that formed during this time interval are known as the Carboniferous System; they include a wide variety of sedimentary, igneous, and metamorphic rocks. Sedimentary rocks in the lower portion of the Carboniferous are typically carbonates, such as limestones and dolostones, and locally some evaporites. The upper portions of the system are usually composed of cyclically repeated successions of sandstones, coals, shales, and thin limestones. *See* Sedimentary rocks.

The economic importance of the Carboniferous is evident in its name, which refers to coal, the important energy source that fueled the industrialization of northwestern Europe in the early 1800s and led to the Carboniferous being one of the first geologic systems to be studied in detail. Carboniferous coals formed in coastal and fluvial environments in many parts of the world. Petroleum, another important energy resource, accumulated in many Carboniferous marine carbonate sediments, particularly near shelf margins adjacent to basinal black shale source rocks. In many regions the cyclical history of deposition and exposure has enhanced the permeability and porosity of the shelfal rocks to make them excellent petroleum reservoirs. The limestones of the Lower Carboniferous are extensively quarried and used for building stone, especially in northwestern Europe and the central and eastern United States. *See* Coal; Petroleum.

The base of the Carboniferous is placed at the first appearance of the conodont *Siphonodella sulcata*, a fossil that marks a widely recognized biozone in most marine sedimentary rocks. The reference locality for this base is an outcrop in Belgium. The top of the Carboniferous is placed at the first appearance of the conodont *Streptognathus isolatus* a few meters below the first appearance of the Permian fusulinacean foraminiferal zone of *Sphaeroschwagerina fusiformis*. The reference locality is in the southern Ural region in Kazakhstan. The equivalent biozone is at the base of *Pseudoschwagerina* in North America. *See* Conodont; Fusulinacea.

The International Subcommission on Carboniferous Stratigraphy reached general agreement in the 1970s and 1980s that the Carboniferous would be divided into two parts: a Lower Carboniferous Mississippian Subsystem and an Upper Carboniferous Pennsylvanian Subsystem. The two Carboniferous subsystems are subdivided into a number of series and stages that are variously identified in different parts of the world, based on biostratigraphic evidence using evolutionary successions in fossils or overlapping assemblage zones.

Perhaps the strongest of the many ecological factors that controlled biotic distributions were the paleogeographic changes within the Carboniferous that were brought about by the initial assembling of the supercontinent Pangaea and the associated mountain-building activities, which greatly modified climate, ocean currents, and seaways. In the Early Carboniferous, a nearly continuous equatorial seaway permitted extensive tropical and subtropical carbonate sedimentation on the shelves and platforms in North America, northern and southern Europe, Kazakhstan, North and South China, and the northern shores of the protocontinent Gondwana (such as northern Africa).

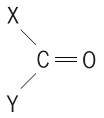
The gradual collision of northern Gondwana against northern Europe-North America (also called Euramerica or Laurussia) started the formation of the supercontinent of Pangaea. *See* Continental drift; Continents, evolution of; Paleogeography; Plate tectonics.

An additional ramification of the formation of Pangaea was the beginning of very extensive glaciation in the Southern Hemisphere polar and high-latitude regions of the supercontinent. Glacial deposits are also known from smaller continental fragments that were at high paleolatitudes in the Northern Hemisphere. The Earth's climate cooled, tropical carbonate-producing areas became restricted toward the Equator, and eustatic sea-level fluctuations became prominent in the sedimentary record. *See* Glacial epoch.

During the Carboniferous, life evolved to exploit fully the numerous marine and nonmarine aquatic environments and terrestrial and aerial habitats. Single-cell protozoan foraminifers evolved new abilities to construct layered, calcareous walls. Insects have remarkable evolutionary histories during the Carboniferous. They adapted to flight and dispersed into many terrestrial and fresh-water habitats. Vertebrates also evolved rapidly. Although acanthodian fish declined from their Devonian peak, sharklike fishes and primitive bony fishes adapted well to the expanded environments and the new ecological food chains of the Carboniferous. Some sharklike groups invaded fresh-water habitats, where they were associated with coal swamp deposits. Carboniferous amphibians evolved rapidly in several directions. The earliest were the labyrinthodont embolomeres, which had labyrinthodont teeth and were mainly aquatic. Another significant labyrinthodont group was the rhachitomes, which originated in the Early Carboniferous and became abundant, commonly reaching about 1 m (3 ft) or more; they were widespread in terrestrial habitats during the Late Carboniferous and Permian. Primitive reptiles evolved from one of the embolomere amphibian lineages during the Late Carboniferous. They formed the basal stock from which all other reptiles have evolved including the earliest mammallike reptiles in the Late Carboniferous. During the Late Carboniferous, early reptiles coexisted with several advanced amphibian groups which shared at least some, but probably not all, of their reptilelike characters.

Terrestrial plants also showed major diversification of habitats and the evolution of important new lineages during the Carboniferous. Initially, Early Carboniferous plants were predominantly a continuation of latest Devonian groups; however, they were distinguished in part by their large sizes with many arborescent lycopods and large articulates, and pteridosperms (seed ferns) and ferns became increasingly abundant and varied. By the Late Carboniferous, extensive swamps formed along the broad, nearly flat coastal areas; and these coal-forming environments tended to move laterally across the coastal plain areas as the sea level repeatedly rose. Other coal-forming marshes were common in the floodplains and channel fills of the broad rivers of upper delta distributary systems. During the Late Carboniferous, primitive conifers appeared and included araucarias, which became common in some, probably drier ecological habitats. *See* Paleobotany; Paleozoic. [C.A.R.; J.R.P.R.]

Carbonyl A functional group found in organic compounds in which a carbon atom is doubly bonded to an oxygen atom:



Depending upon the nature of the other groups attached to carbon, the most common compounds containing the carbonyl group are aldehydes (X and Y = H; X = H, Y = alkyl or aryl), ketones (X and Y = alkyl or aryl), carboxylic acids (X = OH, Y = H, alkyl, or aryl), esters (X = O-alkyl or aryl; Y = H, alkyl, or aryl), and amides (X = N—H, N-alkyl, or N-aryl; Y = H, alkyl, or aryl). Other compounds that contain the carbonyl group are acid halides, acid anhydrides, lactones, and lactams. *See* Acid anhydride; Acid halide; Aldehyde; Amide; Ester; Ketone.

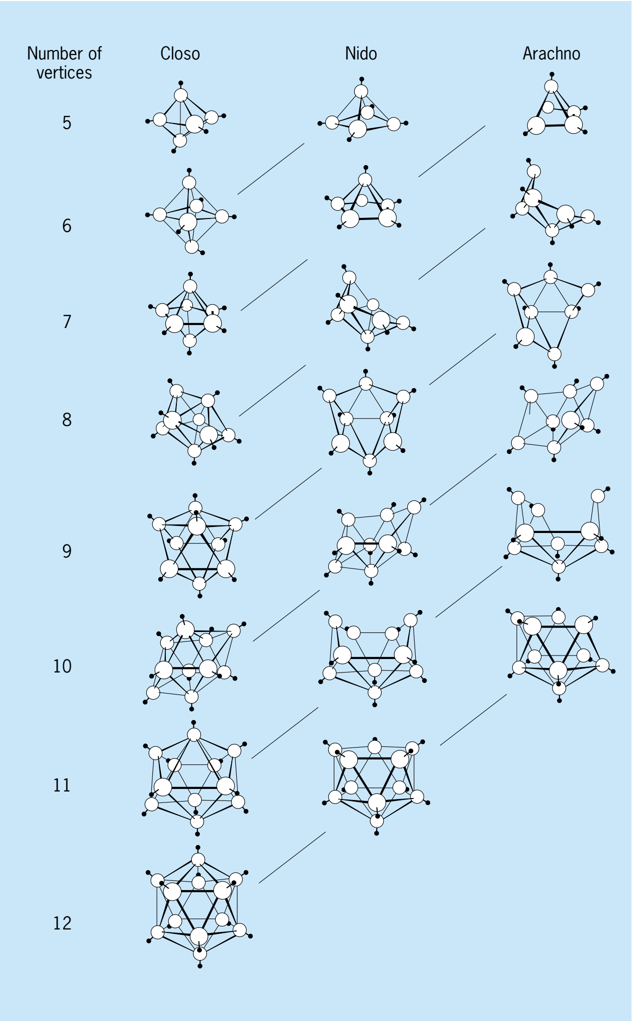
All the compounds containing this functional group are referred to in a general way as carbonyl compounds. It is important, however, to distinguish these compounds from a large group formed from metals and carbon monoxide, which are known as metal carbonyls. In these latter compounds, there is only one group attached to the carbon in addition to the oxygen, and the carbon atom is viewed as triply bonded to the oxygen. *See* Metal carbonyl. [J.P.Fr.]

Carborane

Carborane A cluster compound containing both carbon (C) and boron (B) atoms as well as hydrogen (H) atoms external to the framework of the cluster. A cluster compound is one with insufficient electrons to allow for classical two-center two-electron bonds between all adjacent atoms. Sometimes the term carborane is used as a synonym for *closo*-1,2-$C_2B_{10}H_{12}$, commonly referred to as *ortho*-carborane. Carboranes are of interest because of their nonclassical bonding, their relatively high thermal stability, and their ability, when containing the ^{10}B isotope, to capture neutrons efficiently. *See* BORANE.

The structures of carboranes are based upon a series of three-dimensional, cagelike geometric shapes possessing triangulated faces; such shapes are termed delta polyhedra. The structure for any given carborane may be predicted by determining the framework electrons, by determining the number of electrons involved in bonding the boron and carbon atoms of the cluster framework together, and by using Wade's rule. Wade's rule states that a cluster containing n framework electrons will be derived from a delta polyhedron containing $(n - 2)/2$ vertices, the parent cluster. Once this parent cluster has been determined, the geometry of the cluster framework may be predicted by clipping off vertices from the parent cluster until a polyhedron whose number of vertices is equivalent to the sum of boron and carbon atoms in the cluster framework is obtained.

Carboranes are placed, according to their structure, into several classifications. The most common classifications are closo (closed), nido (nestlike), and arachno (cobweb) (see illustration). If a carborane's framework structure is that of a closed delta polyhedron, the carborane is said to be a *closo*-carborane. If a carborane's framework structure is that of a closed delta polyhedron minus one or two vertices, the carborane is said to be a *nido*- or *arachno*-carborane, respectively.



Parent clusters from which carborane structures are determined. The diagonal lines define series of related closo, nido, and arachno structures.

The bonding within a carborane can be thought of in terms of localized atomic orbitals forming both classical two-center two-electron bonds and nonclassical three-center two-electron bonds. Each vertex boron and carbon atom can be thought of as being sp^3 hybridized, with three of these hybrid orbitals of each vertex atom employed in framework bonding. Employing this simple approach, the bonding within carboranes can be represented by employing resonance structures. For example, *nido*-$C_2B_4H_8$ exhibits three resonance structures. The existence of resonance structures implies a delocalization of electron density throughout the cluster framework. Indeed, carboranes exhibit a high degree of electron density delocalization, and their bonding can be described more accurately by employing molecular orbital theory. *See* CHEMICAL BONDING; DELOCALIZATION; MOLECULAR ORBITAL THEORY; RESONANCE (MOLECULAR STRUCTURE).

The typical synthesis of a carborane involves the reaction of a boron hydride cluster, containing only boron and hydrogen, with an alkyne. The resulting carborane contains two carbon atoms in its skeletal structure, a dicarbon carborane. The dicarbon carboranes, because of their relative ease of preparation, have been the most widely studied group of carboranes. In particular, *closo*-1,2-$C_2B_{10}H_{12}$, the most readily available carborane, has been extensively studied. Other common groups of carboranes include the monocarbon and tetracarbon carboranes. *See* ALKYNE.

[T.D.G.]

Carboxylic acid

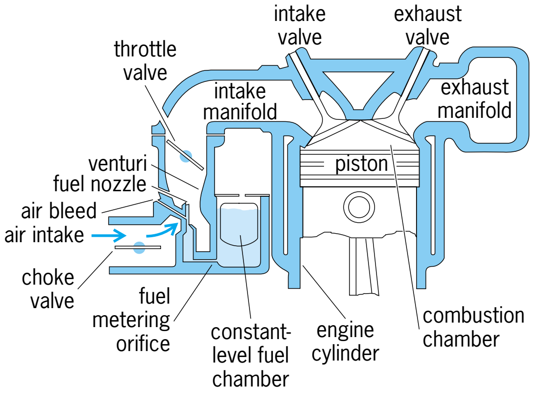
Carboxylic acid One of a large family of organic substances widely distributed in nature, and characterized by the presence of one or more carboxyl groups (—COOH). These groups typically yield protons in aqueous solution. In the type formula, $R(CXY)_nCOOH$, symbols R, X, and Y can be hydrogen, saturated or unsaturated groups, carboxyl, alicyclic, or aromatic groups, halogens, or other substituents, and n may vary from zero (formic acid, HCOOH) to more than 100, provided that the normal carbon covalence of four is maintained.

Physical and chemical properties of carboxylic acids are represented, grossly, by the resultant of the various chemical groupings present in the molecule. A short-chain aliphatic acid, wherein the carboxyl is dominant, is a pungent, corrosive, water-soluble liquid of abnormally high boiling point (because of molecular association), with specific gravity close to 1 (higher for formic and acetic acids). With increasing molecular weight, the hydrocarbon grouping overbalances the carboxyl; sharpness of odor diminishes, boiling and melting points rise, the specific gravity falls toward that of the parent hydrocarbon, and the water solubility decreases. Thus the typical high-molecular-weight saturated acid is a bland, waxlike solid.

Acids are used in large quantities in the production of esters, acid halides, acid amides, and acid anhydrides. They find wide use in the manufacture of soaps and detergents, in thickening lubricating greases (stearate soaps), in modifying rigidity in plastics, in compounding buffing bricks and abrasives, and in the manufacture of crayons, dictaphone cylinders, and phonograph records. The solvent action of acids finds use in manufacture of carbon paper, inks, and in the compounding of synthetic and natural rubber. Because of the stability of saturated fatty acids toward oxidation, these are often used as solvents for carrying out oxidation reactions upon sensitive compounds. [E.B.R.]

Carburetor

Carburetor A device that controls the power output and fuel feed of internal combustion spark-ignition engines used for automotive, aircraft, and auxiliary services. Its duties include control of the engine power by the air throttle; metering, delivery, and mixing of fuel in the airstream; and graduating the



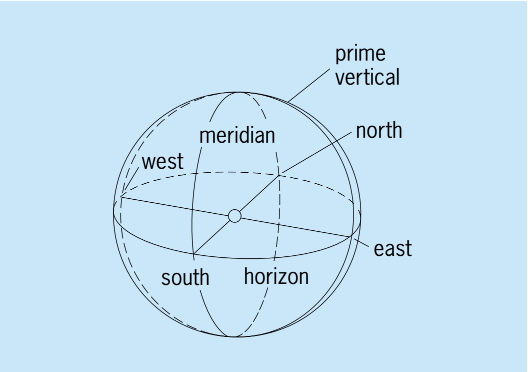
Elements that basically determine air and fuel charges received by the engine through the carburetor.

fuel-air ratio according to engine requirements in starting, idling, and load and altitude changes. The fuel is usually gasoline or similar liquid hydrocarbon compounds, although some engines with a carburetor may also operate on a gaseous fuel such as propane or compressed natural gas. A carburetor may be classified as having either a fixed venturi, in which the diameter of the air opening ahead of the throttle valve remains constant, or a variable venturi, which changes area to meet the changing demand. *See* Automobile; Engine; Fuel system; Venturi tube.

A simple updraft carburetor with a fixed venturi illustrates basic carburetor action (see illustration). Intake air charge, at full or reduced atmospheric pressure as controlled by the throttle, is drawn into the cylinder by the downward motion of the piston to mix with the unscavenged exhaust remaining in the cylinder from the previous combustion. A cylinder is most completely filled with the fuel-air mixture when no other cylinder is drawing in through the same intake passage at the same time. The fuel is usually metered through a calibrated orifice, or jet, at a differential pressure derived from the pressure drop in a venturi in the intake air passage. [D.L.An.]

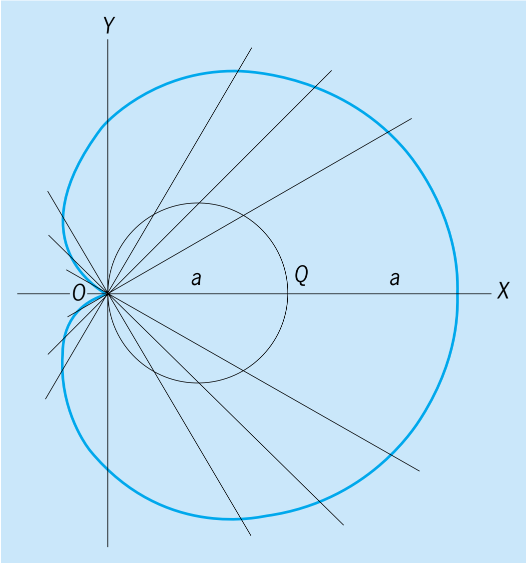
Cardamon The plant *Elettaria cardamomum* (Zingiberaceae), a perennial herb that is a native of India. The small, light-colored seeds, borne in capsules, have a delicate flavor. They are used in curries, cakes, pickles, and in general cooking, as well as in medicine. *See* Zingiberales. [P.D.St./E.L.C.]

Cardinal points The four intersections of the horizon with the meridian and with the prime vertical circle, or simply prime vertical, the intersections with the meridian being designated north and south, and the intersections with the prime vertical being designated east and west (see illustration). The cardinal points are 90° apart; they lie in a plane with each other and correspond to the cardinal regions of the heavens. The four intermediate points, northeast, southeast, northwest, and southwest, are the collateral points. [F.H.R.]



Cardinal points around the horizon.

Cardioid A heart-shaped curve generated by a point of a circle that rolls (without slipping) on a fixed circle of the same diameter. In point-wise construction of the curve, let O be a fixed point of a circle C of diameter a, and Q a variable point of C. Lay off distance a along the secant OQ, in both directions from Q. The locus of the two points thus obtained is a cardioid (see illustration). If a rectangular coordinate system is chosen with O for origin initially and y axis tangent to C at O, the cardioid has equation $(x^2 + y^2 - ax)^2 = a^2(x^2 - y^2)$. The equation in polar coordinates is $p = a(1 + \cos\theta)$. Its area is $3/2\pi a^2$, or six times the area of C, and its length is $8a$. *See* Analytic geometry. [L.M.Bl.]



A cardioid (symbols are explained in the text).

Cardiovascular system Those structures, such as the heart, or pumping mechanism, and the arteries, veins, and capillaries, which provide channels for the flow of blood. The cardiovascular system is sometimes called the blood-vascular system. The circulatory system includes both the cardiovascular and lymphatic systems; the latter consists of lymph channels (lymphatics), nodes, and fluid lymph which finally empties into the bloodstream. *See* Blood; Heart (vertebrate); Hematopoiesis; Lymphatic system. [C.K.W.]

Circulatory physiology describes the structure and operation of the circulation in living animals, and enquires as to how or why the circulatory system may have evolved. The circulatory system in all vertebrates has multiple functions, but all functions are involved in regulating the internal environment of the animal (promoting homeostasis). In all vertebrates the circulatory system consists of a central pump, the heart, which drives a liquid transport medium, the blood, continuously around a closed system of tubes, the vascular system. The arterial portion of this system is divided into larger elastic and smaller resistance vessels (arterioles) which distribute blood to specialized regions or organs where transfer of nutrients, oxygen, or waste products takes place across the walls of a fine network of microscopic capillaries. Blood from the capillaries passes through the venules (small venous vessels) into the main vein and returns to the heart. The arterioles, venules, and capillaries make up the microcirculation, which is arguably the most important functional role of the vertebrate circulatory system from a functional point of view.

Cardiovascular system disorders are those disorders which involve the arteries, veins, and lymphatics. *See* Arteriosclerosis; Lymphadenitis; Phlebitis. [D.R.J.]

Carnauba wax Product exuded from the leaves of the wax palm, *Copernicia cerifera*, a native of Brazil and other regions in tropical South America. It is the hardest, highest-melting natural wax and is used in making candies, shoe polish, high-luster wax, varnishes, phonograph records, and surface coating of automobiles. *See* Wax, animal and vegetable. [E.L.C.]

Carnivora One of the larger orders of placental mammals, including fossil and living dogs, raccoons, pandas, bears, weasels, skunks, badgers, otters, mongooses, civets, cats, hyenas, seals, walruses, and many extinct groups organized into 12 families, with about 112 living genera and more than twice as many extinct genera. The subdivision of the order into three superfamilies has long been practiced and the following groups seem appropriate: Miacoidea, Canoidea, and Feloidea. The primary adaptation in this order was for predation on other vertebrates and invertebrates. A few carnivorans (for example, bear and panda) have secondarily become largely or entirely herbivorous, but even then the ancestral adaptations for predation are still clearly evident in the structure of the teeth and jaws. The Carnivora have been highly successful animals since their first appearance in the early Paleocene.

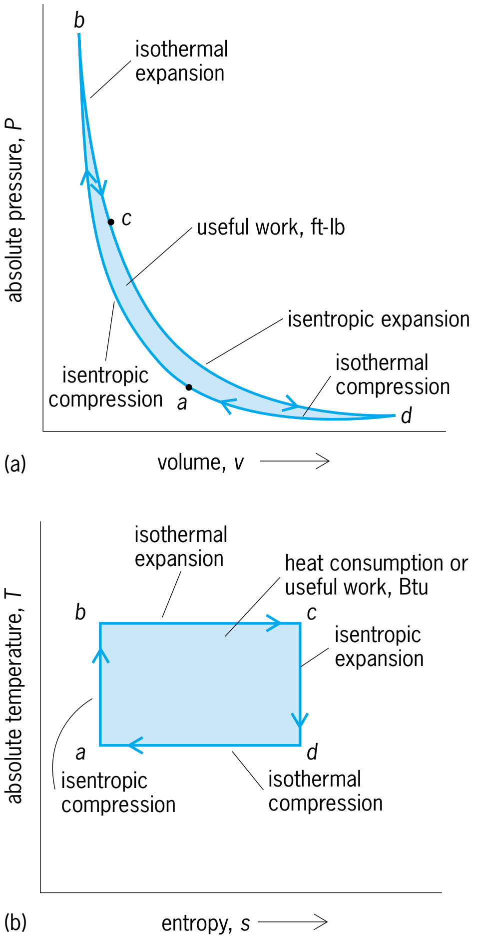
Structural adaptations involve the teeth and jaws. The dentition is sharply divided into three functional units. The incisors act as a tool for nipping and delicate prehension, and the large, interlocking upper and lower canines for heavy piercing and tearing during the killing of prey. The cheek teeth are divided into premolars (for heavy prehension) and molars (for slicing and grinding), which may be variously modified depending on the specific adaptation, but there is a constant tendency for the last (fourth) upper premolar and the first lower molar to enlarge and form longtitudinal opposed shearing blades (the carnassials). In all carnivorans the jaw articulation is arranged in such a manner that movement is limited to vertical hinge motions and transverse sliding. The temporal muscle dominates the jaw musculature, forming at least one-half of the total mass of the jaw muscles.

The earliest fossil records are early Paleocene, but the earliest well-represented material comes from the middle Paleocene of North America. During the Paleocene and Eocene the stem-carnivorans or miacoids underwent considerable diversification in both the Old and New World. At the end of Eocene and beginning of Oligocene time throughout the Northern Hemisphere, a dramatic change took place within the Carnivora; this was the appearance of primitive representatives of modern carnivoran families. *See* Badger; Bear; Cat; Civet; Coati; Dog; Ferret; Fisher; Hyena; Mammalia; Marten; Mink; Mongoose; Otter; Panda; Pinnipeds; Raccoon; Skunk; Weasel; Wolverine. [R.H.T.]

Carnot cycle A hypothetical thermodynamic cycle used as a standard of comparison for actual cycles. The Carnot cycle shows that, even under ideal conditions, a heat engine cannot convert all the heat energy supplied to it into mechanical energy; some of the heat energy must be rejected.

In a Carnot cycle, an engine accepts heat energy from a high-temperature source, or hot body, converts part of the received energy into mechanical (or electrical) work, and rejects the remainder to a low-temperature sink, or cold body. The greater the temperature difference between the source and sink, the greater the efficiency of the heat engine.

The Carnot cycle (see illustration) consists first of an isentropic compression, then an isothermal heat addition, followed by an isentropic expansion, and concludes with an isothermal heat rejection process. In short, the processes are compression, addition of heat, expansion, and rejection of heat, all in a qualified and definite manner. The net effect of the cycle is that heat is added at a constant high temperature, somewhat less heat is rejected at a constant low temperature, and the algebraic sum of these heat quantities is equal to the work done by the cycle.



Carnot cycle for air. (*a*) Absolute pressure versus volume. (*b*) Absolute temperature versus entropy.

A Carnot cycle consists entirely of reversible processes; thus it can theoretically operate to withdraw heat from a cold body and to discharge that heat to a hot body. To do so, the cycle requires work input from its surroundings. The heat equivalent of this work input is also discharged to the hot body. Just as the Carnot cycle provides the highest efficiency for a power cycle operating between two fixed temperatures, so does the reversed Carnot cycle provide the best coefficient of performance for a device pumping heat from a low temperature to a higher one. *See* Heat pump; Refrigeration cycle.

Good as the ideal Carnot cycle may be, there are serious difficulties that emerge when one wishes to make an actual Carnot engine. The necessarily high peak pressures and temperatures limit the practical thermal efficiency that an actual engine can achieve. Although the Carnot cycle is independent of the working substance, and hence is applicable to a vapor cycle, the difficulty of efficiently compressing a vapor-liquid mixture renders the cycle impractical. *See* Power plant; Thermodynamic cycle; Thermodynamic principles. [T.Ba.]

Carnotite A mineral that is a hydrous vanadate of potassium and uranium, $K_2(UO_2)_2(VO_4)_2 \cdot nH_2O$. The water content varies at ordinary temperatures from one to three molecules. Carnotite generally occurs as a powder or as a slightly coherent microcrystalline aggregate. Color ranges from bright yellow to lemon- and greenish-yellow.

In the United States the principal region of carnotite mineralization is the Colorado Plateau and adjoining districts of Utah, New Mexico, and Arizona. Carnotite is found also in Wyoming and in Carbon County, Pennsylvania. Deposits are located at Radium Hill near Olary, Australia, and in Katanga (Zaire). Carnotite is the chief source of uranium in the United States. It is also a source of radium and vanadium. *See* RADIOACTIVE MINERALS; URANIUM; VANADIUM. [W.R.Lo.]

Carotenoid Any of a class of yellow, orange, red, and purple pigments that are widely distributed in nature. Carotenoids are generally fat-soluble unless they are complexed with proteins. In plants, carotenoids are usually located in quantity in the grana of chloroplasts in the form of carotenoprotein complexes. Carotenoprotein complexes give blue, green, purple, red, or other colors to crustaceans, echinoderms, nudibranch mollusks, and other invertebrate animals. Some coral coelenterates exhibit purple, pink, orange, or other colors due to carotenoids in the calcareous skeletal material. Cooked or denatured lobster, crab, and shrimp show the modified colors of their carotenoproteins.

The general structure of carotenoids is that of aliphatic and aliphatic-alicyclic polyenes, with a few aromatic-type polyenes. Most carotenoid pigments are tetraterpenes with a 40-carbon (C_{40}) skeleton. More than 300 carotenoids of known structure are recognized, and the number is still on the rise. *See* TERPENE.

There are several biochemical functions in which the role of carotenoids is well understood. These include carotenoids in the photosynthetic apparatus of green plants, algae, and photosynthetic bacteria, where carotenoids function as a blue light-harvesting pigment (antenna or accessory pigment) for photosynthesis. Thus carotenoids make it possible for photosynthetic organisms more fully to utilize the solar energy in the visible spectral region. *See* CHLOROPHYLL; PHOTOSYNTHESIS.

Another function of carotenoids is to protect biological systems such as the photosynthetic apparatus from photodynamic damage. This is done by quenching the powerful photodynamic oxidizing agent, singlet oxygen, produced as an undesirable by-product of the exposure of pigmented organisms to light.

Perhaps the most important industrial application of carotenoids is in safe coloration of foods, as exemplified in the coloring and fortification of margarine and poultry feedstuff. [P.-S.S.; T.Y.L.]

Carotid body A special sensory organ (glomus caroticum) which is located in the angle between the bifurcation of the common carotid artery into the external and internal carotid arteries. The carotid body is a bilateral ovoid structure which in humans measures approximately 0.2 by 0.3 in. (5 by 7 mm) and is usually embedded within the outer connective tissue layer of the adjacent common carotid artery. The carotid bodies are termed chemoreceptors because they closely monitor the oxygen and carbon dioxide (CO_2) content of the blood. *See* CHEMORECEPTION. [J.Ha.]

Carp The common name for a number of cypriniform fishes of the family Cyprinidae. The carp (*Cyprinus carpio*) is closely related to the goldfish (*Crassius auratus*). The fish originated in China, where for centuries it was raised for food. It was imported into the United States from Europe, where it also has been raised for years as a source of food.

The carp has pharyngeal teeth and a suckerlike mouth. A very long dorsal fin is preceded by a strong spine. The swim bladder of the carp is associated with a group of small bones at the anterior end, the Weberian ossicles. This structural modification enables the carp to perceive sound quite well. *See* CYPRINIFORMES. [C.B.C.]

Carpal tunnel syndrome A condition caused by the thickening of ligaments and tendon sheaths at the wrist with consequent compression of the median nerve at the palm. Affected individuals report numbness, tingling, and pain in the hand; the discomfort often becomes worse at night or after use of the hand. A physical examination of the injured hand during the early stages of the syndrome often reveals no abnormality. With more severe nerve compression, the individual experiences sensory loss over some or all of the digits innervated by the median nerve (thumb, index finger, middle finger, and ring finger) and weakness of thumb movement.

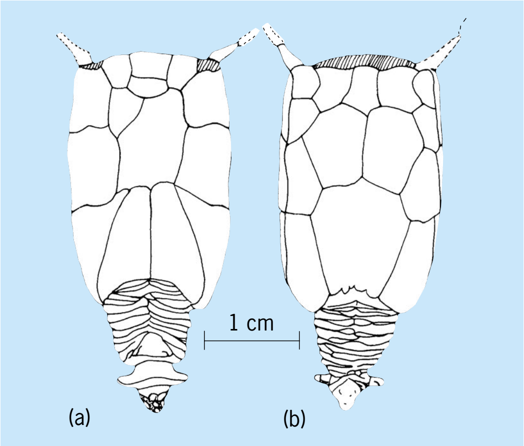
The incidence of carpal tunnel syndrome is greater among electronic-parts assemblers, frozen-food processors, musicians, and dental hygienists. Highly repetitive wrist movements, use of vibrating tools, awkward wrist positions, and movements involving great force seem to be correlated with the disorder. Awkward and repetitive wrist motions occur in many office tasks, such as typing and word processing.

Carpal tunnel syndrome probably accounts for a minority of the cases of overuse syndrome (cumulative trauma syndrome), which is a common problem in occupational settings. Overuse syndrome symptoms include muscle pain, tendinitis, fibrositis (inflammation of connective tissue in a joint region), and epicondylitis (inflammation of the eminence on the condyle of a bone). Although the causative relationship between the two disorders has not been conclusively proven, the incidence of both carpal tunnel syndrome and overuse syndrome appears to increase in tandem in individuals who are at risk.

The increase in pressure within the carpal canal is usually caused by nonspecific inflammation of flexor tendon sheaths. Diabetes, pregnancy, rheumatoid arthritis, and hypothyroidism are the most common medical conditions associated with carpal tunnel syndrome. A reduction in the flow of blood to the nerve can account for the intermittent tingling that occurs at night or with wrist flexion. *See* AMYLOIDOSIS; ARTHRITIS; DIABETES; THYROID GLAND DISORDERS.

Nonsurgical treatment includes avoidance of the use of the wrist, use of a splint to keep the wrist in a neutral position, and anti-inflammatory medications. These treatments are especially useful in individuals with an acute flare-up and in those with minimal and intermittent symptoms. Surgical treatment may be used if conservative approaches fail. The procedure is usually done on an outpatient basis with prognoses of good to excellent in 80% of the cases. Although 40% of the individuals regain normal function, the condition of 5% may worsen. [D.M.D.]

Carpoids The common name for four extinct classes of primitive echinoderms that have a flattened theca or body lacking radial symmetry. These enigmatic fossils were originally classified together in the class Carpoidea, but more recent echinoderm researchers have assigned them to four separate classes in the subphylum Homalozoa: the Stylophora (or Calcichordates), Homoiostelea, Homostelea, and Ctenocystoidea. These four classes include about 50 genera that range from the Early or Middle Cambrian to the Late Carboniferous. Carpoids have a flattened theca that varies from asymmetrical to nearly bilaterally symmetrical (see illustration) and is made up of sutured, multiporous, single-crystal, calcite plates like those found in other echinoderms. Three of the classes have a long plated appendage attached to the theca that was used for locomotion and, in the Stylophora, also for feeding. Carpoids were apparently mobile, bottom-living or shallow-burrowing, detritus or suspension feeders, sifting out small food particles from the



***Enoploura popei*, a stylophoran carpoid from the Late Ordovician of Ohio. (*a*) Concave lower side and (*b*) convex upper side of the plated theca showing part of the attached, tapering appendage used for locomotion and feeding at the bottom.**

top layer of soft sediment or from the surrounding seawater. Because of the distinctive skeletons, most researchers consider carpoids as true echinoderms, although they seem only distantly related to other fossil and living echinoderms that have well-developed pentameral symmetry. *See* Echinodermata; Homalozoa. [J.Sp.]

Carrageenan A polysaccharide that is a major constituent of the cell walls of certain red algae (Rhodophyceae), especially members of the families Gigartinaceae, Hypneaceae, Phyllophoraceae, and Solieriaceae. Extracted for its suspending, emulsifying, stabilizing, and gelling properties, it is one of three algal polysaccharides of major economic importance, the others being agar and alginate.

The main sources of carrageenan are *Chondrus crispus* (Gigartinaceae) from the Maritime Provinces of Canada and various species of *Eucheuma* (Solieriaceae) from the Philippines. *Chondrus*, popularly called Irish moss, is harvested from naturally occurring intertidal stands, while *Eucheuma* is successfully grown in mariculture on nets and lines.

About 80% of the refined carrageenan is used in food processing; the dairy industry is the chief consumer. The rest is used in the cosmetic, pharmaceutical, printing, and textile industries. *See* Agar; Alginate; Rhodophyceae. [P.C.Si.; R.L.Moe.]

Carrier A periodic waveform upon which an information-bearing signal is impressed. This process is known as modulation and comprises a variety of forms such as amplitude, phase, and frequency modulation. The most common type of carrier is the sinusoidal carrier, but any periodic waveform followed by a band-pass filter can serve as a carrier. *See* Amplitude modulation; Frequency modulation; Modulation; Phase modulation. [L.B.M.]

Carrot A biennial umbellifer (*Daucus carota*) of Asiatic and Mediterranean origin belonging to the plant order Apiales. The carrot is grown for its edible roots which are eaten raw or cooked. Varieties are classified according to length of root (long or short or stump-rooted) and use (fresh market or processing). Popular varieties for fresh market are Imperator and Gold Pak; for processing, Red Cored Chantenay and Royal Chantenay. Texas, California, and Arizona are important producing states. *See* Apiales. [H.J.C.]

Cartilage A firm, resilient connective tissue of vertebrates and some invertebrates. Isolated pieces act to provide support and anchor muscles, or with bone to contribute its resilience and interstitial growth to skeletal functions. Cartilage comprises a firm extracellular matrix synthesized by large, ovoid cells (chondrocytes) located in holes called lacunae. The matrix elements are water bound by the high negative charge of extended proteoglycan (protein-polysaccharide) molecules, and a network of fine collagen fibrils. The elements furnish mechanical stability, give, and tensile strength, but allow the diffusion of nutrients and waste to keep the cells alive. *See* Bone; Collagen.

Cartilage is modified in several ways. In elastic cartilage, elastic fibers in the matrix increase resilience, as in cartilages supporting the Eustachian tube, mammalian external ear, and parts of the larynx. Where cartilage joins bones tightly at certain joints with limited mobility, for example, at the pubic symphysis and between vertebrae, the matrix of fibrocartilage contains prominent collagen fibers and has less proteoglycan than the typical hyaline variety. Hyaline cartilage, named for its glassy translucence, is the major support in the airway; and throughout the embryo, pieces of it develop as a precursor to the bony skeleton, except in the face and upper skull. *See* Ear (vertebrate); Larynx.

The primitive cartilaginous skeleton undergoes another modification, by locally calcifying its matrix. At sites of calcification, invading cells destroy the cartilage and mostly replace it by bone, leaving permanent hyaline cartilage only at the joint or articular surfaces, in some ribs, and, until maturity, at growth plates set back from the joints and perpendicular to the long axis of limb bones. The precarious physiological balance between chondrocytes and matrix materials in the heavily loaded articular cartilage breaks down in old age or in inflamed joints. *See* Arthritis; Connective tissue; Joint (anatomy); Skeletal system. [W.A.Be.]

Cartography The techniques concerned with constructing maps from geographic information. Maps are spatial representations of the environment. Typically, maps take graphic form, appearing on computer screens or printed on paper, but they may also take tactile or auditory forms for the visually impaired. Other representations such as digital files of locational coordinates or even mental images of the environment are also sometimes considered to be maps, or virtual maps.

Maps are composed of two kinds of geographic information: attribute data and locational data. Attribute data are quantitative or qualitative measures of characteristics of the landscape, such as terrain elevation, land use, or population density. Locations of features on the Earth's surface are specified by use of coordinate systems; among these, the most common is the geographical coordinate system of latitudes and longitudes. *See* Latitude and longitude.

Geographical coordinates describe positions on the spherical Earth. These must be transformed to positions on a two-dimensional plane before they can be depicted on a printed sheet or a computer screen. Hundreds of map projections—mathematical transformations between spherical and planar coordinates—have been devised, but no map projection can represent the spherical Earth in two dimensions without distorting spatial relationships among features on Earth's surface in some way. One specialized body of knowledge that cartographers bring to science is the ability to specify map projections that preserve the subset of geometric characteristics that are most important for particular mapping applications.

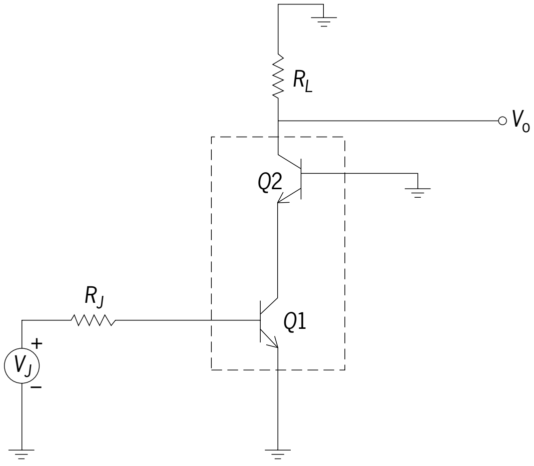
Although many broadly applicable map design principles have been established, the goal of specifying an optimal map for a particular task is less compelling than it once was. Instead, there is interest in the potential of providing map users with multiple, modifiable representations via dynamic media. Maps, graphs, diagrams, movies, text, and sound can be incorporated in multimedia software applications that enable users to navigate through vast electronic archives of geographic information. Interactive computer graphics are eliminating the distinction between the mapmaker and the map user. Modern cartography's challenge is to provide access to geographic information and to cartographic expertise through well-designed user interfaces. *See also* MAP DESIGN; MAP PROJECTIONS. [D.DiB.]

Caryophyllales An order of flowering plants, division Magnoliophyta (Angiospermae), in the core eudicots. The order consists of 26 families and about 12,500 species. The order has been expanded from the traditional concept of 12 families (core Caryophyllales), which are characterized by P-type sieve-tube plastids, the presence of betalains (except in Caryophyllaceae) instead of anthocyanins, and frequent occurrence of succulent habit. The four largest families of core Caryophyllales are Aizoaceae (about 2500 species), Amaranthaceae (about 2300 species), Cactaceae (about 2000 species), and Caryophyllaceae (about 2000 species). The expanded order is more difficult to define on the basis of morphology, but anomalous secondary growth, multicellular glands (trichomes), ellagic acid, and naphthaquinones occur frequently. Many representatives grow in marginal environments such as saltmarshes and deserts.

Polygonaceae (about 1000 species) are among the additional families in the expanded order, many of the others being small, little-known groups. *See* MAGNOLIOPHYTA; PLANT KINGDOM. [M.F.F.; M.W.C.]

Caryophyllidae A relatively small subclass of the class Magnoliopsida (dicotyledons) of the division Magnoliophyta (Angiospermae), the flowering plants, consisting of 3 orders, 14 families, and about 11,000 species. Most of these plants contain betalain pigments instead of anthocyanins, and the seeds very often have a perisperm. Most of the families and species of the subclass belong to the order Caryophyllales. The other orders (Plumbaginales and Polygonales) have only a single family each. *See* CARYOPHYLLALES; MAGNOLIOPHYTA; MAGNOLIOPSIDA; PLANT KINGDOM; PLUMBAGINALES; POLYGONALES. [A.Cr.; T.M.Ba.]

Cascode amplifier An amplifier stage consisting of a common-emitter transistor cascaded with a common-base transistor (see illustration). The common-emitter-common-base (CE-CB) transistor pair constitutes a multiple active device which essentially corresponds to a common-emitter stage with improved high-frequency performance. In monolithic integrated-circuit design the use of such active compound devices is much more economical than in discrete designs. A similar compound device is the common-collector-common-emitter connection (CC-CE), also known as the Darlington pair. *See* INTEGRATED CIRCUITS.



Cascade amplifier. Broken lines enclose a transistor pair consisting of a common-emitter transistor *Q*1 and a commonbase transistor *Q*2.

The cascode connection is especially useful in wideband amplifier design as well as the design of high-frequency tuned amplifier stages. The improvement in high-frequency performance is due to the impedance mismatch between the output of the common-emitter stage and the input of the common-base stage.

Another important characteristic of the cascode connection is the higher isolation between its input and output than for a single common-emitter stage, because the reverse transmission across the compound device stage is much smaller than for the common-emitter stage. In effect, the second (common-base) transistor acts as an impedance transformer. This isolation effect makes the cascode configuration particularly attractive for the design of high-frequency tuned amplifier stages where the parasitic cross-coupling between the input and the output circuits can make the amplifier alignment very difficult. *See* AMPLIFIER; TRANSISTOR. [C.C.H.]

Casein The principal protein fraction of cows' milk. It accounts for about 80% of the protein content and is present in concentrations of 2.5–3.2%. Casein is a mixed complex of phosphoproteins existing in milk as colloidally dispersed micelles 50 to 600 nanometers in diameter. Caseins can be separated from the whey proteins of cows' milk by gel filtration, high-speed centrifugation, salting-out with appropriate concentrations of neutral salts, acid precipitation at pH 4.3–4.6, and coagulation with rennet (or other proteolytic enzymes), and as a coprecipitate with whey proteins. The first three methods yield preparations in essentially their native micellar state, but are impractical for commercial exploitation. Thus, commercial caseins are produced by methods more amenable to industrial practices. *See* MICELLE.

The early production of casein isolates was stimulated by their application in industrial products such as paper, glue, paint, and plastics. These applications have been replaced by petroleum-based polymers. Thus the emphasis has shifted to their utilization in food systems, where they add enhanced nutritional and functional characteristics. They are widely used in the formulation of comminuted meat products, coffee whitener, processed cereal products, bakery products, and cheese analogs. *See* CHEESE; FOOD MANUFACTURING; MILK. [J.R.Bru.]

Cashew A medium-sized, spreading evergreen tree (*Anacardium occidentale*) native to Brazil, but now grown widely in the tropics for its edible nuts and the resinous oil contained in the shells. The fruit consists of a fleshy, red or yellow, pear-shaped receptacle, termed the apple, at the distal end of which is borne a hard-shelled, kidney-shaped ovary or nut. Although cashew trees are spread throughout the tropics, commercial production is centered in India, which handles 90% of the world trade.

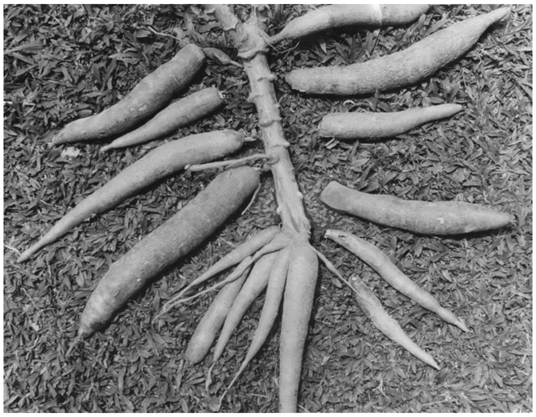
Cashew nut kernels are eaten as nuts and used extensively in the confectionery and baking trade. The cashew shell liquid is a valuable by-product, containing 90% anacardic acid and 10% cardol, and is used in the varnish and plastic industries.

The cashew apples are too astringent for eating without being processed, but when processed may be used for jams, chutney, pickles, and wine. *See* SAPINDALES. [L.H.MacD.]

Cashmere The natural fiber obtained from the Cashmere goat, native to the Himalayan region of China and India. The fleece of this goat has long, straight, coarse outer hair of little value; but the small quantity of underhair, or down, is made into luxuriously soft woollike yarns with a characteristic highly napped finish. Cashmere is a much finer fiber than mohair or wool fiber obtained from sheep. However, it is not as durable as wool. *See* MOHAIR; NATURAL FIBER; WOOL. [M.D.P.]

Cassava The plant *Manihot esculenta* (Euphorbiaceae), also called manioc. It is one of the 10 most important food plants, and the most important starchy root or tuber of the tropics. It originated in Central or South America, possibly Brazil, and was domesticated and widely distributed well before the time of Columbus. Subsequent distribution has established cassava as a major crop in eastern and western Africa, in India, and in Indonesia.

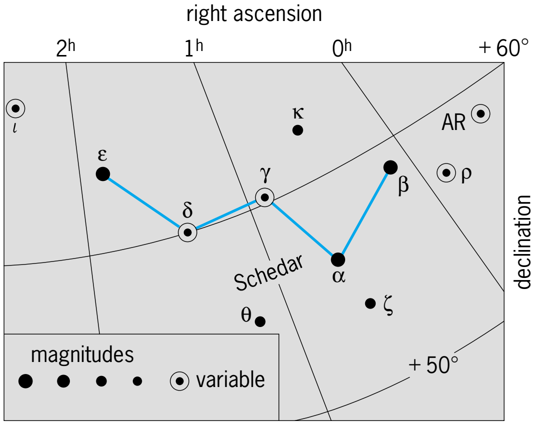
The cassava plant is a slightly woody, perennial shrub. The leaves are deeply palmately lobed; the flowers are inconspicuous, and the prominent capsules are three-seeded and explosive at maturity. The roots (see illustration) are enlarged by the deposition of starch and constitute the principal source of food from the plant. The leaves are also eaten (after cooking), and are noteworthy for their high protein content.



Tuberous roots from a single cassava plant.

The chief use of cassava is as a boiled vegetable. It is also a source of flour, called *farinha* in Brazil and *gari* in western Africa, and of toasted starch granules, the familiar tapioca. In spite of its popularity, however, cassava root is a poor food. Its protein content is extremely low, and its consumption as a staple food is associated with the protein deficiency disease kwashiorkor. *See* GERANIALES. [F.W.M.]

Cassiopeia A prominent northern circumpolar constellation as seen from the middle latitudes. The five main bright second- and third-magnitude stars of Cassiopeia form the rather distorted W or M by which the constellation is usually identified (see illustration). Cassiopeia and the Big Dipper lie across the opposite sides of the North Celestial Pole. *See* CONSTELLATION; URSA MAJOR. [C.S.Y.]



Line pattern of the constellation Casslopeia. The grid lines represent the coordinate of the sky. Magnitudes of the stars are shown by the sizes of the "dots."

Cassiterite A mineral having the composition SnO_2. It is the principal ore of tin. Cassiterite is usually massive granular, but may be in radiating fibrous aggregates with reniform shapes (wood tin). The hardness is 6–7 (Mohs scale), and the specific gravity is 6.8–7.1 (unusually high for a nonmetallic mineral). The luster is adamantine to submetallic. Pure tin oxide is white, but cassiterite is usually yellow, brown, or black because of the presence of iron.

Cassiterite is most abundantly found as stream tin (rolled pebbles in placer deposits). The world's supply comes mostly from placer or residual deposits in the Malay Peninsula, Indonesia, Zaire, and Nigeria. It is also mined in Bolivia. *See* TIN. [C.S.Hu.]

Cast iron A generic term describing a family of iron alloys containing 1.8–4.5% carbon. Cast iron usually is made into specified shapes, called castings, for direct use or for processing by machining, heat treating, or assembly. In special cases it may be forged or rolled moderately. Generally, it is unsuitable for drawing into rods or wire, although to a limited extent it has been continuously cast into rods and shapes from a liquid bath or swaged from bars into smaller-dimensional units. Silicon usually is present in amounts up to 3%, but special compositions are made containing up to 6% (Silal) and up to 12% (Duriron). Cast iron of the above composition range is often made into blocks or rough shapes and called pig iron. It is an intermediate form of cast iron used for remelting into iron castings. Cast iron may be purchased in several commercial grades called gray iron, chilled iron, mottled iron, white iron, malleable iron, ductile iron, spheroidal graphite iron, nodular iron, and austenitic cast iron. *See* ALLOY; IRON ALLOYS; WROUGHT IRON. [J.S.V.]

Castor plant A plant, *Ricinus communis*, belonging to the spurge family (Euphorbiaceae). Castor seeds are poisonous and also contain allergens.

Current distribution is in the warmer regions of the world, the plant often growing in waste places. The castor oil plant has been of utilitarian value since antiquity. Oil from the seeds is among the world's oldest nonfood products in commerce. Castor oil contains about 85% ricinoleic acid, used in making industrial products such as alkyde resins for surface coatings, blown oil used in plasticizers, cracked oil for production of synthetic perfumes, nylon, sebacic acid, synthetic detergents, drying oils, and special lubricating oils.

Production in the United States, mostly in west Texas, peaked in 1968 but declined to nil because of larger economic return from food and fiber crops. Brazil is the world's largest producer and exporter of castor seed and oil. [L.H.Z.]

Casuarinales An order of flowering plants, division Magnoliophyta (Angiospermae), in the subclass Hamamelidae of the class Magnoliopsida (dicotyledons). The order consists of a single family (Casuarinaceae) and genus (*Casuarina*), with about 50 species. Native to the southwestern Pacific region, especially Australia, they are sometimes called Australian pine. They are trees with much reduced flowers and green twigs that bear whorls of scalelike, much reduced leaves. Some species are grown as street trees in tropical and subtropical regions. *See* HAMAMELIDAE; MAGNOLIOPSIDA. [A.Cr.]

Cat The term used to describe any member of the mammalian family Felidae. Morecommonly, the term is restricted to the domestic cat and those felids that resemble it in size, shape, and habits. Those that are larger in size are referred to as the big cats. All members of the cat family have a round head, are digitigrade (walk on their toes), have retractile claws (with the exception of the cheetah), and have 30 teeth. All species are carnivorous.

The origin of domestic cats is unknown, but it is established that they have been associated with humans for many centuries. Domestic mixed-breed cats are generally characterized by long, thin tails, straight ears, and short hair of a variety of colorations. The pure breeds, however, are notable exceptions to this general description. There is a long-haired race, apparently developed in Persia, which is represented by the Persian and the Angora. The Abyssinian breed, in contrast to the common domestic cat, is characterized by being ruddy brown in color and having a longer face and ears. There are at least two tailless breeds, of which the best known is the Manx from the Isle of Man. The other tailless variety is found in Japan. One of the most popular breeds is the Siamese cat. Its eyes are deep blue, it has a long, kinky tail, and its fur is short and cream to buff in color.

Wildcats include cats such as the lynx, bobcat, serval, ocelot, puma, leopard, lion, tiger, jaguar, and cheetah. In addition there are a few lesser known forms that are of interest. Among these are the Scottish wildcat and the caracal. *See* CARNIVORA. [C.B.C.]

Cat scratch disease In humans, typically a benign, subacute regional disease of the lymph nodes (lymphadenopathy) resulting from dermal inoculation of the causative agent, the bacterium *Bartonella henselae*. The domestic cat is the major reservoir of *B. henselae*, and the cat flea, *Ctenocephalides felis*, is the main vector of transmission from cat to cat. *Bartonella clarridgeiae* has been isolated from domestic cats. Recently, a new bacterium, *B. koehlerae*, has also been isolated from the blood of domestic cats.

Cat scratch disease occurs in immunocompetent patients of all ages, with 55–80% being less than 20 years of age. More than 90% of cases have a history of contact with cats, and 57–83% recall being scratched by a cat. Incidence varies by season; most cases occur in the fall and winter. More cases are observed in males than females.

In humans, 1–3 weeks may elapse between the scratch (or bite) and the appearance of clinical signs. In 50% of the cases, a small skin lesion, often resembling an insect bite, appears at the inoculation site (usually on the hand or forearm) and evolves from a pimple (papule) to a skin blister to partially healed ulcers. These lesions resolve within a few days to a few weeks. Inflammation of lymph nodes develops approximately 3 weeks after exposure. Swelling of the lymph node is usually painful and persists for several weeks or months. In 25% of the cases, a discharge of pus occurs. A large majority of the cases show signs of systemic infection, such as fever, chills, malaise, anorexia, or headaches. In general, the disease is benign and heals spontaneously without aftereffects.

No major clinical signs of cat scratch disease have been reported in cats, although enlargement of the lymph nodes caused by a cat scratch disease–like organism has been reported.

Most individuals with cat scratch disease experience mild illness and require minimal treatment. In severe forms, antibiotics such as ciprofloxacin, rifampin, or gentamicin have been recommended. Use of oral azithromycin for 5 days has shown significant clinical benefit in typical cat scratch disease. [B.B.Ch.]

Cataclysmic variable A type of close binary star system containing a cool star transferring material to its hotter, high-density, degenerate white dwarf companion. The mass transfer results in a large range of observed variability, including cataclysmic events called outbursts, which can increase the brightness of the systems by 2–10 magnitudes (a logarithmic scale with each magnitude being a factor of 2.5 in brightness) from quiescence, equivalent to a factor of 6–10,000 times in intensity. The specific behavior of each system and the extent and cause of the variability are related to whether the transferred material accumulates in an accretion disk surrounding the white dwarf, or whether it flows in a ballistic stream directly from the cool star to the white dwarf surface. Which of these processes will occur depends on the magnetic field strength of the white dwarf and the separation of the two stars in the binary, properties which are determined during the formation of the system. *See* MAGNITUDE (ASTRONOMY).

If the white dwarf magnetic field is under 100 tesla (1 megagauss), an accretion disk will form and extend close to the white dwarf surface, while a hot spot will form where the mass stream from the cool star hits the disk. Systems in which the mass transfer occurs in this way constitute the most common type among the roughly 1000 known cataclysmic variables. They can be further classified as novae, dwarf novae, and novalike systems. These categories probably represent different phases of evolution of similar systems, and each is determined by the current mass-transfer rate.

Novae are the most spectacular cataclysmic variables, with 7–10-magnitude (factor of 630–10,000 times) outbursts caused by thermonuclear runaways triggered when a critical mass of hydrogen builds up in the atmosphere of the white dwarf. Usually this occurs every few thousand years, although a handful of novae with high-mass white dwarfs and mostly giant cool stars recur on time scales of tens of years. *See* NOVA.

Dwarf novae have much smaller outbursts of 2–5 magnitudes or a factor of 6–100 times (a small number may be as large as 9 magnitudes or a factor of 4000), and they recur much more frequently, on time scales of weeks or months. Their light curves and theoretical models indicate that their outbursts are probably due to accretion disk instabilities, resulting in increased accretion onto the white dwarf when the disk reaches a critical density.

Novalike systems have the highest mass-transfer rates, so that their disks dominate the light output of the system and do not undergo the instability of outbursts.

At very high magnetic fields, over 1000 T (10 MG), and small separations (short orbital periods), the mass-transfer stream follows the magnetic field lines of the white dwarf to the white dwarf surface. This type of magnetic cataclysmic variable is termed an AM Her star (after its prototype, AM Herculis) or as a polar (after its accretion mode). The approximately 60 known polars were primarily discovered by x-ray satellites due to their large x-ray emission, caused by an accretion shock (producing hard x-rays) as the material is channeled to the magnetic pole of the white dwarf and by the subsequent heating of the white dwarf surface (producing soft x-rays). *See* X-RAY ASTRONOMY; X-RAY TELESCOPE.

For magnetic fields of 100–1000 T (1–10 MG) and larger separations, the material will form an outer accretion disk ring and then flow from its inner edge to the white dwarf following the magnetic field lines. The dozen known systems that exhibit this behavior are termed DQ Her stars (after DQ Herculis) or intermediate polars (IPs). *See* BINARY STAR; STELLAR EVOLUTION; VARIABLE STAR; WHITE DWARF STAR. [P.Sz.]

Catalysis The phenomenon in which a relatively small amount of foreign material, called a catalyst, augments the rate of a chemical reaction without itself being consumed. A catalyst is material, and not light or heat. It increases a reaction rate. *See* ANTIOXIDANT; INHIBITOR (CHEMISTRY).

If the reaction $A + B \rightarrow D$ occurs very slowly but is catalyzed by some catalyst (Cat), the addition of Cat must open new channels for the reaction. In a very simple case,

$$\left.\begin{array}{r} \mathrm{A} + \mathrm{Cat} \longrightarrow \mathrm{ACat} \\ \mathrm{ACat} + \mathrm{B} \longrightarrow \mathrm{D} + \mathrm{Cat} \end{array}\right\} \text{Chain propagation}$$

$$\mathrm{A} + \mathrm{B} \longrightarrow \mathrm{D} \qquad \text{Overall reaction}$$

the two propagation processes, which are fast compared to the uncatalyzed reactions, $A + B \rightarrow D$, provide the new channel for the reaction. The catalyst reacts in the first step, but is regenerated in the second step to commence a new cycle. A catalytic reaction is thus a kind of chain reaction.

If a reaction is in chemical equilibrium under some fixed conditions, the addition of a catalyst cannot change the position of equilibrium without violating the second law of thermodynamics. Therefore, if a catalyst augments the rate of $A + B \rightarrow D$, it must also augment the reverse rate, $D \rightarrow A + B$. *See* CHEMICAL THERMODYNAMICS.

Catalysis is conventionally divided into three categories: homogeneous, heterogeneous, and enzyme. In homogeneous catalysis, reactants, products, and catalyst are all present molecularly in one phase, usually liquid. Homogeneous catalysis is important in the petrochemical and chemical industries. In heterogeneous catalysis, the catalyst is in a separate phase; usually the reactants and products are in gaseous or liquid phases and the catalyst is a solid. Heterogeneous catalysis plays a dominant role in chemical processes in the petroleum, petrochemical, and chemical industries. Transformations of matter in living organisms occur by an elaborate sequence of reactions, most of which are catalyzed by biocatalysts called enzymes. Enzyme catalysis plays a key role in all metabolic processes and in some industries, such as the fermentation industry. The mechanisms of these categories involve chemical interaction between the catalyst and one or more reactants. In phase-transfer catalysis the interaction is physical. Electrocatalysis and photocatalysis are more specialized forms of catalysis. *See* ENZYME; HETEROGENEOUS CATALYSIS; HOMOGENEOUS CATALYSIS; PHASE-TRANSFER CATALYSIS.

In most cases of catalysis, a given set of reactants could react in two or more ways. The degree to which just one of the possible reactions is favored over the other is called selectivity. The fraction of reactants that react by a specific path is called the selectivity by that path, and it will vary from catalyst to catalyst. Selectivity is a key property of a catalyst in any practical application of the catalyst.

The number of sets of molecules that react consequent to the presence of a catalytic site (heterogeneous or enzyme catalysis) or molecule of catalyst (homogeneous catalysis), the turnover number, is substantially greater than unity and may be very large. The turnover frequency is the number of sets of molecules that react per site or catalyst molecule per second. It must be greater than one or the reaction is stoichiometric, not catalytic.

In practical applications, catalyst life, that is, the time or number of turnovers before the reaction rate becomes uselessly low, is important. It will be reduced by the presence of molecules that adsorb at (react with) and block the active site (poisons). *See* ADSORPTION. [R.L.Bu.; G.L.H.]

Catalytic antibody An antibody that can cause useful chemical reactions. Catalytic antibodies are produced through immunization with a hapten molecule that is usually designed to resemble the transition state or intermediate of a desired reaction.

Antibodies are the recognition arm of the immune system. They are elicited, for example, when an animal is infected with a bacterium or virus. The animal produces antibodies with binding sites that are exactly complementary to some molecular feature of the invader. The antibodies can thus recognize and bind only to the invader, identifying it as foreign and leading to its destruction by the rest of the immune system. Antibodies are also elicited in large quantity when an animal is injected with molecules, a process known as immunization. A small molecule used for immunization is called a hapten. Ordinarily, only large molecules effectively elicit antibodies via immunization, so small-molecule haptens must be attached to a large protein molecule, called a carrier protein, prior to the actual immunization. Antibodies that are produced after immunization with the hapten-carrier protein conjugate are complementary to, and thus specifically bind, the hapten. *See* ANTIBODY; ANTIGEN-ANTIBODY REACTION; IMMUNITY.

Ordinarily, antibody molecules simply bind; they do not catalyze reactions. However, catalytic antibodies are produced when animals are immunized with hapten molecules that are specially designed to elicit antibodies that have binding pockets capable of catalyzing chemical reactions. For example, in the simplest cases, binding forces within the antibody binding pocket are enlisted to stabilize transition states and intermediates, thereby lowering a reaction's energy barrier and increasing its rate. This can occur when the antibodies have a binding site that is complementary to a transition state or intermediate structure in terms of both three-dimensional geometry and charge distribution. This complementarity leads to catalysis by encouraging the substrate to adopt a transition-state-like geometry and charge distribution. Not only is the energy barrier lowered for the desired reaction, but other geometries and charge distributions that would lead to unwanted products can be prevented, increasing reaction selectivity. *See* CATALYSIS.

Making antibodies with binding pockets complementary to transition states is complicated by the fact that true transition states and most reaction intermediates are unstable. Thus, true transition states or intermediates cannot be isolated or used as haptens for immunization. Instead, so-called transition-state analog molecules are used. Transition-state analog molecules are stable molecules that simply resemble a transition state (or intermediate) for a reaction of interest in terms of geometry and charge distribution. To the extent that the transition-state analog molecule resembles a true reaction transition state or intermediate, the elicited antibodies will also be complementary to that transition state or intermediate and thus lead to the catalytic acceleration of that reaction.

Catalytic antibodies bind very tightly to the transition-state analog haptens that were used to produce them during the immunization process. The transition-state analog haptens only bind and do not react with catalytic antibodies. It is the substrates, for example, the analogous ester molecules, that react. For this reason, transition-state analog haptens can interfere with the catalytic reaction by binding in the antibody binding pocket, thereby preventing any substrate molecules from binding and reacting. This inhibition by the transition-state analog hapten is always observed with catalytic antibodies, and is used as a first level of proof that catalytic antibodies are responsible for any observed catalytic reaction.

The important feature of catalysis by antibodies is that, unlike enzymes, a desired reaction selectivity can be programmed into the antibody by using an appropriately designed hapten. Catalytic antibodies almost always demonstrate a high degree of substrate selectivity. In addition, catalytic antibodies have been produced that have regioselectivity sufficient to produce a single product for a reaction in which other products are normally observed in the absence of the antibody. Finally, catalytic antibodies have been produced by immunization with a single-handed version (only left- or only right-handed) of a hapten, and only substrates with the same handedness can act as substrates for the resulting catalytic antibodies. The net result is that a high degree of stereoselectivity is observed in the antibody-catalyzed reaction. *See* STEREOCHEMISTRY. [B.I.]

Catalytic converter An aftertreatment device used for pollutant removal from automotive exhaust. Since the 1975 model year, increasingly stringent government regulations for the allowable emission levels of carbon monoxide (CO), hydrocarbons (HC), and oxides of nitrogen (NO_x) have resulted in the use of catalytic converters on most passenger vehicles sold in the United States. The task of the catalytic converter is to promote chemical reactions for the conversion of these pollutants to carbon dioxide, water, and nitrogen.

For automotive exhaust applications, the pollutant removal reactions are the oxidation of carbon monoxide and hydrocarbons and the reduction of nitrogen oxides. Metals are the catalytic agents most often employed for this task. Small quantities of these metals, when present in a highly dispersed form (often as individual atoms), provide sites upon which the reactant molecules may interact and the reaction proceed.

Two types of catalyst systems, oxidation and three-way, are found in automotive applications. Oxidation catalysts remove only CO and HC, leaving NO_x unchanged. Platinum and palladium are generally used as the active metals in oxidation catalysts. Three-way catalysts are capable of removing all three pollutants simultaneously, provided that the catalyst is maintained in a "chemically correct" environment that is neither overly oxidizing nor reducing. In both oxidation and three-way catalyst systems, the production of undesirable reaction products, such as sulfates and ammonia, must be avoided.

Maintaining effective catalytic function over long periods of vehicle operation is often a major problem. Catalytic activity will deteriorate due to two causes, poisoning of the active sites by contaminants, such as lead and phosphorus, and exposure to excessively high temperatures. To achieve efficient emission control, it is thus paramount that catalyst-equipped vehicles be operated only with lead-free fuel and that proper engine maintenance procedures be followed. *See* AUTOMOTIVE ENGINE; CATALYSIS. [N.Ot.]

Cataract Any clouding or opacity of the crystalline lens of the eye. The essential biochemical change in a cataractous lens is the coagulation of its protein. Cataracts vary markedly in degree of density and may be due to many causes, but the majority are associated with aging. Cataracts are the single leading cause of blindness in the world.

Senile cataract occurs with aging and is by far the most common type. Progressively blurred vision is the only symptom. There are a number of other varieties (congenital, metabolic, secondary, or traumatic) and causes (such as a reaction to certain drugs or irradiation). Cataracts may also be associated with systemic diseases such as hypoparathyroidism, myotonic dystrophy, atopic dermatitis, galactosemia, and Lowe's, Werner's, and Down syndromes.

At present the treatment for cataracts, when they are sufficiently advanced to impair the vision, is surgical removal. When a cataract is surgically removed, the crystalline lens of the eye is removed much as a lens would be removed from a camera. In order to restore normal vision after surgery, any of a number of methods may be followed: cataract glasses may be prescribed; contact lenses may be fitted; or intraocular lenses made of the plastic polymethylmethacrylate can be inserted into the eye to replace the cataractous lens. *See* EYE (VERTEBRATE). [J.Hart.]

Catastrophe theory A theory of mathematical structure in which smooth continuous inputs lead to discontinuous responses. Water suddenly boils, ice melts, a building crashes to the ground, or the earth unexpectedly buckles and quakes. The French mathematician René Thom conceived and developed an eclectic collection of ideas into catastrophe theory. His idea was to establish a new basis for a more mathematical approach to biology. Connotations of disaster are misleading, since Thorn's intention was to emphasize sudden, abrupt changes.

Advanced areas of modern mathematics, including algebraic geometry, differential topology, and dynamical system theory, contributed to the creation of catastrophe theory. A complete mathematical theory exists for the elementary catastrophes, which can be written as the gradient of an energylike function. The physical, chemical, and engineering applications are less developed, although many are known in optics, laser theory, thermodynamics, elasticity, and chemical reaction theory. The Thom classification theorem gives exactly seven elementary catastrophes. Although a theory of generalized catastrophes exists, which extends the theory beyond gradient systems, it is not nearly as well developed mathematically or physically as that of elementary catastrophes. It does include remarkable examples of chaos (or stochastic behavior) in the solutions to nonlinear deterministic equations. These solutions include strange attractors and omega explosions among the examples of nonelementary catastrophes. *See* GEOMETRY; PERIOD DOUBLING; TOPOLOGY.

There are two important aspects of catastrophe theory which are frequently overlooked or misconstrued. One is that as a rigorous mathematical theory the characteristic catastrophe features can be proved. These features include: jumps in the response; hysteresis or a path dependence in the response, representing a storage of energy for some paths; divergence, where a small path change produces a large response change (as if a source or sink were crossed); and type changes in the response, where a smooth response occurs on one path which becomes discontinuous along a nearby path.

All of these features are topological, so that they are independent of the coordinates used to describe the potential. They are, therefore, qualitative features of the solutions. Some critics have concluded that because these aspects were qualitative, they could not be quantitative. This is contradicted by the solid and growing body of quantitative studies in catastrophe theory. (Problems in quantum optics, thermodynamics, and scattering theory have all been clarified by catastrophe theory.) [B.DeF.]

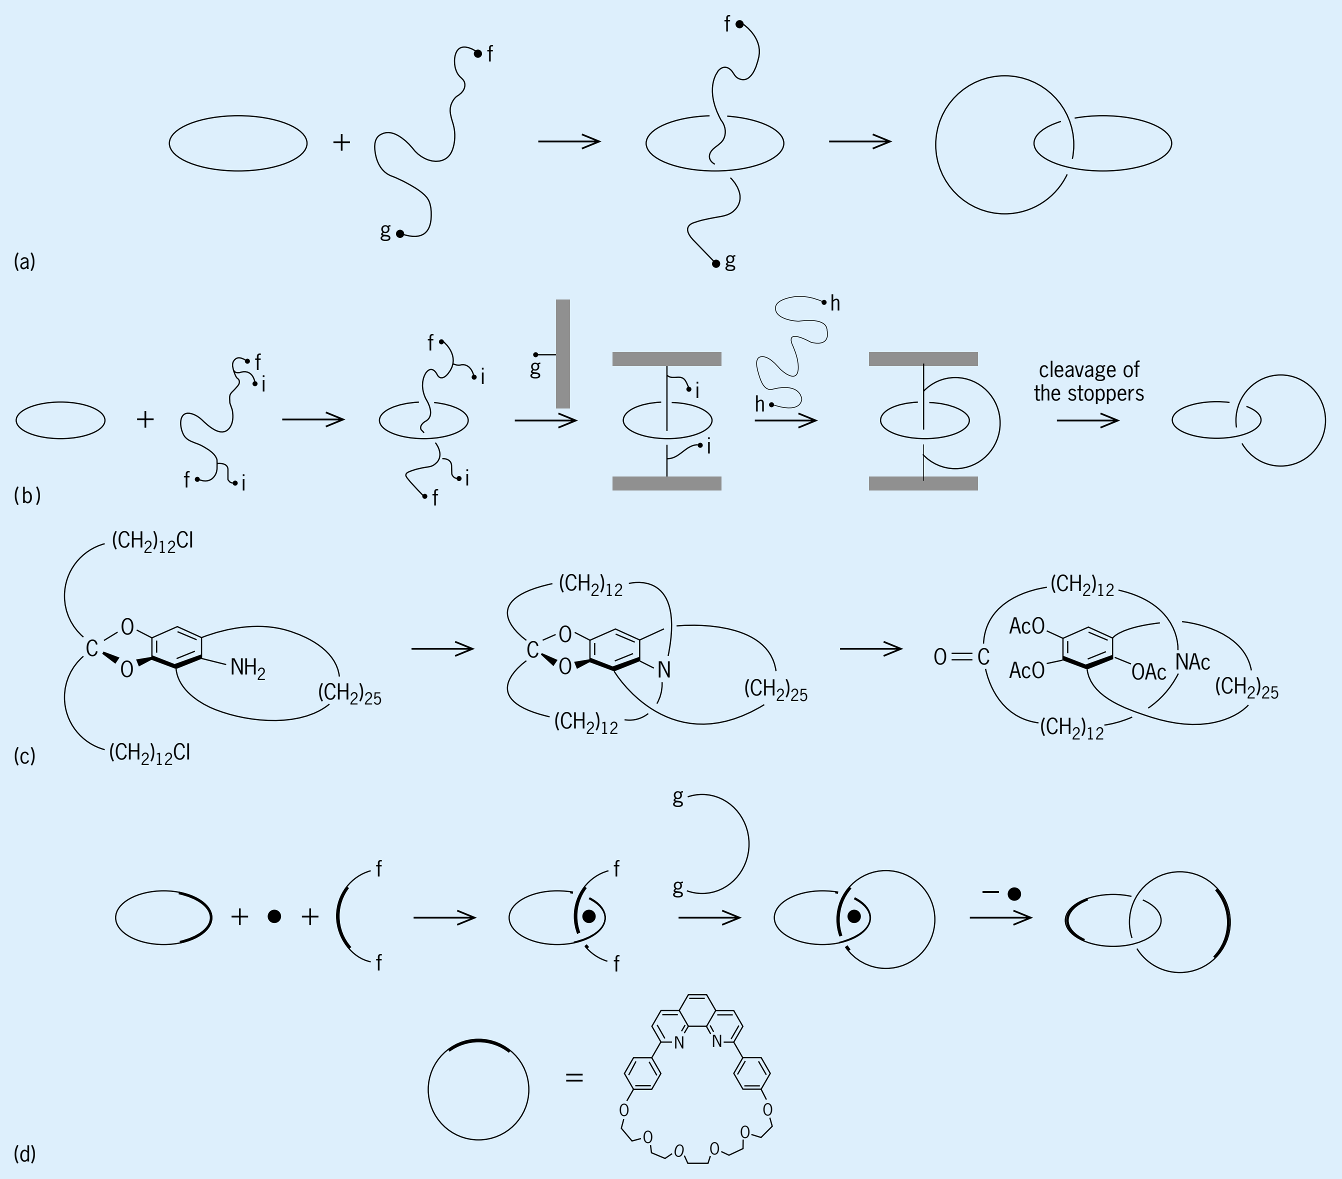
Catenanes Compounds that are made of interlocking macrocycles. The interlocking rings are said to be mechanically rather than chemically bound. Catenanes are named according to the number of interlocking rings. The simplest catenane, containing two interlocking rings, is called [2]-catenane. The most common catenanes consist of a linear arrangement of interlocking rings, so [2]-catenane is the first member of this series. Next is [3]-catenane, and so on. Catenanes involving necklace arrangements of beadlike rings have also been synthesized. [7]-Catenane combines linear and necklace topologies; it is the highest-order molecular catenane isolated so far.

Molecular catenanes are compounds of synthetic origin. However, natural deoxyribonucleic acid (DNA) macromolecules were shown to assemble, in certain conditions, into catenated structures, which were studied by electron microscopy.

The rings of the catenanes may be purely organic macrocycles or metallomacrocycles, that is, macrocycles including transition-metal ions in their bond sequences. Actually, the chemical nature of the ring is dictated by the method of synthesis. Basically, three methods have been developed for the synthesis of catenanes (see illustration): statistical, directed, and template syntheses.

Statistical synthesis relies on the probability that a macrocycle can be threaded onto a molecular string to afford an intermediate that will undergo the cyclization react (illus. *a*). Convincing approaches to the statistical method used the trick of stabilizing the threaded complex by stoppering the extremities of the string with bulky groups: a so-called rotaxane species is obtained (illus. *b*). Subsequently, conventional macrocycle synthesis is used to prepare the catenane, which is obtained after removal of the stoppers. This method produced the first hydrocarbon catenane, made of interlocked $(CH_2)_{28}$ and $(CH_2)_{46}$ macrocycles.

Directed synthesis uses a catechol-based acetal incorporated in a macrocycle (illus. *c*). Two pendent arms, as precursors to the second macrocycle, are anchored perpendicularly to the plane



Synthetic routes to catenanes. (*a*) Statistical; f and g are complementary functions that react to close the ring. (*b*) Statistical, using a rotaxane intermediate; f and g are complementary functions that react to anchor the stoppers; i and h are complementary functions that react to form the second, interlocked ring. (*c*) Directed. (*d*) Transition-metal-templated; the thick ring portions represent the coordination sites, and the black disk is the metal; f and g are complementary functions that react to close the second, interlocked ring.

of the first macrocycle. Their functionalized extremities are compelled to react with a complementary function localized inside the first macrocycle, so that the construction of the second macrocycle is directed to take place inside the first one. The last key step is the cleavage of the bonds linking the two macrocyclic sequences of atoms. This multistep synthetic method was used to prepare [2]- and [3]-catenanes.

Template synthesis methods are highly directed and economical in terms of numbers of steps. In these methods, metal cations or molecules gather and preorganize reactive molecular fragments in a spatially controlled manner, so that the desired structure will be obtained preferentially over many others. In one method, the transition-metal-templated synthesis of catenanes, the metal [generally Cu(I)] gathers a macrocycle incorporating a chelating subunit and a linear fragment made up of the complementary chelate such that both components are more or less at right angles to each other (illus. *d*). Cyclization of the linear fragment affords the metallocatenane, or catenate. Removal of the metal template by competitive complexation provides the catenane as a free ligand, or catenand. In the one-step alternative strategy, two open-chain chelates are assembled orthogonally at a metal center. A double cyclization reaction provides the catenate in one step.

Applications of catenanes are a research field in its infancy, and therefore they are more or less speculative. Promising approaches include incorporation of catenane structures into polymeric species to endow the polymers with peculiar rheological properties, because of the mechanical linking; and use of catenanes as elements of molecular machines—for example, the mechanical link of catenanes could be used for making a primitive rotary motor at the molecular level. *See* SUPRAMOLECULAR CHEMISTRY. [J.C.Ch.; C.O.D.B.; J.P.Sa.]

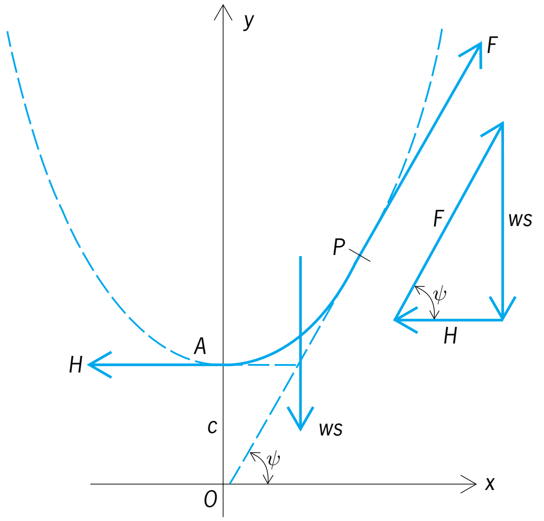
Catenary The curve formed by an ideal heavy uniform string hanging freely from two points of support. The lowest point *A* (see illustration) is the vertex. The portion *AP* is in equilibrium under the horizontal tension *H* at *A*, the tension *F* directed along the tangent at *P*, and the weight *W* of *AP*. If the weight of the string is w per unit length and s is the arc *AP*, $W = ws$; and from the force triangle, $\tan\psi = ws/H = s/c$, where $c = H/w$ is called the parameter of the catenary. Thus the catenary has the differential equation (1).

$$dy/dx = s/c \qquad (1)$$

The horizontal line at a distance c below the vertex *A* is the directrix of the catenary. With the x axis as directrix and the y axis through the vertex, the integration of Eq. (1) yields Eqs. (2)

$$y = c\cosh\frac{x}{c} \qquad s = c\sinh\frac{x}{c} \qquad (2)$$

for the ordinate and arc of the catenary. All catenaries are geometrically similar to the hyperbolic cosine curve, $y = \cosh x$.



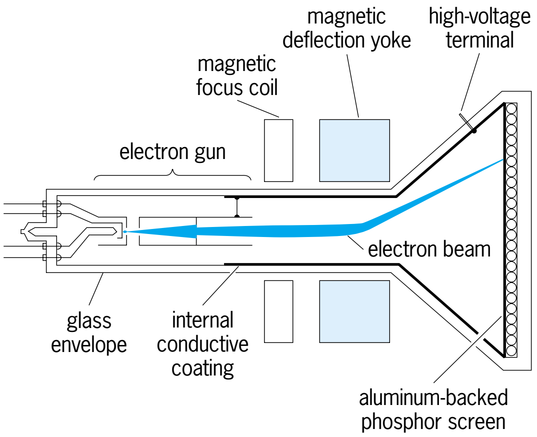
Catenary: force triangle.

The surface generated by revolving a catenary about its directrix is a minimal surface, the catenoid. The catenary is an extremal for the problem of finding a curve joining two given points so that the surface generated by revolving it about a given line has minimum area. *See* HYPERBOLIC FUNCTION. [L.Br.]

Cathode-ray tube An electron tube in which a beam of electrons can be focused to a small cross section and varied in position and intensity on a display surface. In common usage, the term cathode-ray tube (CRT) is usually reserved for devices in which the display surface is cathodoluminescent under electron bombardment, and the output information is presented in the form of a pattern of light. The character of this pattern is related to, and controlled by, one or more electrical signals applied to the cathode-ray tube as input information. *See* CATHODOLUMINESCENCE; ELECTRON TUBE.

Hundreds of millions of cathode-ray tubes were in service at the end of the twentieth century, and tens of thousands more were manufactured daily. These tubes were commonplace in television sets, computers, homes, hospitals, banks, and airplanes. Even so, the cathode-ray tube is being supplanted in many of its traditional uses by flat-panel electronic devices. This trend is expected to continue until, except for perhaps a few specialized applications, the cathode-ray tube will be primarily of historical interest.

The three elements of the basic cathode-ray tube are the envelope, the electron gun, and the phosphor screen (see illustration).



Elements of a cathode-ray tube.

The envelope is usually made of glass, although ceramic envelopes and metal envelopes have been used. It is typically funnel-shaped. The small opening is terminated by the stem, a disk of glass through which pass metal leads that apply voltages to the several elements of the electron gun. The electron gun is mounted within the neck portion of the envelope and is connected to the leads coming through the stem. The neck is often made sufficiently narrow to allow positioning of deflection and focusing components outside it.

The large end of the funnel is closed by a faceplate, on the inside of which the phosphor screen is deposited. The faceplate is made of high-quality clear glass in order to provide an undistorted view of the display on the phosphor screen.

The electron gun consists of an electrical element called a heater, a thermionic cathode, and an assemblage of cylinders, caps, and apertures which are all held in the proper orientation.

The cathode is a source of electrons when maintained at about 1750°F (1100 K) by thermal radiation from the heater. Electrons emitted by the cathode are formed into a beam, and controlled in intensity by other elements of the electron gun. Means are provided, either within the electron gun itself or externally, to focus the electron beam to a small cross section at its intersection with the phosphor screen and to deflect it to various locations on the screen. *See* CHARGED PARTICLE OPTICS; ELECTRON EMISSION.

In most cases, monochrome cathode-ray tubes employ a single electron gun. Nearly all color picture tubes employ the shadow-mask principle and use three electron guns.

The deflection path of the electron beam on the phosphor screen depends on the intended use of the cathode-ray tube. In oscillography, a horizontal trace is swept across the phosphor screen, with vertical excursions of the beam which coincide with variations in the strength of some electrical signal. In television, a raster of closely spaced horizontal lines is scanned on the phosphor screen by the electron beam, which is intensity-modulated to produce a visible picture. Radar makes use of a variety of specialized electron-beam scanning patterns to present information to an observer.

In the display of computer output information, two general approaches to beam deflection are used: The raster-scan technique may be identical in format to that used for television or may utilize a greater number of scanning lines for increased definition. The random-scan technique involves computer control to direct the electron beam to locations which may be anywhere on the tube face.

The phosphor screen consists of a layer of luminescent material coated on the inner surface of the glass faceplate. Monochrome cathode-ray tubes generally use a single layer of a homogeneous luminescent material. Color cathode-ray tubes typically utilize a composite screen made up of separate red-, green-, and blue-emitting luminous materials. *See* LUMINESCENCE; PHOSPHORESCENCE.

Two basic types of deflection are electrostatic deflection and magnetic deflection.

With electrostatic deflection, it is possible to very quickly deflect the beam from one location to any other location on the screen. Operation is possible over a wide frequency range.

Magnetic deflection systems generally require more time, perhaps tens of microseconds, to deflect the electron beam from one location on the screen to another. This is because a change in position requires a change in the value of the current through an inductive coil. Magnetic deflection systems do have an important advantage in that they can deflect the beam through a much wider deflection angle with less distortion in the shape of the cross section of the beam than is possible with electrostatic deflection.

A wide variety of available envelopes, electron guns, and phosphor screens have been combined in different ways to fashion cathode-ray tubes specialized to meet the needs of different applications.

Direct view cathode-ray tubes involve either the presentation on the screen of an actual picture with a full black and white halftone range or with full color, such as is required for television, or the presentation of a computer-generated display which may consist of alphanumerics, graphics, or a variety of pictorial subjects. Tubes for the direct viewing of such presentations are required to have large display sizes, high brightness, high resolution, and in many cases a full halftone range and full color capability. Cathode-ray tubes for these presentations have always employed magnetic deflection and generally electrostatic-focus electron guns operating at high voltages from 15 to 36 kV.

Cathode-ray tubes for computer-generated data-display applications are very similar.

Projection tubes are not intended to be directly viewed. The display on the phosphor screen is projected by using an optical system, such as a lens, onto large screens. Screen sizes vary widely, the largest being those in theaters and sports arenas that are equipped for projection television.

Cathode-ray tubes for projection applications are usually of the general type described above but generally are optimized for extremely high brightness and resolution capability.

On a different scale, projection tubes used in avionics helmet-mounted displays make use of infinity optics to project images directly onto the retina of the aviators. Such cathode-ray tubes must be very small, light, low-voltage, low-power devices.

Another class of cathode-ray tubes which are not intended for direct viewing by human observers comprises photorecording tubes. The applications for these tubes require that the phosphor screen display be projected by an optical system, such as a lens, onto a photosensitive medium, such as photographic film. Applications include electronic phototypesetting and the storage of computer output information on microfilm. Photorecording cathode-ray tubes are required to have extremely high resolution capability, to be extremely stable over long periods of time, and to have accurate and precise display geometry. *See* PICTURE TUBE; TELEVISION. [N.W.P.]

Cathode rays The name given to the electrons originating at the cathodes of gaseous discharge devices. The term has now been extended to include low-pressure devices such as cathode-ray tubes. Furthermore, cathode rays are now used to designate electron beams originating from thermionic cathodes, whereas the term was formerly applied only to cold-cathode devices. *See* CATHODE-RAY TUBE. [G.H.M.]

Cathodoluminescence A luminescence resulting from the bombardment of a substance with an electron (cathode-ray) beam. The principal applications of cathodoluminescence are in television, computer, radar, and oscilloscope displays. In these a thin layer of luminescent powder (phosphor) is evenly deposited on the transparent glass faceplate of a cathode-ray tube. After undergoing acceleration, focusing, and deflection by various electrodes in the tube, the electron beam originating in the cathode impinges on the phosphor. The resulting emission of light is observed through the glass faceplate, that is, from the unbombarded side of the phosphor coating. *See* CATHODE-RAY TUBE.

The luminescence of most phosphors comes from a few sites (activator centers) occupied by selected chemical impurities which have been incorporated into the matrix or host solid. Because of the complex mode of interaction of cathode rays with phosphors, the energy efficiency of light production by cathodoluminescence is lower than the best efficiencies obtainable with photoluminescence. Conversion efficiencies of currently used display phosphors are between 2 and 23%. *See* LUMINESCENCE. [H.N.H.; J.S.H.]

Cauliflower A cool-season biennial crucifer (*Brassica oleracea* var. *botrytis*) of Mediterranean origin. Cauliflower belongs to the plant order Capparales. It is grown for its white head or curd, a tight mass of flower stalks, which terminates the main stem. Cauliflower is commonly cooked fresh as a vegetable; to a lesser extent, it is frozen or pickled and consumed as a relish. California and New York are important cauliflower-producing states. *See* CAPPARALES. [H.J.C.]

Causality In physics, the requirement that interactions in any space-time region can influence the evolution of the system only at subsequent times; that is, past events are causes of future events, and future events can never be the causes of events in the past. Causality thus depends on time orientability, the possibility of distinguishing past from future. Not all spacetimes are orientable.

The laws of a deterministic theory (for example, classical mechanics) are such that the state of a closed system (for example, the positions and momenta of particles in the system) at one instant determines the state of that system at any future time. Deterministic causality does not necessarily imply practical predictability. It was long implicitly assumed that slight differences in initial conditions would not lead to rapid divergence of later behavior, so that predictability was a consequence of determinism. Behavior in which two particles starting at slightly different positions and velocities diverge rapidly is called chaotic. Such behavior is ubiquitous in nature, and can lead to the practical impossibility of prediction of future states despite the deterministic character of the physical laws. *See* CHAOS.

Quantum mechanics is deterministic in the sense that, given the state of a system at one instant, it is possible to calculate later states. However, the situation differs from that in classical mechanics in two fundamental respects. First, conjugate variables, for example, position x and momentum p, cannot be simultaneously determined with complete precision. Second, the state variable ψ gives only probabilities that a given eigenstate will be found after the performance of a measurement, and such probabilities are also all that is calculable about a later state ψ' by the deterministic prediction. Despite its probabilistic character, the quantum state still evolves deterministically. However, which eigenvalue (say, of position) will actually be found in a measurement is unpredictable. *See* DETERMINISM; EIGENVALUE (QUANTUM MECHANICS); NONRELATIVISTIC QUANTUM THEORY; QUANTUM MECHANICS; QUANTUM THEORY OF MEASUREMENT; UNCERTAINTY PRINCIPLE.

Nonrelativistic mechanics assumes that causal action can be propagated instantaneously, and thus that an absolute simultaneity is definable. This is not true in special relativity. While the state of a system can still be understood in terms of the positions and momenta of its particles, time order, as well as temporal and spatial length, becomes relative to the observer's frame, and there is no possible choice of simultaneous events in the universe that is the same in all reference frames. Only space-time intervals in a fused “spacetime” are invariant with respect to choice of reference frame. The theory of special relativity thus rejects the possibility of instantaneous causal action. Instead, the existence of a maximum velocity of signal transmission determines which events can causally influence others and which cannot. The investigation of a spacetime with regard to which events can causally influence (signal) other regions and which cannot is known as the study of the causal structure of the spacetime. *See* SPACE-TIME. [D.Sha.]

Cave A natural cavity located underground or in the side of a hill or cliff, generally of a size to admit a human. Caves occur in all types of rocks and topographic situations. They may be formed by many different erosion processes. The most important are created by ground waters that dissolve the common soluble rocks—limestone, dolomite, gypsum, and salt. Limestone caves are the most frequent, longest, and deepest. Lava-tube caves, sea caves created by wave action, and caves caused by piping in unconsolidated rocks are the other important types. The science of caves is known as speleology. *See* DOLOMITE; GYPSUM; HALITE; LIMESTONE.

Caves are important sediment traps, preserving evidences of past erosional, botanic, and other phases that may be obliterated aboveground. Chemical deposits are very important. More than 100 different minerals are known to precipitate in caves. Most abundant and significant are stalactites, stalagmites, and flowstones of calcite. These may be dated with uranium series methods, thus establishing minimum ages for the host caves. They contain paleomagnetic records. Their oxygen and carbon isotope ratios and trapped organic materials may record long-term changes of climate and vegetation aboveground that can be dated with great precision. As a consequence, cave deposits are proving to be among the most valuable paleoenvironmental records preserved on the continents. *See* STALACTITES AND STALAGMITES. [D.C.F.]

Cavies Rodents comprising the family Caviidae, which includes the guinea pig, rock cavies, mountain cavies, capybara, salt-desert cavy, and mara. All members of the group are indigenous to South America and comprise 15 species in six genera. Cavies have either rounded bodies with large heads and short ears and limbs, or rabbitlike bodies with long limbs and moderately long ears.

The guinea pig (*Cavia aperea*) originated in Peru, where there is still a wild stock. The domestic form (*C. porcellus*) has been produced by selective breeding and is a valuable laboratory animal with a life-span of 3–5 years. Closely related to the guinea pig is the mara or Patagonian cavy (*Dolichotis patagonum*) which resembles a large hare. The salt-desert cavy (*Pediolagus salinicola*) is a smaller species found in the salt deserts of southern Argentina. The largest of all rodents is the capybara or carpincho (Hydrochoerus hydrochaeris) which grows to the size of a small pig. It is essentially an aquatic animal which lives in small groups along the banks of lakes and streams in tropical South America. *See* RODENTIA. [C.B.C.]

Cavitation The formation of vapor- or gas-filled cavities in liquids. If understood in this broad sense, cavitation includes the familiar phenomenon of bubble formation when water is brought to a boil under constant pressure and the effervescence of champagne wines and carbonated soft drinks due to the diffusion of dissolved gases. In engineering terminology, the term cavitation is used in a narrower sense, namely, to describe the formation of vapor-filled cavities in the interior or on the solid boundaries created by a localized pressure reduction produced by the dynamic action of a liquid system without change in ambient temperature. Cavitation in the engineering sense is characterized by an explosive growth and occurs at suitable combinations of low pressure and high speed in pipelines; in hydraulic machines such as turbines, pumps, and propellers; on submerged hydrofoils; behind blunt submerged bodies; and in the cores of vortical structures. This type of cavitation has great practical significance because it restricts the speed at which hydraulic machines may be operated and, when severe, lowers efficiency, produces noise and vibrations, and causes rapid erosion of the boundary surfaces, even though these surfaces consist of concrete, cast iron, bronze, or other hard and normally durable material.

Acoustic cavitation occurs whenever a liquid is subjected to sufficiently intense sound or ultrasound (that is, sound with frequencies of roughly 20 kHz to 10 MHz). When sound passes through a liquid, it consists of expansion (negative-pressure) waves and compression (positive-pressure) waves. If the intensity of the sound field is high enough, it can cause the formation, growth, and rapid recompression of vapor bubbles in the liquid. The implosive bubble collapse generates localized heating, a pressure pulse, and associated high-energy chemistry. *See* SOUND; ULTRASONICS.

Both experiments and calculations show that with ordinary flowing water cavitation commences as the pressure approaches or reaches the vapor pressure, because of impurities in the water. These impurities, called cavitation nuclei, cause weak spots in the liquid and thus prevent it from supporting higher tensions. The exact mechanism of bubble growth is generally described by mathematical relationships which depend upon the cavitation nuclei. Cavitation commences when these nuclei enter a low-pressure region where the equilibrium between the various forces acting on the nuclei surface cannot be established. As a result, bubbles appear at discrete spots in low-pressure regions, grow quickly to relatively large size, and suddenly collapse as they are swept into regions of higher pressure. [M.L.Bi.]

Cavity resonator An enclosure capable of resounding or resonating and thereby intensifying sound tones or electromagnetic waves. Resonance is the phenomenon which results when the frequency of the impressed driving force is the same as the natural vibration of the cavity. Vibrating rods, the tuning fork, musical instrument strings, radio and television channel tuners, and so forth, constitute resonating systems as well. The cavity resonator enclosure has a volume which stores energy oscillating between one form and another. In the case of sound, the oscillation is between displacement and velocity of particles. In the case of electromagnetic waves, the energy oscillates between the magnetic and the electric fields. *See* MUSICAL INSTRUMENTS; TUNING FORK; VIBRATION.

Cavity pipes are used as resonators in musical instruments such as pipe organs and flutes to increase their sonority. The frequency of resonance is determined (to a degree of approximation) by the length of the pipe, by the velocity of sound at the ambient temperature and pressure, by the intensity of the driving force, and by the condition at the ends of the pipe: closed or open. The resulting frequency is related to multiples of quarter-wavelengths or half-wavelengths (depending on the end conditions) contained in the length of pipe. The driving force, if sufficiently strong, can force oscillations to occur at overtone frequencies which are higher multiples of the lowest or fundamental frequency, as well as at the fundamental. *See* ACOUSTIC RESONATOR; SOUND.

At very high radio frequencies, losses due to radiation can be eliminated and resistive losses can be minimized by using closed resonant cavities instead of lumped-circuit resonators. A cavity resonator stores both magnetic and electric fields, the energy oscillating between the two, losing energy only to the conducting walls if a perfect dielectric fills the space. The resonant frequency of the cavity is determined by the shape of the cavity and the mode, or allowable field distribution, of the electromagnetic energy that the cavity contains. Microwave transmission devices use such cavities. *See* KLYSTRON; MAGNETRON. [D.J.A.]

Cayley-Klein parameters A set of four complex numbers used to specify the orientation of a body, or equivalently, the rotation *R* which produces that orientation, starting from some reference orientation. They can be expressed in terms of the Euler angles ψ, θ, and ϕ, as in the equations below.

$$\alpha = \cos\frac{\theta}{2}\, e^{-i(\psi-\phi)/2} \qquad \beta = -i\sin\frac{\theta}{2}\, e^{i(\psi-\phi)/2}$$

$$\gamma = -i\sin\frac{\theta}{2}\, e^{-i(\psi-\phi)/2} \qquad \delta = \cos\frac{\theta}{2}\, e^{i(\psi-\phi)/2}$$

Although these parameters have been used to simplify somewhat the mathematics of spinning top motion, their main use is in quantum mechanics. There they are related to the Pauli spin matrices and represent the change in the spin state of an electron or other particle of half-integer spin under the space rotation $R(\psi, \theta, \phi)$. *See* Matrix theory; Spin (quantum mechanics). [B.G.]

Caytoniales A group of Mesozoic plants. The remains consist of palmately compound leaves with 3–6 lanceolate leaflets previously known as *Sagenopteris phillipsi*, pinnately branched microsporophylls (named *Caytonanthus arberi*) that bore winged pollen in four-chambered microsporangia, and fruit-bearing inflorescences, *Caytonia* (with two species), which bore a dozen or more globular, short-stalked fruits in subopposite rows. The Caytoniales appear related to the pteridosperms. They range from the Triassic to the Cretaceous. *See* Paleobotany. [C.A.A.]

Cedar Any of a large number of evergreen trees having fragrant wood of great durability. Arborvitae is sometimes called northern white cedar. *See* Arborvitae.

Chamaecyparis thyoides, the southern white cedar, grows only in swamps near the eastern coast of North America, where it is also known as Atlantic white cedar. The wood is soft, fragrant, and durable in the soil and is used for boxes, crates, small boats, tanks, woodenware, poles, and shingles. The Port Orford cedar (*C. lawsoniana*), also known as Lawson cypress, is native to southwestern Oregon and northwestern California. It is the principal wood for storage battery separators, but is also used for venetian blinds and construction purposes. Alaska cedar (*C. nootkatensis*) is found from Oregon to Alaska. The wood is used for interior finish, cabinetwork, small boats, and furniture. It is also grown as an ornamental tree. Incense cedar (*Libocedrus decurrens*) is found from Oregon to western Nevada and Lower California. Incense cedar is one of the chief woods for pencils, and is also used for venetian blinds, rough construction, and fence posts and as an ornamental and shade tree.

Eastern red cedar (*Juniperus virginiana*) is distributed over the eastern United States and adjacent Canada. The very fragrant wood is durable in the soil and is used for fence posts, chests, wardrobes, flooring, and pencils. Cedarwood oil is used in medicine and perfumes. Cedar of Lebanon (*Cedrus libani*) and Atlas cedar (*C. atlantica*) resemble the larch, but the leaves are evergreen and the cones are much larger and erect on the branches. The cedar of Lebanon is a native of Asia Minor. *See* Larch.

The cigarbox cedar (*Cedrela odorata*), also known as the West Indian cedar, belongs to the mahogany family, is a broadleaved tree with pinnate, deciduous leaves, and is related to the *Ailanthus* and sumac. The wood is very durable and fragrant and is valued in the West Indies for the manufacture of cabinets, furniture, and canoes. *See* Pinales. [A.H.G./K.P.D.]

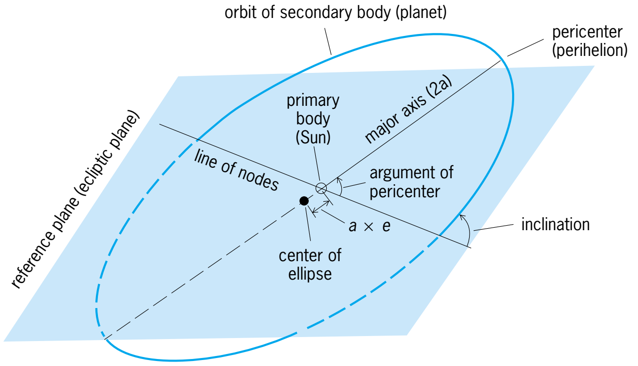
Celastrales An order of flowering plants, division Magnoliophyta (Angiospermae), in the subclass Rosidae of the class Magnoliopsida (dicotyledons). The order consists of 11 families and more than 2000 species, with the families Celastraceae (about 800 species), Aquifoliaceae (about 400 species), Icacinaceae (about 400 species), and Hippocrateaceae (about 300 species) forming the core of the group. The order is marked by its simple leaves and regular flowers, varying from hypogynous (those with the perianth and stamens attached directly to the receptacle, beneath the ovary) to perigynous (those with the perianth and stamens united at the base into a hypanthium distinct from the ovary) and with a single set of stamens which alternate with the petals. Nearly all of the species are woody plants. Various species of holly (*Ilex,* family Aquifoliaceae) and *Euonymus* (Celastraceae) are often cultivated. *See* Holly; Magnoliophyta; Magnoliopsida; Plant kingdom; Rosidae. [A.Cr.; T.M.Ba.]

Celery A biennial umbellifer (*Apium graveolens* var. *dulce*) of Mediterranean origin and belonging to the plant order Umbellales. Celery is grown for its petioles or leafstalks, which are most commonly eaten as a salad but occasionally cooked as a vegetable. California, Florida, and Michigan are important producing states. *See* Apiales. [H.J.C.]

Celestial mechanics The field of dynamics as applied to celestial bodies moving under their mutual gravitational influence in systems with few bodies. It usually describes and predicts motions in the solar system, both of natural bodies such as planets, satellites, asteroids, and comets, and of artificial bodies such as space probes. It can also be applied to small stellar systems.

Isaac Newton's law of universal gravitation is the foundation of most of the field. It states that the force produced by one particle upon another is attractive along the line connecting the bodies, is proportional to the product of the masses of the bodies, and is inversely proportional to the square of the distance between the bodies. The constant of proportionality is *G*, the universal constant of gravitation. Newton's second law of motion then says that the acceleration experienced by a body is equal to the force on that body divided by its mass. *See* Force; Kinetics (classical mechanics); Newton's laws of motion.

The simplest and only exactly solvable problem in celestial mechanics is that of one particle moving about another. Since any body with spherical symmetry looks gravitationally like a point mass from the outside, the results from this problem may be used to describe approximately the relative motion of two finite bodies, such as a planet around the Sun or a satellite around a planet. The principal results from this problem had already been recognized empirically by Johannes Kepler and are embodied in his three laws of planetary motion. Usually the motion of the smaller body (the secondary) is described relative to the larger one (the primary). This relative motion is confined to a plane, and the path traced is a conic section such that the primary occupies one focus. If the bodies are gravitationally bound, the conic is an ellipse. The longest segment connecting opposite points on the ellipse is called the major axis, and half this length is called the semimajor axis *a* (see illustration). The departure of the ellipse from a circle is called the eccentricity *e*, which is usually quite small for planetary orbits. The tilt of the plane from some reference plane is called the inclination, and for the solar system that reference plane is the plane of the Earth's orbit, known as the ecliptic plane. Planetary inclinations are also usually quite small. The line of intersection of the plane of motion with the reference plane is called the line of nodes. The point on the orbit closest to the primary, which is at one end of the major axis, is called the pericenter (specifically for planetary orbits, the perihelion), and its angular distance from the node is called the argument of pericenter. The time at which the secondary passes through the pericenter is called the epoch of pericenter. A seventh parameter is the period of revolution, and the cube of the semimajor axis divided by the square of the period is proportional to the sum of the two masses. Since a planetary mass is small compared to that of the Sun, this ratio is essentially constant for the planets; this is Kepler's third law, also known as the harmonic law. *See* Ellipse.



Relative motion of one body about another when the bodies are gravitationally bound. Parameters used to describe the motion are shown. (Terms used to describe the motion of a planet about the Sun are given in parentheses.) e = eccentricity.

A second result applies whenever the forces are directed along the line connecting the two bodies. Angular momentum is conserved, which causes the line connecting the two bodies to sweep out equal areas in equal times, a result stated in Kepler's second law. This results in the relative velocity in the orbit being inversely proportional to the square root of the separation. Ellipses are not the only type of relative motion permitted, and the type of conic depends on the total energy in the orbit. If there is just enough energy for the bodies to escape from each other, the relative orbit is a parabola. If there is more than enough energy for escape, such that some relative velocity would still remain, the orbit is a hyperbola. A hyperbola would also describe the relative motion of two independent bodies encountering each other, as in the case of two stars within the galaxy. *See* Conic section; Escape velocity; Orbital motion; Planet.

One of the major operational problems of celestial mechanics is that of determining the orbit of a body in the solar system from observations of its position, or distance plus line-of-sight velocity, at various times. The objective is to determine the numerical values of the parameters characterizing the orbit, known as orbital elements. A minimum of three observations is required. Usually there are more than three observations, which means that best values must be estimated in some statistical sense. Once the orbit is known, the future locations of the object can be predicted. A table of predicted positions is called an ephemeris. *See also* Ephemeris.

Another important problem is determining the proper orbit to get from one point at one time to another point at another time. This may involve getting from one body to another (space flight) or from one point to another on the same body (ballistics). For space flight, the approach is to consider several two-body problems and then patch them together. For economy, an orbit with as little energy change as possible is desired. This dictates an elliptic heliocentric orbit that is just tangent to one planetary orbit at one extreme and just tangent to the other orbit at the other extreme. Such an orbit is known as a Hohmann transfer orbit, and it is unique for each pair of planets. *See* Space navigation and guidance; Space probe.

Only slightly increased in complexity is this problem of the motion of a massless particle moving in the gravitational field of two bodies moving around each other in two-body motion. This problem has no general solution; the analytic and numerical study of the problem is concerned with stability, periodic orbits, and topology of solutions. There are five specific solutions—the fixed points or libration points. If the massless particle is placed at any of these points with zero velocity in the coordinate system rotating with the primaries, it will remain at that point in the rotating system. Three of these points are located along the line connecting the primaries, and the other two points form equilateral triangles with the primaries, one ahead and one behind as they revolve. Unlike the linear points, these triangular points can be stable, in that a slight displacement of the massless particle away from the point will not produce unbounded motion but rather an oscillation (called a libration) about the point. There are asteroids, known as the Trojans, librating about both triangular points in the Sun-Jupiter system. *See* Trojan asteroids.

If there are three or more bodies, all of which have mass and therefore all of which influence each other, the problem becomes almost hopeless. The degree of complexity is essentially independent of the number of bodies, so the problem is called the n-body problem. This is usually studied by purely numerical means, but in two extreme cases some analytical progress can be made. One is when the number of bodies, n, becomes so large that statistical approaches are possible; this leads into the dynamics of star clusters and galaxies and out of the field of celestial mechanics. The other is when relative geometries or masses are such that the situation becomes a series of two-body problems with small coupling influences, or perturbations. These perturbations can be treated in some approximate way, such as series expansions or iterative solutions. *See* Galaxy, external; Milky Way Galaxy; Star clusters.

There are two classical areas of general perturbation theory. One is the development of lunar theory, the representation of the motion of the Moon about the Earth, under the influence of rather strong perturbations from the Sun. The other has been planetary theory, the description of the motion of planets (either major or minor) about the Sun, under the influence of (other) major planets. *See* Moon; Perturbation (astronomy).

The newtonian law of universal gravitation has been remarkably successful in explaining most astronomical dynamical phenomena. However, there have been some discrepancies, the most glaring being a small unexplainable motion in the perihelion of Mercury. The problem was resolved by Einstein's theory of general relativity. Philosophically, gravitation is quite different in the two theories, but the mathematical description of motion in general relativity shows that Newton's simple relationship is "almost" correct. The effects are, however, easily detectable in spacecraft trajectories, and thus now have to be routinely considered. *See* Gravitation; Relativity. [R.S.H.]

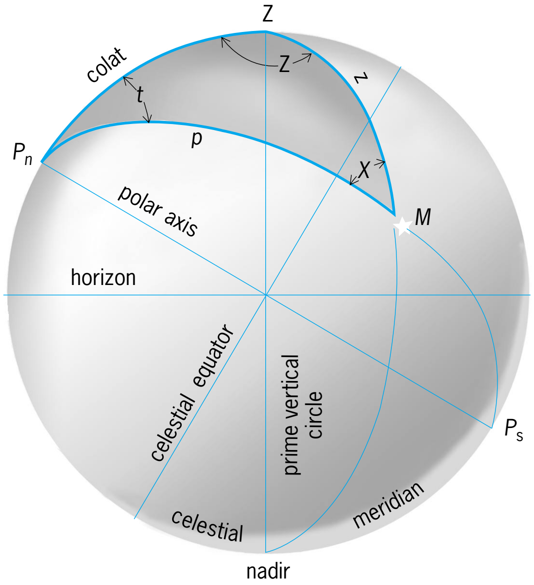
Celestial navigation Navigation with the aid of celestial bodies, primarily for determination of position when landmarks are not available. In celestial navigation, position is not determined relative to the objects observed, as in navigation by piloting, but in relation to the points on the Earth having certain celestial bodies directly overhead.

Celestial bodies are also used for determination of horizontal direction on the Earth and for regulating time, which is of primary importance in celestial navigation because of the changing positions of celestial bodies in the sky as the Earth rotates daily on its axis.

The navigator, concerned less with the actual motions of celestial bodies than with their apparent motions as viewed from the Earth, pictures the heavens as a hollow celestial sphere of infinite radius, with the Earth at its center and the various celestial bodies on its inner surface. The navigator visualizes this sphere as rotating on its axis once in about 23 h 56 min—one sidereal day.

Several systems of coordinates are available to identify points on the celestial sphere. The celestial equator system of coordinates is an extension of the equatorial system commonly used on the Earth. The navigator also uses the horizon system of coordinates, in which the primary great circle is the horizon of the observer. *See* Astronomical coordinate systems.

Position determination in celestial navigation is primarily a matter of converting one set of coordinates to the other. This is done by solution of a spherical triangle called the navigational triangle.



The navigational triangle.

The concept of the spherical navigational triangle is graphically shown in the illustration, a diagram on the plane of the celestial meridian. The celestial meridian passes through the zenith of the observer, and is therefore a vertical circle of the horizon system. Elements of both systems are shown in this illustration, indicating that an approximate solution can be made graphically.

The vertices of the navigational triangle are the elevated pole (P_n), the zenith (Z), and the celestial body (M). The angles at the vertices are, respectively, the meridian angle (t), the azimuth angle (Z), and the parallactic angle (X). The sides of the triangle are the codeclination of the zenith or the colatitude (colat) of the observer, the coaltitude or zenith distance (z) of the body, and the codeclination or polar distance (p) of the body.

A navigational triangle is solved, usually by computation, and compared with an observed attitude to obtain a line of position by a procedure known as sight reduction. With the emergence of electronic computers and hand-held calculators, sight reduction has been performed increasingly with limited use or elimination of tables.

To establish a celestial line of position, the navigator observes the altitude of a celestial body, noting the time of observation. Observation is made by a sextant, so named because early instruments had an arc of one-sixth of a circle. By means of the double reflecting principle, the altitude of the body is double the amount of arc used. The marine sextant uses the visible horizon as the horizontal reference. An air sextant has an artificial, built-in horizontal reference based upon a bubble or occasionally a pendulum or gyroscope. The sextant altitude, however measured, is subject to certain errors, for which corrections are applied. *See* SEXTANT.

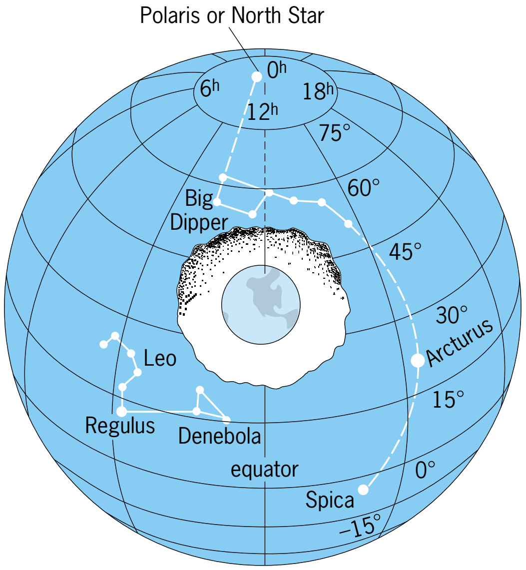
Time is repeatedly mentioned as an important element of a celestial observation because the Earth rotates at the approximate rate of 1 minute of arc each 4 s of time. An error of 1 s in the timing of an observation might introduce an error in the line of position of as much as one-quarter of a mile. Time directly affects longitude determination, but not latitude. The long search for a method of ascertaining longitude at sea was finally solved two centuries ago by the invention of the marine chronometer, a timepiece with a nearly steady rate. *See* NAVIGATION; PILOTING. [A.B.M.]

Celestial reference system A system for specifying reference orientation coordinates for locating celestial objects. The International Celestial Reference System (ICRS) was adopted by the International Astronomical Union in 1994 as the new fundamental reference system. The International Celestial Reference System is realized by the International Celestial Reference Frame (ICRF) made up from the positions of approximately 400 extragalactic radio sources observed with very long baseline interferometry. These sources are very distant, so they do not have any apparent proper motions, but they can have structure that changes with time. The resulting reference frame is accurate to about 0.3 milliarcsecond. The International Celestial Reference Frame replaces the historical use of fundamental star catalogs, such as the FK4 and FK5, which were based on optical observations of nearby bright stars. *See* RADIO ASTRONOMY; RADIO TELESCOPE; STAR.

There is a corresponding International Terrestrial Reference Frame (ITRF) consisting of coordinates on the surface of the Earth. These positions are subject to the variations due to geophysical effects such as plate tectonics and tidal effects. *See* ASTROMETRY; EARTH TIDES; GEODESY; PLATE TECTONICS. [P.K.S.]

Celestial sphere The imaginary sphere, on the inside surface of which the astronomical objects appear to be located. Its center is the center of the Earth. The sphere is so large in proportion to the size of the Earth that its center can be considered as the same point as the observer, wherever he or she may be on the Earth.

A section of the celestial sphere has been removed in the illustration to show the Earth at the center. The Earth's axis has been extended from the North Pole to intersect the celestial sphere in a point called the north celestial pole, which is only about 1° from Polaris, the North Star. *See* POLARIS.



The celestial sphere and the Earth. (*After C. H. Cleminshaw, The Beginner's Guide to the Skies, T. Y. Crowell, 1977*)

Halfway between the north and south celestial poles is the celestial equator. Parallel to it are circles of declination. Declination is the angular distance north or south of the celestial equator, corresponding to latitude on the Earth.

Corresponding to the Earth's meridians, which run from pole to pole, are the hour circles on the celestial sphere. Similar to the way in which longitude is measured on Earth, right ascension is measured along the celestial equator in hours of time. *See* ASTRONOMICAL COORDINATE SYSTEMS; LATITUDE AND LONGITUDE. [C.H.C.]

Celestite A mineral with the chemical composition $\mathrm{SrSO4}$. Celestite occurs commonly in colorless to sky-blue, orthorhombic, tabular crystals. Fracture is uneven and luster is vitreous.

Hardness is 3–3.5 on Mohs scale and specific gravity is 3.97. It fuses readily to a white pearl. The strontium present in celestite imparts a characteristic crimson color to the flame.

Celestite occurs in association with gypsum, anhydrite, salt beds, limestone, and dolomite. Large crystals are found in vugs or cavities of limestone. It is deposited directly from sea water, by groundwater, or from hydrothermal solutions. Celestite is the major source of strontium: Although celestite deposits occur in Arizona and California, domestic production of celestite has been small and sporadic. Much of the strontium demand is satisfied by imported ores from England and Mexico. *See* Strontium.

[E.C.T.C.]

Cell (biology) Cells can be separated into prokaryotic and eukaryotic categories. Eukaryotic cells contain a nucleus. They comprise protists (single-celled organisms), fungi, plants, and animals, and are generally 5–100 micrometers in linear dimension. Prokaryotic cells contain no nucleus, are relatively small (1–10 μm in diameter), and have a simple internal structure. They include two classes of bacteria: eubacteria (including photosynthetic organisms, or cyanobacteria), which are common bacteria inhabiting soil, water, and larger organisms; and archaebacteria, which grow under unusual conditions. *See* Eukaryotae; Prokaryotae.

Prokaryotic (bacterial) cells. All eubacteria have an inner (plasma) membrane which serves as a semipermeable barrier allowing small nonpolar and polar molecules such as oxygen, carbon dioxide, and glycerol to diffuse across (down their concentration gradients), but does not allow the diffusion of larger polar molecules (sugars, amino acids, and so on) or inorganic ions such as Na^+, K^+, Cl^-, Ca^{2+} (sodium, potassium, chlorine, calcium). The plasma membrane, which is a lipid bilayer, utilizes transmembrane transporter and channel proteins to facilitate the movement of these molecules. Eubacteria can be further separated into two classes based on their ability to retain the dye crystal violet. Gram-positive cells retain the dye; their cell surface includes the inner plasma membrane and a cell wall composed of multiple layers of peptidoglycan. Gram-negative bacteria are surrounded by two membranes: the inner (plasma) membrane and an outer membrane that allows the passage of molecules of less than 1000 molecular weight through porin protein channels. Between the inner and outer membranes is the peptidoglycan-rich cell wall and the periplasmic space. *See* Cell permeability.

Eubacteria contain a single circular double-stranded molecule of deoxyribonucleic acid (DNA), or a single chromosome. As prokaryotic cells lack a nucleus, this genomic DNA resides in a central region of the cell called the nucleoid. The bacterial genome contains all the necessary information to maintain the structure and function of the cell.

Many bacteria are able to move from place to place, or are motile. Their motility is based on a helical flagellum composed of interwoven protein called flagellin. The flagellum is attached to the cell surface through a basal body, and propels the bacteria through an aqueous environment by rotating like the propeller on a motor boat. The motor is reversible, allowing the bacteria to move toward chemoattractants and away from chemorepellants.

Eukaryotic cells. In a light microscopic view of a eukaryotic cell, a plasma membrane can be seen which defines the outer boundaries of the cell, surrounding the cell's protoplasm or contents. The protoplasm includes the nucleus, where the cell's DNA is compartmentalized, and the remaining contents of the cell (the cytoplasm). The eukaryotic cell's organelles include the nucleus, mitochondria, endoplasmic reticulum, Golgi apparatus, lysosomes, peroxisomes, cytoskeleton, and plasma membrane (Fig. 1). The organelles occupy approximately half the total volume of the cytoplasm. The remaining compartment of cytoplasm (minus organelles) is referred to as the cytosol or cytoplasmic ground substance. Eukaryotic cells also differ from prokaryotic cells in having a cytoskeleton that gives the cell its shape, its capacity to move, and its ability to transport organelles and vesicles from one part of the cell cytoplasm to another. Eukaryotic cells are generally larger than prokaryotic cells and therefore require a cytoskeleton and membrane skeleton to maintain their shape, which is related to their functions.

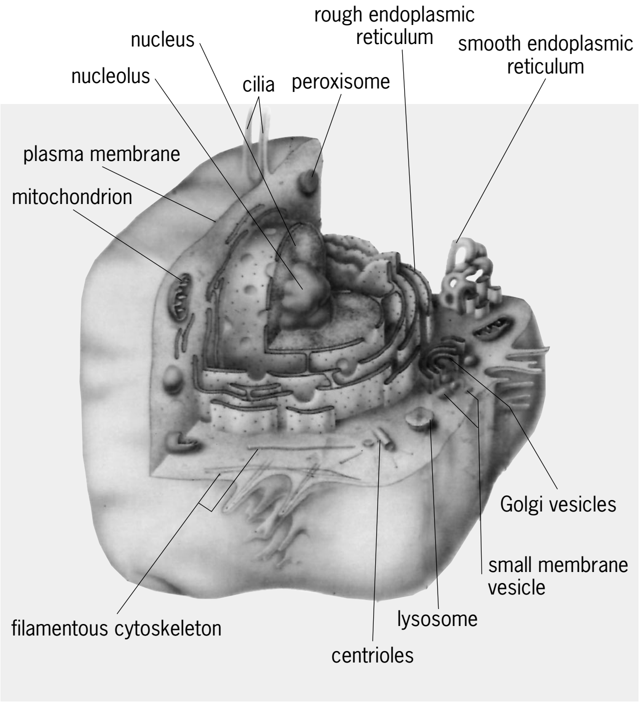


Fig. 1. Artist's rendition of a eukaryotic animal cell. (*Modified from H. Lodish et al., Molecular Cell Biology, 3d ed., Scientific American, New York, 1995*)

Eukaryotic cells contain a large amount of DNA (about a thousandfold more than bacterial cells), only approximately 1% of which encodes protein. The remaining DNA is structural (involved in DNA packaging) or regulatory (helping to switch on and off genes).

Plasma membrane. The plasma membrane serves as a selective permeability barrier between a cell's environment and cytoplasm. The fundamental structure of plasma membranes (as well as organelle membranes) is the lipid bilayer, formed due to the tendency of amphipathic phospholipids to bury their hydrophobic fatty acid tails away from water. Human and animal cell plasma membranes contain a varied composition of phospholipids, cholesterol, and glycolipids. *See* Cell membranes.

Cytoskeleton. The cytoskeleton is involved in establishing cell shape, polarity, and motility, and in directing the movement of organelles within the cell. The cytoskeleton includes microfilaments, microtubules, intermediate filaments, and the two-dimensional membrane skeleton that lines the cytoplasmic surface of cell membranes. *See* Cytoskeleton.

Nucleus. One of the most prominent organelles within a eukaryotic cell is the nucleus. The nuclear compartment is separated from the rest of the cell by a specialized membrane complex built from two distinct lipid bilayers, referred to as the nuclear envelope. However, the interior of the nucleus maintains contact with the cell's cytoplasm via nuclear pores. The primary function of the nucleus is to house the genetic apparatus of the cell; this genetic machinery is composed of DNA (arranged in linear units called chromosomes), RNA, and proteins. Nuclear proteins aid in the performance of nuclear functions and include polypeptides that have a direct role in the regulation of gene function and those that give structure to the genetic material. *See* Cell nucleus.

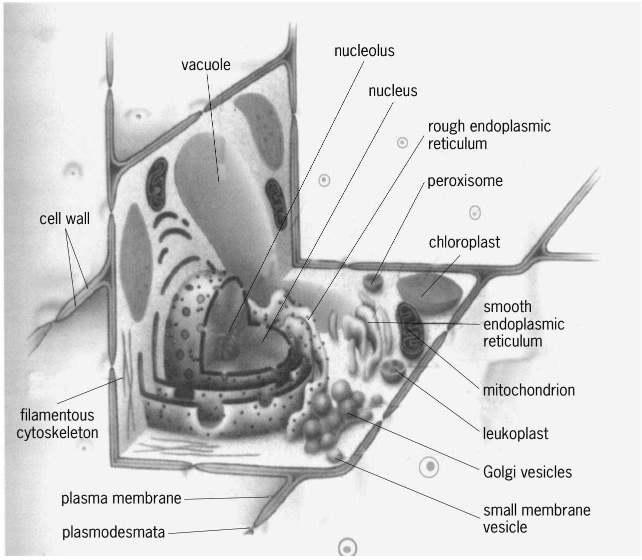

Fig. 2. Artist's rendition of a typical plant cell. (*Modified from H. Lodish et al., Molecular Cell Biology, 3d ed., Scientific American, New York, 1999*)

Endoplasmic reticulum. The endoplasmic reticulum is composed of membrane-enclosed flattened sacs or cisternae. The enclosed compartment is called the lumen. The endoplasmic reticulum is morphologically separated into rough (RER) and smooth (SER). PER is studded with ribosomes and SER is not. RER is the site of protein synthesis, while lipids are synthesized in both RER and SER. *See* ENDOPLASMIC RETICULUM.

Golgi apparatus. The final posttranslational modifications of proteins and glycolipids occur within a series of flattened membranous sacs called the Golgi apparatus. Vesicles which bud from the endoplasmic reticulum fuse with a specialized region of the cis Golgi compartment called the cis Golgi network. In the trans Golgi network, proteins and lipids are sorted into transport vesicles destined for lysosomes, the plasma membrane, or secretion. *See* GOLGI APPARATUS.

Lysosomes. Lysosomes are membrane-bound organelles with a luminal pH of 5.0, filled with acid hydrolyses. Lysosomes are responsible for degrading materials brought into the cell by endocytosis or phagocytosis, or autophagocytosis of spent cellular material. *See* ENDOCYTOSIS; LYSOSOME.

Mitochondria. The mitochondrion contains a double membrane: the outer membrane, which contains a channel-forming protein named porin, and an inner membrane, which contains multiple infolds called cristae. The inner membrane, which contains the protein complexes responsible for electron transport and oxidative phosphorylation, is folded into numerous cristae that increase the surface area per volume of this membrane. The transfer of electrons from nicotinamide adenine dinucleotide (NADH) or flavin adenine dinucleotide ($FADH_2$) down the electron transfer chain to oxygen causes protons to be pumped out of the mitochondrial matrix into the intermembrane space. The resulting proton motive force drives the conversion of ADP plus inorganic orthophosphate (P_i) to ATP by the enzyme ATP synthetase. *See* MITOCHONDRIA.

Peroxisomes. Within the peroxisome, hydrogen atoms are removed from organic substrates and hydrogen peroxide is formed. The enzyme catalase can then utilize the hydrogen peroxide to oxidize substrates such as alcohols, formaldehydes, and formic acid in detoxifying reactions. *See* PEROXISOME.

Plant cells. Plant cells are distinguished from other eukaryotic cells by various features. Outside their plasma membrane, plant cells have an extremely rigid cell wall. This cell wall is composed of cellulose and other polymers and is distinct in composition from the cell walls found in fungi or bacterial cells. The plant cell wall expands during cell growth, and a new cell wall partition is created between the two daughter cells during cell division. Similar cell walls are not observed in animal cells (Fig. 2).

Most plant cells contain membrane-encapsulated vacuoles as major components of their cytoplasm. These vacuoles contain water, sucrose, ions, nitrogen-containing compounds formed by nitrogen fixation, and waste products.

Chloroplasts are the other major organelle in plant cells that is not found in other eukaryotic cells. Like mitochondria, they are constantly in motion within the cytoplasm. One of the pigments found in chloroplasts is chlorophyll, which is the molecule that absorbs light and gives the green coloration to the chloroplast. Chloroplasts, like mitochondria, have an outer and inner membrane. Within the matrix of the chloroplast there is an intricate internal membrane system. The internal membranes are made up of flattened interconnected vesicles that take on a disc-like structure (thylakoid vesicles). The thylakoid vesicles are stacked to form structures called grana, which are separated by a space called the stroma. Within the stroma, carbon dioxide (CO_2) fixation occurs, in which carbon dioxide is converted to various intermediates during the production of sugars. Chlorophyll is found within the thylakoid vesicles; it absorbs light and, with the involvement of other pigments and enzymes, generates ATP during photosynthesis. *See* PLANT CELL. [S.R.G.]

Cell, spectral analysis of Living cells contain various substances, the concentrations and biological activity of which can be investigated by observing the spectrum of light passed through the cells. Such investigations take advantage of the fact that many substances absorb light in an individually characteristic manner. Thus, the spectrum of light passed through a green leaf has two black bands where red and blue light should appear. The absorption of red and blue light is characteristic of the chlorophylls, the photosynthetic pigments. Today, investigations of cells by optical methods go far beyond the routine analysis of brightly colored pigments that are found widespread and in high concentration, for example, hemoglobin and chlorophyll. Such methods allow the investigation of light-absorbing molecules within the cell whose concentration is 1000 times smaller that that of hemoglobin or of chlorophyll. *See* CHLOROPHYLL; HEMOGLOBIN.

Because the color of biological molecules changes when they undergo chemical reactions, such reactions in the cell can be monitored by spectral analyses. These analyses can be used to monitor reactions occurring in times ranging from 10^{-15} s to minutes. In some cases, the spectral properties can also indicate the environment of the biological molecules in the cell, that is, whether they are rigidly held or free to move and how they react with one another within the cell.

Different parts of the spectrum provide different information about molecules in cells. Infrared spectra (700–5000 nanometers) give information about the structure of molecules; all molecules absorb in the infrared in a characteristic manner. Visible light spectra (400–700 nm) give information concerning those relatively few biological molecules that absorb light in this region. These molecules thus can be specifically studied in a cell that may contain tens of thousands of other types of molecules. Ultraviolet spectra (200–400 nm) give information on those molecules that absorb light in this region. Such spectra are not very useful when working with living cells or other light-scattering samples.

Fluorescence and phosphorescence spectra are produced by light emission. When some molecules absorb light in the ultraviolet and visible spectral regions, they can be energized into various electronic excited states. In many instances, the energy of the excited states is dissipated rapidly as heat, and the molecule returns to its original ground state. However, the appropriate excited state can also be dissipated relatively slowly by emitting light at wavelengths slightly longer than that of the excitation light. The emitted light can take one of two forms: fluorescence, which occurs rapidly after excitation and lasts 10^{-9} to 10^{-6} s; and phosphorescence, which has a longer decay time and wavelength range than fluorescence and lasts on the order of 10^{-6} to 10^{2} s. Relatively few molecules emit light after absorption.

Light scattering is of two types. When light is scattered without changing wavelength (elastic scattering), the scattering reveals the size and shape of molecules. Another type is Raman scattering. In this case, molecules alter the light by slightly shifting the wavelength in a manner that is very specific for the particular molecule. *See* RAMAN EFFECT; SCATTERING OF ELECTROMAGNETIC RADIATION.

Spectral analysis by optical methods is limited to those substances which show characteristic peaks, or maxima, of absorption when light absorption is plotted as a function of light wavelength. Whether or not a given substance can be detected depends on the intensity of absorption relative to other substances present at a given absorption maximum. Substances of biological interest that are found in cells and that can be studied optically include pigments such as hemoglobin, flavoproteins, and the pyridine nucleotides. The spectral properties of these substances depend on their oxidation state.

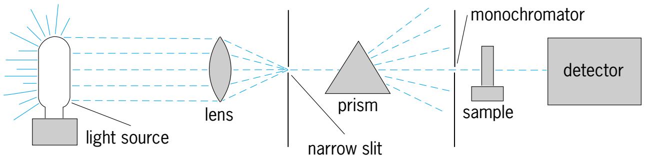
There is a large group of proteins, the iron-sulfur proteins, which are of considerable biological importance. These substances, referred to individually as iron-sulfur clusters, do not have the properties that can be characterized by optical spectroscopy. However, they can be studied in detail by magnetic resonance spectroscopy, a technique where the spectrum involves magnetic fields and light in the microwave spectral region. This technique is also used to study the position of protein complexes relative to one another in biological membranes.

It is characteristic of biological processes that various proteins, enzymes, and coenzymes react with one another in cycles or sequences. In the processes of cellular respiration, there is a sequence of reactions which involve pyridine nucleotides, flavoproteins, iron-sulfur clusters, and cytochromes in processes involving energy transfer and oxygen consumption. Similarly, photosynthesis involves chlorophylls and accessory pigments, cytochromes, pyridine-nucleotides, and iron-sulfur clusters. It is particularly important to discover which components are included in various biological processes and the order in which they react with one another; spectral analysis provides the methods for such investigations.

Because of light-scattering problems and the limited numbers of single cells available, it is extraordinarily difficult to study specific processes within a single cell. Rather, it has proven much more profitable to investigate suspensions of subcellular organelles which can be isolated in a reasonably undamaged state, for example, mitochondria and chloroplasts. Such suspensions, prepared by destroying the cell structure, contain a variety of substances suitable for optical, fluorescent, and magnetic resonance analysis and in sufficient concentration to allow precise and quantitative study. Suspensions of mitochondria and chloroplasts have been used extensively in the development of the understanding of cellular respiration and of photosynthesis. *See* CELL (BIOLOGY); CELL PLASTIDS; MITOCHONDRIA.

Any spectral analysis, regardless of its application, utilizes the components in the illustration. These components consist of a light source from which the light is focused by means of a lens on a narrow slit. The narrow beam of light is then resolved into its component wavelengths by means of a prism or a grating. Lasers have been used as a source of monochromatic light. A narrow band of such light is isolated by means of a second narrow slit and passes through the sample onto an appropriate detector. The signal produced on activation of the detector may be amplified and displayed or recorded on a suitable device.

[W.D.Bo.; J.M.V.]



Basic components used for spectral analysis.

Cell biology The study of the activities, functions, properties, and structures of cells. Cells were discovered in the middle of the seventeenth century after the microscope was invented. In the following two centuries, with steadily improved microscopes, cells were studied in a wide variety of plants, animals, and microorganisms, leading to the discovery of the cell nucleus and several other major cell parts. By the 1830s biologists recognized that all organisms are composed of cells, a realization that is now known as the Cell Doctrine. The Cell Doctrine constitutes the first major tenet upon which the contemporary science of cell biology is founded. By the late 1800s biologists had established that cells do not arise de novo, but come only by cell division, that is, division of a preexisting cell into two daughter cells. This is the second major tenet upon which the modern study of cells is based. *See* CELL DIVISION; MICROSCOPE.

By the end of the nineteenth century chromosomes had been discovered, and biologists had described mitosis—the distribution at cell division of chromosomes to daughter cells. Subsequent studies showed that the chromosomes contain genes and that mitosis distributes a copy of every chromosome and hence every gene to each daughter cell during cell division. This established the basis of cell heredity and ultimately the basis of heredity in multicellular organisms. *See* CHROMOSOME; MITOSIS.

Microscope studies established that some kinds of organisms are composed of a single cell and some, such as plants and animals, are made up of many cells—usually many billions. Unicellular organisms are the bacteria, protozoa, some fungi, and some algae. All other organisms are multicellular. An adult human, for example, consists of about 200 cell types that collectively amount to more than 10^{14} cells.

All modern research recognizes that in both unicellular and multicellular organisms the cell is the fundamental unit, housing the genetic material and the biochemical organization that account for the existence of life. Many millions of different species of cells exist on Earth. Cells as different as a bacterium, an ameba, a plant leaf cell, and a human liver cell appear to be so unrelated in structure and life-style that they might seem to have little in common; however, the study of cells has shown that the similarities among these diverse cell types are more profound than the differences. These studies have established a modern set of tenets that bring unity to the study of many diverse cell types. These tenets are: (1) All cells store information in genes made of deoxyribonucleic acid (DNA). (2) The genetic code used in the genes is the same in all species of cells. (3) All cells decode the genes in their DNA by a ribonucleic acid (RNA) system that translates genetic information into proteins. (4) All cells synthesize proteins by using a structure called the ribosome. (5) Proteins govern the activities, functions, and structures in all cells. (6) All cells need energy to operate; all use the molecule adenosine triphosphate (ATP) as the currency for transfer of energy from energy sources to energy needs. (7) All cells are enclosed by a plasma membrane composed of lipid and protein molecules. *See* CELL MEMBRANES; GENETICS; RIBOSOMES.

In the twentieth century the study of cells, which had been dominated for more than 200 years by microscopy, has been enormously expanded with many other experimental methods. The breaking open of a large mass of cells and the separation of released cell parts into pure fractions led to the discovery of functions contributed by different structures and organelles.

Contemporary research in cell biology is concerned with many problems of cell operation and behavior. Cell reproduction is of special concern because it is essential for the survival of all unicellular and multicellular forms of life. Cell reproduction is the means by which a single cell, the fertilized egg, can give rise to the trillions of cells in an adult multicellular organism. Disrupted control of cell reproduction, resulting in accumulation of disorganized masses of functionally useless cells, is the essence of cancer. Indeed, all diseases ultimately result from the death or misfunctioning of one or another group of cells in a plant or animal. The study of cells pervades all areas of medical research and medical treatment. Great advances have been made in learning how cells of the immune system combat infection, and the nature of their failure to resist the acquired immune deficiency syndrome (AIDS) virus. *See* ACQUIRED IMMUNE DEFICIENCY SYNDROME (AIDS); CANCER (MEDICINE); CELL SENESCENCE AND DEATH.

The development of methods to grow plant and animal cells in culture has provided new ways to study cells free of the experimental complications encountered with intact plants and animals. Cell culture has greatly facilitated analysis of abnormal cells, including transformation of normal cells into cancer cells. Cultured cells are also used extensively to study cell differentiation, cell aging, cell movement, and many other cell functions. *See* TISSUE CULTURE. [D.M.Pr.]

Cell constancy The condition in which the entire body of an adult animal or plant consists of a fixed number of cells that is the same in all members of the species. This phenomenon is also called eutely. The largest group of animals exhibiting eutely are the nematode worms, one of the largest of all animal phyla, and of great medical and agricultural importance as parasites of plants, animals, and humans. A plant that exhibits eutely is usually called a coenobium. Many species of semimicroscopic aquatic green algae exist as coenobia, such as the common *Volvox* and *Pandorina*.

Numerical limitation occurs in certain organs and organ systems, notably the brain and muscles of annelid worms, mollusks, and vertebrates. A related but different phenomenon, observed for many animal cells when cultured, is that normal cells divide some specific number of times and then stop dividing. Thus the life-span, as measured by number of cell cycles, is limited; for many human cell types this is about 50 cell generations.

In annelids and vertebrates, cell proliferation is more or less continuous throughout life only in those tissues that are subject to wear. Thus, in adults, cell division may be found in the germinative zones of the skin, hair, finger and toe nails, the lining of the alimentary canal, and especially in the blood cell-forming tissues. The muscles and nervous system, however, appear to undergo no cell division after early embryonic or fetal stages. In both earthworms and mammals, including humans, it has been demonstrated that the number of muscle nuclei and muscle fibers, but not fibrils, is fixed early and does not increase with subsequent growth. An earthworm hatches from its egg cocoon with the adult number of muscle fibers and nuclei. A human fetus, about 5 in. (13 cm) from crown to rump, has as many muscle fibers and nuclei as an adult. It has been shown that the number of glomeruli in each kidney of a rat or human, and therefore presumably of any mammal, is fixed before birth, and that the subsequent growth of the glomeruli, either normally or resulting from compensatory hypertrophy after unilateral nephrectomy, is due entirely to the enlargement of cells already present. The same holds true for the cells of the ciliated nephrostomes of earthworms. [G.B.M.]

Cell cycle The succession of events that culminates in the asexual reproduction of a cell; also known as cell division cycle. In a typical cell cycle, the parent cell doubles its volume, mass, and complement of chromosomes, then sorts its doubled contents to opposite sides of the cell, and finally divides in half to yield two genetically identical offspring. Implicit in the term "cycle" is the idea that division brings the double-sized parent cell back to its original size and chromosome number, and ready to begin another cell cycle. This idea fits well with the behavior of many unicellular organisms, but for multicellular organisms the daughter cells may differ from their parent cell and from each other in terms of size, shape, and differentiation state.

The time required for completion of a eukaryotic cell cycle varies enormously from cell to cell. Embryonic cells that do not need to grow between divisions can complete a cell cycle in as little as 8 min, whereas cycling times of 10–24 h are typical of the most rapidly dividing somatic cells. Many somatic cells divide much less frequently; liver cells divide about once a year, and mature neurons never divide. Such cells may be thought of as temporarily or permanently withdrawing from the cell cycle.

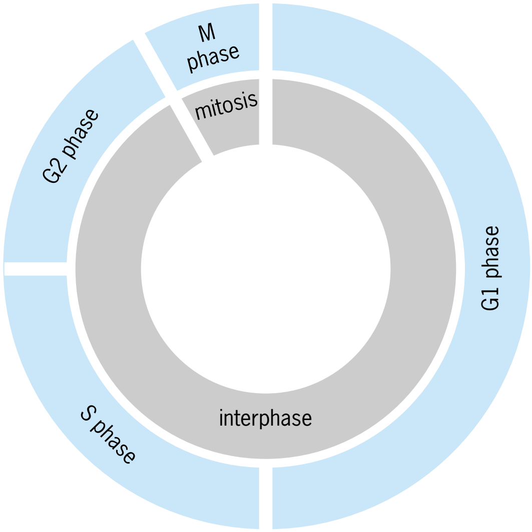
Eukaryotic phases. The cell cycle is divided into two main parts: interphase and mitosis (see illustration). During interphase, the cell grows and replicates its chromosomes. Interphase accounts for all but an hour or two of a 24-h cell cycle, and is subdivided into three phases: gap phase 1 (G1), synthesis (S), and gap phase 2 (G2). Interphase is followed by mitosis (nuclear division) and cytokinesis (cell division). This relatively brief part of the cell cycle includes some of the most dramatic events in cell biology.

G1 phase. Gap phase 1 begins at the completion of mitosis and cytokinesis and lasts until the beginning of S phase. This phase is generally the longest of the four cell cycle phases and is quite variable in length. During this phase, the cell chooses either to replicate its deoxyribonucleic acid (DNA) or to exit the cell cycle and enter a quiescent state (the G0 phase).

S phase. Replication of the chromosomes is restricted to one specific portion of interphase, called S phase (DNA synthesis phase), which typically lasts about 6 h. In mammalian cells, the start of S phase—the actual initiation of DNA synthesis—takes place several hours after the cell has committed to carrying out DNA synthesis. During S phase, each chromosome replicates exactly once to form a pair of physically linked sister chromatids. In animal cells, a pair of centrioles is also duplicated during S phase. *See* CHROMOSOME; GENETICS.

G2 phase. The portion of interphase that follows S phase is called gap phase 2. Some cells can exit the cell cycle from G2 phase, just as they can from G1 phase.

M phase. M phase includes the overlapping processes of mitosis and cytokinesis. Mitosis is divided into five stages: prophase, prometaphase, metaphase, anaphase, and telophase. Cytokinesis usually begins during anaphase and ends at a point after the completion of mitosis. At the end of cytokinesis, the parent cell has formed its two G1 phase progeny and the cell is ready to repeat the cycle. *See* CYTOKINESIS; MITOSIS.



Phases of the eukaryotic cell cycle.

Control of cell cycle. The network of proteins that regulate DNA synthesis (G1/S), mitotic entry (G1/M), and mitotic exit (the transition from mitotic metaphase to anaphase and then out of mitosis) appears to be well conserved throughout eukaryotic evolution. At the heart of these cell cycle transtions is the periodic activation and inactivation of cyclin-dependent protein kinases. In addition, in multicellular eukaryotes, pathways regulating entry into and exit from the cell cycle entrain these central cyclin-dependent kinases to extrinsic signals. [J.E.F.]

Cell differentiation

The mechanism by which cells in a multicellular organism become specialized to perform specific functions in a variety of tissues and organs. Specialized cells are the product of differentiation. The process can be understood only from a historical perspective, and the best place to start is the fertilized egg. Different kinds of cell behavior can be observed during embryogenesis: cells double, change in shape, and attach at and migrate to various sites within the embryo without any obvious signs of differentiation. Cleavage is a rapid series of cell cycles during which the large egg cell is divided into a ball of small cells that line the primitive body cavity as a single layer of embryonic cells. This blastula stage is followed by gastrulation, a complex coordinated cellular migration which not only shapes the embryo but segregates the single-cell layer of the blastula into the three germ layers: endoderm, mesoderm, ectoderm. They give rise to specific cell types; for example, skin and nerves from the ectoderm, the digestive tract from the endoderm, and muscle and connective tissue from the mesoderm. *See* BLASTULATION; CELL CYCLE; CLEAVAGE (EMBRYOLOGY); EMBRYOGENESIS; GASTRULATION.

The stable differentiated state is a consequence of multicellularity. A complex organism maintains its characteristic form and identity because populations of specialized cell types remain assembled in a certain pattern. Thus several kinds of cells make up a tissue, and different tissues build organs. The variable assortment of about 200 cell types allows for an almost infinite variety of distinct organisms.

Epithelia, sheets of cells of specific structure and function, cover the outer surface of the vertebrate body and line the lungs, gut, and vascular system. The stable form of a vertebrate is due to its rigid skeleton built from bone and cartilage, forming cells to which the skeletal muscles adhere. All other organs, such as liver and pancreas, are embedded in connective tissue that is derived from fibroblast cells which secrete large amounts of soft matrix material.

Some cells, like nerve cells, are so specialized that they need divide no longer in order to maintain a complex network. Their finite number decreases even during embryonic development. Other cell types are constantly worn out and must be replaced; for example, fibroblasts and pancreas cells simply divide as needed, proving that the differentiated state of cells is heritable, as the daughter cells remember and carry out the same special functions. The renewal of terminally differentiated cells that are unable to divide anymore, such as skin and blood cells, is carried out by stem cells. They are immortal and choose, as they double, whether to remain a stem cell or to embark on a path of terminal differentiation. Most stem cells are unipotent because they give rise to a single differentiated cell type. However, all cell types of the blood are derived from a single blood-forming stem cell, a pluripotent stem cell. A fertilized egg is a totipotent stem cell giving rise to all other cell types that make up an individual organism. *See* EMBRYONIC DIFFERENTIATION; EMBRYONIC INDUCTION; OOGENESIS. [H.Sa.]

Cell lineage

A type of embryological study in which the history of individual blastomeres (cells formed during division of the zygote) or meristem cells is traced to their ultimate differentiation into tissues and organs.

The question of how the animal genome can be regulated to produce the various cell types found in the larval and adult organism is a central concern in developmental biology. A possible approach to this problem would involve tracing the structural fates of the descendants of each of a population of progenitor cells, and then trying to determine which gene products are required for particular steps in the process of cell differentiation.

Some of the most promising cell lineage studies are conducted on a nematode worm, *Caenorhabditis elegans*, which is a small (1 mm or 0.04 in. in length), nearly transparent worm that lives in soil. Adults are either males or hermaphrodites; the hermaphrodites contain 959 somatic nuclei. The origin of each somatic cell can be traced back to a single blastomere, and the clonal history of each cell has been determined. A detailed genetic map for the 80,000-kilobase genome has been worked out. *See* CLEAVAGE (EMBRYOLOGY); FATE MAPS (EMBRYOLOGY). [S.J.B.]

Cell lineage analysis in plants, as in animals, involves tracing the origin of particular cells in the adult body back to their progenitor cells. The adult body of a typical plant consists primarily of leaves, stems, and roots. Cells arise continuously during plant life from specialized dividing cell populations called meristems. A shoot apical meristem produces the leaves and stem, and a root apical meristem produces root tissue. The shoot apical meristem will also produce specialized structures, such as cones, flowers, and thorns. Because plant cells do not move during development, and in many cases the plane of cell division is constant, lines of cells, called cell files, all derive from a single meristem cell at the base of the file. [V.W.]

Cell membrane

The membrane that surrounds the cytoplasm of a cell; it is also called the plasma membrane or, in a more general sense, a unit membrane. This is a very thin, semifluid, sheetlike structure made of four continuous monolayers of molecules. The plasma membrane and the membranes making up all the intracellular membranous organelles display a common molecular architectural pattern of organization, the unit membrane pattern, even though the particular molecular species making up the membranes differ considerably. All unit membranes consist of a bilayer of lipid molecules, the polar surfaces of which are directed outward and covered by at least one monolayer of nonlipid molecules on each side, most of which are protein, packed on the lipid bilayer surfaces and held there by various intermolecular forces. Some of these proteins, called intrinsic proteins, traverse the bilayer and are represented on both sides. The segments of the polypeptide chains of these transverse proteins within the core of the lipid bilayer may form channels that provide low-resistance pathways for ions and small molecules to get across the membrane in a controlled fashion. Sugar moieties are found in both the proteins and lipids of the outer half of the unit membrane, but not on the inside next to the cytoplasm. The molecular composition of each lipid monolayer making up the lipid bilayer is different. The unit membrane is thus chemically asymmetric. *See* CELL ORGANIZATION.

Unit membrane. The unit membrane of a cell is a continuous structure having one surface bordered by cytoplasm and the other by the outside world. It appears in thin sections with the electron microscope as a triple-layered structure about 7.5–10 nanometers thick consisting of two parallel dense strata each about 2.5 nm thick separated by a light interzone of about the same thickness. The plasma membrane may become tucked into the cytoplasm and pinch off to make an isolated vesicle containing extracellular material by a process called endocytosis. During endocytosis the membrane maintains its orientation, with its cytoplasmic surface remaining next to cytoplasm. In this sense the contents of intracellular organelles, such as the endoplasmic reticulum, Golgi apparatus sacs, nuclear membrane, lysosomes, peroxisomes, and secretion granules, are material of the outside world, since at some time the space occupied by this material may become continuous directly or indirectly with the outside world. Hence the surface of the membrane bordering such material and lying between it and cytoplasm is topographically an external membrane surface even though it may be contained completely within the cell. *See* ENDOCYTOSIS.

Eukaryotic cells are characterized by the triple-layered nature of the unit membrane. The genetic material is segregated into a central region bounded by the nuclear membrane that is penetrated by many pores containing special proteins. Bacteria (prokaryotes) do not contain such elaborate systems of internal membranes, but some have an external unit membrane separated from the plasma membrane by a special material called periplasm. The membrane does not normally flip over, so that the surface that borders the outside world, either at the cell surface or inside the cell, comes to border cytoplasm. This principle is maintained in all membranous organelles.

Mitochondria are a special case because the inner mitochondrial membrane is believed to be the membrane of a primitive one-celled organism that is symbiotically related to the cell and lies inside a cavity containing material of the outside world as defined above. The outer mitochondrial membrane is in this sense a membrane of the cell analogous to a smooth endoplasmic reticulum membrane, and the inner membrane of the mitochondrion is the plasma membrane of the included organism, which normally does not become continuous with the membrane of the cell. Thus it has its own unit membrane, and again the orientation of this unit membrane is always maintained, with one side directed toward the cytoplasm, in this case the cytoplasm of the mitochondrion. *See* MITOCHONDRIA.

Function. The cell membrane functions as a barrier that makes it possible for the cytoplasm to maintain a different composition from the material surrounding the cell. The unit membrane is freely permeable to water molecules but very impermeable to ions and charged molecules. It is permeable to small molecules in inverse proportion to their size but in direct proportion to their lipid solubility. It contains various pumps and channels made of specific transverse membrane proteins that allow concentration gradients to be maintained between the inside and outside of the cell. For example, there is a cation pump that actively extrudes sodium ions (Na^+) from the cytoplasm and builds up a concentration of potassium ions (K^+) within it. The major anions inside the cell are chlorine ions (Cl^-) and negatively charged protein molecules, the latter of which cannot penetrate the membrane. The presence of the charged protein molecules leads to a buildup of electroosmotic potential across the membrane. Action potentials result from the transient opening of Na^+ or calcium ion (Ca^{2+}) channels depolarizing the membrane, followed by an opening of K^+ channels leading to repolarization. This is one of the most important functions of membranes, since it makes it possible for the brain to work by sending or receiving signals sent over nerve fibers for great distances, as well as many other things. *See* BIOPOTENTIALS AND IONIC CURRENTS.

The plasma membrane contains numerous receptor molecules that are involved in communication with other cells and the outside world in general. These respond to antigens, hormones, and neurotransmitters in various ways. For example, thymus lymphocytes (T cells) are activated by attachment of antigens to specific proteins in the external surfaces of the T cells, an important part of the immune responses of an organism. Hormones such as epinephrine and glucagon attach to a receptor protein in the surfaces of cells and cause the activation of adenylate cyclase, which in turn causes the formation of cyclic adenosine monophosphate. Neurotransmitters attach to the postsynaptic membrane in synapses and mediate the transfer of information between neurons. There is a class of membrane proteins called cell adhesion molecules, components of the outer surfaces of cell membranes in the developing nervous system, that is thought to be involved in guiding embryonic development.

Membrane lipids. The major lipids of membranes are phospholipids with a glycerol backbone including phosphophatidyl ethanolamine, phosphatidyl choline, phosphatidyl serine, phosphatidyl inositol, and cardiolipin. Cardiolipin is more complex because it contains two glycerols and four fatty acids. It is important in bacterial membranes and is also found in the mitochondrial inner membrane.

The sphingolipids are another class of membrane lipids having the compound sphingosine as their backbone structure instead of glycerol. Ceramide is a fatty acid derivative of sphingosine that is the parent substance of many important membrane lipids. Sphingomyelin is ceramide with phosphatidyl choline added. This molecule, like phosphatidyl choline and phosphatidyl ethanolamine, is a zwitterion at pH 7; that is, it is uncharged. Phosphatidyl serine is negatively charged.

The glycolipids are an important class of lipid not containing phosphorus and based on ceramide. These include the uncharged cerebrosides that have only one sugar group, either glucose or galactose, and the gangliosides that may contain branched chains of as many as seven sugar residues including sialic acid, which is charged.

Cholesterol is a very important membrane lipid. It is present only in eukaryotes and is a prominent constituent of red blood cells, liver cells, and nerve myelin. *See* CHOLESTEROL.

The different lipid molecules are not equally distributed on both sides of the bilayer. The amino lipids, glycolipids, and cholesterol are located primarily in the outer monolayer, and the choline and sphingolipids are located mainly in the internal monolayer. The fatty acids of the outer half of the bilayer tend to have longer, more saturated carbon chains than those of the inner half.

The lipid bilayer has a considerable degree of fluidity, with the lipid molecules tending to rotate and translate easily, but they do not ordinarily flipflop from one side of the bilayer to the other. Furthermore, some lipids are firmly attached to membrane proteins and translate laterally only as the proteins do so. Some membrane proteins form extended two-dimensional crystals, and their lateral movement is thus restricted. Nevertheless, there is a considerable degree of fluidity in membranes overall. *See* LIPID.

Membrane proteins. The ratio of protein to lipids in membranes is often about 1:1, but in some cases, such as nerve myelin, there is only about 20% protein. Usually polypeptide chains are folded into a globular structure with hydrophilic amino acid side chains to the outside and hydrophobic ones tucked inside. For this reason the common globular protein is hydrophilic. Sometimes stretches of hydrophobic amino acids occur in the chain and may divide it into two hydrophilic domains. If there is a stretch of hydrophobic amino acids long enough (about 20) to stretch across the hydrophobic interior of a membrane bilayer, the extrusion of the protein across the bilayer during protein synthesis may stop, leaving a hydrophilic part of the protein on the cytoplasmic side and another hydrophilic part on the outside. This protein then becomes an intrinsic amphiphilic transmembrane protein. Such proteins can be removed only with chaotropic agents that destroy the bilayer.

The classification of membrane proteins as intrinsic and extrinsic is not always easy. Some proteins clearly become attached to either the inside or outside of the bilayer by more specific interactions with the polar heads of the lipid molecules, and sometimes it is not clear whether such proteins should be called extrinsic or intrinsic. They are extrinsic in that they can be removed without using detergents to disrupt the lipid bilayer completely, but they are intrinsic in that they are permanent parts of the membrane and retain some tightly bound lipids when removed. Spectrin and anchorin in the erythrocyte membrane are firmly bound to the cytoplasmic surfaces presumably by polar head group interactions and can thus be regarded as intrinsic. *See* CELL (BIOLOGY); PLANT CELL; PROTEIN. [J.D.Ro.]

Cell metabolism The sum of chemical reactions which transpire within cells. The cell performs chemical, osmotic, mechanical, and electrical work, for which it needs energy. Plant cells obtain energy from sunlight; using light energy, they convert simple compounds such as carbon dioxide and various nitrogen, phosphate, and sulfur compounds into more complex materials. The energy in light is thus "stored" as chemical substances, mostly carbohydrates, within plant cells. Animal cells cannot use sunlight directly, and they obtain their energy by breaking down the stored chemical compounds of plant cells. Bacterial cells obtain their energy in various ways, but again mostly by the degradation of some of the simple compounds in their environment. *See* BACTERIAL PHYSIOLOGY AND METABOLISM; PHOTOSYNTHESIS; PLANT METABOLISM.

Cells have definite structures, and even the chemical constituents of these structures are being constantly renewed. This continuing turnover has been called the dynamic state of cellular constituents. For example, an animal cell takes in carbohydrate molecules, breaks down some of them to obtain the energy which is necessary to replace the chemical molecules that are being turned over, while another fraction of these molecules is integrated into the substance of the cell or its extracellular coverings. The cell is constantly striving to maintain an organized structure in the face of an environment which is continuously striving to degrade that structure into a random mixture of chemical molecules.

All the large molecules of the cell have specific functions: Carbohydrates, fats, and proteins constitute the structures of the cells; these, particularly the former two, are also used for food, or energy, depots; the nucleic acids are the structures involved in the continuity of cell types from generation to generation. All these large molecules are really variegated polymers of smaller molecules. These smaller molecules interact with one another in chemical reactions which are catalyzed at cellular temperature by enzymes. All these reactions are very specific each enzyme only reacting with its own specified substrate or substrates. At present, about a thousand chemical reactions are known which occur within cells; thus, about a thousand specific enzymes are known. By studying how enzymes operate and what substrates they attack, the biochemist has learned in general, and in many cases in specific, how fats, carbohydrates, proteins, and nucleic acids are synthesized and degraded in cells. Mainly through the use of radioactive tracer atoms, the pathways of many chemical compounds within the cell have been realized. For example, it is known what part of the carbohydrate molecule is used for energy production, what part is used in fat storage, and what parts end up in proteins and nucleic acids. *See* CARBOHYDRATE METABOLISM; ENZYME; LIPID METABOLISM; NUCLEIC ACID; PROTEIN METABOLISM.

Via the vast array of enzymatic reactions which go on inside cells, the substances which a cell brings in are completely changed, becoming transformed into cell substance. This changeover needs energy for accomplishment. This energy comes from a chemical compound called adenosine triphosphate (ATP); it is synthesized enzymatically by the cell in a number of reactions in which various compounds coming from foodstuffs are oxidized, and the energy gained as a result is stored in ATP. Subsequently, all cellular reactions which require synthesis of cell-specific substances use this ATP as a source of energy. *See* ADENOSINE TRIPHOSPHATE (ATP).

Remarkably, even with these constant replacements going on, the cell never loses its own distinctive structure and function. The reason is that the ordering of the cell resides in a code of nucleic acids, which directs the syntheses of specific enzymes designed to do specific tasks; when these enzymes are degraded and have to be resynthesized, they are made again in exactly the same way as before. In this way continuity is ensured. *See* DEOXYRIBONUCLEIC ACID (DNA); GENETICS; RIBONUCLEIC ACID (RNA).

Although a great deal is known of the metabolism of a large variety of compounds (their degradation, syntheses, and interactions), little is known of how these multitudinous reactions are regulated within the cell to effect growth, particular size, and division into daughter cells having the same structure and functioning characteristics as those of the parent cells. It is known that enzymatic reaction activities within cells are strictly governed so that in quite a few cases knowledge has been gained of how a cell shuts off the synthesis of a compound of which it has enough, or speeds up the syntheses of those in short supply. This is done by an enzyme so constructed that the compound which it synthesizes, say, can interact with the enzyme to inhibit its further activity.

Almost the sole justification for cell metabolism is the functioning of a vehicle whose major task is to reproduce as precise a replica of itself as possible. The efficiency of this metabolism has been maximized with this goal in view. *See* CELL (BIOLOGY).

[P.Si.]

Cell motility The movement of cells, changes in cell shape including cell division, and the movement of materials within cells. Many free-living protozoa are capable of movement, as are sperm and ameboid cells of higher organisms. Coordinated movement of cells occurs during embryogenesis, wound healing, and muscle contraction in higher organisms. Cell division is observed in all organisms and is a requirement for reproduction, growth, and development. Many cells also undergo structural changes as they differentiate, such as the outgrowth of axonal and dendritic processes during nerve cell differentiation. A more subtle form of cell motility involves the active transport of membranous organelles within the cytoplasm. This form of movement is required for proper organization of the cytoplasmic contents, and the redistribution of metabolites, hormones, and other materials within the cell.

There are two basic molecular systems responsible for producing a variety of forms of movement in a wide range of cell types: one system involves filamentous polymers of the globular protein actin; the other involves hollow, tube-shaped polymers of the globular protein tubulin, known as microtubules. Associated with both actin filaments and microtubules are accessory enzymes that convert the chemical energy stored in adenosine triphosphate (ATP) into mechanical energy. Other proteins are responsible for regulating the arrangement, assembly, and organization of actin filaments and microtubules within the cell.

Actin and myosin. Muscle contraction represents one of the most extensively studied forms of cell movement, and it is from muscle that much basic knowledge of actin-based movement has been derived. Striated muscle cells found in skeletal muscle and heart muscle contain highly organized arrays of actin filaments interdigitating with filaments of the protein myosin. Myosin has an enzymatic activity that catalyzes the breakdown of ATP to adenosine diphosphate (ADP) and phosphate. The released energy is used to produce force against the actin filaments, which results in sliding between the actin and myosin filaments. *See* MUSCLE PROTEINS.

These proteins have by now been found in virtually all cell types. Actin is involved in a wide variety of movements in many cell types, such as ameboid movement, lamellipodial extension, cytoplasmic streaming, and cytokinesis. *See* CYTOKINESIS.

Microtubules, dynein, and kinesin. Like actin filaments, microtubules have by now been found within the cytoplasm of almost all eukaryotic cells. They are involved in a variety of forms of movement, including ciliary and flagellar movement in eukaryotes, organelle movement in cytoplasm, and chromosome movement during mitosis. *See* CILIA AND FLAGELLA; MITOSIS.

Two different molecules, dynein and kinesin, have been identified as enzymes that break down ATP to ADP and phosphate to produce force along microtubules. Dynein is a large enzyme complex that was initially identified in cilia and flagella. It has also been found associated with cytoplasmic microtubules. Kinesin is a force-producing enzyme that was initially found in microtubules prepared from neuronal cells. It is now also known to be widespread.

Despite the basic similarity in how the three force-producing enzymes (myosin, dynein, and kinesin) work, they differ from each other in structure and enzymatic properties and there is no evidence that they are evolutionarily related. Kinesin and dynein differ from each other in another important way: they produce force in opposite directions along microtubules. This suggests that they play complementary roles in the cell. As yet, no enzyme has been identified that produces force along actin filaments in the direction opposite to myosin.

Other motile proteins. Other motile mechanisms certainly exist. For example, bacterial flagella are very fine helical hairs, unlike the more substantial flagella and cilia of eukaryotic cells. Bacterial flagella rotate about their axis and propel the bacterium by a corkscrewlike mechanism, unlike the bending and whiplashing movements of eukaryotic cilia and flagella. Bacterial flagella are hollow filamentous polymers, like microtubules, but are composed of the protein flagellin, which has no apparent relationship to tubulin. *See* Bacteria.

Other forms of bacteria glide over solid substrata by using an excreted slime for propulsion; the mechanism of gliding is not understood. Gliding motility is also seen in a number of algae and blue-green algae.

The sperm cells of roundworms differ from other types of sperm cells in that they lack flagella and exhibit a form of ameboid movement. These cells, however, contain neither actin, which is involved in ameboid movement in other ameboid cells, nor tubulin. Movement may be produced by insertion of lipid in the forward region of the plasma membrane and rearward flow of the membrane.

A contractile protein, spasmin, has been identified in *Vorticella* and related ciliated protozoa. Spasmin is organized into a long, thick fiber within the stalk portion of the organism. In response to calcium, the fiber undergoes a rapid, drastic contraction. It is not known whether spasmin exists in other organisms. *See* Cell (biology).

Disease. Understanding how cells move increases the ability to control abnormal cell behavior, such as the increased level of cell division responsible for cancer and the migration of cancer cells from their site of origin in the body. Errors in chromosome segregation are also known to be responsible for Down syndrome, and are prevalent during the progression of neoplastic tumors.

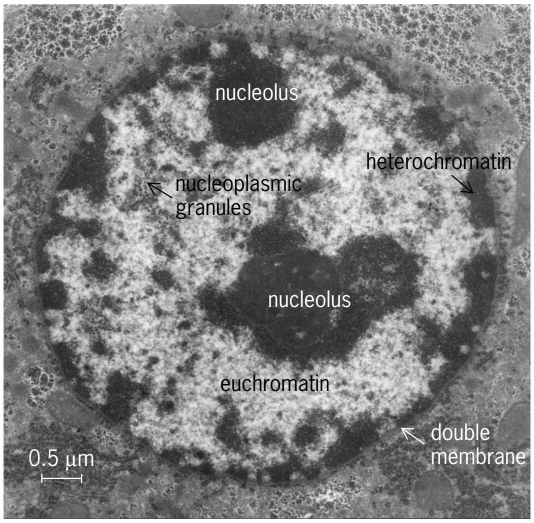
Because the normal functioning of cells is so dependent on proteins that compose and regulate microtubules and actin filaments, defects in these proteins are expected to have severe effects on cell viability. An example of a microtubule defect has been identified in Alzheimer's disease: a microtubule-associated protein (termed tau) is found to be a prominent component of abnormal neurofibrillary tangles seen in affected nerve cells. However, it remains unknown whether the defect involving tau is part of the cause of the disease or represents one of its effects. *See* Alzheimer's disease; Cancer (medicine); Down syndrome.

[R.V.]

Cell nucleus

Cell nucleus The largest of the membrane-bounded organelles which characterize eukaryotic cells; it is thought of as the control center since it contains the bulk of the cell's genetic information in the form of deoxyribonucleic acid (DNA). The nucleus has two major functions: (1) It is the site of synthesis of ribonucleic acid (RNA), which in turn directs the formation of the protein molecules on which all life depends; and (2) in any cell preparing for division, the nucleus precisely duplicates its DNA for later distribution to cell progeny. *See* Deoxyribonucleic acid (DNA); Eukaryotae; Ribonucleic acid (RNA).

The diameter of nuclei ranges from 1 micrometer in intracellular parasites and yeast cells to several millimeters in some insect sperm. Spherical or ellipsoidal nuclei are found in most cell types, although occasionally spindle-shaped, lobulated, disc-shaped, or cup-shaped nuclei may be observed. Although nuclear size and shape are somewhat consistent features of a particular cell type, these features are more variable in cancer cells. In addition, tumor cell nuclei are characterized by indentation, furrowing, elongation, and budding.



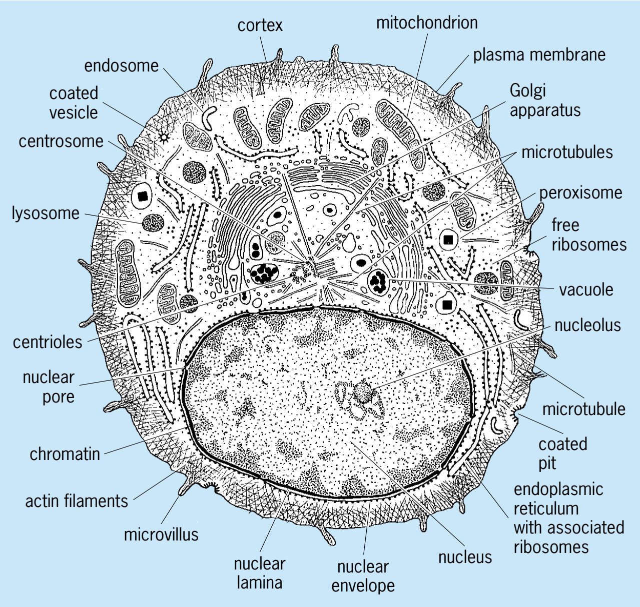
Transmission electron micrograph of a thin section of a rat liver cell nucleus.

The nucleus is bounded by a double membrane (the nuclear envelope) and contains several major components: chromatin, which is composed of DNA and chromosomal proteins; the nucleolus, which is the site of ribosomal RNA (rRNA) synthesis; and nucleoplasmic fibrils and granules, some of which are involved in the processing and transport of messenger RNA out of the nucleus (see illustration). The constituents of the nucleus are contained within a framework referred to as the nuclear matrix.

[D.L.S]

Cell organization

Cell organization Cells are divided into several compartments, each with a characteristic structure, biochemical composition, and function (see illustration). These compartments are called organelles. They are delimited by membranes composed of phospholipid bilayers and a number of proteins specialized for



Section through an animal cell showing the major components visible by electron microscopy. To simplify, a few important components, including intermediate filaments, have been omitted.

each type of organelle. All eukaryotic cells have a nucleus surrounded by a nuclear envelope, and a plasma membrane that borders the whole cell. Most eukaryotic cells also have endoplasmic reticulum, a Golgi apparatus, lysosomes, mitochondria, and peroxisomes. Plant cells have chloroplasts for photosynthesis in addition to the organelles that both they and animal cells possess. These organelles are suspended in a gellike cytoplasmic matrix composed of three types of protein polymers called actin filaments, microtubules, and intermediate filaments. In addition to holding the cell together, the actin filaments and microtubules act as tracks for several different types of motor proteins that are responsible for cell motility and organelle movements within the cytoplasm.

A major challenge in the field of cell biology is to learn how each organelle and the cytoplasmic matrix are assembled and distributed in the cytoplasm. This is a very complex process since cells consist of more than 2000 different protein molecules together with a large number of lipids, polysaccharides, and nucleic acids, including both deoxyribonucleic acid (DNA) and many different types of ribonucleic acid (RNA). *See* NUCLEIC ACID.

The cell must possess enough information to specify which molecules are to be associated in a specific compartment, to route the appropriate groups of molecules to their compartments, and then to position each type of component appropriately in the cell. As a result of intense research on each of these topics, a number of specific chemical reactions that contribute to organizing cells are now recognized, but even more important, a small number of general principles that explain these complex processes of life can be appreciated.

Normal cells regulate the production and degradation of all of their constituent molecules so that the right balance of molecules is present at any given time. The genes stored in nuclear DNA are duplicated precisely once per cell cycle. The supply of each of thousands of proteins is usually regulated at the level of the genes at the time of biosynthesis and by the rate of degradation. These proteins serve as enzymes that determine the rate of synthesis of themselves as well as of other cellular components such as nucleic acids, carbohydrates, and lipids. Each of these processes is regulated by molecular feedback loops to assure the proper levels of each cellular constituent. *See* CELL CYCLE; CELL METABOLISM.

A large majority of cellular components are generated by the self-assembly of their constituent molecules. Self-assembly means that the information required for molecules to bind together in the proper orientation is contained in the molecules themselves. Some examples include the binding of histones to DNA, the formation of bilayers from phospholipids, and the polymerization of actin molecules into filaments. The molecules are usually brought together by diffusion. The energy required to hold them together derives from the exclusion of water from their complementary surfaces as well as from the formation of ionic bonds and hydrogen bonds. The variety of molecular structures found in proteins allows each type to self-assemble specifically, only with their correct partner molecules.

After biosynthesis, proteins and nucleic acids are routed to their proper cellular compartment by specific recognition signals consisting of parts of the molecule or, in the case of some proteins, by sugar side chains. These signals are recognized by compartment-specific receptors that guide the molecules to the correct compartment. For example, proteins destined for lysosomes have a specific sugar side chain added in the Golgi apparatus that guides them to lysosomes. Similarly, proteins destined for the nucleus all contain short sequences of amino acids that target the proteins for uptake by the nucleus. These so-called nuclear recognition sequences most likely bind to specific receptors associated with the nuclear pores, the channels through the nuclear envelope that connect the nucleus with the cytoplasm.

Most molecules move to their correct compartment by the process of diffusion down concentration gradients, but organelles generally require transport systems composed of microtubules or actin filaments together with specific motor proteins to position them correctly in the cytoplasm. For example, a protein molecule destined to be part of a mitochondrion will diffuse from the site of biosynthesis through the cytoplasm to a mitochondrion, where it will bind to a receptor that guides its incorporation into the mitochondrion. On the other hand, the mitochondrion itself is too large to diffuse through the network of protein fibers in the cytoplasmic matrix, and so it must be pulled through the matrix by a motor protein that moves along microtubules to the correct place in the cell.

Some cellular components, such as ribosomes and the filaments in the cytoplasmic matrix, assemble afresh from their constituent molecules, but all organelles composed of membranes form only by the growth and division of preexisting organelles. The reason that these organelles require precursors is that biological membranes composed of phospholipids can grow only by expansion of preexisting bilayers. As a consequence, organelles such as mitochondria and the endoplasmic reticulum are inherited maternally starting from the egg and expanding into every cell in the body by continued growth and partition into both daughter cells at every cell division. Other membrane-bound organelles, such as lysosomes, form by budding off the Golgi apparatus.

Many of the individual self-assembly reactions required for normal cell growth can be reproduced in the test tube, but the cell is the only place known where the entire range of reactions, including biosynthesis, targeting, and assembly, can go to completion. Thus, cells are such a special environment that the chain of life has required an unbroken lineage of cells stretching from all living cells back through their ancestors to the earliest forms of life. This requirement for cellular continuity explains why extinction is an irreversible process. [T.Po.]

Cell permeability The permitting or activating of the passage of substances into, out of, or through cells, or from one cell to another. These materials traverse either the cell surface that demarcates the living cytoplasm from the extracellular space or the boundaries between adjacent cells. In many cases the materials also traverse the cell wall. *See* CELL WALLS (PLANT).

The cell can control many properties of its membranes, including those related to permeability. Control can be exerted in the following ways: (1) by varying the number and variety of membranes; (2) by varying the specific nature of the lipid components in the membrane; (3) by varying the glycocalyx proteins or lipid-associated sugar molecules on the outside of the cell, or the membrane-associated proteins on the inside; (4) by causing large areas of membrane to flow from one place to another, or to fold, indent, evert, or pinch off, carrying with these movements substances bound to one or the other surface of the membrane, or embedded in it; (5) by selectively moving integral membrane proteins in the plane of the membrane, allowing these proteins to carry with them substances, particles, molecules, or other materials bound to them; (6) by varying the properties of a single integral membrane protein or of a closely associated group of them so as to allow or prevent the passage across the membrane of substances such as ions or proteins of a specific character. *See* CELL MEMBRANES. [H.S.Be.]

Cell plastids Specialized structures found in the cytoplasm of plant cells, diverse in distribution, size, shape, composition, structure, function, and mode of development. A number of different types are recognized. Chloroplasts occur in the green parts of plants and are responsible for the green coloration, for they contain the chlorophyll pigments. These pigments, along with certain others, absorb the light energy that drives the processes of photosynthesis, by which sugars, starch, and other organic materials are synthesized. Amyloplasts, nearly or entirely colorless, are packed with starch grains and occur in cells of storage tissue. Proteoplasts are less common and contain crystalline, fibrillar, or amorphous masses of protein, sometimes along with starch grains. In chromoplasts the green pigment is masked or replaced by others, notably carotenoids, as in the cells of carrot roots and many flowers and fruits. *See* CAROTENOID; CHLOROPHYLL.

All types of plastids have one structural feature in common, a double envelope consisting of two concentric sheets of membrane. The outer of these is in contact with the cytoplasmic ground substance; the inner with the plastid matrix, or stroma. They are separated by a narrow space of about 10 nanometers.

Another system of membranes generally occupies the main body of the plastid. This internal membrane system is especially well developed in chloroplasts, where the unit of construction is known as a thylakoid. In its simplest form this is a sac such as would be obtained if a balloon-shaped, membrane-limited sphere were to be flattened until the internal space was not much thicker than the membrane itself. It is usual, however, for thylakoids to be lobed, branched, or fenestrated.

The surface area of thylakoids is very large in relation to the volume of the chloroplast. This is functionally significant, for chlorophyll molecules and other components of the light-reaction systems of photosynthesis are associated with these membranes. A chloroplast, however, is much more than a device for carrying out photosynthesis. It can use light energy for uptake and exchange of ions and to drive conformational changes. The stroma contains the elements of a protein-synthesizing system—as much deoxyribonucleic acid (DNA) as a small bacterium, various types of ribonucleic acid (RNA), distinctive ribosomes, and polyribosomes. There is evidence to indicate that much of the protein synthesis of a leaf takes place within the chloroplasts. *See* PHOTOSYNTHESIS; PROTEIN; RIBOSOMES.

One of the most challenging problems in cell biology concerns the autonomy of organelles, such as the plastids. Chloroplasts, for instance, have their own DNA, DNA-polymerase, and RNA-polymerase; can make proteins; and, significantly, can mutate. All this suggests a measure of independence. It is known, however, that some nuclear genes can influence the production of molecules that are normally found only in chloroplasts, so their autonomy cannot be complete. It remains to be seen whether they control and regulate their own morphogenetic processes. [B.E.S.G.]

Cell polarity (biology) The highly organized condition in most cells that is characterized by a distinct apical-basal axis with an asymmetric distribution of cytoplasmic organelles. This phenomenon of polarization is critical for living organisms to function. For example, cells in secretory organs such as the gall bladder generally secrete only at one end where secretory vesicles are localized. Another example would be a cell in the intestinal wall that must collect nutrients on the side near the lumen and transport them through the cell to the opposite end, where they can be delivered to the blood supply for transport to the rest of the body. Clearly, this cell must exhibit a polarized distribution of membrane proteins so that those necessary for sugar uptake are concentrated in the membrane facing the lumen and those needed to move the sugar out of the cell are located at the opposite side.

Most organisms begin life as a rather symmetrical, spherical, single cell called an egg. During early development the fertilized egg divides many times and forms an embryo, which exhibits much more intricate patterns (such as the polarized intestine) than were initially expressed by the egg. Determining how the embryo controls the development of such patterns has been an area of active research, and there is evidence that the plasma (outer) membrane can influence the development of cell polarity by driving ionic currents through the cell which, in turn, can influence the polarization process by generating ion concentration gradients within the cell or voltage gradients between cells. *See* BIOPOTENTIALS AND IONIC CURRENTS; CELL (BIOLOGY); DEVELOPMENTAL BIOLOGY. [R.Nu.]

Cell senescence and death The limited capacity of all normal human and other animal cells to reproduce and function. The gradual decline in normal physiological function of the cells is referred to as aging or senescence. The aging process ends with the death of individual cells and then, generally, the whole animal. Aging occurs in all animals, except those that do not reach a fixed body size such as some tortoises and sharks, sturgeon, and several other kinds of fishes. These animals die as the result of accidents or disease, but losses in normal physiological function do not seem to occur. Examples of cells that do not age are those composing the germ plasm (sex cells) and many kinds of cancer cells. These cells are presumed to be immortal.

Although cultured normal human and other animal cells are mortal, they can be converted to a state of immortality. The conversion can be produced in human cells by the SV40 virus and in other animal cells by other viruses, chemicals, and irradiation. This conversion from mortality to immortality is called transformation, and is characterized by the acquisition of many profoundly abnormal cell properties, including changes in chromosome number and form, and the ability of the cells to grow unattached to a solid surface. These changes, and many more, are characteristic of most cancer cells. *See* CANCER (MEDICINE); ONCOLOGY; SENESCENCE; TUMOR VIRUSES. [L.H.]

Cell-surface ionization All living cells suspended in aqueous salt solutions at neutral pH values possess a negative charge. The charge is due to the dissociation of ionogenic, or charged, groups (carboxyl, amino, and others) in the cell surface. The charge carried by the cells can thus be measured electrophoretically to give information regarding the nature of the components in their surfaces. For example, studies have been used to measure the frequency distribution of bacterial variants in a mixed population and can assist in the selection of material for vaccine production. The occurrence and nature of tumor cells and the selection of yeasts for brewing have been also been studied electrophoretically. *See* BIOLOGICALS; ELECTROPHORESIS.

Factors which may affect the charge of cell surfaces are of three types: (1) biological factors—in bacterial and yeast cells, such things as sex, strain, age, growth conditions, presence of capsules or fimbriae, antibiotic resistance, virulence, and toxicity; in mammalian cells, such things as species, type of tissue, normal or pathological conditions, and the like; (2) nature of suspension medium, that is, ionic strength, pH, presence of dyes, drugs, or surface-active agents in the medium; and (3) chemical or enzymatic treatment of the surface. It is often possible to correlate alteration of charge with changes in the nature or number of ionogenic groups in the surface and hence with a particular biological property. [A.M.J.]

Cell walls (plant) The cell wall is the layer of material secreted by the plant cell outside its plasma membrane. All plants have cell walls that are generally very similar in chemical composition, organization, and development. The walls of the Chlorophyta (green algae) show characteristics virtually identical to those of flowering plants, an indication that flowering plants are derived evolutionarily from this division of algae. The wall serves as the first point of entry of materials into cells, functions in the movement of water throughout the plant, and is one of the major mechanical strengthening factors. In addition, the wall must be sufficiently flexible and plastic to withstand mechanical stresses while still permitting the growth of the cell. *See* CELL MEMBRANES.

The plant primary wall is initiated during the process of cell division. After chromosomes line up along the metaphase plate and begin to be pulled apart toward the poles of the cells by the spindle fibers (the anaphase portion of mitosis), a cell plate or phragmoplast can be observed at the equator of the dividing cell. Vesicles line up on both sides of the equator to form the proteinaceous cell plate. Elements of the endoplasmic reticulum fuse with the cell plate, marking the location of plasmodesmatal pores and pits which will eventually provide the intercellular connections between adjacent cells. The cell plate forms the matrix within which the middle lamella and primary walls are formed. The middle lamella is composed of pectic substances which are polymers of pectins plus smaller amounts of other sugars. The middle lamella provides some of the observed plasticity and extensibility of cell walls during cell growth, and it has also been suggested that pectins are capable of hydrogen-bonding to the cellulose that forms the plant cell primary wall. During the early stages in cell wall formation, the cellulose wall is isotropic without any ordered orientation, but as cell walls continue to develop in area and in thickness and the cell grows to mature size, the walls become anisotropic, or highly ordered. *See* CYTOKINESIS.

Cellulose, like starch, is basically a polymer of glucose, a six-carbon monosaccharide. Each chain of cellulose may be as long as 8000 to 12,000 glucose monomers, or up to 4 micrometers long. These are arranged linearly, with no side branching. Cellulose chains are aggregated into bundles of approximately 40 chains each, the cellulose micelles, which are held together by hydrogen bonds. The micelle is a very regular, quasicrystalline structure.

The micelles are embedded in a matrix of other polysaccharides, the hemicelluloses. Hemicellulose serves to bind the micelle into a fairly rigid unit which retains a good deal of flexibility. Micelles, in bundles of variable number, are bound together into the cellulose microfibril, a unit sufficiently large to be seen under the electron microscope; these, in turn, are bound together into macrofibrils which are observable under the light microscope. *See* CELLULOSE; HEMICELLULOSE.

During the formation of the primary wall, at locations predetermined by attachments of endoplasmic reticulum to the middle lamella, cellulose microfibrillar deposition is minimal, leaving a thin place in the primary wall which forms the plasmodesmatal connections. Running through these pores are fine strands of protoplasm, the plasmodesmata proper, which contain a tube of endoplasmic reticulum–like material. The plasmodesmata provide a cytoplasmic connection between adjacent cells. Such connections are found among all the living cells of a plant, a fact which has led to the concept that all plant cells are so interconnected that the entire plant is a cytosymplast or single unit.

Although there are differences in nomenclature and terminology, secondary walls of plant cells are defined as those laid down after the primary wall has stopped increasing in surface area, essentially at that time when the plant cell has reached mature size. This is particularly true of those cells that, at maturity, have irreversibly differentiated into specialized cells, some of which are destined to lose their cytoplasm and become functional only as dead cells, including xylem vessels and tracheids, and sclereids. The secondary wall of most plants seems to have the same chemical structure and physical orientation of fibrils and hemicelluloses as do primary walls. While there may be little orientation of fibrils in young primary walls, the secondary walls are composed of fibrils that are highly ordered. In most secondary walls, and particularly those of the xylem, the fibrillar structure of the primary as well as the secondary walls may become impregnated with more substances, the most prominent of these being lignin. The chemical nature and biological role of lignin is of considerable interest because of the use of wood in the lumber and pulpwood-paper industries. The primary roles of the lignins include their ability to render walls mechanically strong, rigid, and—at least to some extent—water-impermeable. It has been suggested that lignins may also serve to make wood less subject to microbially caused decay. *See* LIGNIN; PLANT CELL; PLANT GROWTH; WOOD ANATOMY. [R.M.K.]

Cellophane A clear, flexible film made from cellulose. It first appeared commercially in the United States in 1924, and it revolutionized the packaging industry, which had been using opaque waxed paper or glassine as wrapping materials. Cellophane was also the first transparent mending tape. By 1960, petrochemical-based polymers (polyolefins) such as polyethylene had surpassed cellophane for use as a packaging film. Nevertheless, cellophane is still often used for packaging because it is stiffer and more easily imprinted than are polyolefin films. *See* CELLULOSE.

Cellophane is manufactured in a process that is very similar to that for rayon. Special wood pulp, known as dissolving pulp, which is white like cotton and contains 92–98% cellulose, is treated with strong alkali in a process known as mercerization. The mercerized pulp is aged for several days. *See* TEXTILE CHEMISTRY.

The aged, shredded pulp is then treated with carbon disulfide, which reacts with the cellulose and dissolves it to form a viscous, orange solution of cellulose xanthate known as viscose. Rayon fibers are formed by forcing the viscose through a small hole into an acid bath that regenerates the original cellulose while carbon disulfide is given off. To make cellophane, the viscose passes through a long slot into a bath of ammonium sulfate which causes it to coagulate. The coagulated viscose is then put into an acidic bath that returns the cellulose to its original, insoluble form. The cellophane is now clear. *See* MANUFACTURED FIBER.

The cellophane is then treated in a glycerol bath and dried. The glycerol acts like a plasticizer, making the dry cellophane less brittle. The cellophane may be coated with nitrocellulose or wax to make it impermeable to water vapor; it is coated with polyethylene or other materials to make it heat sealable for automated wrapping machines. Cellophane is typically 0.03 mm (0.001 in.) thick, is available in widths to 132 cm (52 in.), and can be made to be heat sealable from 82 to 177°C (180 to 350°F). *See* POLYMER. [C.J.Bi.]

Cellular adhesion The process whereby cells interact and attach to other cells or to inanimate surfaces, mediated by interactions between the molecules on the surface of the cell. This process has been studied extensively in embryonic cells of higher organisms, where species and tissue specificity of adhesion has been shown. However, adhesion is a common feature in the life of most organisms.

Prokaryotic microorganisms do not frequently exhibit cell-to-cell interactions, but adhere to surfaces forming biofilms. In these interactions with a surface, some microorganisms cause corrosion of metal by adhering and producing corrosive acid by-products as a result of their metabolism. Adhesion of microorganisms to the cells of higher plants and animals is often a prerequisite for causing disease. Eukaryotic microorganisms often exhibit specific cell-to-cell interactions, allowing complex colonial forms and multicellular organisms to be constructed from individual or free-living cells. Adhesion between different plant cells is apparent in several cases, as in the interaction between a pollen grain and the stigma during fertilization.

Interactions between two cell surfaces may be quite specific, involving certain types of cell-surface protein molecules, or general, involving production of a sticky extracellular matrix that surrounds the cell, as frequently occurs in bacterial adhesion. Cellular adhesion is important in cellular recognition, in the generation of form or pattern, and possibly in regulation of cellular differentiation. *See* CELL (BIOLOGY); CELL DIFFERENTIATION.

All adhesion is mediated by the cell surface, either directly involving integral components of the plasma membrane, or indirectly through material excreted and deposited on the outside of the cell. Most theories of cellular adhesion suggest that cell-surface glycoproteins serve as ligands involved in attaching cell surfaces together. When a specific cell interacts with an identical cell, the attachment is said to be homotypic. Heterotypic adhesion involves interactions between different cell types. If the ligand-specific attachment involves interaction between identical cell-surface ligands, it is homophilic, and between two different ligands, heterophilic. The interaction between a pollen grain and the stigma cells described previously is an example of a heterotypic, heterophilic interaction.

Many studies of species and tissue specificity have been done with embryonic chick and mouse systems. In general, it would seem that homotypic adhesion is stronger that heterotypic adhesion. Also, tissue and species specific adhesion can be shown, but tissue specificity seems to be more frequent. For example, when dissociated embryonic neural retina of mouse and chick are mixed and allowed to aggregate, there is very little sorting, and mosaic tissue is formed. This is not true in all tissues, as heart and liver tissue show much greater species specificity than neural retina.

Throughout development, it is necessary for specific adhesion among cells to establish and maintain form. It is also important during development that cells change position, as occurs during gastrulation, or migrate, as with neural crest cells that move from the neural tube to various positions, forming ganglia. In these cases, it would seem to be necessary for certain cells to dissociate or alter their adhesive properties in response to the proper developmental cues. Throughout development, there are a series of primary and secondary inductions that affect cellular differentiation and pattern formation. These inductions depend on interactions between cell types having different histories, either due to being in different embryonic layers or due to interaction between cells derived from the same layer but previously differentiated. These changes in form are related to specific changes in cell-adhesion molecules. [M.Ha.]

Cellular immunology The field concerning the interactions among cells and molecules of the immune system, and how such interactions contribute to the recognition and elimination of pathogens. Humans (and vertebrates in general) possess a range of nonspecific mechanical and biochemical defenses against routinely encountered bacteria, parasites, viruses, and fungi. The skin, for example, is an effective physical barrier to infection. Basic chemical defenses are also present in blood, saliva, and tears, and on mucous membranes. True protection stems from the host's ability to mount responses targeted to specific organisms, and to retain a form of "memory" that results in a rapid, efficient response to a given organism upon a repeat encounter. This more formal sense of immunity, termed adaptive immunity, depends upon the coordinated activities of cells and molecules of the immune system.

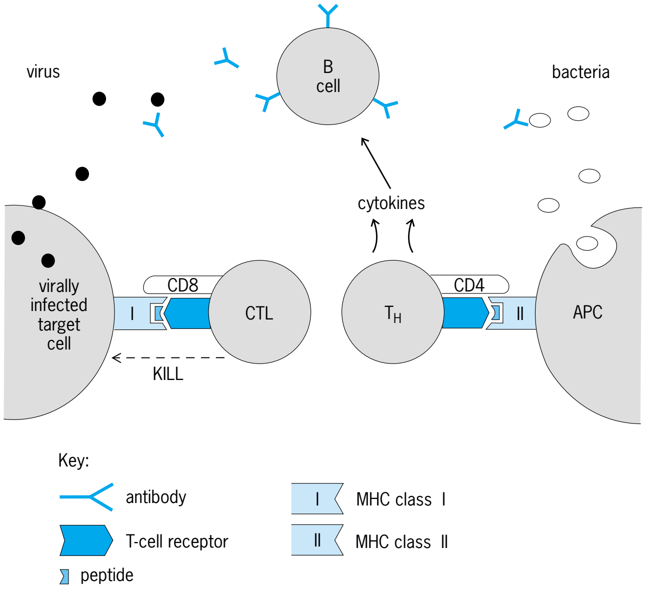
Cells involved. Several types of cells play a role in protecting the body from infection, and they are found primarily in the blood and lymph. Specific immune responses mainly involve the activities of T-lymphocytes and B-lymphocytes, two types of white blood cells. A response is initiated when a pathogen triggers the activity of one or both of the two major types of T-cells: CD4+ cells, also known as helper T-cells (T_H); and CD8+ cells, also known as cytotoxic T-lymphocytes (CTL) [see illustration].

When CD4+ T-cells are triggered, they release factors called cytokines, which in turn stimulate B-lymphocytes to make and secrete antibodies. *See* Antibody; Cytokine.

When CD8+ T-cells are triggered, they release factors that kill a cell harboring an infectious agent, and they also release cytokines. Virus-infected cells commonly are the targets of cytotoxic T-lymphocytes, since viruses need to get inside a cell in order to reproduce.

Antigen recognition. The immune system must detect a pathogen before a response can be made. This phase of the response is shown in the interaction between a T-cell and an antigen-presenting cell (APC) [see illustration]. An antigen is a molecule, or portion of a molecule, that is recognized by a T-cell receptor (TCR) or antibody molecule. The cell surface molecules involved in antigen recognition by T-cells are the T-cell receptor and class I or class II molecules of the major histocompatibility complex (MHC). Each T-cell expresses a unique T-cell receptor that will interact specifically with a limited set of antigens. The antigens recognized by T-cell receptors are short peptides bound to MHC molecules. *See* Histocompatibility.

Co-stimulation. Antigen recognition, as mediated by the T-cell receptor–MHC–peptide interaction, is necessary, but generally it is not sufficient for the initiation of an immune response. Several other molecular interactions occur between molecules on the T-cell surface and those on the antigen-presenting cells. The co-stimulation provided by these additional interactions drives the production of cytokines by T-cells and induces their proliferation.



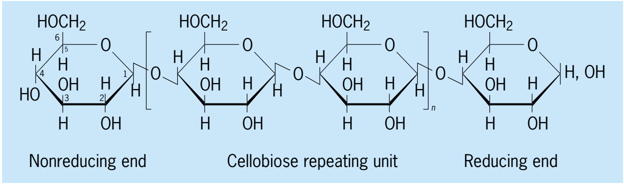
Key processes in a specific immune response.

Memory. Once an immune response has been initiated, T-cells and B-cells proliferate and become mature responder cells. These cells do not have the same requirement for co-stimulation once a response is under way. As pathogen elimination nears completion, many of the T- and B-cells involved in the response die. However, a subset of cells remain as memory cells, which can be quickly called into action if the same pathogen is encountered on a future occasion. *See* Acquired immunological tolerance; Cellular immunology; Immunity; Immunology. [D.J.L.]

Cellulose A linear polymer of (1→4)-linked β-D-glucopyranosyl units, and the most abundant of all naturally occurring substances. Cellulose constitutes approximately a third of all vegetable matter and thus it exists in far greater quantity than any other polysaccharide. It occurs as a principal structural component of the cell walls of mosses and seaweeds (25–30%), annual plants (25–35%), and trees (40–50%); cotton fiber contains 98% cellulose. Cellulose also is produced by some microorganisms, in a few cases reaching amounts of 20–30%. *See* Cell walls (plant).

Cellulose for chemical modification, particularly for derivatization, is often obtained from cotton linters by boiling them with 1% sodium hydroxide solution. High-quality cellulose may be obtained from bast fibers such as flax (80–90% cellulose), hemp (65–75%), jute (60–70%), and ramie (85%). Cellulose fibers used for paper, for cardboard, or for conversion to film and synthetic fiber are obtained from wood pulp. *See* Paper.

While cellulose is a uniform, linear polymer of a β-D-glucopyranosyl units linked (1→4), the β-D-glucosidic bond causes alternate units to be positioned as shown in the structure here, so that the molecule is essentially a polymer of the



disaccharide, cellobiose, actually the cellobiosyl unit. The molecule has a nonreducing end and an aldehyde end, although at times the latter may be oxidized to a carboxyl group. Chain length varies with previous treatment, but native cellulose molecules have 7000 to 15,000 units, which are termed degrees of polymerization. *See* POLYMER; POLYSACCHARIDE.

[D.G.B.; R.L.Wh.]

Cement A material, usually finely divided, that when mixed with water forms a paste, and when molded sets into a solid mass. The term cement is sometimes used to refer to organic compounds used for adhering or for fastening materials, but these are more correctly known as adhesives. *See* ADHESIVE; ADHESIVE BONDING.

In the fields of architecture, engineering, and construction, the term portland cement is applied to most of the hydraulic cements used for concrete, mortars, and grouts. Portland cement sets and hardens by reacting chemically with water. In concrete, it combines with water and aggregates (sand and gravel, crushed stone, or other granular material) to form a stonelike mass. In grouts and mortars, cement is mixed with water and fine aggregates (sand) or fine granular materials. *See* CLAY, COMMERCIAL; CONCRETE; MORTAR.

Adjustments in the physical and chemical compositions allow for tailoring portland cements and other hydraulic cements to special applications. Blended hydraulic cements are produced with portland cements and materials that by themselves might not possess binding characteristics. Special cements are produced for mortars and architectural or engineering applications: white portland cement, masonry cement, and oil-well cement, expansive cement, and plastic cement. In addition to acting as the key ingredient in concrete, mortars, and grouts, portland cements are specified for soil-cement and roller-compacted concrete, used in pavements and in dams, and other water resource structures, and as reagents for stabilization and solidification of organic and inorganic wastes. [D.Ma.]

Cenozoic Cenozoic (Cainozoic) is the youngest and the shortest of the three Phanerozoic geological eras. It represents the geological time (and rocks deposited during that time) extending from the end of the Mesozoic Era to the present day.

Traditional classifications subdivide the Cenozoic Era into two periods (Tertiary and Quaternary) and seven epochs (from oldest to youngest): Paleocene, Eocene, Oligocene, Miocene, Pliocene, Pleistocene, and Holocene. The older five epochs, which together constitute the Tertiary Period, span the time interval from 65 to 1.8 million years before present. The Tertiary is often separated into two subperiods, the Paleogene (Paleocene through Oligocene epochs, also collectively called the Nummulitic in older European literature) and the Neogene (Miocene and Pliocene epochs). These subperiods were introduced by M. Hornes in 1853. The Quaternary Period, which encompasses only the last 1.8 million years, includes the two youngest epochs (Pleistocene and Holocene). Holocene is also often referred to as the Recent, from the old Lyellian classification. Recent stratigraphic opinions are leaning toward abandoning the use of Tertiary and Quaternary (which are seen as the unnecessary holdovers from obsolete classifications) and in favor of retaining Paleogene and Neogene as the prime subdivisions of Cenozoic. *See* EOCENE; HOLOCENE; MIOCENE; OLIGOCENE; PALEOCENE; PLEISTOCENE; PLIOCENE.

Many of the tectonic events (mountain-building episodes or orogenies, changes in the rates of sea-floor spreading, or tectonic plate convergences) that began in the Mesozoic continued into the Cenozoic. The Laramide orogeny that uplifted the Rocky Mountains in North America, which began as early as Late Jurassic, continued into the Cretaceous and early Cenozoic time. In its post-Cretaceous phase the orogeny comprised a series of diastrophic movements that deformed the crust until some 50 million years ago, when it ended abruptly. The Alpine orogeny, which created much of the Alps, also began in the Mesozoic, but it was most intense in the Cenozoic when European and African plates converged at an increased pace. *See* CRETACEOUS; JURASSIC; MESOZOIC; OROGENY.

Another major long-term affect of the tectonic uplift of Tibetan Plateau, which is dated to have been significant by 40 million years ago, may have been the initiation of the general global cooling trend that followed this event. The uplifted plateau may have initiated a stronger deflection of the atmospheric jet stream, strengthening of the summer monsoon, and increased rainfall and weathering in the Himalayas. Increased weathering and dissolution of carbonate rock results in greater carbon dioxide drawdown from the atmosphere. The decreased partial pressure of carbon dioxide levels may have ultimately led to the Earth entering into a renewed glacial phase.

The modern circulation and vertical structure of the oceans and the predominantly glacial mode that the Earth is in at present was initiated in the mid-Cenozoic time. The early Cenozoic was a period of transition between the predominantly thermospheric circulation of the Mesozoic and the thermohaline circulation that developed in the mid-Cenozoic. By the mid-Cenozoic the higher latitudes had begun to cool down, especially in the Southern Hemisphere due to the geographic isolation of Antarctica, leading to steeper latitudinal thermal gradients and accentuation of seasonality. The refrigeration of the polar regions gave rise to the cold high-latitude water that sank to form cold bottom water. The development of the psychrosphere (cold deeper layer of the ocean) and the onset of thermohaline circulation are considered to be the most significant events of Cenozoic ocean history, which ushered the Earth into its modern glacial-interglacial cyclic mode.

The Quaternary climatic history is one of repeated alternations between glacial and interglacial periods. At least five major glacial cycles have been identified in the Quaternary of northwestern Europe. The most recent glacial event occurred between 30,000 and 18,000 years ago when much of North America and northern Europe was covered with extensive ice sheets. The late Pliocene and Pleistocene glacial cyclicity led to repeated falls in global sea level as a result of sequestration of water as ice sheets in higher latitudes during the glacial intervals. For example, the sea level is estimated to have risen some 110 m (360 ft) since the end of the last glacial maximum. As a by-product of these repeated drops in sea level and movement of the shorelines toward the basins, large deltas developed at the mouths of the world's major drainage systems during the Quaternary. These bodies of sand and silt constitute ideal reservoirs for hydrocarbon accumulation. *See* DELTA; PALEOCLIMATOLOGY.

At the end of the Cretaceous a major extinction event had decimated marine biota and only a few species survived into the Cenozoic. The recovery, however, was relatively rapid. During the Paleocene through middle Eocene interval, the overall global sea-level rise enlarged the ecospace for marine organisms, and an associated climatic optimum led to increased speciation through the Paleocene, culminating in high marine diversities during the early and middle Eocene. Limestone-building coral reefs were also widespread in the tropical-temperate climatic belt of the early Cenozoic, and the tropical Tethyan margins were typified by expansive distribution of the larger foraminifera known as *Nummulites* (giving the Paleogene its informal name of the Nummulitic period). *See* NUMMULITES.

The late Eocene saw a rapid decline in diversities of marine phyto- and zooplankton due to a global withdrawal of the seas from the continental margins and the ensuing deterioration in climate. Marine diversities reached a new low in the mid-Oligocene, when the sea level was at its lowest, having gone through a major withdrawal of seas from the continental margins. The climates associated with low seas were extreme and much less conducive to biotic diversification. The late Oligocene and Neogene as a whole constitute an interval characterized by increasing partitioning of ecological nichesinto tropical, temperate, and higher-latitude climatic belts, and greater differentiation of marine fauna and flora.

Mammals evolved and spread rapidly to become dominant in the Cenozoic. The evolution of grasses in the early Eocene and the wide distribution of grasslands thereafter may have been catalytic in the diversification of browsing mammals. Marsupials and insectivores as well as rodents (which first appeared in the Eocene) diversified rapidly, as did primates, carnivores, and ungulates. The ancestral horse first appeared in the early Eocene in North America, where its lineage evolved into the modern genus *Equus*, only to disappear from the continent in the late Pleistocene. A complete evolution of the horse can be followed in North America during the Cenozoic. Increase in overall size, reduction in the number of toes, and increasing complexity of grinding surface of the molars over time are some of the obvious trends. Hominoid evolution began during the Miocene in Africa. Modern hominids are known to have branched off from the hominoids some 5 million years ago. Over the next 4.5 million years the hominids went through several evolutionary stages to finally evolve into archaic *Homo sapiens* about 1 million years ago. Truly modern *Homosapiens* do not enter the scene until around 100 thousand years ago. *See* DINOSAUR; FOSSIL HUMANS; MAMMALIA; ORGANIC EVOLUTION. [B.U.H.]

Centaurus The Centaur, in astronomy; one of the most magnificent of the southern constellations. Two first-magnitude navigational stars, Alpha and Beta Centauri, mark the right and left front feet, respectively, of the centaur. The former is Rigil Kentaurus, or simply Rigil Kent, and the latter Hadar. Rigil Kent is the third brightest star in the whole sky, fainter than only Sirius and Canopus. The line joining Rigil Kent and Hadar points to the constellation Crux (Southern Cross). Thus they are also called the Southern Pointers, in contradistinction to the northern pointers of the Big Dipper. *See* CONSTELLATION. [C.-S.Y.]

Center of gravity A fixed point in a material body through which the resultant force of gravitational attraction acts. The resultant of all forces or attractions produced by the Earth's gravity on a body constitutes its weight. This weight is considered to be concentrated at the center of gravity in mechanical studies of a rigid body. The location of the center of gravity for a body remains fixed in relation to the body regardless of the orientation of the body. If supported at its center of gravity, a body would remain balanced in its initial position. *See* GRAVITY; RESULTANT OF FORCES. [N.S.F.]

Center of mass That point of a material body or system of bodies which moves as though the system's total mass existed at the point and all external forces were applied at the point. The Earth-Moon system moves in the Sun's gravitational field as though both masses were located at a center of mass some 3000 mi (4700 km) from the Earth's geometric center. The function of the center-of-mass concept is to permit analysis of the motion of an entire system as distinguished from that of its individual parts.

Consider a system of mass M composed of n bodies with masses $m_1, m_2, \ldots, m_n$, and radius vectors $r_1, r_2, \ldots, r_n$ measured from some common reference point. Define a point with radius vector R, such that Eq. (1) holds. Then, it is possible to derive Eq. (2), an expression of Newton's second law, which states that

$$MR = \sum_j m_j r_j \tag{1}$$

$$\frac{d^2R}{dt^2} = \frac{F}{M} \tag{2}$$

the center of mass at R moves as though it possessed the total mass of the system and were acted upon by the total external force.

A simplification of the description of collisions can be obtained by using a coordinate system which moves with the velocity of the center of mass before collision. *See* COLLISION (PHYSICS); RIGID-BODY DYNAMICS. [J.P.H.]

Center of pressure A point on a plane surface through which the resultant force due to pressure passes. Such a surface can be supported by a single mounting fixture at its center of pressure if no other forces act. For example, a water gate in a dam can be supported by a single shaft at its center of pressure. *See* RESULTANT OF FORCES. [N.S.F.]

Central force A force whose line of action is always directed toward a fixed point. The central force may attract or repel. The point toward or from which the force acts is called the center of force. If the central force attracts a material particle, the path of the particle is a curve concave toward the center of force; if the central force repels the particle, its orbit is convex to the center of force. Undisturbed orbital motion under the influence of a central force satisfies Kepler's law of areas. [R.L.Du.]

Central heating and cooling The use of a single heating or cooling plant to serve a group of buildings, facilities, or even a complete community through a system of distribution pipework that feeds each structure or facility. Central heating plants are basically of two types: steam or hot-water, The latter type uses high-temperature hot water under pressure and has become the more usual because of its considerable advantages. Steam systems are only used today where there is a specific requirement for high-pressure steam. Central cooling plants utilize a central refrigeration plant with a chilled water distribution system serving the air-conditioning systems in each building or facility.

Advantages of a central heating or cooling plant over individual ones for each building or facility in a group include reduced labor cost, lower energy cost, less space requirement, and simpler maintenance. Central cooling plants, using conventional, electrically driven refrigeration compressors, have the advantage of utilizing bulk electric supply, at voltages as high as 13.5 kV, at wholesale rates. Additionally, their flexible load factor, resulting from load divergency in the various buildings served, results in major operating economies.

The disadvantages of a central heating plant concern mainly the maintenance of the distribution system where steam is used. Corrosion of the condensate water return lines shortens their life, and the steam drainage traps need particular attention. These disadvantages do not occur with high-temperature hot-water installations. *See* AIR CONDITIONING; BOILER; COMFORT HEATING; REFRIGERATION; STEAM HEATING; WARM-AIR HEATING SYSTEM. [J.K.M.P.]

Central nervous system That portion of the nervous system composed of the brain and spinal cord. The brain is enclosed in the skull, and the spinal cord within the spinal canal of the vertebral column. The brain and spinal cord are intimately covered by membranes called meninges and bathed in an extracellular fluid called cerebrospinal fluid. Approximately 90% of the cells of the central nervous system are glial cells which support, both physically and metabolically, the other cells, which are the nerve cells or neurons. *See* MENINGES; NEURON.

Functionally similar groups of neurons are clustered together in so-called nuclei of the central nervous system. When groups of neurons are organized in layers (called laminae) on the outer surface of the brain, the group is called a cortex, such as the cerebral cortex and cerebellar cortex. The long processes (axons) of neurons course in the central nervous system in functional groups called tracts. Since many of the axons have a layer of shiny fat (myelin) surrounding them, they appear white and are called the white matter of the central nervous system. The nuclei and cortex of the central nervous system have little myelin in them, appear gray, and are called the gray matter of the central nervous system. *See* BRAIN; NERVOUS SYSTEM (VERTEBRATE); SPINAL CORD. [D.B.W.]

Centrifugal force A fictitious or pseudo outward force on a particle rotating about an axis which by Newton's third law is equal and opposite to the centripetal force. Like all such action-reaction pairs of forces, they are equal and opposite but do not act on the same body and so do not cancel each other. Consider a mass M tied by a string of length R to a pin at the center of a smooth horizontal table and whirling around the pin with an angular velocity of ω radians per second. The mass rotates in a circular path because of the centripetal force $F_C = M\omega^2R$ which is exerted on the mass by the string. The reaction force exerted by the rotating mass M, the so-called centrifugal force, is $M\omega^2R$ in a direction away from the center of rotation. *See* CENTRIPETAL FORCE.

From another point of view, consider an experimenter in a windowless, circular laboratory that is rotating smoothly about a centrally located vetical axis. No object remains at rest on a smooth surface; all such objects move outward toward the wall of the laboratory as though an outward, centrifugal force were acting. To the experimenter partaking in the rotation, in a rotating frame of reference, the centrifugal force is real. An outside observer would realize that the inward force which the experimenter in the rotating laboratory must exert to keep the object at rest does not keep it at rest, but furnishes the centripetal force required to keep the object moving in a circular path. The concept of an outward, centrifugal force explains the action of a centrifuge. *See* CENTRIFUGATION. [C.E.H./R.J.S.]

Centrifugal pump A machine for moving fluid by accelerating it radially outward. More fluid is moved by centrifugal pumps than by all other types combined. Centrifugal pumps consist basically of one or more rotating impellers in a stationary casing which guides the fluid to and from the impeller or from one impeller to the next in the case of multistage pumps. Impellers may be single suction or double suction. Additional essential parts of all centrifugal pumps are (1) wearing surfaces or rings, which make a close-clearance running joint between the impeller and the casing to minimize the backflow of fluid from the discharge to the suction; (2) the shaft, which supports and drives the impeller; and (3) the stuffing box or seal, which prevents leakage between shaft and casing.

The rotating impeller imparts pressure and kinetic energy to the fluid pumped. A collection chamber in the casing converts much of the kinetic energy into head or pressure energy before the fluid leaves the pump. A free passage exists at all times through the impeller between the discharge and inlet side of the pump. Rotation of the impeller is required to prevent back-flow or draining of fluid from the pump. Because of this, only special forms of centrifugal pumps are self-priming. Most types must be filled with liquid, or primed, before they are started.

Every centrifugal pump has its characteristic curve, which is the relation between capacity or rate of flow and pressure or head against which it will pump. At zero pressure-difference, maximum capacity is obtained, but without useful work. As resistance to flow external to the pump increases, capacity decreases until, at a high pressure, flow ceases entirely. This is called shut-off head and again no useful work is done. Between these extremes, capacity and head vary in a fixed relationship at constant rpm. When the required head exceeds that practical for a single-stage pump, several stages are employed. Multistage pumps range from two-stage pumps to pumps built with as many as 20 or 30 stages for high lifts from relatively small-diameter wells. *See* PUMP; PUMPING MACHINERY. [E.F.W.]

Centrifugation A mechanical method of separating immiscible liquids or solids from liquids by the application of centrifugal force. This force can be very great, and separations which proceed slowly by gravity can be speeded up enormously in centrifugal equipment. *See* CENTRIFUGAL FORCE.

Centrifugal force is generated inside stationary equipment by introducing a high-velocity fluid stream tangentially into a cylindrical-conical chamber, forming a vortex of considerable intensity. Cyclone separators based on this principle remove liquid drops or solid particles from gases, down to 1 or 2 μm in diameter. Smaller units, called liquid cyclones, separate solid particles from liquids. The high velocity required at the inlet of a liquid cyclone is obtained with standard pumps. Much higher centrifugal forces than in stationary equipment are generated in rotating equipment (mechanically driven bowls or baskets, usually of metal, turning inside a stationary casing). Rotating a cylinder at high speed induces a considerable tensile stress in the cylinder wall. This limits the centrifugal force which can be generated in a unit of a given size and material of construction. Very high forces, therefore, can be developed only in very small centrifuges.

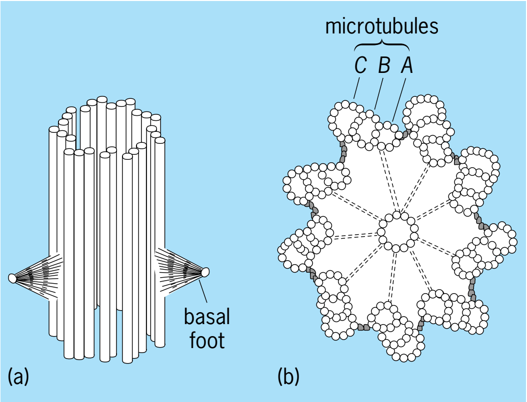
There are two major types of centrifuges: sedimenters and filters. A sedimenting centrifuge contains a solid-wall cylinder or cone rotating about a horizontal or vertical axis. An annular layer of liquid, of fixed thickness, is held against the wall by centrifugal force; because this force is so large compared with that of gravity, the liquid surface is essentially parallel with the axis of rotation regardless of the orientation of the unit. Heavy phases "sink" outwardly from the center, and less dense phases "rise" inwardly. Heavy solid particles collect on the wall and must be periodically or continuously removed.

A filtering centrifuge operates on the same principle as the spinner in a household washing machine. The basket wall is perforated and lined with a filter medium such as a cloth or a fine screen; liquid passes through the wall, impelled by centrifugal force, leaving behind a cake of solids on the filter medium. The filtration rate increases with the centrifugal force and with the permeability of the solid cake. Some compressible solids do not filter well in a centrifuge because the particles deform under centrifugal force and the permeability of the cake is greatly reduced. The amount of liquid adhering to the solids after they have been spun also depends on the centrifugal force applied; in general, it is substantially less than in the cake from other types of filtration devices. *See* MECHANICAL SEPARATION TECHNIQUES. [J.C.Sm.]

Centriole A morphologically complex cellular organelle at the focus of centrosomes in animal cells and some lower plant cells. Prokaryotes, some lower animal cells, higher plant cells, and a few exceptional higher animal cells do not have centrioles in their centrosomes. Centrioles typically are not found singly; the centrosome of higher animal cells contains a pair of centrioles (together called the diplosome), arranged at right angles to each other and separated by a distance ranging from 250 nanometers to several micrometers. *See* CENTROSOME.

Centrioles are typically 300–700 nm in length and 250 nm in diameter. Although they can be detected by the light microscope, an electron microscope is required to resolve their substructure. At the electron microscopic level, a centriole consists of a hollow cylinder of nine triplet microtubules in a pinwheel arrangement (see illus.). Within each triplet, one microtubule (the A tubule) is a complete microtubule, while the others (the B and C tubules) share a portion of their wall with the adjacent tubule. In some cells these nine triplet microtubules are embedded in a densely staining cylindrical matrix that is spatially distinct from the pericentriolar material of the centrosome. Structures found in the lumen or core of the centriole include linkers between the triplets, granules, fibers, a cartwheel structure at one end of the centriole, and sometimes a small vesicle.

Centrioles have a close structural similarity to basal bodies, which organize the axoneme of cilia and flagella. In many types of mammalian somatic cells, the older of the two centrioles in the centrosome can act as a basal body during the interphase portion of the cell cycle. In such cases, tapered projections, called basal feet, are often observed on the external surface of the centriole



Diagrams of centriole showing (*a*) arrangement of microtubules and (*b*) cross section of proximal end, with nine triplet microtubules (A, B, and C) and central cartwheel structure.

that is acting as the basal body. Microtubules are attached to the globular tips of the basal feet and may serve to anchor this centriole in the cell.

During interphase the centrosome nucleates the array of cytoplasmic microtubules; later in the cell cycle the centrosome duplicates, and the daughter centrosomes form the poles of the mitotic (or meiotic) spindle. The terms "centriole" and "centrosome" are sometimes erroneously used interchangeably; centrioles are not the centrosome itself, but a part of it. The centrosome of higher animal cells has at its center a pair of centrioles, arranged at right angles to each other and separated by 250 nm or less.

The only clearly demonstrated role for the centriole is to organize the axoneme (central microtubular complex) of the primary cilium in cells having this structure, and the flagellar axoneme in sperm cells. Other possible functions for centrioles are a matter of debate. Some authorities assert that when present in the centrosome, centrioles contain activities that serve to organize the centrosome, determine the number of centrosomes in a cell, and control the doubling of the centrosome as a whole before mitosis. Others believe that centrioles have no role in the formation and doubling of the centrosomes but are associated with the centrosomes only to ensure the equal distribution of basal bodies during cell division. *See* Cell (biology); Cell division. [G.Slu.]

Centripetal force

The inward force required to keep a particle or an object moving in a circular path. It can be shown that a particle moving in a circular path has an acceleration toward the center of the circle along a radius. *See* Acceleration.

This radial acceleration, called the centripetal acceleration, is such that, if a particle has a linear or tangential velocity v when moving in a circular path of radius R, the centripetal acceleration is v^2/R. If the particle undergoing the centripetal acceleration has a mass M, then by Newton's second law of motion the centripetal force F_C is in the direction of the acceleration. This is expressed by the equation below, where ω is the constant angular velocity

$$F_C = Mv^2/R = MR\omega^2$$

and is equal to v/R. From Newton's laws of motion it follows that the natural motion of an object is one with constant speed in a straight line, and that a force is necessary if the object is to depart from this type of motion. Whenever an object moves in a curve, a centripetal force is necessary. In circular motion the tangential speed is constant but is changing direction at the constant rate of ω, so the centripetal force along the radius is the only force involved. [R.J.S.]

Centrode

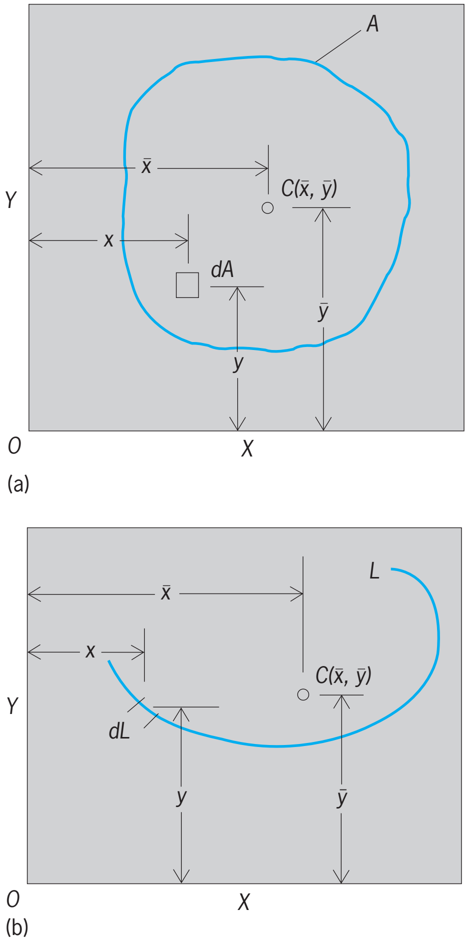
The path traced by the instantaneous center of a plane figure when it undergoes plane motion. If a plane rigid body is constrained to move in its own plane but is otherwise free to undergo an arbitrary translational and rotational motion, it is found that at any instant there exists a point, called the instantaneous center, about which the body is rotating. The path that this instantaneous center traces out in space as the motion unfolds is called the space centrode. The path that it would trace out in a coordinate system which is rigidly attached to the body is called the body centrode. The motion may therefore be specified, when the two centrodes are given, by allowing one curve to roll without slipping along the other. *See* Four-bar linkage; Rigid-body dynamics. [H.C.Co./B.G.]

Centrohelida

An order of the Heliozoia. There is a central cell mass from which thin stiff arms radiate. In the majority of species, the body is coated with a layer of siliceous spines or spicules and measures from 20 to 50 micrometers. These organisms are found in fresh-water and marine habitats, feeding on other protozoa, which adhere to the arms after colliding with them. In addition to about five genera which certainly are closely related (of which *Acanthocystis* and *Raphidiophrys* are among the most widely represented), the group contains a variety of other Heliozoia of uncertain affinities. *See* Actinopodea; Heliozoia; Protozoa; Sarcodina. [D.J.Pa.]

Centroids (mathematics)

Points positioned identically with the centers of gravity of corresponding homogeneous thin plates or thin wires. Centroids are involved in the analysis of certain problems of mechanics, for example, the phenomenon of bending.



Notation of integral equations for centroids. (*a*) Centroid of area. (*b*) Centroid of line.

The centroid of plane area A is point C (illus. *a*). Coordinates $\overline{x}$ and $\overline{y}$ of C as referred to the indicated X and Y coordinate axes are given by Eq. (1). Similarly, the centroidal coordinates of plane curve L (illus. *b*) are given by Eq. (2). In these

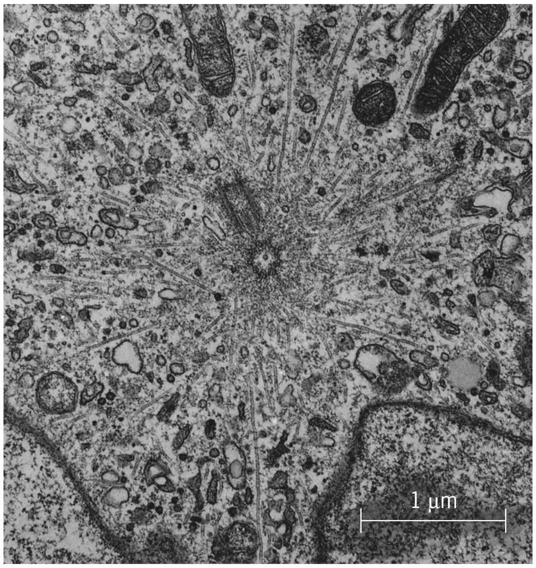
$$\overline{x} = \frac{\int x\,dA}{\int dA} \qquad \overline{y} = \frac{\int y\,dA}{\int dA} \tag{1}$$

$$\overline{x} = \frac{\int x\,dL}{\int dL} \qquad \overline{y} = \frac{\int y\,dL}{\int dL} \tag{2}$$

equations $\overline{x}$ and $\overline{y}$ are the coordinate locations of infinitesimal area element dA and infinitesimal line element dL, respectively. [N.S.F.]

Centrosome An organelle located in the cytoplasm of all animal cells and many plants, fungi, and protozoa that controls the polymerization, position, and polar orientation of many of the cell's microtubules throughout the cell cycle. There is usually one centrosome per cell, located near the cell's center; it doubles during interphase, so there are two when the cell divides. At the onset of mitosis, each centrosome increases the number of microtubules it initiates. These mitotic microtubules are more labile and generally shorter than their interphase counterparts, and as they rapidly grow and shrink they probe the space around the centrosome that initiated them. When the nuclear envelope disperses, the microtubules extend from the centrosome into the former nucleoplasm where the chromosomes have already condensed. Some of these microtubules attach to the chromosomes, while others interact with microtubules produced by the sister centrosome, forming a mitotic spindle that organizes and segregates the chromosomes. During anaphase, sister centrosomes are forced apart as the spindle elongates, allowing each daughter cell to receive one centrosome to organize its microtubules in the next cell generation. *See* CELL CYCLE; CELL MOTILITY.

The shapes of centrosomes differ widely between organisms. The centrosomes of animal cells (see illustration) usually contain a pair of perpendicular centrioles including a parent centriole formed in an earlier cell generation and a daughter centriole formed during the most recent interphase. Centrioles can serve as basal bodies for the initiation of a cilium or flagellum in the cells that make them. They appear to be essential for the formation of these motile appendages, so centriole inheritance by both daughters at cell division is analogous to the transmission of a gene. *See* CENTRIOLE; CILIA AND FLAGELLA; CYTOSKELETON.



Centrosome of a mammalian cell. Many microtubules radiate from the cloud of pericentriolar material which surrounds one of the two centrioles. (*Courtesy of Kent McDonald*)

Centrosome action is regulated as a function of time in the cell cycle. The increase in microtubule number that occurs prior to mitosis is correlated with a significant increase in the extent of phosphorylation of several centrosomal proteins. The protein kinase p34^{cdc2}, which helps to regulate the cell cycle, is concentrated at the centrosome, together with cyclin-B, a positive regulator of this kinase. *See* MITOSIS. [J.R.Mc.]

Cephalaspidomorpha The subclass of Agnatha that includes the jawless vertebrates with a single median nostril. The Cephalaspidomorphi, sometimes called Monorhina, includes the superorder Hyperotreti, containing the modern Myxinoidea or hagfishes, and the superorder Hyperoartii, containing the living Petromyzonida or lampreys, as well as the extinct Osteostraci and Anaspida. *See* AGNATHA. [R.H.De.]

Cephalobaenida One of two orders in the class Pentastomida of the phylum Arthropoda. This order includes primitive pentastomids with six-legged larvae. The hooks are simple, lacking a fulcrum, and disposed in trapeziform pattern, with the anterior pair internal to the posterior pair. The mouth is anterior to the hooks. There are two families: Raillietiellidae, which contains two genera (*Raillietiella* and *Cephalobaena*); and Reighardiidae, which contains the single genus Reighardia with one species. *See* PENTASTOMIDA. [H.W.S.]

Cephalocarida A group of minute marine crustaceans of great interest to students of arthropod evolution because its members have been postulated to possess many primitive characters and to show relationships not only to various other groups of Crustacea but perhaps also to the trilobites. Nine species are recognized, placed in four genera. They have been found in flocculent surface deposits of mud or silty sand, from the intertidal zone down to depths of 5000 ft (1500 m), on the shores of all continents except Europe. Population densities up to an average of 16 individuals/ft^2 (177/m^2) have been recorded.

The best-known species is *Hutchinsoniella macracantha*, from the east coast of North and South America, about 0.12–0.16 in. (3–4 mm) long, with a shovel-shaped head and a slender, very flexible body which is not covered by a carapace. Other species are similar. Among the features that appear to be primitive, most notable is the pronounced serial homology seen in the trunk limbs, the trunk musculature, the ventral nerve cord, and the heart. Other features in the anatomy of *Hutchinsoniella* that seem likely to be primitive are the uniramous, multisegmented antennules, the biramous antennae with both rami multisegmented, the large, flattened pleura on all the limb-bearing somites, and the telson freely articulated with the trunk and bearing a caudal furca. In the larval development, there is a primitive "nauplius" stage, followed by stages showing an unusually regular addition of new somites and limbs.

Hutchinsoniella is a nonselective deposit feeder, subsisting on the organic matter present in its habitat. Cephalocarids are nonswimming, bottom-creeping, nonselective deposit feeders. Distal claws on the endopods of the thoracopods scratch up particles that are passed into the median ventral food groove and moved forward to the mouth by metachronal beating of the thoracopods. *See* CRUSTACEA. [J.H.Lo.; P.McL.]

Cephalochordata A subphylum of the phylum Chordata comprising the lancelets, including *Branchiostoma* (amphioxus). They are also known as the Leptocardii. Lancelets are small fishlike animals, not exceeding 3.2 inches (80 mm) in length. They burrow in sand on the ocean bed or in estuaries in tropical and temperate regions throughout the world. Only two genera are recognized: *Branchiostoma* (23 species) and *Asymmetron* (6 species).

The structure of the lancelet is based on the same fundamental plan as all other chordates, but there is neither head nor paired fins. The skeletal rod of the back, or notochord, extends the entire length of the body. The animal is thus pointed at both ends and lanceolate in form.

The adults burrow in rather coarse sand or shell gravel and usually lie with the mouth open at the surface of the sand. Large numbers of lancelets congregate in small areas for spawning. The egg develops into a larva which at first is bottom-living, but later becomes planktonic. Metamorphosis takes place after about 11–12 weeks of life. The young adult sinks to the bottom and swims actively until a suitable sand in which it can burrow and remain undisturbed is found.

The importance of lancelets lies chiefly in their being one of the most primitive chordates. However, lancelets are eaten by the Chinese. *See* CHORDATA. [J.E.We.]

Cephalopoda The most highly evolved class of the phylum Mollusca. It consists of squids, cuttlefishes, octopuses, and the chambered nautiluses. The earliest known cephalopods are small, shelled fossils from the Upper Cambrian rocks of northeast China that are 500 million years old. Cephalopods always have been marine, never fresh-water or land, animals. Most fossil cephalopods, among them the subclasses Nautiloidea and Ammonoidea, had external shells and generally were shallow-living, slow-moving animals. Of the thousands of species of such shelled cephalopods that evolved, all are extinct except for four species of the only surviving genus, *Nautilus*. All other recent cephalopods belong to four orders of the subclass Coleoidea, which also contains five extinct orders.

Living cephalopods are bilaterally symmetrical mollusks with a conspicuously developed head that has a crown of 8–10 appendages (8 arms and 2 tentacles) around the mouth. These appendages are lined with one to several rows of suckers or hooks. *Nautilus* is exceptional in having many simple arms. The mouth contains a pair of hard chitinous jaws that resemble a parrot's beak and a tonguelike, toothed radula (a uniquely molluscan organ). Eyes are lateral on the head; they are large and well developed. The "cranium" contains the highly developed brain, the center of the extensive, proliferated nervous system. The shell of ancestral cephalopods has become, in living forms, internal, highly modified, reduced, or absent; and is contained in the sac- or tubelike, soft muscular body, the mantle. A pair of fins may occur on the mantle as an aid to locomotion, but primary movement is achieved through jet propulsion in which water is drawn into the mantle cavity and then forcibly expelled through the nozzlelike funnel. Fewer than 1000 species of living cephalopods inhabit all oceans and seas.

The classification given here concentrates on the living groups and lists only the major fossil groups; see separate articles on each subclass and order.

- Class Cephalopoda
  - Subclass Nautiloidea
  - Subclass Ammonoidea
  - Subclass Coleoidea
    - Order Belemnoidea
    - Order Sepioidea
    - Order Teuthoidea
      - Suborder Myopsida
      - Suborder Oegopsida
    - Order Vampyromorpha
    - Order Octopoda
      - Suborder Cirrata
      - Suborder Incirrata

Species of cephalopods inhabit most marine habitats. Cephalopods inhabit tide pools, rocky patches, sandy bottoms, coral reefs, grass beds, mangrove swamps, coastal waters, and the open ocean from the surface through the water column to depths on the abyssal bottom at over 16, 000 ft (5000 m). *See* NERVOUS SYSTEM (INVERTEBRATE).

Cephalopods are high-level, active predators that feed on a variety of invertebrates, fishes, and even other cephalopods. The relatively sluggish nautiluses feed primarily on slow-moving prey such as reed shrimps, and even are scavengers of the cast-off shells of molted spiny lobsters. Cuttlefishes prey on shrimps, crabs, and small fishes, while squids eat fishes, pelagic crustaceans, and other cephalopods. Benthic octopuses prey mostly on clams, snails, and crabs. Salivary glands secrete toxins that subdue the prey and, in octopuses, begin digestion.

To protect themselves from predators cephalopods would rather hide than fight. To this end they have become masters of camouflage and escape. Benthic forms especially (for example, *Sepia* and *Octopus*) have evolved an intricate, complex system of rapid changes in color and patterns via thousands of individually innervated chromatophores (pigment cells) that allow precise matching to the color and pattern of the background. In addition, they regulate the texture of their skins by erecting papillae, flaps, and knobs that simulate the texture of the background. Many midwater oceanic squids camouflage against predation from below by turning on photophores (light organs) that match the light intensity from the surface and eliminate their silhouettes. *See* CHROMATOPHORE; PHOTOPHORE GLAND; PROTECTIVE COLORATION.

Cephalopods have perfected jet propulsion for many modes of locomotion, from hovering motionless, to normal cruising, to extremely rapid escape swimming. Water enters the mantle cavity through an opening around the neck when the muscular mantle (body) expands. The mantle opening seals shut as the mantle contracts and jets the water out through the hoselike funnel, driving the cephalopod tail-first through the water.

The sexes are separate in cephalopods, and many species display complex courtship, mating, spawning, and parental care behavior. At mating, the male of most species transfers the spermatophores to the female with a specially modified arm, the hectocotylus. The spermatophores are implanted into the female's mantle cavity, around the neck, under the eyes, or around the mouth, depending on the species. Incubation takes a few weeks to a few months depending on the species.

Cephalopods are extremely important in the diets of toothed whales (sperm whales, dolphins), pinnipeds (seals, sea lions), pelagic birds (petrels, albatrosses), and predatory fishes (tunas, billfishes, groupers). For example, pilot whales in the North Atlantic feed almost exclusively on one species of squid, *Illex illecebrosus*, that aggregates for spawning in the summer. *See* MOLLUSCA. [C.F.E.R.]

Cephalosporins A group of antibiotics that are effective in eradicating streptococcal, pneumococcal, staphylococcal, *Klebsiella*, *Neisseria*, and enteric gram-negative rod bacteria that produce pulmonary, skin and soft tissue, bone and joint, endocardial, surgical, urinary, and bacteremic infections. They have been used most often in a preventive or prophylactic fashion at the time of various surgical procedures. All the third-generation cephalosporins penetrate well into tissues, and antibacterially active levels in various body fluids and tissues such as bone are excellent. The toxic potential of the agents, considering their broad antibacterial spectrum, has been minor. Toxicities which are seen are those of bleeding due to vitamin K depletion. *See* ANTIBIOTIC. [H.N.]

Cepheids A class of highly luminous yellow stars that vary periodically in brightness. The importance of Cepheids to astronomy comes both in their application to practical problems of distance determination (within the Milky Way Galaxy itself, and far beyond) and in their acting as critical tests of both stellar evolution and pulsation theory. From observations it is known that the luminosity of a Cepheid is closely predicted by the period of oscillation, a relation known as the period-luminosity relation, discovered by Henrietta Leavitt in 1912. This relation provides a powerful tool for estimating distances, since the period can be determined without prior knowledge of the distance. Using the period to predict how bright a given star would appear at various distances, it is possible to calculate the distance of a Cepheid from the observer, given its apparent luminosity.

In the 1920s, Edwin Hubble conclusively ended the debate as to whether other galaxies existed in addition to the Milky Way when he discovered Cepheids in nebulae now considered to make up the Local Group of galaxies. Hubble went on to show that the distances of galaxies correlated with their apparent recession velocities, consistent with an expanding universe. *See* Galaxy, external; Hubble constant; Local Group.

Cepheids are generally identified by the distinctive and periodic optical variations in their light output. The time period over which a complete cycle is executed ranges from a few days to a few hundred days. Analysis of spectroscopic properties, including the time variation of the radial velocities of Cepheids, led to the identification of the mechanism behind the changing light. The total light variation is the result of temperature changes in the stellar atmosphere, induced by, and combined with, an inward and outward motion of the surface of the star. Measurements of the color variation, interpreted as surface temperature variations, suggest that the surface temperature is changing by a few hundred kelvins during the pulsation cycle. The surface temperature changes the surface brightness and, especially at visible wavelengths, this is the primary cause of the large observed periodic light variation of a Cepheid. *See* Astronomical spectroscopy; Variable star.

The second helium ionization layer is the main driver of pulsation in Cepheid variables. If slightly perturbed in temperature, this zone can either add considerable energy to the flow of radiation from the center of the star, by recombining and releasing the ionization energy, or it can extract energy from the flow by ionizing new material. This situation is unstable to slight perturbations in temperature because there is an opportunity for a cycling between these two states of ionization to occur.

With the aid of the Hubble Space Telescope, Cepheids have been found in galaxies as far away as the Virgo cluster, more than 20 times farther away than the Andromeda galaxy, M31, in the Local Group. At these distances, the general expansion of the universe begins to dominate the radial velocities of the galaxies. (For nearby galaxies, the motions of galaxies can be perturbed by the interaction with neighbors, or motions due to bulk flows can be a significant component of the observed velocity.) Cepheids currently provide the most accurate zero point for the calibration of other (secondary) distance methods (for example, bright supernovae) which extend the range of distance measurements by over a factor of 10. At such distances, the observed velocities are representative of the overall expansion of the universe. *See* Cosmology; Star; Universe; Variable star. [B.F.M.; W.L.F.]

Ceramics Inorganic, nonmetallic materials processed or consolidated at high temperature. This definition includes a wide range of materials known as advanced ceramics and is much broader than the common dictionary definition, which includes only pottery, tile, porcelain, and so forth. The classes of materials generally considered to be ceramics are oxides, nitrides, borides, carbides, silicides, and sulfides. Intermetallic compounds such as aluminides and beryllides are also considered ceramics, as are phosphides, antimonides, and arsenides. *See* Intermetallic compounds.

Ceramic materials can be subdivided into traditional and advanced ceramics. Traditional ceramics include clay-base materials such as brick, tile, sanitary ware, dinnerware, clay pipe, and electrical porcelain. Common-usage glass, cement, abrasives, and refractories are also important classes of traditional ceramics.

Typical properties for some ceramic materials

Property	Aluminum oxide	Silicon nitride	Silicon carbide	Partially stabilized zirconia
Density, g/cm^3	3.9	3.2	3.1	5.7
Flexure strength, MPa	350	850	450	790
Modulus of elasticity, GPa	407	310	400	205
Fracture toughness (K_{IC}), MPa · m$^{1/2}$	5	5	4	12
Thermal conductivity, W/mK	34	33	110	3
Mean coefficient of thermal expansion ($\times 10^{-6}$/°C)	7.7	2.6	4.4	10.2

Advanced materials technology is often cited as an enabling technology, enabling engineers to design and build advanced systems for applications in fields such as aerospace, automotive, and electronics. Advanced ceramics are tailored to have premium properties through application of advanced materials science and technology to control composition and internal structure. Examples of advanced ceramic materials are silicon nitride, silicon carbide, toughened zirconia, zirconia-toughened alumina, aluminum nitride, lead magnesium niobate, lead lanthanum zirconate titanate, silicon-carbide-whisker-reinforced alumina, carbon-fiber-reinforced glass ceramic, silicon-carbide-fiber-reinforced silicon carbide, and high-temperature superconductors. Advanced ceramics can be viewed as a class of the broader field of advanced materials, which can be divided into ceramics, metals, polymers, composites, and electronic materials. There is considerable overlap among these classes of materials. *See* Cermet; Composite material; Glass; Polymer.

The general advantages of advanced structural ceramics over metals and polymers are high-temperature strength, wear resistance, and chemical stability, in addition to the enabling functions the ceramics can perform. Typical properties for some engineering ceramics are shown in the table.

Advanced ceramics are used in systems such as automotive engines, aerospace hardware, and electronics. The primary disadvantages of most advanced ceramics are in the areas of reliability, reproducibility, and cost. Major advances in reliability are being made through development of tougher materials such as partially stabilized zirconia and ceramic whiskers; and reinforced ceramics such as silicon-carbide-whisker-reinforced alumina used for cutting tools, and silicon-carbide-fiber-reinforced silicon carbide for high-temperature engine applications. [D.E.N.]

Cerargyrite A mineral with composition AgCl. Its structure is that of the isometric NaCl type, but well-formed cubic crystals are rare. The hardness is $2^1/_2$ on Mohs scale and specific gravity 5.5. Cerargyrite is colorless to pearl-gray but darkens to violet-brown on exposure to light. It is perfectly sectile and can be cut with a knife-like horn; hence the name horn silver. Bromyrite, AgBr, is physically indistinguishable from cerargyrite and the two minerals form a complete series. Both minerals are secondary ores of silver and occur in the oxidized zone of silver deposits. *See* Hardness scales; Silver. [C.S.Hu.]

Ceratophyllales An order of flowering plants (angiosperms) previously thought to be related closely to the waterlilies because one genus of the latter, *Cabomba* (Nymphaeaceae), similarly has highly dissected leaves. Studies of deoxyribonucleic acid (DNA) sequences have revealed that the single genus of the order, *Ceratophyllum* (Ceratophyllaceae), has no close relationship to any other extant group of flowering plants. It is an old, highly specialized plant, modified for a fresh-water aquatic habitat. Fossil fruits attributed to it are more than 120 million years old, which makes it the oldest extant angiosperm genus. The plants are submersed, rootless aquatics with highly dissected, branching leaves; they have reduced, separately sexed, petalless flowers. There are probably only six species distributed throughout fresh-water systems worldwide. *See* Flower; Fossil seeds and fruits; Magnoliophyta; Plant evolution. [M.W.C.; M.F.F.]

Cercaria The larval generation which terminates the development of a digenetic trematode in the intermediate host, a mollusk or rarely an annelid. It becomes the adult fluke after entering the definitive host, a vertebrate. Access to the vertebrate may be either direct or indirect by entering a second intermediate, or vector, host which is ingested by the vertebrate. The intermediate host is usually aquatic and the cercaria has a tail used in swimming when it escapes from that host, but the tail may be inactive, reduced, or absent and the larva unable to swim. When the tail is absent, the organism is called a cercariaeum. Larvae with unknown life cycles are commonly described and named as species such as *Cercaria micrura* or *Cercariaeum helicis*.

The cercaria is important in taxonomy because that stage of closely related trematodes usually is less variable than the adult, and thus indicates kinships that may be masked in the adult by adaptations to parasitism of the vertebrate host. *See* Digenea; Trematoda. [R.M.C.]

Cereal Any member of the grass family (Gramineae) which produced edible grains usable as food by humans and livestock. Common cereals are rice, wheat, barley, oats, maize (corn), sorghum, rye, and certain millets, with corn, rice, and wheat being the most important. Developed by scientists, triticale is a new cereal derived from crossing wheat and rye and then doubling the number of chromosomes in the hybrid. Occasionally, grains from other grasses (for example, teff) are used for food. Cereals provide more food for human consumption than any other crops.

Four general groups of foods are prepared from the cereal grains. (1) Baked products, made from flour or meal, include breads, pastries, pancakes, cookies, and cakes. (2) Milled grain products, made by removing the bran and usually the germ (or embryo of the seed), include polished rice, farina, wheat flour, cornmeal, hominy, corn grits, pearled barley, semolina (for macaroni products), prepared breakfast cereals, and soup, gravy, and other thickenings. (3) Beverages such as beer and whiskey, made from fermented grain products (distilled or undistilled) and from boiled, roasted grains. (4) Whole-grain products include rolled oats, brown rice, popcorn, shredded and puffed gains, and breakfast foods.

All cereal grains have high energy value, mainly from the starch fraction but also from the fat and protein. In general, the cereals are low in protein content, although oats and certain millets are exceptions. *See* Grain crops; Grass. [L.P.R.]

Cerebral palsy A collection of syndromes (not a disease) of nonprogressive motor dysfunction arising from abnormal development of or damage to the brain, either prenatally, at birth, or postnatally. Most cases of cerebral palsy develop in utero. Premature birth is associated with an increased risk of cerebral palsy, with the lowest birth weights carrying the highest risk. A maximum of 15% of cases are related to birth injury or perinatal oxygen deprivation. *See* Pregnancy disorders.

Although the brain damage in cerebral palsy is nonprogressive and thus deterioration does not occur, the neurological manifestations of cerebral palsy may change with neurological maturation. The precise form of cerebral palsy rarely can be characterized prior to 6 months of age; often it cannot be characterized until the individual is 2 years old. Cerebral palsy is only rarely familial. Its incidence is stable at 0.1–0.3% of live births.

Cerebral palsy is classified by the form and distribution of the motor handicap. Spasticity, seen in 75% of cases, presents a clinical picture of muscle stiffness, weakness, and imbalance of muscle tone. Common findings are contractures of joints, resulting in shortened heel cords and thus toe walking. Tightness of the adductor muscles in the thigh may result in a scissors gait. Painful dislocation of the hip is a common problem associated with severe spasticity. Dyskinetic syndromes, occuring in 20% of cases, are characterized by a severe lack of voluntary muscle control. Unclear speech (dysarthria) can be quite severe. Ataxic syndromes, characterized by impaired coordination without altered motor tone, are uncommon. A fourth syndrome, characterized by severely decreased motor tone (hypotonia), is called atonic cerebral palsy. Distribution of the altered motor tone (that is, what parts of the body are involved) is of great importance in predicting the degree of handicap, especially in the spastic forms.

Treatment of cerebral palsy is aimed at maximizing lifetime independence within the limitations of the individual's handicap. Common treatment modalities include physical and occupational therapy to prevent contractures and facilitate optimal motor control. Speech therapy is used to improve feeding technique and communication skills. Surgical procedures to correct contractures and improve muscle balance are valuable in the spastic syndromes. Surgical and pharmacological approaches to reducing spasticity and dyskinesia remain largely experimental. [H.deC.P.]

Cerenkov radiation Light emitted by a high-speed charged particle when the particle passes through a transparent, nonconducting, solid material at a speed greater than the speed of light in the material. The blue glow observed in the water of a nuclear reactor, close to the active fuel elements, is radiation of this kind. The emission of Cerenkov radiation is analogous to the emission of a shock wave by a projectile moving faster than sound, since in both cases the velocity of the object passing through the medium exceeds the velocity of the resulting wave disturbance in the medium.

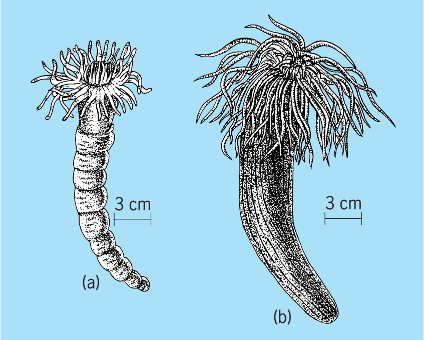
Particle detectors which utilize Cerenkov radiation are called Cerenkov counters. They are important in the detection of particles with speeds approaching that of light, such as those produced in large accelerators and in cosmic rays, and are used with photomultiplier tubes to amplify the Cerenkov radiation. These counters can emit pulses with widths of about 10^{-10} s, and are therefore useful in time-of-flight measurements when very short times must be measured. They can also give direct information on the velocity of the passing particle. *See* Particle detector. [W.B.Fr.]

The properties of Cerenkov radiation have been exploited in the development of a branch of gamma-ray astronomy that covers the energy range of about 10^5–10^8 MeV. A high-energy gamma ray from a source external to the Earth creates in the atmosphere a cascade of secondary electrons and positrons. This cascade is generated by the interplay of two processes: electron-positron pair production from gamma rays, and gamma-ray emission as the electrons and positrons are accelerated by the electric fields of nuclei in the atmosphere (bremsstrahlung). For a primary gamma ray having an energy of 10^{12} eV (1 teraelectronvolt), as many as 1000 or more electrons and positrons will contribute to the cascade. The combined Cerenkov light of the cascade is beamed to the ground over an area a few hundred meters in diameter and marks the arrival direction of the initiating gamma ray to about 1°. On a clear, dark night this radiation may be detected as a pulse of light lasting a few nanoseconds, by using an optical reflector. *See* Bremsstrahlung; Electron-positron pair production.

This technique offers a means to study regions of the universe where charged particles are accelerated to extreme relativistic energies. Such regions involve highly magnetized, rapidly spinning neutron stars; supernova remnants; and active galactic nuclei. These same motivations drive the satellite observations of the EGRET instrument of the *Compton Gamma-Ray Observatory* at lower gamma-ray energies (up to about 10^4 MeV). *See* Gamma-ray astronomy. [R.C.La.]

Ceres The first asteroid discovered. It was found serendipitously by G. Piazzi on January 1, 1801. With a diameter of roughly 950 km (590 mi), Ceres is the largest asteroid but not the brightest since it reflects only 10% of the visual light it receives. Ceres' mass of 9.5×10^{20} kg (2.1×10^{21} lb, that is, 1.6×10^{-4} that of the Earth) contains approximately one-third of the asteroid belt's total mass. *See* ASTEROID. [E.F.T.]

Ceriantharia An order of the Zoantharia, typified by *Cerianthus*, which lives in sandy marine substrata (illus. *a* and *b*). The animal is enclosed in a sheath formed by mucus secreted from gland cells of the column ectoderm, in which discharged nematocysts, sand grains, and other foreign objects are embedded.



Ceriantharia. (*a*) *Cerianthus solitarlus*. (*b*) *Pachycerlanthus multiplicatus*.

The polyp is a muscular, skeletonless, elongated, cylindrical body with a smooth wall. Long, slender, unbranching, freely retractile tentacles are arranged in two cycles and consist of smaller labial and larger marginal ones. *See* ZOANTHARIA. [K.At.]

Cerium A chemical element, Ce, atomic number 58, atomic weight 140.12. It is the most abundant metallic element of the rare-earth group in the periodic table. The naturally occurring element is made up of the isotopes ^{136}Ce, ^{138}Ce, ^{140}Ce, and ^{142}Ce. A radioactive α-emitter, ^{142}Ce has a half-life of 5×10^{15} years. Cerium occurs mixed with other rare earths in many minerals, particularly monazite and blastnasite, and is found among the products of the fission of uranium, thorium, and plutonium. *See* PERIODIC TABLE.

Although the common valence of cerium is 3, it also forms a series of quadrivalent compounds and is the only rare earth which occurs as a quadrivalent ion in aqueous solution. Although it can be separated from the other rare earths in high purity by ion-exchange methods, it is usually separated chemically by taking advantage of its quadrivalent state. [F.H.Sp.]

Cermet A group of composite materials consisting of an intimate mixture of ceramic and metallic components. Cermets can be fabricated by mixing the finely divided components in the form of powders or fibers, compacting the components under pressure, and sintering the compact to produce physical properties not found solely in either of the components. Cermets can also be fabricated by internal oxidation of dilute solutions of a base metal and a more noble metal. When heated under oxidizing conditions, the oxygen diffuses into the alloy to form a base metal oxide in a matrix of the more noble metal. *See* COMPOSITE MATERIAL; CORROSION; POWDER METALLURGY; SINTERING.

The combination of metallic and ceramic components can result in cermets characterized by increased strength and hardness, higher temperature resistance, improved wear resistance, and better resistance to corrosion, each characteristic depending on the variables involved in composition and processing. Friction parts as well as cutting and drilling tools have been successfully made from cermets for many years. Certain nuclear reactor fuel elements, such as dispersion-type elements, are also made as cermets. *See* CERAMICS. [H.H.H.]

Cerussite The mineral form of lead carbonate, $PbCO_3$. Cerussite is common as a secondary mineral associated with lead ores. In the United States it occurs mostly in the central and far western regions. Cerussite is white when pure but is sometimes darkened by impurities. Hardness is $3^1/_4$ on Mohs scale and specific gravity is 6.5. Crystals may be tabular, elongated, or arranged in clusters. *See* CARBONATE MINERALS. [R.I.Ha.]

Cesium A chemical element, Cs, with an atomic number of 55 and an atomic weight of 132.905, the heaviest of the alkali metals in group I of the periodic table (except for francium, the radioactive member of the alkali metal family). Cesium is a soft, light, very low-melting metal. It is the most reactive of the alkali metals and indeed is the most electropositive and the most reactive of all the elements. *See* PERIODIC TABLE.

Cesium reacts vigorously with oxygen to form a mixture of oxides. In moist air, the heat of oxidation may be sufficient to melt and ignite the metal. Cesium does not appear to react with nitrogen to form a nitride, but does react with hydrogen at high temperatures to form a fairly stable hydride. Cesium reacts violently with water and even with ice at temperatures as low as −116°C (−177°F). Cesium reacts with the halogens, ammonia, and carbon monoxide. In general, cesium undergoes some of the same type of reactions with organic compounds as do the other alkali metals, but it is much more reactive. *See* SODIUM.

The physical properties of cesium metal are summarized in the table.

Physical properties of cesium metal

Property	Temp., °C	Valve
Density	20	1.9 g/cm^3
Melting point	28.5	
Boiling point	705	
Heat of fusion	28.5	3.8 cal/g
Heat of vaporization	705	146 cal/g
Viscosity	100	4.75 millipoises
Vapor pressure	278	1 mm
	635	400 mm
Thermal conductivity	28.5	0.044 cal/(s)(cm^2)(°C)
Heat capacity	28.5	0.06 cal/(g)(°C)
Electrical resistivity	30	36.6 microhm−cm

Cesium is not very abundant in the Earth's crust, there being only 7 parts per million (ppm) present. Like lithium and rubidium, cesium is found as a constituent of complex minerals and not in relatively pure halide form as are sodium and potassium. Indeed, lithium, rubidium, and cesium frequently occur together in lepidolite ores, such as those from Rhodesia.

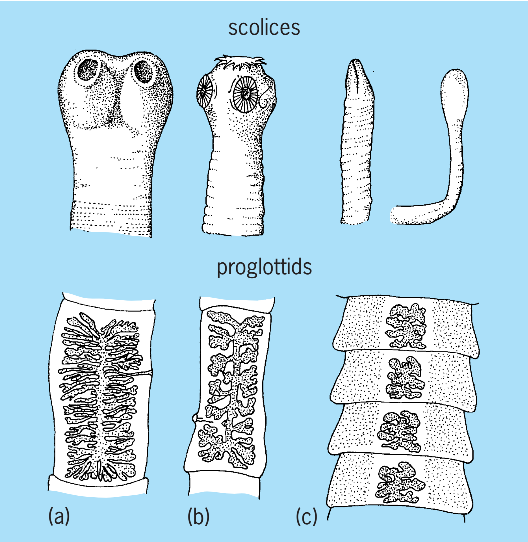
Cesium metal is used in photoelectric cells, spectrographic instruments, scintillation counters, radio tubes, military infrared signaling lamps, and various optical and detecting devices.

Cesium compounds are used in glass and ceramic production, as absorbents in carbon dioxide purification plants, as components of getters in radio tubes, and in microchemistry. Cesium salts have been used medicinally as antishock agents after administration of arsenic drugs. The isotope cesium-137 is supplanting cobalt-60 in the treatment of cancer. *See* ALKALI METALS. [M.Si.]

Cestida An order of the phylum Ctenophora comprising two genera, *Cestum* and *Velamen*. The morphology of these organisms is unusual; the transparent bodies are flattened in the tentacular plane and greatly elongated in the stomodeal plane so that they have the shape of a belt or ribbon. Cestids are capable of rapid swimming by wriggling the body. *Cestum* is widely distributed in oceanic waters and are among the commonest and most spectacular of epipelagic ctenophores. *See* Ctenophora. [L.P.M.]

Cestoda A subclass of tapeworms including most of the members of the members of the class Cestoidea. All species are endoparasites of vertebrates, living in the intestine or related ducts.

Like other members of the class, the cestodes have no digestive tract or mouth. Nutrition presumably occurs by absorption of food through the body surface. The body is usually very elongated and tapelike and frequently divided into segments, or proglottids, with replication of the hermaphroditic reproductive systems. In a few species there is duplication of both male and female organs within a single segment. The anterior end is usually modified into a holdfast organ, the scolex. Since a digestive tract is completely absent, the scolex is of solid construction, typically highly muscular with sucking depressions and hooks (see illustration).



Scolices and mature proglottids of (*a*) *Taenia saginata*, (*b*) *T. solium*, and (*c*) *Dibothriocephalus*. (*After T. I. Storer and R. L. Usinger, General Zoology, 3d ed. McGraw-Hill, 1957*)

The worms require carbohydrate for growth and reproduction, and this requirement is satisfied only from the host ingesta. On the other hand, nitrogenous nutrients and many micronutrients may be obtained from the body stores of the host; deleting such materials from the host's diet has no appreciable effect on the worms.

Most authorities agree that the tapeworms are ancient parasites, probably evolving as parasites of the earliest fishes. It seems probable that the tapeworms did not evolve from trematodes or other present-day groups of parasitic flatworms. Their ancestry may be directly derived from the acoele or rhabdocoele turbellarians and represents a line of evolution which is completely independent of other parasitic flatworms. These relationships remain obscure in the absence of any fossil record. *See* Cestoidea; Turbellaria. [C.P.R.]

Cestodaria A subclass of worms belonging to the class Cestoidea. Only a few species are known. All are endoparasites of primitive fishes. The subclass is usually divided into two orders, Amphilinidea and Gyrocotylidea. These worms differ from the other Cestoidea in being unsegmented, in not having the anterior end modified as a holdfast organ, and in frequently occurring as parasites of the coelomic cavity rather than the digestive tract. Some species have the posterior end modified into a holdfast organ. The animals are hermaphroditic and sexual reproduction occurs in the vertebrate host. *See* Amphilinidea; Cestoidea; Gyrocotylidea. [C.P.R.]

Cestoidea A class of the phylum Platyhelminthes commonly referred to as tapeworms. All members are endoparasites, usually in the digestive tract of vertebrates. The class has been subdivided as follows:

- Class Cestoidea
  - Subclass Cestodaria
    - Order: Amphilinidea
    - Gyrocotylidea
  - Subclass Cestoda
    - Order: Proteocephaloidea
    - Tetraphyllidea
    - Lecanicephaloidea
    - Trypanorhyncha
    - Diphyllidea
    - Pseudophyllidea
    - Cyclophyllidea
    - Nippotaeniidea

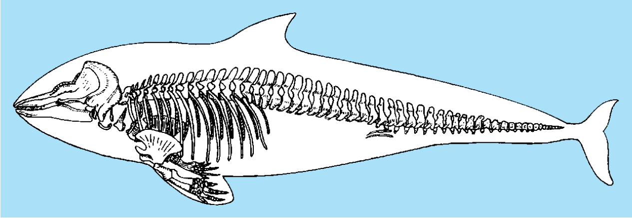
See separate articles on each group listed.

The tapeworms range from less than 0.04 in. (1 mm) to several feet in length. The class is differentially characterized by the presence of a cuticle rather than a cellular epidermis and by the total absence of a mouth and digestive tract. Food materials are presumed to be absorbed through the external surface. In most species of the class the body is divided into proglottids, each proglottid containing one or two hermaphroditic reproductive systems. The anterior end is usually modified into a holdfast organ, bearing suckers or sucking grooves, and frequently armed with hooks. Early embryonic development occurs in the parental body, usually in a uterus, to a hook-bearing stage, the oncosphere. The oncosphere leaves the parental body through a uterine pore or by liberation of the terminal segment from the main body of the worm. Further development of the worm always occurs within the body of a host, most often an invertebrate, which commonly ingests the larval form. Further larval growth and development of the holdfast may require a second host. Development of the sexual phase from the larva occurs in another host. Growth with strobilation and development of reproductive systems follow, the worm usually staying in the digestive tract. *See* Platyhelminthes; Pseudophyllidea. [C.P.R.]

Cetacea A mammalian order comprising approximately 90 living species of whales, dolphins, and porpoises and their fossil relatives. Like all other mammals but unlike all fish, cetaceans nurse their young with milk produced by the mother, are endothermic (warm-blooded), breathe air, have a lower jaw that consists of a single bony element (the dentary), and have three small bones (hammer, anvil, and stirrup) subserving sound transmission within the ear.

Living cetaceans are aquatic animals that cannot live on land. They have streamlined bodies, with the nasal opening (blowhole) on top of the head (see illustration). Their forelimbs are modified into flippers, they lack external hindlimbs, and their tail forms a flat horizontal fluke. Modern cetaceans lack hair except for whiskers in the young of some species. Many of these features are common in aquatic vertebrates, and they have evolved convergently as adaptations for life in water.

The brain of cetaceans is large and highly developed, and they are thought to be very intelligent. The cetacean sense of smell is nearly or totally absent. In most species the nerve that



Skeleton of a porpoise, highly specialized for an aquatic life. (*After Guide to the Hall of Biology of Mammals, Amer. Mus. Nat. Hist. Guide Leafl. Ser. 76, 1933*)

carries olfactory information to the brain is absent, which is very unusual among mammals. The eyes of most species are well developed. The ear is the most important sense organ. Toothed whales (Odontoceti) echolocate, emitting high-frequency sounds and using the echoes to determine shapes and distances in their surroundings. Odontocetes do not emit sounds with their voice box (larynx) like other mammals, but have modified nasal passages through which bursts of air are forced. Mysticetes (baleen whales) do not echolocate; rather, they produce low-frequency sounds with their larynx. These sounds can travel through the ocean for hundreds of miles and are used for communication. *See* ECHOLOCATION.

The two extant suborders of cetaceans, odontocetes and mysticetes, have different dietary specializations. Most odontocetes have simple, pronglike teeth which are used to grab and hold, but not chew, large prey items. Prey includes a variety of fish of all sizes, crustaceans, and squid and other mollusks. Some of the larger odontocetes, such as the killer whale (*Orcinus orca*), eat large prey, including sea lions and dolphins. A pod of killer whales will also hunt together, attacking much larger prey such as gray whales. Modern mysticetes do not have teeth and are filter feeders, straining water filled with clouds of marine organisms (krill) through a network of baleen. Baleen is a keratinlike substance that hangs down in plates from the upper jaws of the whale.

All modern cetaceans swim by swinging their horizontal tail fluke through the water, while their forelimbs are used for steering and navigating. The flippers of modern cetaceans resemble flat oars, although the bones for five fingers are present internally. The dorsal fin stabilizes the body during swimming. Under the skin of cetaceans is a layer of blubber, a fatty tissue that serves to insulate the animal and affects its buoyancy and streamlining. Some species are capable of diving to great depths [commonly more than 5000 ft (1500 m) in the sperm whale], yet all cetaceans must come to the surface to breathe. Whales have a number of adaptations for diving and staying underwater for long periods of time. They exhale before they dive, allowing them to submerge faster. They store oxygen in the muscle (myoglobin) and not in the lungs or blood (hemoglobin) and change circulation patterns of blood to save oxygen. Their chests can easily collapse under increasing pressure (with depth) without causing permanent damage. *See* ADIPOSE TISSUE; DIVING ANIMALS; HEMOGLOBIN.

A variety of social structures are found among cetaceans. Two examples are marine dolphins and sperm whales. Most marine dolphins live in schools that may contain dozens of animals, sometimes composed of multiple species. Herds of sperm whales consist of related females and juveniles. Clusters of young males form bachelor groups, and adult males, much larger than the females, are solitary.

Cetaceans are found in all oceans and seas. Some species are restricted to coastal environments (such as bottlenosed dolphins), whereas others live only in the open sea (such as sperm whales). Some species live in all seas and oceans of the world (such as killer whales). Many mysticetes and sperm whales are migratory. A number of dolphin species have left the sea and live permanently in rivers.

Cetaceans originated from a four-footed terrestrial ancestor. This predecessor, a mesonychian, may have resembled a wolf or a hyena and lived approximately 55 million years ago. Modern odontocetes are diverse, ranging from the enormous sperm whales [up to 20 m (66 ft) long and 52,000 kg (114,500 lb)] to the tiny porpoises [Phocaenidae, smallest around 9 kg (20 lb), length 1.5 m (5 ft)]. Dolphins (Delphinidae, which includes the killer whale), porpoises (Phocaenidae), and fresh-water dolphins (Iniidae, Pontoporidae, Platanistidae) are the smallest odontocetes. The largest animal ever to live on Earth is the blue whale (*Balaenoptera musculus*), a baleen whale that is 25 m (82 ft) long and weighs 130,000 kg (286,340 lb). Other examples of mysticetes are humpback whales, right whales, gray whales, and minke whales. *See* MAMMALIA. [J.G.M.B.]

Cetane number A number, usually between 30 and 60, that indicates the ability of a diesel engine fuel to ignite quickly after being injected into the cylinder. The higher the cetane number, the more easily the fuel can be ignited. In high-speed diesel engines, a fuel with a long ignition delay tends to produce rough operation. *See* DIESEL ENGINE; DIESEL FUEL. [D.An.]

Cetomimiformes An order of oceanic, mostly deep-water fishes that are structurally diverse and rare; most of the 41 species are known from one or a few specimens. Thus, their scientific study has been hindered, the anatomy is imperfectly known, and the relationships are in dispute. Five of the 10 families and 11 of the 21 genera currently placed in the order have been described since World War II. There is no fossil record.

Cetomimiforms are soft-rayed fishes. In most the mouth is large. Many are naked but a few have scales that are thin and deciduous or form an irregular mosaic; a few have the skin spinulose. Pelvic fins may be abdominal, thoracic, or jugular in position or, commonly, absent. In most forms the single dorsal and anal fins are placed rather well back and are opposed; an adipose fin is present in only one species.

Because of the diversity, the five currently recognized suborders may be mentioned separately. Best known are the Cetomimoidei (or Cetunculi) whalefishes, a group of 3 families and 15 rare species of small, red or black deep-sea fishes with whale-shaped bodies and enormous mouths; they are bioluminescent. The Ateleopoidei (or Chondrobrachii) consist of 1 family, 3 genera, and 11 species of elongate fishes in which the long anal fin is continuous with the caudal and there is no dorsal fin. The Mirapinnatoidei (or Miripinnati) are tiny, perhaps larval fishes, all recently described. Three families, 4 genera, and 5 species are included. The Giganturoidei, with 2 families, 3 genera, and 6 species, are small mesopelagic fishes with large mouths and strong teeth; some have telescopic eyes. The Megalomycteroidei, or mosaic-scaled fishes, consist of 1 family, 4 genera, and 4 rare species of small, elongate deep-sea fishes with degenerate eyes and irregularly disposed scales. *See* ACTINOPTERYGII; OSTEICHTHYES; TELEOSTEI. [R.M.B.]

Chabazite A mineral belonging to the zeolite family of silicates. Hardness (on the Mohs hardness scale) is in the range of 4–5. Colors range from white to yellow, pink, and red. The ideal composition is $Ca_2Al_2Si_4O_{12} \cdot 6H_2O$ (where Ca = calcium, Al = aluminum, Si = silicon, O = oxygen, H_2O = water), but there is considerable chemical substitution of Ca by sodium (Na) and potassium (K), as well as (Na,K)Si for CaAl. The internal structure of chabazite consists of a framework linkage of (AlO_4) and (SiO_4) tetrahedra, with large cagelike openings bounded by rings of tetrahedra. The cages are connected to each other by open structural channels that allow for the diffusion of molecules through the structure of a size comparable to that of the diameter of the channels (about 0.39 nanometer in diameter). For example, argon (0.384 nm in diameter) is quickly absorbed by the chabazite structure, but isobutane (0.56 nm in diameter) cannot enter the structure. In this manner, chabazite can be used as a sieve on a molecular level. *See* MOLECULAR SIEVE; ZEOLITE. [C.K.]

Chaetodermomorpha A subclass of burrowing, vermiform mollusks in the class Aplacophora. They are covered by a spicular integument and recognizable by the presence of a sensory cuticular oral shield, lack of a foot, and presence of paired gills in a posterior mantle cavity. Chaetoderms range in size from less than 0.08 in. (2 mm) to more than 2.8 in. (70 mm) and are found from shelf depths to hadal depths over 22, 400 ft (7000 m). There are three families with 10 genera and 84 species worldwide. Chaetoderm species are numerically dominant in certain deep-sea localities. *See* APLACOPHORA; MOLLUSCA. [A.H.S.]

Chaetognatha A phylum of abundant planktonic arrowworms. Their bodies are tubular and transparent, and divided into three portions: head, trunk, and tail. The head possesses one or two rows of minute teeth anterior to the mouth and usually 7–10 larger chaetae, or seizing jaws, on each side of the head. One or two pairs of lateral fins and a caudal fin are present.

Nine genera and about 42 species are recognized by some specialists. Most species belong to the genus *Sagitta*, which can be recognized by the presence of two pairs of teeth and two pairs of lateral fins.

Chaetognaths are cosmopolitan forms which live not only at the surface but also at great depths; however, no one species is found in all latitudes and at all depths. One of the Arctic species, *Eukrohnia hamata*, may extend to the Antarctic by way of deep water across the tropics. A few species are neritic and are not found normally beyond the continental shelf. Their food consists principally of copepods and other small planktonic crustaceans; however, they are very predacious and will even eat small fish larvae and other chaetognaths on rare occasions.

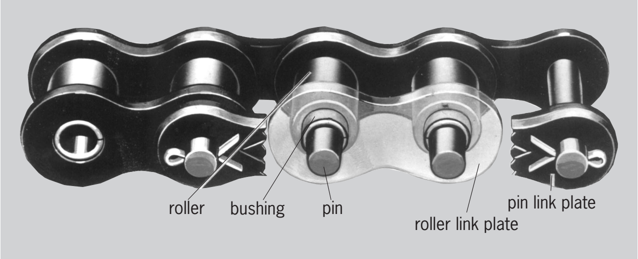
Studies have shown them to be useful as indicator organisms. Certain species appear to be associated with characteristic types or masses of water, and when this water is displaced into an adjacent water mass, the chaetognaths may be used as temporary evidence for such displacement. [E.L.P.]

Chaetonotida An order of the phylum Gastrotricha. Members have Y-shaped pharyngeal lumina. *Neodasys* is a marine and macrodasyid-like form that reaches 0.8 mm (0.03 in.) in length and has front, side, and rear adhesive tubes. Others seldom exceed 0.3 mm (0.01 in.); they have only two rear adhesive tubes borne on a posterior furca, or none at all. The family Chaetonotidae comprises half of all gastrotrichs: *Musellifer* and *Halichaetonotus* are marine; *Polymerurus* is fresh-water; *Aspidiophorus*, *Chaetonotus*, *Heterolepidoderma*, *Ichthydium*, and *Lepidodermella* have species in each habitat. *Musellifer* lives in mud; all others inhabit sands of streams, beaches, or offshore banks, or live in the surface detritus of ponds or lake bottoms. The other seven genera, in four families, are all fresh-water and either are rare or tend toward a semiplanktonic life, especially *Neogossea* and *Stylochaeta*. *See* GASTROTRICHA. [W.D.Hu.]

Chain drive A flexible device of connected links used to transmit power. A drive consists of an endless chain which meshes with sprockets located on the shaft of a driving source, such as an electric motor/reducer and a driven source, such as the head shaft of a belt conveyor.

The roller chain (see illustration) meets the demands of heavy-duty oil well drilling equipment, high-production agricultural machinery, construction machinery, and similar equipment. It also meets the precise timing requirements of lighter-duty equipment such as printing, packaging, and vending equipment.

Another type of chain, the engineering steel chain, is usually identified by the offset/cranked link sidebar design. Generally, larger pitch sizes as compared to the roller chain and higher-strength chains characterize such chains. A third group used for chain drives is the inverted tooth/silent chains. A familiar application is their use as automotive timing chains in automobile engines.



Single-strand roller chain.

The use of chains for power transmission rather than another device, such as V-belts or a direct coupling to the power source, is usually based on the cost effectiveness and economy of chains and sprockets. Chains and sprockets offer the following advantages: large speed ratios; sufficient elasticity to absorb reasonable shocks; a constant speed ratio between the driving and driven shaft; long life without excessive maintenance; mechanical understandability regarding installation and functionality; coupling and uncoupling with simple tools; and a simple means to get power from its source to the location where needed. *See* BELT DRIVE. [V.D.P.]

Chain reaction (chemistry) A chemical reaction in which many molecules undergo chemical reaction after one molecule becomes activated. In ordinary chemical reactions, every molecule that reacts must first become activated by collision with other rapidly moving molecules. The number of these violent collisions per second is so small that the reaction is slow. After a chain reaction is started, it is not necessary to wait for more collisions with activated molecules to accelerate the reaction because the reaction now proceeds spontaneously.

A typical chain reaction is the photochemical reaction between hydrogen and chlorine as described by the following reactions.

$$\mathrm{Cl_2 + light \rightarrow Cl + Cl}$$

$$\mathrm{Cl + H_2 \rightarrow HCl + H}$$

$$\mathrm{H + Cl_2 \rightarrow HCl + Cl}$$

$$\mathrm{Cl + H_2 \rightarrow HCl + H}$$

The light absorbed by a chlorine molecule dissociates the molecule into chlorine atoms; these in turn react rapidly with hydrogen molecules to give hydrogen chloride and hydrogen atoms. The hydrogen atoms react with chlorine molecules to give hydrogen chloride and chlorine atoms. The chlorine atoms react further with hydrogen and continue the chain until some other reaction uses up the free atoms of chlorine or hydrogen. The chain-stopping reaction may be the reaction between two chlorine atoms to give chlorine molecules, or between two hydrogen atoms to give hydrogen molecules. Again the atoms may collide with the walls of the containing vessel, or they may react with some impurity which is present in the vessel only as a trace.

Certain oxidations in the gas phase are known to be chain reactions. The carbon knock which occurs at times in internal combustion engines is caused by a too-rapid combustion rate caused by chain reactions. This chain reaction is reduced by adding tetraethyllead, which acts as an inhibitor.

The polymerization of styrene to give polystyrene and the polymerization of other organic materials to give industrial plastics involve chain reactions. The spoilage of foods, the precipitation of insoluble gums in gasoline, and the deterioration of certain plastics in sunlight involve chain reactions, which can be minimized with inhibitors. *See* CHEMICAL DYNAMICS; PHOTOCHEMISTRY. [F.D.]

Chain reaction (physics) A succession of generation after generation of acts of division (called fission) of certain heavy nuclei. The fission process releases about 200 MeV (3.2×10^{-4} erg = 3.2×10^{-11} joule) in the form of energetic particles including two or three neutrons. Some of the neutrons from one generation are captured by fissile species (^{233}U, ^{235}U, ^{239}Pu) to cause the fissions of the next generations. The process is employed in nuclear reactors and nuclear explosive devices. [N.C.R.]

Chalcanthite A mineral with the chemical composition $CuSO_4 \cdot 5H_2O$. Chalcanthite commonly occurs in blue to greenish-blue triclinic crystals or in massive fibrous veins or stalactites. Fracture is conchoidal and luster is vitreous. Hardness is 2.5 on Mohs scale and specific gravity is 2.28. It has a nauseating taste and is readily soluble in water. It dehydrates in dry air to a greenish-white powder. Although deposits of commercial size occur in arid areas, chalcanthite is generally not an important source of copper ore. Its occurrence is widespread in the western United States. [E.C.T.C.]

Chalcedony A fine-grained fibrous variety of quartz, silicon dioxide. The individual fibers that compose the mineral aggregate usually are visible only under the microscope. Subvarieties of chalcedony recognized on the basis of color differences, some valued since ancient times as semiprecious gem materials, include carnelian (translucent, deep flesh red to clear red in color), sard (orange-brown to reddish-brown), and chrysoprase (apple green). *See* GEM; QUARTZ.

Chalcedony occurs as crusts with a rounded, mammillary, or botryoidal surface and as a major constituent of nodular and bedded cherts. The hardness is 6.5–7 on Mohs scale. The specific gavity is 2.57–2.64.

Crusts of chalcedony generally are composed of fairly distinct layers concentric to the surface. Agate is a common and important type of chalcedony in which successive layers differ markedly in color and degree of translucency. In the most common kind of agate the layers are curved and concentric to the shape of the cavity in which the material formed. *See* AGATE. [R.Si.]

Chalcocite A mineral having composition Cu_2S and crystallizing in the orthorhombic system (below 217°F or 103°C). Crystals are rare and small, usually with hexagonal outline because of twinning. Most commonly, the mineral is fine-grained and massive with a metallic luster and a lead-gray color which tarnishes to dull black on exposure. The Mohs hardness is 2.5–3, and the density 5.5–5.8. Chalcocite is an important copper ore found at Miami, Morenci, and Bisbee, Arizona; Butte, Montana; Kennecott, Alaska; and Tsumeb, South-West Africa. [L.Gr.]

Chalcopyrite A mineral having composition $CuFeS_2$. Crystals are usually small and resemble tetrahedra. Chalcopyrite is usually massive with a metallic luster, brass-yellow color, and sometimes an iridescent tarnish. The Mohs hardness is 3.5–4.0, and the density 4.1–4.3. Chalcopyrite is a so-called fool's gold, but is brittle while gold is sectile. Pyrite, the most widespread fool's gold, is harder than chalcopyrite. *See* PYRITE.

Chalcopyrite is the most widespread primary copper ore mineral. It is commonly found in veins (Braden mine, Chile; Cornwall, England; Butte, Montana; Freiberg, Saxony; Tasmania; Rio Tinto, Spain). Chalcopyrite is also found in contact metamorphic deposits in limestone (Bisbee, Arizona) and as sedimentary deposits (Mansfeld, Germany). *See* COPPER. [L.Gr.]

Chalk The term sometimes used in a broad sense for any soft, friable, or weathered fine-grained limestone; however the term is mostly restricted to pelagic (biogenic) limestones. Chalk is a uniformly fine-grained, typically light-colored marine limestone primarily composed of the remains of calcareous nannofossils and microfossils. These minute pelagic organisms live in surface and near-surface oceanic waters and include coccolithophores (algae) and planktic foraminifers (Protozoa). Larger fossil constituents may be present, but only in subordinate amounts. The dominant pelagic skeletal remains are composed of low-magnesium calcite and have accumulated where the sea floor lies at a depth of less than about 4 km or 13,000 ft (the carbonate is redissolved at greater depths). Typical chalk sedimentation rates are 30 m (100 ft) per million years, so chalk accumulation is also dependent on the exclusion of diluting materials such as reefal detritus or terrigenous debris (clay, silt, or sand) transported from land areas by rivers. Chalks therefore form mainly in isolated outer shelf or deeper-water settings that are far from land areas. *See* CALCITE; LIMESTONE.

The unique combination of light color, compositional purity, softness, and fine texture led to many of the early uses of chalk for writing on blackboards. Chalks are also widely used in the manufacture of portland cement, as lime for fertilizers, and in powders, abrasives, and coatings. [P.A.Sc.]

Chameleon The name for about 80 species of small-to-medium-sized lizards that make up the family Chamaeleontidae and occur mainly in Africa and Madagascar. The American chameleons (*Anolis*) belong to a different family of lizards, the Iguanidae.

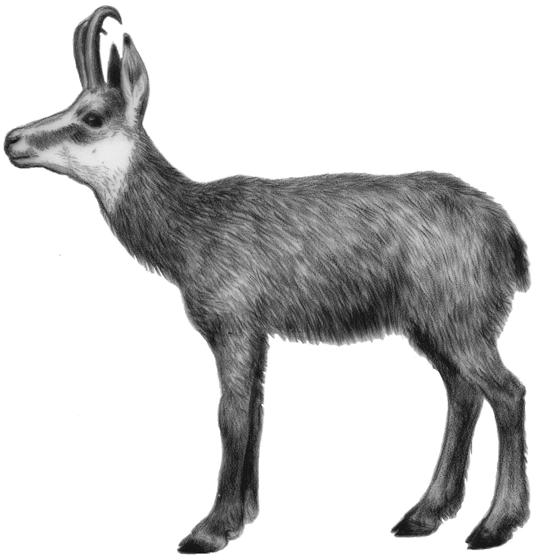
Chamaeleo chamaeleon is the most common species and is a typical example of the group. Its body is flattened from side to side; it has a long, prehensile tail; and both the forelimbs and hindlimbs have two digits that oppose the other three. These feet and the tail make the chameleon well adapted for its arboreal habitat. The eyes are large and can move independently of each other in all directions. The tongue is also prehensile, being extensible for a great distance, about the length of the animal itself, and is a highly efficient organ for capturing insects. The head is triangular in profile and has a pointed crest. Chameleons are noted for their ability to change color. Color changes appear to be related to environmental temperatures as well as other external stimuli.

The chameleon is oviparous. The female digs out a hollow in the ground for a nest where several dozen eggs are laid and then covered with soil. The period of incubation varies inversely with the temperature and may be as short as 4 months or as long as 10 months. Parental care of the young has not been observed. *See* CHROMATOPHORE; SQUAMATA. [C.B.C.]

Chamois One of several species of mammals included in the tribe Rupicaprini of the family Bovidae. The group is heterogeneous in form, but all are intermediate in characteristics between the goats and antelopes. The chamois is the only European species of the group and is indigenous to the mountainous areas, especially the Alps. About nine races are recognized, based on their geographical range. The chamois is, however, becoming rare.

The chamois (*Rupicapra rupicapra*) lives in small herds of both sexes in numbers from 10 to 50. The adult is almost 3 ft high and weighs about 90 lb (40 kg) maximum. Both sexes bear horns which are set close together on the forehead, project almost at right angles, and are straight except for the sharp curve backward at the top (see illustration). A soft, pliable leather, known as chamois cloth, is obtained from the skin of this animal.

The goral, serow, and Rocky Mountain goat are included in the same tribe of bovids as the chamois. Both the goral (genus *Naemorhedus*) and serow (genus *Capricornis*) are found in Asia. The goral is about 2 ft (0.6 m) high and has short horns. The male of the Rocky Mountain goat (*Oreamnos americanus*) is larger than the female, weighing between 200 and 300 lb (90 and 135 kg) and standing over 3 ft (1 m) high. Both sexes are

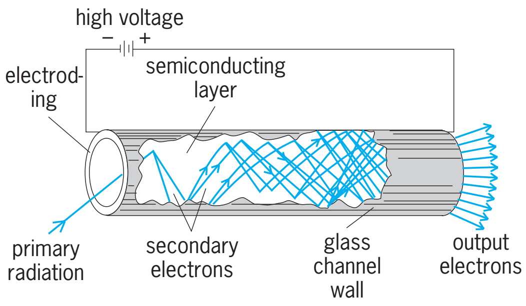


The chamois (*Rupicapra rupicapra*).

covered with thick, long white hair and have horns and beards. *See* ANTELOPE; MAMMALIA. [C.B.C.]

Channel electron multiplier A single-particle detector which in its basic form (see illustration) consists of a hollow tube (channel) of either glass or ceramic material with a semiconducting inner surface. The detector responds to one or more primary electron impact events at its entrance (input) by producing, in a cascade multiplication process, a charge pulse of typically 10^4–10^8 electrons at its exit (output). Because particles other than electrons can impact at the entrance of the channel electron multiplier to produce a secondary electron, which is then subsequently multiplied in a cascade, the channel electron multiplier can be used to detect charged particles other than electrons (such as ions or positrons), neutral particles with internal energy (such as metastable excited atoms), and photons as well. As a result, this relatively simple, reliable, and easily applied device is employed in a wide variety of charged-particle and photon spectrometers and related analytical instruments, such as residual gas analyzers, mass spectrometers, and spectrometers used in secondary ion mass spectrometry (SIMS), electron spectroscopy for chemical analysis (ESCA), and Auger electron spectroscopy. *See* AUGER EFFECT; ELECTRON SPECTROSCOPY; MASS SPECTROMETRY; OPTICAL DETECTORS; PHOTOEMISSION; SECONDARY ION MASS SPECTROMETRY (SIMS); SPECTROSCOPY.

A related device is the channel electron multiplier array, often called a microchannel plate. The channel electron multiplier array is usually a disk-shaped device with a diameter between 1 and 4 in. (2.5 and 10 cm) and a thickness of a fraction of a millimeter, and consists of millions of miniature channel electron multiplier devices arranged with channel axes perpendicular to the face of the disk. Channel electron multiplier arrays find application as image intensifiers in night vision devices, and are employed to add either large detection area or imaging capabilities, or both, to charged-particle detectors and spectrometers. *See* IMAGE TUBE (ASTRONOMY); LIGHT AMPLIFIER; PARTICLE DETECTOR. [S.B.E.]



Cutaway view of a straight, single-channel electron multiplier, showing the cascade of secondary electrons resulting from the initial, primary radiation event, which produces an output charge pulse. (*After J. L. Wiza, Microchannel plate detectors, Nucl. Instrum. Meth., 162:587–601, 1979*)

Channeling in solids The steering of positively charged energetic particles between atomic rows or planes of a crystalline solid. The particles can be positive ions, protons, positrons, or muons. If the angle between the direction of the particle and a particular axis or plane in the crystal is within a small predictable limit (typically a few degrees or less), then the gradually changing electrostatic repulsion between the particle and each successive atomic nucleus of the crystal produces a smooth steering through the crystal lattice. *See* CRYSTAL STRUCTURE.

An obvious consequence of this steered motion is that it prevents violent collisions of the particles with atoms on the lattice sites. Hence, as compared with a randomly directed beam of particles, the channeled beam loses energy more slowly, penetrates more deeply, creates much less damage to the crystal along its track, and is prevented from participating in all close-encounter processes (nuclear reactions, Rutherford scattering, and so forth) with lattice atoms. *See* NUCLEAR REACTION; SCATTERING EXPERIMENTS (NUCLEI).

A related channeling phenomenon is the channeling of energetic electrons or other negative particles. In this case, the particles are attracted to the positively charged atomic nuclei, so that the probability of violent collisions with atoms on lattice sites is enhanced rather than being prevented, and the particles are steered along the rows or planes of nuclei rather than between them.

A closely related phenomenon is called blocking. In this case, the energetic positive particles originate from atomic sites within the crystal lattice by means of fission, alpha-particle decay, or by wide-angle scattering of a nonchanneled external beam in a very close encounter with a lattice atom. Those particles emitted almost parallel to an atomic row or plane will be deflected away from the row by a steering process. Consequently, no particles emerge from the crystal within a certain critical blocking angle of each major crystallographic direction. A piece of film placed some distance from the crystal provides a simple technique for recording blocking patterns. Theoretical considerations show that the same principle is involved in blocking as in channeling; hence, both phenomena exhibit an identical dependence on particle energy, nuclear charge, lattice spacing, and so forth. *See* NUCLEAR FISSION; RADIOACTIVITY.

Applications of channeling include the location of foreign atoms in a crystal, the study of crystal surface structure, and the measurement of nuclear lifetimes. The location of foreign (solute) atoms in a crystal is one of the simplest channeling applications. It is accomplished by measuring the yields of Rutherford back-scattered particles, characteristic x-rays, or nuclear reaction products produced by the interaction of channeled particles with the solute atoms. Such yields are enhanced for solute atoms that are displaced into channels of the crystal. This method has been used to determine the lattice positions of solute atoms that have been introduced into crystals, and to determine the amount of lattice damage created by ion implantation. These and similar applications have proved extremely useful in the development of semiconductor devices. *See* ION IMPLANTATION; LASER-SOLID INTERACTIONS. [J.A.Da.; M.L.Sw.]

Chaos System behavior that depends so sensitively on the system's precise initial conditions that it is, in effect, unpredictable and cannot be distinguished from a random process, even though it is deterministic in a mathematical sense.

Throughout history, sequentially using magic, religion, and science, people have sought to perceive order and meaning in a seemingly chaotic and meaningless world. This quest for order reached its ultimate goal in the seventeenth century when newtonian dynamics provided an ordered, deterministic view of the entire universe epitomized in P. S. de Laplace's statement, "We ought then to regard the present state of the universe as the effect of its preceding state and as the cause of its succeeding state."

But if the determinism of Laplace and Newton is totally accepted, it is difficult to explain the unpredictability of a gambling game or, more generally, the unpredictably random behavior observed in many newtonian systems. Commonplace examples of such behavior include smoke that first rises in a smooth, streamlined column from a cigarette, only to abruptly burst into wildly erratic turbulent flow (see illustration); and the unpredictable phenomena of the weather. *See* FLUID FLOW; TURBULENT FLOW.

At a more technical level, flaws in the newtonian view had become apparent by about 1900. The problem is that many newtonian systems exhibit behavior which is so exquisitely sensitive to the precise initial state or to even the slightest outside perturbation that, humanly speaking, determinism becomes a physically meaningless though mathematically valid concept. But even more is true. Many deterministic newtonian-system orbits are so erratic that they cannot be distinguished from a random process even though they are strictly determinate, mathematically speaking. Indeed, in the totality of newtonian-system orbits, erratic unpredictable randomness is overwhelmingly the most common behavior. *See* CLASSICAL MECHANICS; DETERMINISM; STOCHASTIC PROCESS.

One example of chaos is the evolution of life on Earth. Were this evolution deterministic, the governing laws of evolution would have had built into them anticipation of every natural crisis which has occurred over the centuries plus anticipation of every possible ecological niche throughout all time. Nature, however, economizes and uses the richness of opportunity available through chaos. Random mutations provide choices sufficient to meet almost any crisis, and natural selection chooses the proper one. *See* ORGANIC EVOLUTION.

Transition from order to chaos (turbulence) in a rising column of cigarette smoke. The initial smooth streamline flow represents order, while the erratic flow represents chaos.

Another example concerns the problem that the human body faces in defending against all possible invaders. Again, nature appears to choose chaos as the most economical solution. Loosely speaking, when a hostile bacterium or virus enters the body, defense strategies are generated at random until a feedback loop indicates that the correct strategy has been found. A great challenge is to mimic nature and to find new and useful ways to harness chaos. *See* IMMUNITY.

Another matter for consideration is the problem of predicting the weather or the world economy. Both these systems are chaotic and can be predicted more or less precisely only on a very short time scale. Nonetheless, by recognizing the chaotic nature of the weather and the economy, it may eventually be possible to accurately determine the probability distribution of allowed events in the future given the present. At that point it may be asserted with mathematical precision that, for example, there is a 90% chance of rain 2 months from today. Much work in chaos theory seeks to determine the relevant probability distributions for chaotic systems. *See* WEATHER FORECASTING AND PREDICTION.

Finally, many physical systems exhibit a transition from order to chaos, as exhibited in the illustration, and much work studies the various routes to chaos. Examples include fibrillation of the heart and attacks of epilepsy, manic-depression, and schizophrenia. Physiologists are striving to understand chaos in these systems sufficiently well that these human maladies can be eliminated. *See* PERIOD DOUBLING.

Reduced to basics, chaos and noise are essentially the same thing. Chaos is randomness in an isolated system; noise is randomness entering this previously isolated system from the outside. If the noise source is included to form a composite isolated system, there is again only chaos. *See* ELECTRICAL NOISE. [J.Fo.]

Chaparral A vegetation formation characterized by woody plants of low stature (3.3–10 ft or 1–3 m tall), impenetrable because of tough, rigid, interlacing branches, with small, simple, waxy, evergreen, thick leaves. The term refers to evergreen oak, Spanish *chapparo*, and therefore is uniquely southwestern North American. This type of vegetation has its center in California and occurs continuously over wide areas of mountainous to sloping topography. The Old World Mediterranean equivalent is called maquis or macchie, with nomenclatural and ecological variants in the countries from Spain to the Balkans. Physiognomically similar vegetation occurs also in South Africa, Chile, and southwestern Australia in areas of Mediterranean climates, that is, with very warm, dry summers and maximum precipitation during the cool season. The floras of these five areas with Mediterranean climates are altogether different.

The characteristic species of the true chaparral of California include *Adenostema fasciculatum*, *Ceanothus cuneatus*, *Quercus dumosa*, *Heteromeles arbutifolia*, *Rhamnus californica*, *R. crocea*, and *Cercocarpus betuloides*, plus a host of endemic species of *Arctostaphylos* and *Ceanothus* and other Californian endemics, both shrubby and herbaceous. These plants determine the formation's physiognomy. It is a dense, uniform-appearing, evergreen, shrubby cover with sclerophyllous leaves and deep-penetrating roots.

Ecologically, chaparral occurs in a climate which is hot and dry in summer, cool but not much below freezing in winter, with little or no snow, and with excessive winter precipitation that leaches the soil of nutrients. The need for water and its supply are exactly out of phase.

Chaparral soils are generally rocky, often shallow, or of extreme chemistry such as those derived from serpentine, and are always low in fertility. In the very precipitous southern Californian mountains, soil erosion rates may be 0.04 in. (1 mm) per year over large watershed areas. [J.Ma.]

Character recognition The process of converting scanned images of machine-printed or handwritten text (numerals, letters, and symbols) into a computer-processable format; also known as optical character recognition (OCR). A typical OCR system contains three logical components: an image scanner, OCR software and hardware, and an output interface. The image scanner optically captures text images to be recognized. Text images are processed with OCR software and hardware. The process involves three operations: document analysis (extracting individual character images), recognizing these images (based on shape), and contextual processing (either to correct misclassifications made by the recognition algorithm or to limit recognition choices). The output interface is responsible for communication of OCR system results to the outside world.

Commercial OCR systems can largely be grouped into two categories: task-specific readers and general-purpose page readers. A task-specific reader handles only specific document types. Some of the most common task-specific readers read bank checks, letter mail, or credit-card slips. These readers usually utilize custom-made image-lift hardware that captures only a few predefined document regions. For example, a bank-check reader may scan just the courtesy-amount field (where the amount of the check is written numerically) and a postal OCR system may scan just the address block on a mail piece. Such systems emphasize high throughput rates and low error rates. Applications such as letter-mail reading have throughput rates of 12 letters per second with error rates less than 2%. The character recognizer in many task-specific readers is able to recognize both handwritten and machine-printed text.

General-purpose page readers are designed to handle a broader range of documents such as business letters, technical writings, and newspapers. These systems capture an image of a document page and separate the page into text regions and nontext regions. Nontext regions such as graphics and line drawings are often saved separately from the text and associated recognition results. Text regions are segmented into lines, words, and characters, and the characters are passed to the recognizer. Recognition results are output in a format that can be postprocessed by application software. Most of these page readers can read machine-written text, but only a few can read hand-printed alphanumerics. *See* COMPUTER; WORD PROCESSING. [S.N.Sh.; S.W.L.]

Characteristic curve A graphical display depicting complex nonlinear relationships in electronic circuits. A typical use is to show voltage-current relationships in semiconductor devices. Device amplification capabilities, for example, are exhibited by a characteristic plot which traces output current versus output voltage with a third controlling variable as a parameter. This control variable could be the base current of a bipolar junction transistor (BJT) or the gate-to-source voltage of a metal-oxide-semiconductor (MOS) transistor.

Other characteristics often included in transistor data sheets are displays of current gain versus bias current, gain versus frequency, and input and output impedances versus frequency. Less commonly, other graphical nonlinear relationships, such as the variation of thermocouple voltage with temperature or the dependence of electrical motor torque with current, also are known as characteristic curves.

In the past, characteristic curves were used as tools in the graphical solution of nonlinear circuit equations that are followed by relationships of this type. In current practice, this analysis is performed using computer packages for circuit simulation. Designers still use characteristic curves from data sheets, however, to evaluate relative performance capabilities when selecting devices, and to provide the information needed for a preliminary pencil-and-paper circuit design. *See* AMPLIFIER; ELECTRICAL MODEL; TRANSISTOR. [P.V.L.]

Charadriiformes A large, diverse, worldwide order of shore and aquatic birds. It may be closely related to the pigeons (Columbiformes) on the one side and to the cranes, rails, and their allies (Gruiformes) on the other. *See* COLUMBIFORMES; GRUIFORMES.

The order Charadriformes is arranged into three suborders and 17 families as follows: (1) Charadrii, with superfamily jacanoidea containing the families jacanidae (jacanas; 8 species) and Rostratulidae (painted snipe; 2 species); superfamily Charadrioidea containing the families Graculavidae, Presbyornithidae, Haematopodidae (oyster catchers; 7 species), Charadriidae (plovers and lapwings; 64 species), Scolopacidae (sandpipers, curlews, phalaropes, and snipe; 86 species), Recurvirostridae (stilts and avocets; 10 species), Dromadidae (crab plovers; 1 species), Burhinidae (thick-knees; 9 species), and Glareolidae(pratincoles; 16 species); and superfamily Chionidoidea with the families thinocoridae (seed snipe; 4 species) and Chionidae (sheathbills; 2 species). (2) Lari, with the families Sterocorariidae (skyas, 5 species), Laridae (gulls and terns; 88 species), and Rynchopidae (skimmers; 3 species). (3) Alcae, with the single family Alcidae (auks, murres, and puffins; 23 species).

The three suborders of charadiiforms are quite different groups. The Charadrii are the typical shorebirds, usually found in marshy areas and along shores, but some are in dry areas, and a few, the phalaropes, are mainly aquatic. They can and fly well. Most live in flocks, although most breed solitarily in nests placed on the ground. Most feed on insects and other small animals; the seed snipes are mainly vegetarian. The Lari include the skuas, gulls, terns, and skimmers, predominantly aquatic birds that find their food by flying over the water. They are long-winged, excellent fliers with short legs, but they can walk well. The feet are webbed. Most species breed in large colonies. Alcae include only the alcids, which are true marine, swimming and diving birds found only in the Northern Hemisphere. They have webbed feet and reduced wings. Alcids are excellent divers, and swim underwater by using their wings, which are reduced to rather stiff, paddlelike structures. Alcids feed on fish and other aquatic animals. They breed in large colonies, on rocky ledges or in burrows. *See* AVES. [W.J.B.]

Charcoal A porous solid product containing 85–98% carbon produced by heating carbonaceous materials such as cellulose, wood, peat, and coals of bituminous or lower rank at 930–1100°F (500–600°C) in the absence of air.

Chars or charcoals from cellulose or wood are soft and friable. They are used chiefly for decolorizing solutions of sugar and other foodstuffs and for removing objectionable tastes and odors from water. Chars from nutshells and coal are dense, hard carbons. They are used in gas masks and in chemical manufacturing for many mixture separations. Another use is for the tertiary treatment of waste water. Residual organic matter is adsorbed effectively to improve the water quality. *See* ADSORPTION; CARBON. [J.H.Fi.]

Charge-coupled devices Semiconductor devices wherein minority charge is stored in a spatially defined depletion region (potential well) at the surface of a semiconductor, and is moved about the surface by transferring this charge to similar adjacent wells. The formation of the potential well is controlled by the manipulation of voltage applied to surface electrodes. Since a potential well represents a nonequilibrium state, it will fill with minority charge from normal thermal generation. Thus a charge-coupled device (CCD) must be continuously clocked or refreshed to maintain its usefulness. In general, the potential wells are strung together as shift registers. Charge is injected or generated at various input ports and then transferred to an output detector. By appropriate design to minimize the dispersive effects that are associated with the charge-transfer process, well-defined charge packets can be moved over relatively long distances through thousands of transfers.

There are several methods of controlling the charge motion, all of which rely upon providing a lower potential for the charge in the desired direction. When an electrode is placed in proximity to a semiconductor surface, the electrode's potential can control the near-surface potential within the semiconductor. The basis for this control is the same as for metal oxide semiconductor (MOS) transistor action. If closely spaced electrodes are at different voltages, they will form potential wells of different depths. Free charge will move from the region of higher potential to the one of lower potential.

An important property of a charge-coupled device is its ability to transfer almost all of the charge from one well to the next. Without this feature, charge packets would be quickly distorted and lose their identity. This ability to transfer charge is measured as transfer efficiency, which must be very good for the structure to be useful in long registers. Values greater than 99.9% per transfer are not uncommon. This means that only 10% of the original charge is lost after 100 transfers.

A second important property of a charge-coupled-device register is its lifetime. When the surface electrode is clocked high, the potential within the semiconductor also increases. Majority charge is swept away, leaving behind a depletion layer. If the potential is taken sufficiently high, the surface goes into deep depletion until an inversion layer is formed and adequate minority charge collected to satisfy the field requirements. The time it takes for minority charge to fill the well is the measure of well lifetime. The major sources of unwanted charge are: thermal diffusion of substrate minority charge to the edge of the depletion region, where it is collected in the well; electron-hole pair generation within the depletion region; and the emission of minority charge by traps. Surface-channel charge-coupled devices usually have a better lifetime, since surface-state trap emission is suppressed and the depletion regions are usually smaller. [M.R.Gu.]

The most significant current application of the charge-coupled-device concept is as an imaging device. Charge-coupled-device image sensors utilize the fact that silicon is sensitive to light. In fact, silicon is sensitive to wavelengths from about 400 to 1100 nanometers (from ultraviolet to near-infrared). When light photons penetrate the silicon surface, hole-electron pairs are created in the silicon. The number of hole-electron pairs created is a function of wavelength (photon energy), intensity (number of photons), and duration (length of time exposed to light).

In a charge-coupled-device image sensor, the light is focused upon an array of picture elements (pixels). These pixels collect the electrons as they are created. The number of electrons collected in each pixel is representative of the light intensity projected onto the sensor at that point. Periodically, the charges from all of the pixels are read out, and the image can then be reconstructed from the intensity and pixel location data.

There are two primary categories of image sensors. Linear image sensors have the pixels aligned along a central axis. Area image sensors have the pixels arranged in a rectangular (rows × columns) array pattern. Linear image sensors require relative motion between the sensor and the object being scanned. The relative motion is precisely known so that, as the object is scanned one line at a time, it can then be reconstructed one line at a time. Area image sensors do not require this motion.

The resolution of area image sensors has become equivalent to photographic film, enabling the development of digital photography. Cameras with very large, very high resolution area image sensors provide professional photographers better final pictures than are obtainable with conventional film, while lower-resolution, lower-cost, digital charge-coupled-device cameras are available to consumers. *See* CAMERA.

A miniaturized charge-coupled-device camera allows a dentist to see inside a patient's mouth or a physician to see inside a patient's body. Charge-coupled-device area imagers are also used in intraoral dental x-ray systems. Charge-coupled-device-based systems with very large area image sensors have been introduced in mammography, to image x-rays of the human breast.

Astronomers have long used charge-coupled device area image sensor cameras mounted on very high power telescopes. By synchronizing the motion of the telescope with the Earth's rotation, the camera can "stare" at one spot in space for hours at a time. The long integration times allow distant objects to be imaged that are otherwise invisible. To keep the sensor from being saturated with thermally generated charge, these cameras typically cool the charge-coupled-device chip down to −50° to −100°C (−58° to −148°F). *See* ASTRONOMICAL PHOTOGRAPHY; INTEGRATED CIRCUITS; SEMICONDUCTOR. [S.O.]

Charge-density wave A possible ground state of a metal in which the conduction-electron charge density is sinusoidally modulated in space. The periodicity of this extra modulation is unrelated to the lattice periodicity. Instead, it is determined by the dimension of the conduction-electron Fermi surface in momentum space. *See* FERMI SURFACE.

In a quasi-one-dimensional metal, for which conduction electrons are mobile in one direction only, a charge-density wave can be caused by a Peierls instability. This mechanism involves interaction between the electrons and a periodic lattice distortion having a wave vector Q parallel to the conduction axis. The linear-chain metal niobium triselenide ($NbSe_3$) is prototypical.

For isotropic metals, and quasi-two-dimensional metals, Coulomb interactions between electrons are the cause of a charge-density wave instability. The exchange energy, an effect of the Pauli exclusion principle, and the correlation energy, an effect of electron-electron scattering, both act to stabilize a charge-density wave. However, the electrostatic energy attributable to the charge modulation would suppress a charge-density wave were it not for a compensating charge response of the positive-ion lattice. *See* EXCHANGE INTERACTION; EXCLUSION PRINCIPLE.

A wavelike displacement of this lattice will generate a positive-ion charge density that almost cancels the electronic charge modulation of the charge-density wave. A typical value of the displacement amplitude is about 1% of the lattice constant. Ion-ion repulsive interactions must be small in order to permit such a distortion. Consequently, charge-density waves are more likely to occur in metals having small elastic moduli. *See* BAND THEORY OF SOLIDS; CRYSTAL STRUCTURE; SPIN-DENSITY WAVE. [A.W.O.]

Charged particle beams Unidirectional streams of charged particles traveling at high velocities. Charged particles can be accelerated to high velocities by electromagnetic fields. They are then able to travel through matter (termed an absorber), interacting with it, losing energy, and causing various effects important in many applications. Examples of charged particles are electrons, positrons, protons, antiprotons, alpha particles, and any ions (atoms with one or several electrons removed or added). In addition, some particles are produced artificially and may be short-lived (pions, muons).

In traveling through matter, charged particles interact with nuclei, producing nuclear reactions and elastic and inelastic collisions with the electrons (electronic collisions) and with entire atoms of the absorber (atomic collisions). Usually, in its travel through matter a charged particle makes few or no nuclear reactions or inelastic nuclear collisions, but many electronic and atomic collisions. The average distance between successive collisions is called the mean free path, λ. In solids, it is of the order of 10 cm (4 in.) for nuclear reactions. It ranges from the diameter of the atoms (about 10^{-10} m) to about 10^{-7} m for electronic collisions. The mean free path, λ, depends on the properties of the particle and, most importantly, on its velocity.

If a charged particle is accelerated, it can emit photons called bremsstrahlung. This process is of great importance for electrons as well as for heavy ions whose kinetic energies are much greater than their rest energies. It is used extensively for the production of x-rays in radiology. *See* BREMSSTRAHLUNG.

In gases, all electrons are bound to individual atoms or molecules in well-defined orbits. These electrons can be moved into other bound orbits (excitation) requiring a well-defined energy. Another possibility is the complete removal of the electron from the atom (ionization), requiring an energy equal to or greater than the ionization energy for the particular electron. In both processes, the charged particle will lose energy and will be deflected very slightly.

There are some major differences between electron beams and beams of heavier particles. In general, the path of an electron will be a zigzag. Angular deflections in the collisions will frequently be large. Electron beams therefore tend to spread out laterally, and the number of primary electrons in the beam at a depth x in the absorber decreases rapidly.

In general, for the same dose (the energy deposited per gram along the beam line) heavy charged particles will produce, because of their higher local ionization, larger biological effects than electrons (which frequently are produced by x-rays). *See* NUCLEAR RADIATION (BIOLOGY); RADIATION BIOLOGY; RADIATION INJURY (BIOLOGY).

Electron beams are used in the preservation of food. In medicine, electron beams are used extensively to produce x-rays for both diagnostic and therapeutic (cancer irradiation) purposes. Also, in radiation therapy, deuteron beams incident on Be and ^{3}H targets are used to produce beams of fast neutrons, which in turn produce fast protons, alpha particles, and carbon, nitrogen, and oxygen ions in the irradiated tissue. Energetic pion, proton, alpha, and heavier ion beams can possibly be used for cancer therapy. *See* RADIOLOGY.

Charged particle beams are used in many methods of chemical and solid-state analysis. Nuclear activation analysis can be performed with heavy ions. *See* ACTIVATION ANALYSIS; ELECTRON DIFFRACTION; ELECTRON SPECTROSCOPY; SECONDARY ION MASS SPECTROMETRY (SIMS). [H.Bi.]

Beams of nuclei with lifetimes as short as 10^{-6} s are used for studies in nuclear physics, astrophysics, biology, and materials science. Nuclear beams (or heavy-ion beams) are usually produced by accelerating naturally available stable isotopes. However, radioactive nuclei, most of which do not occur naturally on Earth, must be produced as required in nuclear reactions by using various accelerated beams. Because these radioactive nuclei are produced by the nuclear reactions of primary beams, they are called secondary particles and beams of such nuclei are called radioactive secondary beams. *See* RADIOACTIVITY.

Radioactive secondary beams have made possible the study of the structure of nuclei far from stability. Another important application occurs in the study of nuclear reactions of importance in hot stars and in supernovae, which are crucial for understanding nucleosynthesis in the universe. *See* NUCLEAR STRUCTURE; NUCLEOSYNTHESIS. [I.T.]

Charged particle optics The branch of physics concerned with the motion of charged particles under the influence of electric and magnetic fields. A positively charged particle that moves in an electric field experiences a force in the direction of this field. If the particle falls in the field from a potential of U volts to a potential zero, its energy gain, measured in electronvolts, is equal to the product of U and the particle's charge. For example, if a singly and a doubly charged particle are accelerated by a potential drop of 100 V, the two particles will gain energies of 100 eV and 200 eV, respectively. If both particles were initially at rest, they would have final velocities proportional to the square root of K/m, where K is the energy increase and m is the mass of the particle. This relation describes the velocities of energetic particles accurately as long as these velocities are small compared to the velocity of light $c \approx 300{,}000$ km/s (186,000 mi/s), a speed that cannot be exceeded by any particle. *See* ELECTRIC FIELD; ELECTROSTATICS.

If an ensemble of ions of equal energies but of different masses is accelerated simultaneously, the ion masses can be determined from their arrival times after a certain flight distance. Such time-of-flight mass spectrometers have successfully been used, for instance, to investigate the masses of large molecular ions, up to and beyond 350,000 atomic mass units. *See* TIME-OF-FLIGHT SPECTROMETERS.

If a homogeneous electric field is established between two parallel-plate electrodes at different potentials, a charged particle in the space between the electrodes will experience a force in the direction perpendicular to them. If initially the particle moved parallel to the electrodes, it will be deflected by the electric force and move along a parabolic trajectory. Magnetic fields also deflect charged particles. In contrast to electrostatic fields, however, magnetic fields change only the direction of a particle trajectory and not the magnitude of the particle velocity. Charged particles that enter a magnetic field thus move along circles whose radii increase with the products of their velocities and their mass-to-charge ratios, m/q. If initially all particles start at the same potential U and are accelerated to the potential zero, they will move along radii that are proportional to the square root of $U(m/q)$. Thus, particles of different mass-to-charge ratios can be separated in a magnetic sector field.

A sector-field mass analyzer can be used to determine the masses of atomic or molecular ions in a cloud of such ions. Such systems can also be used to purify a beam of ions that are to be implanted in semiconductors in order to fabricate high-performance transistors and diodes. Finally, such magnetic sector fields are found in large numbers in all types of particle accelerators. *See* ION IMPLANTATION; MASS SPECTROSCOPE.

An Einzel lens consists of three cylindrical tubes, the middle one of which is at a higher potential than the outer two. Positively charged particles entering such a device are first decelerated and then accelerated back to their initial energies. Axially symmetric magnetic lenses have also been constructed. Such lenses, also called solenoids, consist mainly of a coil of wire through which an electric current is passed. The charged particles are then constrained to move more or less parallel to the axis of such a coil. Axially symmetric electric and magnetic lenses are used extensively to focus low-energy particle beams. Particularly important applications are in television tubes and in electron microscopes. *See* CATHODE-RAY TUBE; ELECTRON MICROSCOPE; ELECTROSTATIC LENS; MAGNETIC LENS; PICTURE TUBE.

By passing charged particles through electrode or pole-face arrangements, a particle beam can also be focused toward the optic axis. In such quadrupole lenses the electric or the magnetic field strengths, and therefore the forces that drive the charged particles toward or away from the optic axis, increase linearly with the distance from the axis. While quadrupole lenses are found in systems in which low-energy particle beams must be focused, for instance, in mass spectrometers, such lenses have become indispensable for high-energy beams. Consquently, quadrupole lenses, especially magnetic ones, are found in many types of particle accelerators used in research in, for example, nuclear and solid-state physics, as well as in cancer irradiation treatment facilities. *See* CHARGED PARTICLE BEAMS; ELECTRON LENS; ELECTRON MOTION IN VACUUM; PARTICLE ACCELERATOR. [H.W.]

Charles' law A thermodynamic law, also known as Gay-Lussac's law, which states that at constant pressure the volume of a fixed mass or quantity of gas varies directly with the absolute temperature. Conversely, at constant volume the gas pressure varies directly with the absolute temperature. *See* GAS. [F.H.R.]

Charm A term used to describe a class of elementary particles. Ordinary atoms of matter consist of a nucleus composed of neutrons and protons and surrounded by electrons. Over the years, however, a host of other particles with unexpected properties have been found, associated with both electrons (leptons) and protons (hadrons). The hadrons number in the hundreds, and can be explained as composites of more fundamental constituents, called quarks. The originally simple situation of having an up quark (u) and a down quark (d) has evolved as several more varieties or flavors have had to be added. These are the strange quark (s) with the additional property or quantum number of strangeness to account for the unexpected characteristics of a family of strange particles; the charm quark (c) possessing charm and no strangeness, to explain the discovery of the J/ψ particles, massive states three times heavier than the proton; and a fifth quark (b) to explain the existence of the even more massive upsilon (γ) particles. *See* HADRON; J PARTICLE; QUARKS.

The members of the family of particles associated with charm fall into two classes: those with hidden charm, where the states are a combination of charm and anticharm quarks ($c\overline{c}$), charmonium; and those where the charm property is clearly evident, such as the D^+ ($c\overline{d}$) meson and $\Lambda_c{}^+$ (cud) baryon. Although reasonable progress has been made in the study of charmed states, much work remains to be done. *See* ELEMENTARY PARTICLE. [N.P.S.]

Charophyceae A group of branched, filamentous green algae, commonly known as the stoneworts, brittleworts, or muskgrasses, that occur mostly in fresh- or brackish-water habitats. They are important as significant components of the aquatic flora in some locales, providing food for waterfowl and protection for fish and other aquatic fauna; as excellent model systems for cell biological research; and as a unique group of green algae thought to be more closely related to the land plants.

Charophytes are multicellular, branched, macroscopic filaments from a few inches to several feet in length. Colorless rhizoidal filaments anchor the plants to lake bottoms and other substrates. The main filaments are organized into short nodes forming whorls of branches, and much longer (up to 6 in. or 15 cm) internodal cells. The general morphology varies with environmental conditions such as depth of the water, light levels, and amount of wave action. Reproductive structures occur at the nodes and consist of egg cell-containing structures, the nucules, and sperm cell-containing structures called globules.

Based on the morphology of the vegetative filaments and the reproductive structures, six extant genera are recognized: *Chara, Nitella, Tolypella, Nitellopsis, Lamprothamnium*, and *Lychnothamnus*. There is no agreement on how many valid species exist, but the maximum number of living species is probably fewer than 100. Deoxyribonucleic acid (DNA) sequencing indicates that the charophytes are a distinct natural group that should be recognized at some taxonomic level (for example, as an order, Charales, or as a class, Charophyceae). *See* ALGAE; CHLOROPHYCOTA. [R.L.Cha.]

Cheese A product of milk, selectively concentrated from major milk components. It is generally rich in flavor and contains high-quality nutrients. There are many varieties of cheese, all produced in the following general manner. Raw or pasteurized milk is clotted by acid, rennet, or both. The curd is cut and shaped into the special form of the cheese with or without pressing. Salt is added, or the cheese is brined after pressing.

Acid is produced during manufacture of cheese by fermentation of the milk sugar, lactose. This fermentation is initiated by the addition of a culture of specially selected acid bacteria (starter culture) to the milk. Acid production in cheese curd retards growth of bacteria that cause undesirable fermentations in cheese. Moreover, it favors the expulsion of the whey and the fusion of the curd particles. Fresh cheese (cottage or cream cheese) does not require any ripening, and it is sold soon after it is made. Other varieties of cheese are cured or ripened to obtain the desirable consistency, flavor, or aroma. The flavor and aroma of cheese are obtained by a partial breakdown of mild proteins and fat by the action of microbial, milk, and rennet enzymes. In hard varieties (Cheddar, Gouda, Edam, Emmentaler or Swiss, and provolone) this is done by the microorganisms in the interior of cheese; in semisoft or soft types (Limburger, Camembert, and Roquefort) by the organisms on, or in contact with, the surface of cheese.

Processed cheese is produced from cheeses of different ages by blending. The mixture, melted with the aid of emulsifying salts (citrates and phosphates), is packed in sealed containers (tins, paperboard, foil, or plastic). Few bacteria other than spore-formers survive the heat treatment. No substantial growth of flora occurs in well-preserved process cheese, but spoilage by anaerobic spore-formers may occur. [N.O.]

Key materials for cheesemaking include fresh or precultured milk, cultures, milk-coagulating enzyme preparations, special microorganisms, salt, and beta carotene or annatto color. The amounts used and the manner in which these materials are applied strongly influence the cheese character. Cheese may be made from the milk of the cow, sheep, goat, water buffalo, and other mammals, but the milk of the cow is most widely used despite some limitations. Sheep milk and water buffalo milk generally give more flavor to the cheeses, and the color is uniformly white because of a lack of carotene in such mammalian milks, but they are more expensive to make into cheese.

Two major classes of cheeses exist, fresh and ripened. Fresh cheeses are simpler to make than ripened, are more perishable, and do not develop as intense flavors, but give a mild acid, slightly aromatic flavor and soft, smooth texture. Three basic groups characterize fresh cheese types: group I—ricotta and Broccio; group II—cottage, Neufchatel, and cream; and group III—mozzarella. Most ripened cheeses are contained in one of six basic groups. The characteristic cheeses in each group include: group I—Cheddar and Monterey; group II—Swiss (Emmentaler) and Gruyère; group III—Edam and Gouda; group IV—Muenster, brick, and Limburger; group V—provolone; and group VI—Camembert, Brie, and bleu.

Processed cheese is made from natural types. Nearly any natural cheese can be processed, except that for blue cheese technical difficulties cause blackening of the blue mold due to the high heat. Processed cheese is produced by grinding selected lots of natural cheese and adding cream, color, salt, and emulsifying agents. Processed cheese foods and spreads are made similarly, but include more water and less protein, fat, and other solids. *See* MILK. [F.V.K.]

Chelation A chemical reaction or process involving chelate ring formation and characterized by multiple coordinate bonding between two or more of the electron-pair-donor groups of a multidentate ligand and an electron-pair-acceptor metal ion. The multidentate ligand is usually called a chelating agent, and the product is known as a metal chelate compound or metal chelate complex. Metal chelate chemistry is a subdivision of coordination chemistry and is characterized by the special properties resulting from the utilization of ligands possessing bridged donor groups, two or more of which coordinate simultaneously to a metal ion. *See* COORDINATION CHEMISTRY.

Many of the functional groups of both synthetic and naturally occurring organic compounds can form coordinate bonds to metal ions, producing metal-organic complexes or chelates, many of which are biologically active. Thus chelate compounds are frequently found in an interdisciplinary field of science called bioinorganic chemistry. The biological significance of chelates is demonstrated by the large number of biologically important compounds that are either metal chelates or chelating agents. Included in this group are the alpha amino acids, peptides, proteins, enzymes, porphyrins (such as hemoglobin), corrins (such as vitamin B_{12}), catechols, hydroxypolycarboxylic acids (such as citric acid), ascorbic acid (vitamin C), polyphosphates, nucleosides and other genetic compounds, pyridoxal phosphate (vitamin B_6), and sugars. The ubiquitous green plant pigment, chlorophyll, is a magnesium chelate of a tetradentate ligand formed from a modified porphin compound, and similarly the oxygen transport heme of red blood cells contains an Fe(II) chelate. *See* BIOINORGANIC CHEMISTRY; ORGANOMETALLIC COMPOUND.

The ability of chelating agents to reduce the chemical activity of metal ions has found extensive application in many areas of science and industry. Ethylenediaminetetraacetic acid (EDTA), a hexadentate chelating agent, has been employed commercially for water softening, boiler scale removal, industrial cleaning, soil metal micronutrient transport, and food preservation. Nitrilotriacetic acid (NTA) is a tetradentate chelating agent which, because of lower cost, has taken over some of the commercial applications of EDTA. Many commercially important dyes and pigments, such as copper phthalocyanines, are chelate compounds. Humic and fulvic acids are plant degradation products in lake and sea-water sediments that have been suggested as important chelating agents which regulate metalion balance in natural waters. By virtue of its abundance, low toxicity, low cost, and good chelating tendencies for metal ions that produce water hardness, the tripolyphosphate ion (as its sodium salt) is used in large quantities as a builder in synthetic detergents. Both synthetic ion exchangers and the mineral zeolites are chelating ion-exchange resins which are used in analytical and water-softening applications. As final examples, less conventional chelating agents are the multidentate, cyclic ligands, termed collectively crown ethers, which are particularly suited for the complexation of the alkali and alkaline-earth metals. *See* ETHYLENEDIAMINETETRAACETIC ACID. [A.E.M.; R.J.Mo.]

Chelicerata A subphylum of the phylum Arthropoda. The Chelicerata can be defined as those arthropods with the anteriormost appendages as a pair of small pincers (chelicerae) followed usually by pedipalps and four pairs of walking legs, and with the body divided into two parts: the prosoma (corresponding approximately to the cephalothorax of many crustaceans) and the opisthosoma (or abdomen). There are never antennae or mandibles (lateral jaws). The Chelicerata comprise three classes: the enormous group Arachnida (spiders, ticks, mites, scorpions, and related forms); the Pycnogonida (sea spiders or nobody-crabs); and the Merostomata (including the Xiphosurida or horseshoe crabs). *See* ARACHNIDA; MEROSTOMATA; PYCNOGONIDA; XIPHOSURIDA.

Both Merostomata and Pycnogonida are marine, but the enormous numbers and varied forms of the Arachnida are almost entirely terrestrial. The respiratory structures of chelicerates include gills, book-lungs, and tracheae. Sexes are normally separate, with genital openings at the anterior end of the opisthosoma. Some mites and other small chelicerates are omnivorous scavengers, but the majority of species of larger chelicerates are predaceous carnivores at relatively high trophic levels in their particular ecotopes. *See* ARTHROPODA. [W.D.R.H.]

Chelonia An order of the Reptilia, subclass Anapsida, including the turtles, terrapins, and tortoises. This order is also known as the Testudines. The group first appeared in the Triassic, and its representatives are among the commonest fossils from that time on. Members of the order are most frequently found in fresh-water streams, lakes, and ponds or in marshy areas. However, a number of strictly terrestrial species are known, and several are marine. Turtles occur on all the major continents and continental islands in tropic and temperature regions. The marine forms are basically tropical in distribution, but some individuals stray into temperate waters. *See* ANAPSIDA.

The living turtles are usually divided into two major groups, the suborders Pleurodira and Cryptodira, based upon the structures of the head and neck. The pleurodires have spines on the most posterior cervicals (neck vertebrae) and the head is retractile laterally. In the cryptodires the cervical spines are uniformly reduced and the head is folded directly back to within the shell. In several cryptodires, notably in the marine turtles, the neck is secondarily nonretractible because of a reduction in the shell.

The Chelonia differ from most other vertebrates in possessing a hard bony shell which encompasses and protects the body. The shell is made up of a dorsal portion, the carapace, and a ventral segment, the plastron, connected by soft ligamentous tissue or a bony bridge. The carapace is composed of the greatly expanded ribs and dorsal vertebrae overlain by a series of enlarged dermal ossifications and an outer covering of tough skin or horny scales. The plastron is similarly arranged with remnants of the interclavicle, clavicles, and gastralia fused with dermal ossifications and covered by skin or scales. Other peculiarities associated with the shell include the fusion of the ribs to the vertebrae and the reduction of trunk muscles, the presence of the pectoral girdle completely inside the ribs (found in no other animal), the highly modified short, thick humerus and femur, and the lungs attached dorsally to the shell. In addition, living turtles differ from the tuatara, snakes, lizards, and crocodilians in having an anapsid skull, no true teeth but horny beaks on the jaws, an immovable quadrate, and a single median penis in males.

The rigid bony shell of turtles imposes a basic body plan subject to relatively little variation. The principal obvious differences between them are in the shell shape, limbs, head, and neck. The general outline of the shell is variable, but in most forms the shell is moderately high-arched and covered with epidermal scales. The majority of turtles have limbs more or less adapted to aquatic or semiaquatic life with moderate to well-developed palmate webbed feet. However, in strictly terrestrial forms such as the tortoises, the limbs are elephantine with the weight of the body being borne on the flattened sole of the feet.

Associated with the tendency of most turtles toward a life in or near water is the auditory apparatus. Even though an eardrum is present, hearing is adapted to picking up sounds transmitted through the water or substratum. However, there is evidence that airborne sound can be heard. Vision is also important, and turtles have color vision. Most of the species are gregarious and diurnal, and territoriality is unknown in the order.

The courtship patterns of various turtles are distinctive. In general, aquatic forms mate in the water, but tortoises breed on land. The male mounts the female from above, and fertilization is internal. Sperm may be stored in the cloacal region of the female for extended periods before fertilization. Because of the presence of the large median penis in males, the sexes of many species can be distinguished by the longer and broader tail of the male. All turtles lay shelled eggs which are buried in sand or soil in areas where females congregate. The shell is calcareous in most forms, but the marine turtles have leathery shells. Eggs are rather numerous, as many as 200 being laid by a single individual in some species, and are highly valued as human food. Incubation takes 60–90 days, and the little turtle cuts its way out of the shell with a small horny egg caruncle at the end of the snout.

Turtles feed on all types of organisms. Aquatic species may eat algae, higher plants, mollusks, crustaceans, insects, or fishes; terrestrial forms are similarly catholic in tastes. Most species are omnivores, but some have very specialized diets. The edges and internal surfaces of the horny beaks of these reptiles are frequently denticulate and modified to form specialized mechanisms adapted to handle particular food items. [J.M.S.]

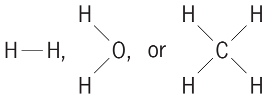
Chemical bonding The force that holds atoms together in molecules and solids. Chemical bonds are very strong. To break one bond in each molecule in a mole of material typically requires an energy of many tens of kilocalories.

It is convenient to classify chemical bonding into several types, although all real cases are mixtures of these idealized cases. The theory of the various bond types has been well developed and tested by theoretical chemists. *See* COMPUTATIONAL CHEMISTRY; MOLECULAR ORBITAL THEORY; QUANTUM CHEMISTRY.

The simplest chemical bonds to describe are those resulting from direct coulombic attractions between ions of opposite charge, as in most crystalline salts. These are termed ionic bonds. *See* COULOMB'S LAW; IONIC CRYSTALS; STRUCTURAL CHEMISTRY.

Other chemical bonds include a wide variety of types, ranging from the very weak van der Waals attractions, which bind neon atoms together in solid neon, to metallic bonds or metallike bonds, in which very many electrons are spread over a lattice of positively charged atom cores and give rise to a stable configuration for those cores. *See* CRYSTAL STRUCTURE; INTERMOLECULAR FORCES.

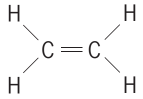
The covalent bond, in which two electrons bind two atoms together, as in



is the most characteristic link in chemistry. The theory that accounts for it is a cornerstone of chemical science. The physical and chemical properties of any molecule are direct consequences of its particular detailed electronic structure. Yet the theory of any one covalent chemical bond, for example, the H—H bond in the hydrogen molecule, has much in common with the theory of any other covalent bond, for example, the O—H bond in the water molecule. The current theory of covalent bonds both treats their qualitative features and quantitatively accounts for the molecular properties which are a consequence of those features. The theory is a branch of quantum theory. *See* NONRELATIVISTIC QUANTUM THEORY; QUANTUM CHEMISTRY.

The problem of the proper description of chemical bonds in molecules that are more complicated than H_2 has many inherent difficulties. The qualitative theory of chemical bonding in complex molecules preserves the use of many chemical concepts that predate quantum chemistry itself; among these are electrostatic and steric factors, tautomerism, and electronegativity. The quantitative theory is highly computational in nature and involves extensive use of computers and supercomputers.

The number of covalent bonds which an atom can form is called the covalence and is determined by the detailed electron configuration of the atom. An extremely important case is that of carbon. In most of its compounds, carbon forms four bonds. When these connect it to four other atoms, the directions of the bonds to these other atoms normally make angles of about 109° to one another, unless the attached atoms are crowded or constrained by other bonds. That is, covalent bonds have preferred directions. However, in accord with the idea that carbon forms four bonds, it is necessary to introduce the notion of double and triple bonds. Thus in the structural formula of ethylene, C_2H_4 (**1**), all lines denote covalent bonds, the double line connecting the carbon atoms being a double bond.



(1)

$H-C\equiv C-H$

(2)

Such double bonds are distinctly shorter, almost twice as stiff, and require considerably more energy to break completely than do single bonds. However, they do not require twice as much energy to break as a single bond. Similarly, acetylene (**2**) is written with a triple bond, which is still shorter than a double bond. A carbon-carbon single bond has a length close to 1.54×10^{-8} cm, whereas the triple bond is about 1.21×10^{-8} cm long. *See* BOND ANGLE AND DISTANCE; VALENCE.

Many substances have some bonds which are covalent and others which are ionic. Thus in crystalline ammonium chloride, NH_4Cl, the hydrogens are bound to nitrogen by electron pairs, but the NH_4 group is a positive ion and the chlorine is a negative ion.

Both electrons of a covalent bond may come from one of the atoms. Such a bond is called a coordinate or dative covalent bond or semipolar double bond, and is one example of the combination of ionic and covalent bonding.

The hydrogen bond is a special bond in which a hydrogen atom links a pair of other atoms. The linked atoms are normally oxygen, fluorine, chlorine, or nitrogen. These four elements are all quite electronegative, a fact which favors a partially ionic interpretation of this kind of bonding. *See* ELECTRONEGATIVITY; HYDROGEN BOND. [R.G.P.]

Chemical conversion A chemical manufacturing process in which chemical transformation takes place, that is, the product differs chemically from the starting materials. Most chemical manufacturing processes consist of a sequence of steps, each of which involves making some sort of change in either chemical makeup, concentration, phase state, energy level, or a combination of these, in the materials passing through the particular step. If the changes are of a strictly physical nature (for example, mixing, distillation, drying, filtration, adsorption, condensation), the step is referred to as a unit operation. If the changes are of a chemical nature, where conversion from one chemical species to another takes place (for example, combustion, polymerization, chlorination, fermentation, reduction, hydrolysis), the step is called a unit process. Some steps involve both, for example, gas absorption with an accompanying chemical reaction in the liquid phase. The term chemical conversion is used not only in describing overall processes involving chemical transformation, but in certain contexts as a synonym for the term unit process. The chemical process industry as a whole has tended to favor the former usage, while the petroleum industry has favored the latter. *See* CHEMICAL PROCESS INDUSTRY; UNIT PROCESSES.

Another usage of the term chemical conversion is to define the percentage of reactants converted to products inside a chemical reactor or unit process. This quantitative usage is expressed as percent conversion per pass, in the case of reactors where unconverted reactants are recovered from the product stream and recycled to the reactor inlet. *See* CHEMICAL ENGINEERING. [W.F.F.]

Chemical dynamics That branch of physical chemistry which seeks to explain time-dependent phenomena, such as energy transfer and chemical reaction, in terms of the detailed motion of the nuclei and electrons which constitute the system.

In principle, it is possible to prepare two reagents in specific quantum states and to determine the quantum-state distribution of the products. In practice, this is very difficult, and experiments have mostly been limited to preparing one reagent or to determining some aspect of the product distribution. This approach yields data concerning the detailed aspects of the dynamics.

Energy distribution. An important question regarding the dynamics of chemical reactions has to do with the product energy distribution in exothermic reactions. For example, because the hydrogen fluoride (HF) molecule is more strongly bound than the H_2 molecule, reaction (1) releases a considerable amount of

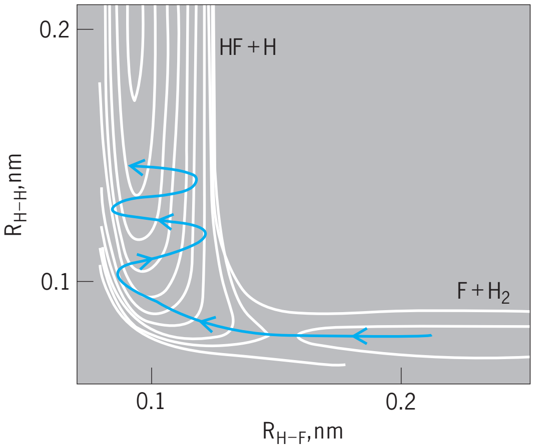
$$F + H_2 \longrightarrow HF + H \qquad (1)$$

energy (more than 30 kcal/mol or 126 kJ/mol). The two possible paths for this energy release to follow are into translations, that is, with HF and H speeding away from each other, or into vibrational motion of HF.

In this case it is vibration, and this has rather dramatic consequences; the reaction creates a population inversion among the vibrational energy levels of HF—that is, the higher vibrational levels have more population than the lower levels—and the emission of infrared light from these excited vibrational levels can be made to form a chemical laser. A number of other reactions also give a population inversion among the vibrational energy levels, and can thus be used to make lasers.

Most effective energy. The rates of most chemical reactions are increased if they are given more energy. In macroscopic kinetics this corresponds to increasing the temperature, and most reactions are faster at higher temperatures. It seems reasonable, though, that some types of energy will be more effective in accelerating the reaction than others. For example, in reaction (2),

$$K + HCl \longrightarrow KCl + H \qquad (2)$$



Contour plot of the potential energy surface for the reaction $F + H_2 = HF + H$, with a typical reactive trajectory indicated.

where potassium (K) reacts with hydrogen chloride (HCl) to form potassium chloride (KCl), studies have shown that if HCl is vibrationally excited (by using a laser), this reaction is found to proceed approximately 100 times faster, while the same amount of energy in translational kinetic energy has a smaller effect. Here, therefore, vibrational energy is much more effective than translational energy in accelerating the reaction.

For reaction (1), however, translational energy is more effective than vibrational energy in accelerating the reaction. The general rule of thumb is that vibrational energy is more effective for endothermic reactions (those for which the new molecule is less stable than the original molecule), while translational energy is most effective for exothermic reactions.

Lasers. Lasers are also important for probing the dynamics of chemical reactions. Because they are light sources with a very narrow wavelength, they are able to excite molecules to specific quantum states (and also to detect what states molecules are in), an example of which is reaction (2). For polyatomic molecules—that is, those with more than two atoms—there is the even more interesting question of how the rate of reaction depends on which vibration is excited.

For example, when the molecule allyl isocyanide, $CH_2{=}CH{-}CH_2{-}NC$, is given sufficient vibrational energy, the isocyanide part (—NC) will rearrange to the cyanide (—CN) configuration. A laser can be used to excite a C-H bond vibrationally. An interesting question is whether the rate of the rearrangement process depends on which C-H bond is excited. Only with a laser is it possible to excite different C-H bonds and begin to answer such questions. This question of mode-specific chemistry—whether excitation of specific modes of a molecule causes specific chemistry to result—has been a subject of great interest. (For the example above, the reaction is fastest if the C-H bond closest to the NC group is excited.) Mode-specific chemistry would allow much greater control over the course of chemical reactions, and it would be possible to accelerate the rate of some reactions (or reactions at one part of a molecule) and not others. *See* LASER.

Theoretical methods. The goal of chemical dynamics is to understand kinetic phenomena from the basic laws of molecular mechanics, and it is thus a field which sees close interplay between experimental and theoretical research. Many different theoretical models and methods have been useful in understanding and analyzing the phenomena described above. Probably the single most useful approach has been the calculation of classical trajectories. Assuming that the potential energy function or a reasonable approximation is known for the three atoms in reaction (1), for example, it is possible by use of electronic computers to calculate the classical motion of the three atoms. It is thus an easy matter to give the initial molecule more or less vibrational or translational energy, and then compute the probability of reaction. Similarly, the final molecule and atom can be studied to see where the energy appears, that is, as translation or as vibration.

It is thus a relatively straightforward matter theoretically to answer the questions and to see whether or not mode-specific excitation leads to significantly different chemistry than simply increasing the temperature under bulk conditions.

The most crucial step in carrying out these calculations is obtaining the potential energy surface—that is, the potential energy as a function of the positions of the atoms—for the system. The illustration shows a plot of the contours of the potential energy surface for reaction (1). Even without carrying out classical trajectory calculations, it is possible to deduce some of the dynamical features of this reaction; for example, the motion of the system first surmounts a small potential barrier, and then it slides down a steep hill, turning the corner at the bottom of the hill. It is evident that such motion will cause much of the energy released in going down the hill to appear in vibrational motion of HF.

This and other theoretical methods have interacted strongly with experimental research in helping to understand the dynamics of chemical reactions. *See* CHEMICAL KINETICS; INORGANIC PHOTOCHEMISTRY. [P.R.B.; W.H.M.]

Chemical ecology The study of ecological interactions mediated by the chemicals that organisms produce. These substances, known as allelochemicals, serve a variety of functions. They influence or regulate interspecific and intraspecific interactions of microorganisms, plants, and animals, and operate within and between all trophic levels—producers, consumers, and decomposers—and in terrestrial, fresh-water, and marine ecosystems.

Function is an important criterion for the classification of allelochemicals. Allelochemicals beneficial to the emitter are called allomones; those beneficial to the recipient are called kairomones. An allomone to one organism can be a kairomone to another. For example, floral scents benefit the plant (allomones) by encouraging pollinators, but also benefit the insect (kairomones) by providing a cue for the location of nectar.

The chemicals involved are diverse in structure and are often of low molecular weight (<10,000). They may be volatile or nonvolatile; water-soluble or fat-soluble. Proteins, polypeptides, and amino acids are also found to play an important role.

Plant allelochemicals are often called secondary compounds or metabolites to distinguish them from those chemicals involved in primary metabolism, although this distinction is not always clear.

Chemical defense in plants. Perhaps to compensate for their immobility, plants have made wide use of chemicals for protection against competitors, pathogens, herbivores, and abiotic stresses. A chemically mediated competitive interaction between higher plants is referred to as allelopathy. Allelopathy appears to occur in many plants, may involve phenolics or terpenoids that are modified in the soil by microorganisms, and is at least partly responsible for the organization of some plant communities. *See* ALLELOPATHY.

Chemicals that are mobilized in response to stress or attack are referred to as active or inducible chemicals, while those that are always present in the plant are referred to as passive or constitutive. In many plants, fungus attack induces the production of defensive compounds called phytoalexins, a diverse chemical group that includes isoflavonoids, terpenoids, polyacetylenes, and furanocoumarins. *See* PHYTOALEXINS.

Defensive chemicals can be induced by herbivore attack. There has been increasing evidence that inducible defenses, such as phenolics, are important in plant-insect interactions.

Constitutive defenses include the chemical hydrogen cyanide. Trefoil, clover, and ferns have been found to exist in two genetically different forms, one containing cyanide (cyanogenic) and one lacking it (acyanogenic); acyanogenic forms are often preferred by several herbivores. *See* ALKALOID; FLAVONOID; PHENOL.

Chemical defenses frequently occur together with certain structures which act as physical defenses, such as spines and hairs. While many chemicals protect plants by deterring herbivore feeding or by direct toxic effects, other defenses may act more indirectly. Chemicals that mimic juvenile hormones, the antijuvenile hormone substances found in some plants, either arrest development or cause premature development in certain susceptible insect species.

Plant chemicals potentially affect not only the herbivores that feed directly on the plant, but also the microorganisms, predators, or parasites of the herbivore. For example, the tomato plant contains an alkaloid, tomatine, that is effective against certain insect herbivores. The tomato hornworm, however, is capable of detoxifying this alkaloid and can thus use the plant successfully—but a wasp parasite of the hornworm cannot detoxify tomatine, and its effectiveness in parasitizing the hornworm is reduced. Therefore, one indirect effect of the chemical in the plant may be to reduce the effectiveness of natural enemies of the plant pest, thereby actually working to the disadvantage of the plant.

Most plant chemicals can affect a wide variety of herbivores and microorganisms, because the modes of action of the chemicals they manufacture are based on a similarity of biochemical reaction in most target organisms (for example, cyanide is toxic to most organisms). In addition, many plant chemicals may serve multiple roles: resins in the creosote bush serve to defend against herbivores and pathogens, conserve water, and protect against ultraviolet radiation.

It is argued that there are two different types of defensive chemicals in plants. The first type occurs in relatively small amounts, is often toxic in small doses, and poisons the herbivore. These compounds may also change in concentration in response to plant damage; that is, they are inducible. These kinds of qualitative defensive compounds are the most common in short-lived or weedy species that are often referred to as unapparent. They are also characteristic of fast-growing species with short-lived leaves. In contrast, the second type of defensive chemicals often occurs in high concentrations, is not very toxic, but may inhibit digestion by herbivores and is not very inducible. These quantitative defenses are most common in long-lived, so-called apparent plants such as trees that have slow growth rates and long-lived leaves. Some plants may use both types of defenses.

There is accumulating evidence that marine plants may be protected against grazing by similar classes of chemicals to those found in terrestrial plants. One interesting difference in the marine environment is the large number of halogenated organic compounds that are rare in terrestrial and fresh-water systems.

Through evolution, as plants accumulate defenses, herbivores that are able to bypass the defense in some way are selected for and leave more offspring than others. This in turn selects for new defenses on the part of the plant in a continuing process called coevolution.

Animals that can exploit many plant taxa are called generalists, while those that are restricted to one or a few taxa are called specialists. Specialists often have particular detoxification mechanisms to deal with specific defenses. Some generalists possess powerful, inducible detoxification enzymes, while others exhibit morphological adaptations of the gut which prevent absorption of compounds such as tannins, or provide reservoirs for microorganisms that accomplish the detoxification. Animals may avoid eating plants, or parts of plants, with toxins.

Some herbivores that have completely surmounted the plant toxin barrier use the toxin itself as a cue to aid in locating plants. The common white butterfly, *Pieris rapae*, for example, uses mustard oil glycosides, which are a deterrent and toxic to many organisms, to find its mustard family hosts.

Chemical defense in animals. Many animals make their own defensive chemicals—such as all of the venoms produced by social insects (bees, wasps, ants), as well as snakes and mites. These venoms are usually proteins, acids or bases, alkaloids, or combinations of chemicals. They are generally injected by biting or stinging, while other defenses are produced as sprays, froths, or droplets from glands.

Animals frequently make the same types of toxins as plants, presumably because their function as protective agents is similar. Other organisms, particularly insects, use plant chemicals to defend themselves. Sequestration may be a low-cost defense mechanism and probably arises when insects specialize on particular plants.

Microbial defenses. Competitive microbial interactions are regulated by many chemical exchanges involving toxins. They include compounds such as aflatoxin, botulinus toxin, odors of rotting food, hallucinogens, and a variety of antibiotics. *See* ANTIBIOTIC; TOXIN.

Microorganisms also play a role in chemical interaction with plants and animals that range from the production of toxins that kill insects, such as those produced by the common biological pest control agent *Bacillus thuringiensis*, to cooperative biochemical detoxification of plant toxins by animal symbionts.

Information exchange. A large area of chemical ecology concerns the isolation and identification of chemicals used for communication. Pheromones, substances produced by an organism that induce a behavioral or physiological response in an individual of the same species, have been studied particularly well in insects. These signals are compounds that are mutually beneficial to the emitter and sender, such as sex attractants, trail markers, and alarm and aggregation signals. Sex pheromones are volatile substances, usually produced by the female to attract males. Each species has a characteristic compound that may differ from that of other species by as little as a few atoms.

Pheromones are typically synthesized directly by the animal and are usually derived from fatty acids. In a few cases the pheromone or its immediate precursors may be derived from plants, as in danaid butterflies.

Very little work has been done in identifying specific pheromones in vertebrates, particularly mammals. It is known, however, that they are important in marking territory, in individual recognition, and in mating and warning signals. Chemical communication may also occur among plants and microorganisms, although it is rarer and less obvious than in animals. *See* REPRODUCTIVE BEHAVIOR; SCENT GLAND; TERRITORIALITY.

[C.G.J.; A.C.L.]

Chemical energy A useful but obsolescent term for the energy available from elements and compounds when they react, as in a combustion reaction. In precise terminology, there is no such thing as chemical energy, since all energy is stored in matter as either kinetic energy or potential energy. *See* COMBUSTION; ENERGY.

When a chemical reaction takes place, the atoms of the reactants change their bonding pattern and become products. The breaking of bonds in the reactants requires energy, and the formation of bonds in the products releases energy. The net change in energy is commonly referred to as chemical energy. To be more precise, when a reaction takes place, there is an overall change in the enthalpy H of the system as bonds are broken and new bonds are formed. This change in enthalpy is denoted ΔH. Under standard conditions [a pressure of 1 bar (100 kilopascals) and all substances pure], the change is noted ΔH° and called the standard enthalpy of reaction. Provided the pressure is constant, the standard enthalpy can be identified with the energy released as heat (when $\Delta H^\circ < 0$) or gained as heat ($\Delta H^\circ > 0$) when the reaction takes place. Reactions for which $\Delta H^\circ < 0$ are classified as exothermic; those for which $\Delta H^\circ > 0$ are classified as endothermic. All combustions are exothermic, the released heat being used either to provide warmth or to raise the temperature of a working fluid in an engine of some kind. There are very few common endothermic reactions; one example is the dissolution of ammonium nitrate in water (a process utilized in medical cold packs). *See* Chemical equilibrium; Chemical thermodynamics; Enthalpy; Thermochemistry.

The "chemical energy" available from a typical fuel (that is, the enthalpy change accompanying the combustion of the fuel, when carbon-hydrogen bonds are replaced by stronger carbon-oxygen and hydrogen-oxygen bonds) is commonly reported as either the specific enthalpy or the enthalpy density. The specific enthalpy is the standard enthalpy of combustion divided by the mass of the reactant. The enthalpy density is the standard enthalpy of combustion divided by the volume of the reactant. The former is of primary concern when mass is an important consideration, as in raising a rocket into orbit. The latter is of primary concern when storage space is a limitation. The specific enthalpy of hydrogen gas is relatively high (142 kilojoules/g), but its enthalpy density is low (13 kJ/L). The values for octane, a compound representative of gasoline, are 48 kJ/g and 38 MJ/L, respectively (note the change in units). The high enthalpy density of octane means that a gasoline tank need not be large to store a lot of "chemical energy." *See* Aircraft fuel; Energy sources; Gasoline; Rocket propulsion. [P.W.A.]

Chemical engineering

The application of engineering principles to conceive, design, develop, operate, or use processes and products based on chemical and physical phenomena. The chemical engineer is considered an engineering generalist because of a unique ability (among engineers) to understand and exploit chemical change. Drawing on the principles of mathematics, physics, and chemistry and familiar with all forms of matter and energy and their manipulation, the chemical engineer is well suited for working in a wide range of technologies.

Although chemical engineering was conceived primarily in England, it underwent its main development in America, propelled at first by the petroleum and heavy-chemical industries, and later by the petrochemical industry with its production of plastics, synthetic rubber, and synthetic fibers from petroleum and natural-gas starting materials. In the early twentieth century, chemical engineering developed the physical separations such as distillation, absorption, and extraction, in which the principles of mass transfer, fluid dynamics, and heat transfer were combined in equipment design. The chemical and physical aspects of chemical engineering are known as unit processes and unit operations, respectively.

Chemical engineering now is applied in biotechnology, energy, environmental, food processing, microelectronics, and pharmaceutical industries, to name a few. In such industries, chemical engineers work in production, research, design, process and product development, marketing, data processing, sales, and, almost invariably, throughout top management. *See* Biochemical engineering; Biomedical chemical engineering; Biotechnology; Chemical conversion; Chemical process industry; Electrochemical process; Food engineering; Unit operations; Unit processes. [W.F.F.]

Chemical equilibrium

In a dynamic or kinetic sense, chemical equilibrium is a condition in which a chemical reaction is occurring at equal rates in its forward and reverse directions, so that the concentrations of the reacting substances do not change with time. In a thermodynamic sense, it is the condition in which there is no tendency for the composition of the system to change; no change can occur in the system without the expenditure of some form of work upon it. From the viewpoint of statistical mechanics, the equilibrium state places the system in a condition of maximum freedom (or minimum restraint) compatible with the energy, volume, and composition of the system. The statistical approach has been merged with thermodynamics into a field called statistical thermodynamics; this merger has been of immense value for its intellectual stimulus, as well as for its practical contributions to the study of equilibria. *See* Chemical thermodynamics; Statistical mechanics.

Of the three viewpoints, the thermodynamic approach is by far the most powerful and fruitful in treating the quantitative relationships between the position of equilibrium and the factors which govern it. Since thermodynamics is concerned with relationships among observable properties, such as temperature, pressure, concentration, heat, and work, the relationships possess general validity, independent of theories of molecular behavior.

Chemical potential. Thermodynamics attributes to each chemical substance a property called the chemical potential, which may be thought of as the tendency of the substance to enter into chemical (or physical) change. Although the chemical potential of a substance cannot be directly measured (except on a relative basis), differences in chemical potential are measurable. (The units are those of energy per mole.)

The importance of the chemical potential lies in its relation to the affinity or driving force of a chemical reaction. Consider general reaction (1). Let μ_A be the chemical potential per mole of

$$a\mathrm{A} + b\mathrm{B} \rightleftharpoons g\mathrm{G} + h\mathrm{H} \tag{1}$$

substance A, μ_B be the chemical potential per mole of B, and so on. Then, according to one of the fundamental principles of thermodynamics (the second law), the reaction will be spontaneous when the total chemical potential of the reactants is greater than that of the products. Thus, for spontaneous change (naturally occurring processes) notation (2) applies When equilibrium is

$$[g\mu_\mathrm{G} + h\mu_\mathrm{H}] - [a\mu_\mathrm{A} + b\mu_\mathrm{B}] < 0 \tag{2}$$

reached, the total chemical potentials of products and reactants become equal; thus Eq. (3) holds at equilibrium. The difference

$$[g\mu_\mathrm{G} + h\mu_\mathrm{H}] - [a\mu_\mathrm{A} + b\mu_\mathrm{B}] = 0 \tag{3}$$

in chemical potentials in Eqs. (2) and (3) is called the driving force or affinity of the process or reaction; naturally, it is zero when the chemical system is in chemical equilibrium.

For reactions at constant temperature and pressure (the usual restraints in a chemical laboratory), the difference in chemical potentials becomes equal to the free energy change ΔG for the process in Eq. (4). The decrease in free energy represents the

$$\Delta G = [g\mu_\mathrm{G} + h\mu_\mathrm{H}] - [a\mu_\mathrm{A} + b\mu_\mathrm{B}] \tag{4}$$

maximum net work obtainable from the process. When no more work is obtainable, the system is at equilibrium. Conversely, if the value of ΔG for a process is positive, some useful work will have to be expended upon the process, or reaction, in order to make it proceed; the process cannot proceed naturally or spontaneously. (The term spontaneously as used here implies only that a process can occur. It does not imply that the reaction will be rapid or instantaneous. Thus, the reaction between hydrogen and oxygen is a spontaneous process in the sense of the term as used here, even though a mixture of hydrogen and oxygen can remain unchanged for years unless ignited or exposed to a catalyst.)

Since by definition a catalyst remains unchanged chemically through a reaction, its chemical potential does not appear in Eqs. (2), (3), and (4). A catalyst, therefore, can contribute nothing to the driving force of a reaction, nor can it, in consequence, alter the position of the chemical equilibrium in a system. *See* Catalysis.

In addition to furnishing a criterion for the equilibrium state of a chemical system, the thermodynamic method goes much further. In many cases, it yields a relation between the change in chemical potentials (or change in free energy) and the equilibrium concentrations of the substances involved in the reaction. To do this, the chemical potential must be expressed as a function of concentration (and other properties of the substance). *See* CONCENTRATION SCALES.

Activity and standard states. It is often convenient to utilize the product fx, called the activity of the substance and defined by $a = fx$. The activity may be looked upon as an effective concentration of the substance, measured in the same units as the concentration x with which it is associated. The standard state of the substance is then defined as the state of unit activity (where $a = 1$) and is characterized by the standard chemical potential μ°. Clearly, the terms μ°, f, and x are not independent; the choice of the activity scale serves to fix the standard state. For example, for an aqueous solution of hydrochloric acid, the standard state for the solute (HCl) would be an (hypothetical) ideal 1 molar (or molal) solution, and for the solvent (H_2O) the standard state would be pure water (mole fraction = 1). The reference state would be an infinitely dilute solution; here the activity coefficients would be unity for both solute and solvent. For the vapor of HCl above the solution, the standard state would be the ideal gaseous state at 1 atm (101.325 kilopascals) partial pressure; the reference state would be a state of zero pressure. (For gases, the term fugacity is used instead of activity.)

It should be noted that the reference state is a limiting state which in many cases can be reached only through an extrapolation from observed behavior. *See* FUGACITY.

Equilibrium constant. If general reaction (1) occurs at constant temperature T and pressure P when all of the substances involved are in their standard states of unit activity, Eq. (4) would become Eq. (5). The quantity ΔG° is known as the standard free

$$\Delta G^\circ = [g\mu^\circ_{\mathrm{G}} + h\mu^\circ_{\mathrm{H}}] - [a\mu^\circ_{\mathrm{A}} + b\mu^\circ_{\mathrm{B}}] \tag{5}$$

energy change for the reaction at that temperature and pressure for the chosen standard states. (Standard state properties are commonly designated by a superscript, ΔG°, μ°.) Since each of the standard chemical potentials (μ°) is a unique property determined by the temperature, pressure, standard state, and chemical identity of the substance concerned, the standard free energy change ΔG° is a constant (parameter) characteristic of the particular reaction for the chosen temperature, pressure, and standard states.

When the system has come to chemical equilibrium at constant temperature and pressure, $\Delta G = 0$, and ΔG° is given by Eq. (6), where the value of K° is shown as Eq. (7), and the activities are

$$\Delta G^\circ = -RT \ln K^\circ \tag{6}$$

$$K^\circ = \left[\frac{a_{\mathrm{G}}{}^{g} a_{\mathrm{H}}{}^{h}}{a_{\mathrm{A}}{}^{a} a_{\mathrm{B}}{}^{b}}\right] \tag{7}$$

the equilibrium values. The ratio of the activities at equilibrium, K°, is called the equilibrium constant or, more precisely, the thermodynamic equilibrium constant. (The terms K° and Q° are written with superscripts to emphasize that they represent ratios of activities.) The equilibrium constant is a characteristic property of the reaction system, since it is determined uniquely in terms of the standard free energy change. The term $-\Delta G^\circ$ represents the maximum net work which the reaction could make available when carried out at constant temperature and pressure with the substances in their standard states.

The kinetic concept of chemical equilibrium introduced by C. M. Guldberg and P. Waage (1864) led to the formulation of the equilibrium constant in terms of concentrations. Although the concept is correct in terms of the dynamic picture of opposing reactions occurring at equal speeds, it has not been successful in coping with the problems of activity coefficients. Conversely, the thermodynamic approach yields no relationship between the driving force of the reaction and the rate of approach to equilibrium. *See* CHEMICAL DYNAMICS.

The influence of temperature upon the chemical potentials, and hence upon the equilibrium constant, is given by the Gibbs-Helmholtz equation, Eq. (8). The derivative on the left

$$\left[\frac{d \ln K^\circ}{dT}\right]_P = \frac{\Delta H^\circ}{RT^2} \tag{8}$$

represents the slope of the curve obtained when values of In K° for a reaction, obtained at different temperatures but always at the same pressure P, are plotted against temperature. The standard heat of reaction ΔH° for the temperature T at which the slope is measured is the heat effect which could also be observed by carrying out the reaction involving the standard states in a calorimeter at the corresponding temperature and pressure. *See* HEAT CAPACITY; THERMOCHEMISTRY.

Homogeneous equilibria. These involve single-phase systems: gaseous, liquid, and solid solutions. In most cases, solid solutions are so far from ideal that equilibrium constants cannot be evaluated, and such systems are treated in terms of the phase rule. A typical gas-phase equilibrium is the ammonia synthesis shown in reaction (9). A typical liquid-phase equilibrium is the dissociation of acetic acid in water, reaction (10).

$$\mathrm{N_2 + 3H_2 \rightleftharpoons 2NH_3} \tag{9}$$

$$\mathrm{HC_2H_3O_2 + H_2O \rightleftharpoons H_2O^+ + C_2H_3O_2{}^-} \tag{10}$$

The solvent appears to be inert, since its chemical potential remains practically unchanged over the useful concentration range. As a result of this apparent inertness of the solvent, it is not possible to determine the extent of hydration of any dissolved species from equilibrium studies. Thus, whether the actual ion is H^+, H_3O^+, or $H_9O_4{}^+$, it is the total stoichiometric concentration that is measured and used. *See* IONIC EQUILIBRIUM.

Heterogeneous equilibria. These are usually studied at constant pressure, since at least one of the phases will be a solid or liquid. The imposed pressure may be that of an equilibrium gaseous phase, or it may be an externally controlled pressure.

In describing such systems, the nature of each phase must be specified. In the following example, the terms *s*, *l*, and *g* identify solid, liquid, and gaseous phases, respectively. For solutions or mixtures, the composition is needed, in addition to the temperature and pressure, to complete the specification of the system. If not obvious, the identity of the solvent must be given.

In the equilibrium shown as reaction (11), the relationship of Eq. (12) holds. Here $K^\circ = p/N$, the ratio of the vapor pressure

$$\mathrm{H_2O}(l) \rightleftharpoons \mathrm{H_2O}(g) \tag{11}$$

$$\Delta G^\circ = \mu^\circ_{\mathrm{g}} - \mu^\circ_{\mathrm{l}} = -RT \ln \frac{p}{N} \tag{12}$$

p to the liquid mole fraction N. For pure water, the equilibrium constant is simply the standard vapor pressure p°, and the Clausius-Clapeyron equation is just a special case of the Gibbs-Helmholtz equation, Eq. (8). Now when a small amount of solute is added, decreasing the mole fraction of solvent, the vapor pressure p must be lowered to maintain equilibrium (Raoult's law). The effect of the total applied pressure P upon the vapor pressure p of the liquid is given by the Gibbs-Poynting equation, Eq. (13). Here V_l and V_g are the molar volumes of liquid and

$$\left[\frac{dp}{dP}\right]_T = \frac{V_l}{V_g} \tag{13}$$

vapor. The vapor pressure will increase as external pressure is applied (activity increases with pressure). If the external pressure is applied to a solution by a semipermeable membrane, an applied pressure can be found which will restore the vapor pressure (or activity) of the solvent to its standard state value. *See* OSMOSIS.

Other heterogeneous equilibria are solubility equilibria, reactions involving two immiscible phases, and reactions involving condensed and immiscible phases. *See* EXTRACTION; SOLUBILITY PRODUCT CONSTANT. [C.E.V.]

Chemical fuel The principal fuels used in internal combustion engines (automobiles, diesel, and turbojet) and in the furnaces of stationary power plants are organic fossil fuels. These fuels, and others derived from them by various refining and separation processes, are found in the earth in the solid (coal), liquid (petroleum), and gas (natural gas) phases.

Special fuels to improve the performance of combustion engines are obtained by synthetic chemical procedures. These special fuels serve to increase the specific impulse of the engine or to increase the heat of combustion available to the engine per unit mass or per unit volume of the fuel. A special fuel which possesses a very high heat of combustion per unit mass is liquid hydrogen. It has been used along with liquid oxygen in rocket engines. Because of its low liquid density, liquid hydrogen is not too useful in systems requiring high heats of combustion per unit volume of fuel (“volume-limited” systems).

A special fuel which produces high flame temperatures of the order of 5000°F (2800°C) is gaseous cyanogen. This is used with gaseous oxygen as the oxidizer. The liquid fuel hydrazine, and other hydrazine-based fuels, with the liquid oxidizer nitrogen tetroxide are used in many space-oriented rocket engines. The boron hydrides, such as diborane and pentaborane, are high-energy fuels which are used in advanced rocket engines.

For air-breathing propulsion engines (turbojets and ramjets), hydrocarbon fuels are most often used. For some applications, metal alkyl fuels which are pyrophoric (that is, ignite spontaneously in the presence of air), and even liquid hydrogen, are being used. *See* METAL-BASE FUEL.

Fuels which liberate heat in the absence of an oxidizer while decomposing either spontaneously or because of the presence of a catalyst are called monopropellants and have been used in rocket engines. Examples of these monopropellants are hydrogen peroxide and nitro-methane.

Liquid fuels and oxidizers are used in most large-thrust rocket engines. When thrust is not a consideration, solid-propellant fuels and oxidizers are frequently employed because of the lack of moving parts such as valves and pumps, and the consequent simplicity of this type of rocket engine. Solid fuels fall into two broad classes, double-base and composites. Double-base fuels are compounded of nitroglycerin (glycerol trinitrate) and nitrocellulose, with no separate oxidizer required. The double-base propellant is generally formed in a mold into the desired shape (called a grain) required for the rocket case. Composite propellants are made of a fuel and an oxidizer. The latter could be an inorganic perchlorate or a nitrate. Fuels for composite propellants are generally the asphalt-oil-type, thermosetting plastics or several types of synthetic rubber and gumlike substances. Metal particles such as boron, aluminum, and beryllium have been added to solid propellants to increase their heats of combustion and to eliminate certain types of combustion instability. *See* HYDROGEN PEROXIDE. [W.Ch.]

Chemical kinetics A branch of physical chemistry that seeks to measure the rates of chemical reactions, describe them in terms of elementary steps, and understand them in terms of the fundamental interactions between molecules.

Reaction kinetics. Although the ultimate state of a chemical system is specified by thermodynamics, the time required to reach that equilibrium state is highly dependent upon the reaction. For example, diamonds are thermodynamically unstable with respect to graphite, but the rate of transformation of diamonds to graphite is negligible. As a consequence, determining the rate of chemical reactions has proved to be important for practical reasons. Rate studies have also yielded fundamental information about the details of the nuclear rearrangements which constitute the chemical reaction.

Traditional chemical kinetic investigations of the reaction between species X and Y to form Z and W, reaction (1), sought a rate of the form given in Eq. (2), where $d[\mathrm{Z}]/dt$ is the rate of

$$\mathrm{X} + \mathrm{Y} \rightarrow \mathrm{Z} + \mathrm{W} \qquad (1)$$

$$d[\mathrm{Z}]/dt = kf([\mathrm{X}], [\mathrm{Y}], [\mathrm{Z}], [\mathrm{W}]) \qquad (2)$$

appearance of product Z, f is some function of concentrations of X, Y, Z, and W which are themselves functions of time, and k is the rate constant. Chemical reactions are incredibly diverse, and often the function f is quite complicated, even for seemingly simple reactions such as that in which hydrogen and bromine combine directly to form hydrogen bromide (HBr). This is an example of a complex reaction which proceeds through a sequence of simpler reactions, called elementary reactions. For reaction (3*d*), the sequence of elementary reactions is a chain mechanism known to involve a series of steps, reactions (3*a*)–(3*c*).

$$\mathrm{Br_2} \rightarrow 2\mathrm{Br} \qquad (3a)$$

$$\mathrm{Br} + \mathrm{H_2} \rightarrow \mathrm{HBr} + \mathrm{H} \qquad (3b)$$

$$\mathrm{H} + \mathrm{Br_2} \rightarrow \mathrm{HBr} + \mathrm{Br} \qquad (3c)$$

$$\mathrm{H_2} + \mathrm{Br_2} \rightarrow 2\mathrm{HBr} \qquad (3d)$$

This sequence of elementary reactions was formerly known as the reaction mechanism, but in the chemical dynamical sense the word mechanism is reserved to mean the detailed motion of the nuclei during a collision.

An elementary reaction is considered to occur exactly as written. Reaction (3*b*) is assumed to occur when a bromine atom hits a hydrogen molecule. The products of the collision are a hydrogen bromide molecule and a hydrogen atom. On the other hand, the overall reaction is a sequence of these elementary steps and on a molecular basis does not occur as reaction (3*d*) is written. With few exceptions, the rate law for an elementary reaction A + B → C + D is given by $d[\mathrm{C}]/dt = k[\mathrm{A}][\mathrm{B}]$. The order (sum of the exponents of the concentrations) is two, which is expected if the reaction is bimolecular (requires only species A to collide with species B). The rate constant k for such a reaction depends very strongly on temperature, and is usually expressed as $k = Z_{\mathrm{AB}}\rho\, \exp(-E_a/RT)$. Z_{AB} is the frequency of collision between A and B calculated from molecular diameters and temperature; ρ is an empirically determined steric factor which arises because only collisions with the proper orientation of reagents will be effective; and E_a, the experimentally determined activation energy, apparently reflects the need to overcome repulsive forces before the reagents can get close enough to react.

In some instances, especially for decompositions, AB → A + B, the elementary reaction step is first-order, Eq. (4), which

$$d[\mathrm{A}]/dt = d[\mathrm{B}]/dt = k[\mathrm{AB}] \qquad (4)$$

means that the reaction is unimolecular. The species AB does not spontaneously dissociate; it must first be given some critical amount of energy, usually through collisions, to form an excited species AB^*. It is the species AB^* which decomposes unimolecularly. [P.R.B.]

Relaxation methods. Considerable use has been made of perturbation techniques to measure rates and determine mechanisms of rapid chemical reactions. These methods provide measurements of chemical reaction rates by displacing equilibria. In situations where the reaction of interest occurs in a system at equilibrium, perturbation techniques called relaxation methods have been found most effective for determining reaction rate constants.

A chemical system at equilibrium is one in which the rate of a forward reaction is exactly balanced by the rate of the corresponding back reaction. Examples are chemical reactions occurring in liquid solutions, such as the familiar equilibrium in pure water, shown in reaction (5). The molar equilibrium

$$H_2O \underset{k_b}{\rightleftharpoons} H^+(aq) + OH^-(aq) \qquad (5)$$

constant at 25°C (77°F) is given by Eq. (6), where bracketed quantities indicate molar concentrations. It arises naturally from the equality of forward and backward reaction rates, Eq. (7). Here k_f and k_b are the respective rate constants that depend on temperature but not concentrations. Furthermore, the combination of Eqs. (6) and (7) gives rise to Eq. (8). Thus

$$K_{eq} = \frac{[H^+][OH^-]}{[H_2O]} = \frac{10^{-14}}{55.5} = 1.8 \times 10^{-16} \qquad (6)$$

$$k_f[H_2O] = k_b[H^+][OH^-] \qquad (7)$$

$$K_{eq} = k_f/k_b = 1.8 \times 10^{-16} \qquad (8)$$

a reasonable question might be what the numerical values of k_f in units of s^{-1} and k_h in units of $dm^3\ mol^{-1}\ s^{-1}$ must be to satisfy Eqs. (6) through (8) in water at room temperature. Stated another way, when a liter of 1 M hydrochloric acid is poured into a liter of 1 M sodium hydroxide (with considerable hazardous sputtering), how rapidly do the hydronium ions, $H^+(aq)$, react with hydroxide ions, $OH^-(aq)$, to produce a warm 0.5 M aqueous solution of sodium chloride? In the early 1950s it was asserted that such a reaction is instantaneous. Turbulent mixing techniques were (and still are) insufficiently fast (mixing time of the order of 1 ms) for this particular reaction to occur outside the mixing chamber. The relaxation techniques were conceived by M. Eigen, who accepted the implied challenge of measuring the rates of seemingly immeasurably fast reactions.

The essence of any of the relaxation methods is the perturbation of a chemical equilibrium (by a small change in temperature, pressure, electric-field intensity, or solvent composition) in so sudden a fashion that the chemical system, in seeking to reachieve equilibrium, is forced by the comparative slowness of the chemical reactions to lag behind the perturbation. [E.M.Ey.]

Gas-phase reactions. The rates of thermal gas-phase chemical reactions are important in understanding processes such as combustion and atmospheric chemistry.

Chemical conversion of one stable, gas-phase molecule into another is an apparently simple process; yet it is highly unlikely to occur in just a single step, but as a web of sequential and parallel reactions involving many species. The oxidation of methane (CH_4) to carbon dioxide (CO_2) and water provides an excellent example. It occurs in combustion (for example, in burning natural gas, which is mostly methane) as well as in the atmosphere. In both cases, the net process may be written down as single reaction (9).

$$CH_4 + 2O_2 \rightarrow 2H_2O + CO_2 \qquad (9)$$

The reaction does not, however, result from collision of two oxygen (O_2) molecules with one methane molecule. Rather, it involves many separate steps.

All elementary reactions fundamentally require a collision between two molecules. Even in the case of a unimolecular reaction, in which a single molecule breaks apart or isomerizes to another form, the energy required for the process comes from collision with other molecules. The species involved in many gas-phase elementary reactions are free radicals, molecules that have one or more unpaired electrons. Such species tend to be highly reactive, and they are responsible for carrying out most gas-phase chemistry.

A reaction rate is the rate at which the concentration of one of the reactants or products changes with time. The objective of a kinetics experiment is not to measure the reaction rate itself but to measure the rate coefficient, an intrinsic property of the reaction that relates the reactant concentrations to their time rates of change. For example, the mathematical expression for the rate of a biomolecular reaction, A + B → products, is differential equation (10). The square brackets denote the concentrations

$$-d[A]/dt = -d[B]/dt = k[A][B] \qquad (10)$$

of A and B, and k is the rate coefficient described above. The dependence of the rate expression on reactant concentrations is determined experimentally, and it also arises from a fundamental tenet of chemistry known as the law of mass action. Once the rate constant is known, the rate of a reaction can be computed for any given set of concentrations.

Rate constants usually change with temperature because of the change in the mean energy of colliding molecules. The temperature dependence often follows an Arrhenius expression, $k = A\exp(-E_A/RT)$, where A is a preexponential factor that is related to the gas-phase collision rate, R is the universal gas constant, and T is the absolute temperature (in kelvins). The key quantity is the activation energy, E_A, the amount of energy required to induce a reaction. Pressure dependences are usually important only for association reactions, A + B → AB, since collision of A with B will form an energized complex, AB^*, that will simply redissociate unless a subsequent collision carries away enough energy to stabilize the AB product. The probability of a stabilizing collision increases with the collision frequency and thus the total pressure.

In the simple case of a unimolecular reaction, A → P, the rate expression is Eq. (11). Equation (11) is first-order since the rate

$$-d[A]/dt = d[P]/dt = k[A] \qquad (11)$$

is proportional to the reactant concentration to the first power, and it leads to an expression for the change in the concentration of A or P with time (called an integrated rate expression), as in Eqs. (12). The subscripts denote the concentrations at zero time

$$[A]_t = [A]_0 \exp(-kt) \qquad (12a)$$

$$[P]_t = [A]_0\{1 - \exp(-kt)\} \qquad (12b)$$

(initial concentration) and an arbitrary time t. The concentration of A decreases (because it is reacting away) as a function of time, while the concentration of P increases with time such that the sum of the concentrations of A and P is always constant and equal to the initial concentration of A. Because first-order reactions are mathematically simple, kineticists try to reduce all studied reactions (if at all possible) to this form. A second-order reaction, for example A + B → products, has the rate expression given in Eq. (10). To reduce the second-order expression to the first-order expression, Eq. (11), one chooses one of the concentrations to be in large excess, for example $[B] \gg [A]$. The concentration of B is then approximately constant during the course of the reaction, and it may be combined with the rate constant to give an expression identical to Eq. (11) that depends on the concentration of A alone. [A.R.Ra.; S.S.B.]

Chemical microscopy A scientific discipline in which microscopes are used to solve chemical problems. The unique ability to form a visual image of a specimen, to select a small volume of the specimen, and to perform a chemical or structural analysis on the material in the selected volume makes chemical microscopy indispensable to modern chemical analysis. *See* ANALYTICAL CHEMISTRY; MICROSCOPE.

Microscopes can be combined with most analytical instruments. For example, a light microscope can be combined with a spectroscope, making it possible to determine the molecular composition of microscopic objects or structures. Similarly, an x-ray spectrometer can be combined with an electron microscope to determine the elemental composition of small objects. *See* ELECTRON MICROSCOPE; SPECTROSCOPY; X-RAY SPECTROMETRY.

Phase analyses can also be made microscopically. The boundaries of amorphous phases can usually be distinguished in the microscope, and an elemental or physical analysis can be used to identify the phase. An example of a physical analysis is the measurement of refractive index. Crystalline phases are even more amenable to microscopical analysis. For example, a polarizing microscope can be used to measure the optical properties of a crystalline phase and thus identify it. Or a transmission electron microscope can be used to select a tiny area of a crystalline phase and identify the crystal structure by means of electron diffraction. *See* Electron diffraction.

The minimum volume that can be analyzed varies widely with the instrument used. Light microscopes can be used to identify particles as small as 1 micrometer in diameter and weighing about 1 picogram. A field ion microscope has been combined with a mass spectrometer and used to identify single atoms extracted from the surface of a specimen. *See* Field-emission microscopy; Mass spectrometry; Optical microscope.

After a portion of a specimen has been selected microscopically, it can be analyzed in many ways. An experienced microscopist may learn to recognize various structures by studying known materials, using published atlases, or an atlas that the individual microscopist has constructed. If the object or structure cannot be recognized, many means of analysis are available. For example, a polarizing microscope may be employed to identify the object by using optical crystallographic methods. Other light microscopes useful for chemical analysis include phase-contrast and interference-contrast microscopes, microspectrophotometers, the confocal scanning laser microscope, and the laser Raman microscope. Physicochemical methods may be used to measure melting points, or mixed-melt phenomena and dispersion staining may also be used. *See* Interference microscope; Laser spectroscopy; Phase-contrast microscope; Raman effect.

Microscopes using other types of image-forming beams serve for chemical analysis. Scanning or transmission electron microscopes are powerful tools for chemical microscopy. Scanning electron microscopes are often fitted with x-ray spectrometers which are capable of both qualitative and quantitative analysis for most of the elements. Other electron microscopes capable of chemical analysis are the Auger electron microscope, field electron microscope, scanning tunneling microscope, and cathodoluminescence microscope. Microscopes which use ion beams, neutron beams, and x-ray beams also have analytical capabilities. *See* Auger effect; Auger electron spectroscopy; Neutron spectrometry; Scanning electron microscope; X-ray microscope. [G.C.]

Chemical process industry An industry, abbreviated CPI, in which the raw materials undergo chemical conversion during their processing into finished products, as well as (or instead of) the physical conversions common to industry in general. In the chemical process industry the products differ chemically from the raw materials as a result of undergoing one or more chemical reactions during the manufacturing process. The chemical process industries broadly include the traditional chemical industries, both organic and inorganic; the petroleum industry; the petrochemical industry, which produces the majority of plastics, synthetic fibers, and synthetic rubber from petroleum and natural-gas raw materials; and a series of allied industries in which chemical processing plays a substantial part. While the chemical process industries are primarily the realm of the chemical engineer and the chemist, they also involve a wide range of other scientific, engineering, and economic specialists.

For a discussion of the more prominent chemical process industries, *see* Adhesive; Biochemical engineering; Biomedical chemical engineering; Cement; Ceramics; Coal chemicals; Coal liquefaction; Dyeing; Electrochemical process; Explosive; Fat and oil; Fermentation; Fertilizer; Fuel gas; Glass; Graphite; Hydrocracking; Insecticide; Lime (industry); Nuclear chemical engineering; Paper; Petrochemical; Petroleum processing and refining; Petroleum products; Plastics processing; Polymer; Radioactive waste management; Rubber; Water softening. [W.F.F.]

Chemical reactor A vessel in which chemical reactions take place. A combination of vessels is known as a chemical reactor network. Chemical reactors have diverse sizes, shapes, and modes and conditions of operation based on the nature of the reaction system and its behavior as a function of temperature, pressure, catalyst properties, and other factors.

Laboratory chemical reactors are used to obtain reaction characteristics. Therefore, the shape and mode of operation of a reactor on this scale differ markedly from that of the large-scale industrial reactor, which is designed for efficient production rather than for gathering information. Laboratory reactors are best designed to achieve well-defined conditions of concentrations and temperature so that a reaction model can be developed which will prove useful in the design of a large-scale reactor model.

Chemical reactions may occur in the presence of a single phase (liquid or gas), in which case they are called homogeneous, or they may occur in the presence of more than one phase and are referred to as heterogeneous. In addition, chemical reactions may be catalyzed. Examples of homogeneous reactions are gaseous fuel combustion (gas phase) and acid-base neutralization (liquid phase). Examples of heterogeneous systems are carbon dioxide absorption into alkali (gas-liquid); coal combustion and automobile exhaust purification (gas-solid); water softening (liquid-solid); coal liquefaction and oil hydrogenation (gas-liquid-solid); and cake reduction of iron ore (solid-solid).

Chemical reactors may be operated in batch, semibatch, or continuous modes. When a reactor is operated in a batch mode, the reactants are charged, and the vessel is closed and brought to the desired temperature and pressure. These conditions are maintained for the time needed to achieve the desired conversion and selectivity, that is, the required quantity and quality of product. At the end of the reaction cycle, the entire mass is discharged and another cycle is begun. Batch operation is labor-intensive and therefore is commonly used only in industries involved in limited production of fine chemicals, such as pharmaceuticals. In a semibatch reactor operation, one or more reactants are in the batch mode, while the coreactant is fed and withdrawn continuously. In a chemical reactor designed for continuous operation, there is continuous addition to, and withdrawal of reactants and products from, the reactor system.

There are a number of different types of reactors designed for gas-solid heterogeneous reactions. These include fixed beds, tubular catalytic wall reactors, and fluid beds. Many different types of gas-liquid-solid reactors have been developed for specific reaction conditions. The three-phase trickle-bed reactor employs a fixed bed of solid catalyst over which a liquid phase trickles downward in the presence of a cocurrent gas phase. An alternative is the slurry reactor, a vessel within which coreactant gas is dispersed into a liquid phase bearing suspended catalyst or coreactant solid particles. At high ratios of reactor to diameter, the gas-liquid-solid reactor is often termed an ebulating-bed (high solids concentration) or bubble column reactor (low solids concentration). Gas-liquid reactors assume a form virtually identical to the absorbers utilized in physical absorption processes. Solid-solid reactions are often conducted in rotary kilns which provide the necessary intimacy of contact between the solid coreactants. *See* Gas absorption operations; Kiln. [J.J.Ca.]

Chemical senses In vertebrates, the senses of smell (olfaction) and taste (gustation) plus the so-called common chemical sense constitute the external chemical senses (as contrasted with internal chemoreceptors). The olfactory cells of vertebrates, usually located in the olfactory mucosa of the upper nasal passages, are specialized neural elements that are responsive to chemicals in the vapor phase. Taste buds of the oral cavity, especially the tongue, are composed of modified epithelial cells responsive to chemicals in solution. The common chemical senses are composed of free nerve endings in the mucous membrane of the eye, nose, mouth, and digestive tract and are responsive to irritants or other chemicals in either the vapor or liquid phase. *See* CHEMORECEPTION.

Among invertebrates, sense organs occur as specialized hairs and sensilla, or minute cones supplied with sensory nerves and nerve cells. Characteristic of male moths, for example, are their distinctive bushy antennae, by which they detect and locate females by sex pheromones. Rodents, ungulates, carnivores, and other mammals also show sexual attraction to female odors produced by specialized glands. Whether humans in general are susceptible to pheromonal influences from other humans is debatable. *See* PHEROMONE.

Taste plays an important role in selection and acceptance of food. Besides the protective, inborn aversion to bitter (many poisons, but not all, are bitter), a single experience with the particular taste of a toxic substance which caused illness may establish a strong and persistent learned taste aversion. By contrast, a compensatory salt hunger may occur in persons or animals suffering salt deficiency. *See* SALT (FOOD).

The limbic system of the brain, which modulates appetitive and emotional behavior and hedonic (pleasant vs. unpleasant) experiences, has both taste and olfactory neural pathways to it, providing the neural substrate for the pleasure or displeasure of sensations. *See* NEUROBIOLOGY; OLFACTION; SENSATION; TASTE.

[C.P.]

Chemical separation techniques Methods used in chemistry to purify substances or to isolate them from other substances, for either preparative or analytical purposes. In industrial applications the ultimate goal is the isolation of a product of given purity, whereas in analysis the primary goal is the determination of the amount or concentration of that substance in a sample. There are three factors of importance to be considered in all separations: (1) the completeness of recovery of the substance being isolated, (2) the extent of separation from associated substances, and (3) the efficiency of the separation.

There are many types of separations based on a variety of properties of materials. Among the most commonly used properties are those involving solubility, volatility, adsorption, and electrical and magnetic effects, although others have been used to advantage. The most efficient separation will obviously be obtained under conditions for which the differences in properties between two substances undergoing separation are at a maximum.

The common aspect of all separation methods is the need for two phases. The desired substance will partition or distribute between the two phases in a definite manner, and the separation is completed by physically separating the two phases. The ratio of the concentrations of a substance in the two phases is called its partition or distribution coefficient. If two substances have very similar distribution coefficients, many successive steps may be required for a separation. The resulting process is called a fractionation.

Based on the nature of the second phase, the more commonly used methods of separation are classified as follows:

1. Methods involving a solid second phase include precipitation, electrodeposition, chromatography (adsorption), ion exchange, and crystallization.
2. The outstanding method involving a liquid second phase is solvent extraction, in which the original solution is placed in contact with another liquid phase immiscible with the first.
3. Methods involving a gaseous second phase include gas evolution, distillation, sublimation, and gas chromatography. Mixtures of volatile substances can often be separated by fractional distillation. *See* EXTRACTION.

[G.H.Mo.]

Chemical symbols and formulas A system of symbols and notation for the chemical elements and the combinations of these elements which form numerous chemical compounds. This system consists of letters, numerals, and marks that are designed to denote the chemical element, formula, or structure of the molecule or compound. These symbols give a concise and instantly recognizable description of the element or compound. In many cases, through the efforts of international conferences, the symbols are recognized throughout the scientific world, and they greatly simplify the universal language of chemistry.

Elements. At the present time, 109 chemical elements have been given symbols, usually derived from the name of the element. Examples of names and symbols are chlorine, Cl; fluorine, F; beryllium, Be; aluminum, Al; oxygen, O; and carbon, C. However, symbols for some elements are derived from Latin or other names for the element. Examples are Au, gold (from *aurum*); Fe, iron (from *ferrum*); Pb, lead (from *plumbum*); Na, sodium (from *natrium*); and K, potassium (from *kalium*). The symbols consist of one or, more commonly, two letters. The first letter is a capital, followed by a lowercase letter.

Inorganic molecules and compounds. Simple diatomic molecules of a single element are designated by the element symbol with a subscript 2, indicating that the molecule contains two atoms. Thus the hydrogen molecule is H_2; the nitrogen molecule, N_2; and the oxygen molecule, O_2. Polyatomic molecules of a single element are designated by the element symbol with a subscript corresponding to the number of atoms in the molecule. Examples are the phosphorus molecule, P_4; the sulfur molecule, S_8; and the arsenic molecule, As_4.

Diatomic covalent molecules containing unlike elements are given a similar designation. The formula for hydrogen chloride is HCl; for iodine monochloride, ICl; and for hydrogen iodide, HI. The more electropositive element is always designated first in the formula.

For polyatomic covalent molecules containing unlike elements, subscripts designate the number of atoms of each element that are present in the molecule. Examples are arsine, AsH_3; ammonia, NH_3; and water, H_2O. Again, the more electropositive element is placed first in the formula.

Ionic inorganic compounds are designated by a similar notation. The positive ion is given first in the formula, followed by the negative ion; subscripts denote the number of ions of each element present in the compound. The formulas for several common compounds are sodium chloride, NaCl; ammonium nitrate, NH_4NO_3; and aluminum sulfate, $Al_2(SO_4)_3$.

More complex inorganic compounds are designated in a similar manner. The positive ion is given first, but may contain attached or coordinated groups, and this is followed by the negative ion. Examples are hexammine-cobalt(III) chloride, $[Co(NH_3)_6]Cl_3$; and potassium trioxalatoferrate(III), $K_3[Fe(C_2O4)_3]$. Hydrates of inorganic compounds, such as copper(II) sulfate pentahydrate, are designated by the formula of the compound followed by the formula for water, the number of water molecules being designated by a prefix. Thus the symbol for the last compound is $CuSO_4 \cdot 5H_2O$.

Organic compounds. Because there are many more organic than inorganic compounds, the designation or notation for the organic group becomes complex. Many different types of organic compounds are known; in the case of hydrocarbons, there are aromatic and aliphatic, saturated and unsaturated, cyclic and polycyclic, and so on. The system of notation must distinguish between the various hydrocarbons themselves as well as setting this group of compounds apart from others such as alcohols, ethers, amines, esters, and phenols. *See* CHEMISTRY; COORDINATION COMPLEXES; INORGANIC CHEMISTRY; ORGANIC CHEMISTRY.

[W.W.We.]

Chemical thermodynamics The application of thermodynamic principles to systems involving physical and chemical transformations in order to (1) develop quantitative relationships among the identifiable forms of energy and their conjugate variables, (2) establish the criteria for spontaneous change, for equilibrium, and for thermodynamic stability, and (3) provide the macroscopic base for the statistical-mechanical bridge to atomic and molecular properties. The thermodynamic principles applied are the conservation of energy as embodied in the first law of thermodynamics, the principle of internal entropy production as embodied in the second law of thermodynamics, and the principle of absolute entropy and its statistical thermodynamic formulation as embodied in the third law of thermodynamics.

The basic goal of thermodynamics is to provide a description of a system of interest in order to investigate the nature and extent of changes in the state of that system as it undergoes spontaneous change toward equilibrium and interacts with its surroundings. This goal implicitly carries with it the concept that there are measurable properties of the system which can be used to adequately describe the state of the system and that the system is enclosed by a boundary or wall which separates the system and its surroundings. Properties that define the state of the system can be classified as extensive and intensive properties. Extensive properties are dependent upon the mass of the system, whereas intensive properties are not. Typical extensive properties are the energy, volume, and numbers of moles of each component in the system, while typical intensive properties are temperature, pressure, density, and the mole fractions or concentrations of the components.

The concept of a boundary enclosing the system and separating it from the surroundings requires specification of the nature of the boundary and of any constraints the boundary places upon the interaction of the system and its surroundings. Boundaries that restrain a system to a particular value of an extensive property are said to be restrictive with respect to that property. A boundary which restrains the system to a given volume is a fixed wall. A boundary which is restrictive to one component of a system but not to the other components is a semipermeable wall or membrane. A system whose boundaries are restrictive to energy and to mass or moles of components is said to be an isolated system. A system whose boundaries are restrictive only to mass or moles of components is a closed system, whereas an open system has nonrestrictive walls and hence can exchange energy, volume, and mass with its surroundings. Boundaries can be restrictive with respect to specific forms of energy, and two important types are those restrictive to thermal energy but not work (adiabatic walls) and those restrictive to work but not thermal energy (diathermal walls).

Changes in the state of the system can result from processes taking place within the system and from processes involving exchange of mass or energy with the surroundings. After a process is carried out, if it is possible to restore both the system and the surroundings to their original states, the process is said to be reversible; otherwise the process is irreversible. All naturally occurring spontaneous processes are irreversible. The first law defines the internal energy as a state function or property of the state of a system, and restricts the system and its surroundings to those processes which conserve energy. The second law establishes which of the permissible processes can occur spontaneously.

According to the first law of thermodynamics, the total energy E of a system is the sum of its kinetic energy T, its potential energy V, and its internal energy U, Eq. (1). If a system has

$$E = T + V + U \tag{1}$$

constant mass and its center of mass is moving with uniform velocity in a uniform potential, then changes in the total energy of the system δE are equal to changes in its internal energy δU. Chemical thermodynamics concentrates on the internal energy of the system, but kinetic and potential energy changes of the system as a whole can be important for chemical systems. The principle of conservation of energy requires that the change in the internal energy of a system be the result of energy transfer between the system and its surroundings. The internal energy U is a function of the set of extensive variables associated with the various forms of internal energy. Each form of internal energy is manifest by the product of an extensive variable and its conjugate intensive variable.

Thermal energy exchange or heat (that form of energy transferred as a result of temperature differences between a system and its surroundings) plays a central role in thermodynamics, and is singled out from the other forms of energy or work. This is expressed by Eq. (2), where δq is the differential thermal energy

$$dU = \delta q + \delta \omega \tag{2}$$

(heat) absorbed by the system from the surroundings and $\delta \omega$ is the differential work performed on the system by the surroundings. It is convenient to write Eqs. (3), where T is temperature, S

$$\delta q = T dS - \delta a \tag{3a}$$

$$dU = T dS + \delta \omega - \delta a \tag{3b}$$

is the entropy, and $(-\delta a)$ is a sum of the nonthermal differential work terms. The term δa can be either zero or nonzero. If it is zero, the heat absorbed by the system is equal to TdS. In an adiabatic process δq is zero and $TdS - \delta a$, and hence if δa is nonzero, it must correspond to an internally generated thermal energy. This is frequently referred to as the uncompensated heat of a process, since it does not result from the transfer of heat from the surroundings. *See* HEAT.

The heat capacity of a system is of particular importance in such thermochemical calculations. The heat capacity is the amount of thermal energy that can be absorbed by a system for a unit rise in temperature. This is defined by Eq. (4), where

$$\delta q = C_{\text{process}} dT \tag{4}$$

C_{process} is the heat capacity of a system for a given type of process. *See* HEAT CAPACITY.

There are many possible and essentially equivalent statements of the second law of thermodynamics. It will suffice to state the empirical result that in all spontaneous processes the uncompensated heat δa in Eqs. (3) is always positive. Equation (3a) can be rewritten as Eq. (5), where the term $\delta q/T$ is the contribution to the

$$dS = \delta q/T + \delta a/T \tag{5}$$

entropy due to heat exchange with the surrounding (d_eS), while $\delta a/T$ is the contribution to the entropy produced as a result of the interconversion of work terms (d_iS). The second law can then be summarized as Eqs. (6), where d_iS greater than zero applies

$$dS = d_eS + d_iS \tag{6a}$$

$$d_iS \geq 0 \tag{6b}$$

to irreversible process. When $d_iS = 0$, that is, for a reversible process, Eq. (7) holds. This is the basic equation for establishing

$$dS = \delta q_{\text{rev}}/T \tag{7}$$

the thermodynamic temperature scale based upon the theoretical limits of reversible cycles. The requirement that $d_iS > 0$ for spontaneous processes provides the criteria for examining the specific conditions for spontaneous paths, and the criteria for establishing the equilibrium state of a system. *See* CARNOT CYCLE; TEMPERATURE.

Many chemical systems can be considered closed systems in which a single parameter ξ can be defined as a measure of the extent of the reaction or the degree of achievement of a process. If the reaction proceeds or the process advances spontaneously, entropy must be produced according to the second law and δa must be positive. In terms of the advancement parameter ξ, this uncompensated heat δa can be given by Eq. (8), where $\underline{A}$ is the

$$\delta a = \underline{A}\,d\xi = T d_i S \tag{8}$$

affinity of the process or reaction. The affinity is related to internal entropy production by Eq. (9). The condition that the entropy

$$\underline{A} = T d_i S/d\xi \geq 0 \tag{9}$$

production is zero represents equilibrium, and hence $\underline{A} = 0$ is an equivalent condition for equilibrium in a closed system. For spontaneous processes, since the signs of A and $d\xi$ must be the same, for positive $\underline{A}$ the process must advance or go in a forward direction in the usual sense of chemical reactions or physical processes, while for negative $\underline{A}$ the process must proceed in the reverse direction.

The affinity of a chemical reaction establishes the spontaneous direction of the reaction, and consequently methods for determining the affinity are important in thermochemical studies. The affinity is simply related to the stoichiometric coefficients of the reaction and the chemical potentials of the reactants and products in the reaction.

Classical equilibrium thermodynamics is primarily concerned with calculations for reversible processes, and deals with irreversibility in terms of inequalities. In the case of irreversible processes in systems slightly removed from equilibrium, the rate of internal entropy production d_iS/dt is related to the fluxes J_i associated with thermal, concentration, or other differences in intensive parameters or potentials X_i. This entropy production is then given by Eq. (10). The fluxes include heat conduction, diffusion, electric conduction, and other direct effects.

$$d_i S/dt = \sum_i J_i X_i \geq 0 \tag{10}$$

In addition, a flux of one type may be coupled to a potential difference of another type. For example, a thermal gradient can result in a mass flux (thermal diffusion), or a concentration gradient in any energy flux. Thermal conductivity, thermoosmosis, and thermoelectric effects are all coupled effects.

Far removed from equilibrium, thermodynamics must be formulated somewhat differently and more cautiously. The interplay of thermodynamic stability and kinetics can give rise to macroscopic structures with both temporal and spatial coherence called dissipative structures. Much theoretical effort is being directed to these studies because of their apparent relevance to biological structures, but it is still too early to assess how far-reaching these theories will be in the future. *See* Thermodynamic principles; Thermodynamic processes. [R.A.Pi.]

Chemiluminescence The type of luminescence wherein a chemical reaction supplies the energy responsible for the emission of light (ultraviolet, visible, or infrared) in excess of that of a blackbody (thermal radiation) at the same temperature and within the same spectral range. Below 900°F (500°C), the emission of any light during a chemical reaction is a chemiluminescence. The blue inner cone of a bunsen burner or the Coleman gas lamp are examples. *See* Blackbody.

Many chemical reactions generate energy. Usually this exothermicity appears as heat, that is, translational, rotational, and vibrational energy of the product molecules; whereas, for a visible chemiluminescence to occur, one of the reaction products must be generated in an excited electronic state (designated by an asterisk) from which it can undergo deactivation by emission of a photon. Hence a chemiluminescent reaction, as shown in reactions (1) and (2), can be regarded as the reverse of a photochemical reaction.

$$\mathrm{A} + \mathrm{B} \rightarrow \mathrm{C}^* + \mathrm{D} \tag{1}$$

$$\mathrm{C}^* \rightarrow \mathrm{C} + h\nu \tag{2}$$

The energy of the light quantum $h\nu$ (where h is Planck's constant, and ν is the light frequency) depends on the separation between the ground and the first excited electronic state of C; and the spectrum of the chemiluminescence usually matches the fluorescence spectrum of the emitter. Occasionally, the reaction involves an additional step, the transfer of electronic energy from C* to another molecule, not necessarily otherwise involved in the reaction. Sometimes no discrete excited state can be specified, in which case the chemiluminescence spectrum is a structureless continuum associated with the formation of a molecule, as in the so-called air afterglow: $\mathrm{NO} + \mathrm{O} \rightarrow \mathrm{NO_2} + h\nu$ (green light). *See* Heat radiation; Luminescence; Photochemistry.

Only very exothermic, or "exergonic," chemical processes can be expected to be chemiluminescent. Partly for this reason, most familiar examples of chemiluminescence involve oxygen and oxidation processes; the most efficient examples of these are the enzyme-mediated bioluminescences. *See* Bioluminescence. [T.Wi.]

Electrogenerated chemiluminescence, also known as electrochemiluminescence, is a luminescent chemical reaction in which the reactants are formed electrochemically. Electrochemical reactions are electron-transfer reactions occurring in an electrochemical cell. In such a reaction, light emission may occur as with chemiluminescence; however, the excitation is from the application of a voltage to an electrode. In chemiluminescence, the luminophore is excited to a higher energetic state by means of a chemical reaction initiated by mixing of the reagents. In electrogenerated chemiluminescence, the emitting luminophore is excited to a higher energy state by reactions of species that are generated at an electrode surface by the passage of current through the working electrode. Upon decay to the electronic ground state, light emitted by the luminophore (fluorescent or phosphorescent) can be detected. The luminophore is typically a polycyclic hydrocarbon, an aromatic heterocycle, or certain transition-metal chelates. *See* Electron-transfer reaction.

Chief among the developments since the early research and discovery of electrogenerated chemiluminescence was the construction of instrumentation for detection of electrogenerated chemiluminescence. These instruments made it possible for the methodology to be used by practitioners other than electrochemists.

Measurement of the light intensity of electrogenerated chemiluminescence is very sensitive and is proportional to the luminophore concentration. Trace amounts of luminophore as low as 10^{-13} mol/liter can be detected, making electrogenerated chemiluminescence very useful in analytical and diagnostic applications.

A commercial application of the phenomenon forms the basis of a highly sensitive technique for detection of biological analytes such as deoxyribonucleic acid (DNA), ribonucleic acid (RNA), proteins, antibodies, haptens, and therapeutic drugs in the clinical laboratory. The technique combines a binding assay method and a system for detecting electrogenerated chemiluminescence. [J.K.Le.; L.Na.; H.Ya.]

Chemiosmosis The coupling of metabolic and light energy to the performance of transmembrane work through the intermediary of electroosmotic gradients. Processes include synthesis of adenosine triphosphate (ATP) by oxidative phosphorylation or by photosynthesis, production of heat, accumulation of small molecules by active transport, movement of bacterial flagella, uptake of deoxyribonucleic acid (DNA) during bacterial conjugation, genetic transformation and bacteriophage infection, and insertion or secretion of proteins into or through membranes.

Mitochondria are the powerhouses of the eukaryotic cell and the site of synthesis of ATP by oxidative phosphorylation. In the oxidation portion of ATP synthesis, reductants, such as reduced nicotinamide adenine dinucleotide (NADH) and succinate, are generated during metabolism of carbohydrates, lipids, and protein. These compounds are oxidized through the series of redox reactions performed by membrane-bound complexes, called electron transport or respiratory chains. *See* ADENOSINE TRIPHOSPHATE (ATP); MITOCHONDRIA.

Bacteria do not contain mitochondria, but many of the functions of the mitochondrial membrane are carried out by the bacterial cytoplasmic membrane. Many bacteria also use respiratory chains. This resemblance to mitochondria is more than chance. The evidence, although mostly circumstantial, suggests that mitochondria, chloroplasts, and perhaps other eukaryotic organelles were originally free-living bacteria. These bacteria and larger proto-eukaryotic cells became mutually symbiotic, so that neither was complete or viable without the other. The animal and plant kingdoms arose from these endosymbiotic events.

Photosynthesis is the conversion of light energy into chemical energy. Overall photosynthetic bacteria and the chloroplasts of eukaryotic plants capture sunlight or other light and use that energy to generate both ATP and a reductant for use in biosynthesis. The mechanism of photophosphorylation, that is, the use of light energy to drive the phosphorylation of adenosine diphosphate (ADP) to ATP, resembles that of oxidative phosphorylation. *See* PHOTOSYNTHESIS.

Oxidative phosphorylation and photophosphorylation are but specialized examples of chemiosmotic energy coupling. Among the forms of useful energy are chemical energy, such as that derived from fossil fuels, and light energy in the case of solar cells. Electricity is transmitted to motors, which couple electrical energy to the performance of work. Bacterial cells, mitochondria, and chloroplasts have protonic generators and protonic motors. Respiratory and photosynthetic electron transport chains are generators of proton currents' proton motive forces, which then drive the various motors of the cell or organelle. When the H^+-translocating ATPase is "plugged in," the proton current drives phosphorylation. There are other motors present in the cell. Most membranes contain specific transport systems for small molecules, such as ions, sugars, and amino acids. Many of these transport systems are protonic; that is, they use the energy of the proton motive force to drive the accumulation or extrusion of their substrate. [B.Ro.]

Chemistry The science that embraces the properties, composition, and structure of matter, the changes in structure and composition that matter undergoes, and the accompanying energy changes. It is important to distinguish chemical change, implicit in this definition, and changes in physical form. An example of the latter is the conversion of liquid water to solid or gas by cooling or heating; the water substance is unchanged. In chemical change, such as the rusting of iron, the metal is consumed as it reacts with air in the presence of water to form the new substance, iron oxide.

Modern chemistry grew out of the alchemy of the Middle Ages, and the attempts to transmute base metals into gold. Seminal observations were made in the early eighteenth century on the changes in volume of air during combustion in a closed vessel, and the French chemist Antoine Lavoisier in the 1770s interpreted these phenomena in essentially modern terms.

Atoms and elements. Underlying all of chemistry is the concept of elementary units of matter which cannot be subdivided. This idea was adumbrated in classical Greek writings, and was clearly expressed by the Englishman John Dalton in 1803, who called these units atoms. Different kinds of atoms were recognized, each corresponding to one of the chemical elements such as oxygen, sulfur, tin, iron, and a few other metals. By the mid-nineteenth century, about 80 elements had been characterized, and these were organized on the basis of regularities in behavior and properties, into a periodic table. *See* ELEMENT (CHEMISTRY); PERIODIC TABLE.

In the early twentieth century, observations of radiation from various sources and its impact on solid targets led to the recognition of three fundamental particles that are common to all elements; the electron, with negative charge; the proton, with positive charge; and the neutron, with zero charge. An atom consists of a nucleus containing protons and neutrons, and a diffuse cloud of electrons, equal in number to the number of protons and arranged in orbitals of progressively higher energy levels as the distance from the nucleus increases. The atomic number of an element (Z) is defined as the number of protons in the nucleus; this is the sequence of ordering in the periodic table. The mass number corresponds to the total number of protons and neutrons. *See* ATOMIC NUMBER; ELECTRON; NEUTRON; PROTON.

Isotopes. Most elements exist as isotopes, which have differing numbers of neutrons. All isotopes of an element exhibit the same chemical behavior, although isotopes can be separated on the basis of differences in atomic mass. The known elements total 116; of these, 88 have been detected in one or more isotopic forms in the Earth's crust. The other elements, including all but one of those with atomic number above 92, are synthetic isotopes produced in nuclear reactions that take place in nuclear piles or particle accelerators. Most of the isotopes of these heavier elements and also some lighter ones are radioactive; that is, the nuclei are unstable and decay, resulting in the emission of radiation. *See* ISOTOPE; PARTICLE ACCELERATOR; RADIOACTIVITY.

Molecules and chemical reactions. Molecules are combinations of two or more atoms, bonded together in definite proportions and specific geometric arrangements. These entities are chemical compounds; a molecule is the smallest unit. The bonding of atoms in compounds involves the distribution of electrons, and is the central concern of chemistry.

Compounds result from chemical reactions of atoms or molecules. The process involves formation and breaking of bonds, and may be either exothermic, in which the net bond charges lead to a more stable (lower-energy) system and heat is evolved, or endothermic, in which energy must be added to overcome a net loss of bonding energy.

A simple case is the reaction of hydrogen and oxygen to give water, which can be expressed as reaction (1). The equation

$$2H_2 + O_2 \rightarrow 2H_2O \quad \Delta H = 572 \text{ kilojoules} \tag{1}$$

is balanced; no atoms are gained or lost in a chemical reaction. The symbols represent the nature of the initial and final materials and also the relative amounts. Thus H_2O represents a molecule of water or a mole, which is the quantity in grams (or other mass units) equivalent to the molecular weight. The symbol ΔH indicates the energy (enthalpy) change for the process. The reaction of hydrogen and oxygen is highly exothermic, and the sign of the energy charge is therefore negative since the system has lost heat to the surroundings. *See* ENTHALPY; MOLE (CHEMISTRY); STOICHIOMETRY.

Bonds. Bonds can be broadly classified as ionic or covalent. An ion is an atom or molecule which has an electric charge. Ionic compounds can be illustrated by salts such as sodium chloride, NaCl, in which a positive sodium ion, Na^+, and negative chloride ion, Cl^-, are associated by electrostatic attractions in regular locations of a crystal lattice. In solution the ions are solvated by water molecules and can conduct an electric current.

In covalent molecules, bonds are formed by the presence of pairs of electrons in overlapping orbitals between two atoms. Thus when two hydrogen atoms ($H\cdot$) come within bonding distance, a molecule of hydrogen is formed in an exothermic reaction, by formation of a covalent bond. In this case the heat of reaction represents the energy of the H—H bond [reaction (2)].

$$2H\cdot \rightarrow H{-}H \quad \Delta H = -435 \text{ kilojoules} \tag{2}$$

See CHEMICAL BONDING.

Chemical compounds. A compound is specified by the elements it contains, the number of atoms of each element, the bonding arrangement, and the characteristic properties. The number of unique compounds that have been isolated from natural sources or prepared by synthesis is enormous; as of 2000, over 15 million substances were registered in the file maintained by Chemical Abstracts (American Chemical Society). Most of these are organic compounds, containing from a few to many hundred carbon atoms. The element carbon, unlike any others, can form long chains of covalently bonded atoms. Moreover, there can be many compounds, called isomers, with the same atomic composition. Thus a molecular formula such as $C_8H_{16}O$ can represent many thousand different compounds. *See* CARBON; MOLECULAR ISOMERISM.

Branches of chemistry. Traditionally, five main subdivisions are designated for the activities, professional organizations, and literature of chemistry and chemists.

Analytical chemistry deals with the determination of the composition of matter and the amount of each component in mixtures of any kind. Analytical measurements are an integral and indispensable part of all chemical endeavor. Originally, analytical chemistry involved detection, separation, and weighing of the substances present in a mixture. Determination of the atomic ratio and thence the molecular formula of a compound is a prerequisite for any other investigation; the development of balances and techniques for doing this on milligram quantities of material had an enormous impact on organic chemistry. Advances have involved increasingly sophisticated instrumentation; mass spectrometers are a notable example. Other important methods include high-resolution chromatography and various applications of electrochemistry. A constant goal in analytical chemistry is the development of methods and instruments of greater sensitivity. It is now possible to detect trace compounds such as environmental pollutants at the picogram level. *See* ANALYTICAL CHEMISTRY.

Biochemistry is the study of living systems from a chemical viewpoint; thus it is concerned with the compounds and reactions that occur in plant and animal cells. Most of the substances in living tissues, including carbohydrates, lipids, proteins, nucleic acids, and hormones, are well-defined organic substances. However, the metabolic and regulatory processes of these compounds and their biological function are the special province of biochemistry. One of the major areas is the characterization of enzymes and their cofactors, and the mechanism of enzyme catalysis. Other topics of interest include the transport of ions and molecules across cell membranes, and the target sites of neurotransmitters and other regulatory molecules. Biochemical methods and thinking have contributed extensively to the fields of endocrinology, genetics, immunology, and virology. *See* BIOCHEMISTRY.

Inorganic chemistry is concerned with any material in which metals and metalloid elements are of primary interest. Inorganic chemistry is therefore concerned with the structure, synthesis, and bonding of a very diverse range of compounds. One of the early interests was the composition of minerals and the discovery of new elements; from this has grown the specialized area of geochemistry. Early synthetic work emphasized compounds of the main group elements, and particularly in the twentieth century, complex compounds of the transition metals. These studies have led to soluble transition-metal catalysts, and a greatly increased understanding of catalytic processes and the pivotal role of metal atoms in major biochemical processes, such as oxygen transport in blood, photosynthesis, and biological nitrogen fixation. Other contributions of inorganic chemistry are seen in advanced ceramics, high-performance composite materials, and the growing number of high-temperature superconductors. *See* CATALYSIS; CERAMICS; COMPOSITE MATERIAL; INORGANIC CHEMISTRY; PHOTOSYNTHESIS.

Organic chemistry is centered on compounds of carbon. Originally these were the compounds isolated from plant and animal sources, but the term was early broadened to include all compounds in which a linear or cyclic carbon chain is the main feature. Two of the major thrusts have been the elucidation of new structures and their preparation by synthesis; another longstanding interest has been study of the reaction mechanisms and rearrangements of organic compounds. Structure work on naturally occurring compounds progressed over a 150-year period from simple straight-chain compounds with 2–10 carbon atoms, hydrogen, and 1 or 2 oxygen atoms to antibiotics and toxins with many rings and as many as 100 carbon atoms. In modern work, nuclear magnetic resonance spectroscopy and x-ray diffraction have become indispensable tools. Paralleling structural studies has been the synthesis of increasingly complex target molecules. Synthetic work is directed also to the preparation of large numbers of compounds for screening as potential drugs and agricultural chemicals. Plastics, synthetic fibers, and other high polymers are other products of organic chemistry. *See* NUCLEAR MAGNETIC RESONANCE (NMR); ORGANIC CHEMISTRY; X-RAY DIFFRACTION.

Physical chemistry deals with the interpretation of chemical phenomena and the underlying physical processes. One of the classical topics of physical chemistry involves the thermodynamic and kinetic principles that govern chemical reactions. Another is a description of the physical states of matter in molecular terms. Experimentation and theoretical analysis have been directed to the understanding of equilibria, solution behavior, electrolysis, and surface phenomena. One of the major contributions has been quantum chemistry, and the applications and insights that it has provided. The methods and instruments of physical chemistry, including such hardware as spectrometers and magnetic resonance and diffraction instruments, are an integral part of every other area. *See* CHEMICAL THERMODYNAMICS; PHYSICAL CHEMISTRY; QUANTUM CHEMISTRY.

Each broad area of chemistry embraces many specialized topics. There are also a number of hybrid areas, such as bioorganic and bioinorganic chemistry, analytical biochemistry, and physical organic chemistry. Each of these areas has borrowed extensively from and contributed to every other one. *See* BIOINORGANIC CHEMISTRY. [J.A.Mo.]

Chemometrics

A chemical discipline that uses mathematical and statistical methods to design or select optimal measurement procedures and experiments and to provide maximum chemical information by analyzing chemical data. Chemometrics is actually a collection of procedures, mathematics, and statistics that can help chemists perform well-designed experiments and proceed rapidly from data, to information, to knowledge of chemical systems and processes.

Medicinal chemists use chemometrics to relate measured or calculated properties of candidate drug molecules to their biological function; this subdiscipline is known as quantitative structure activity relations (QSAR). Environmental chemists use chemometrics to find pollution sources or understand the effect of point pollution sources on regional or global ecosystems by analyzing masses of environmental data. Forensic chemists analyze chemical measurements made on evidence (for example, gasoline in an arson case) or contraband to determine its source. Experimental physical chemists use chemometrics to unravel and identify physical or chemical states from spectral data acquired during the course of an experiment. *See* FORENSIC CHEMISTRY; PHYSICAL CHEMISTRY.

In analytical chemistry, chemometrics has seen rapid growth and widespread application, primarily due to the computerization of analytical instrumentation. Automation provides an opportunity to acquire enormous amounts of data on chemical systems. Virtually every branch of analytical chemistry has been impacted significantly by chemometrics; commercial software implementing chemometrics methods has become commonplace in analytical instruments. *See* ANALYTICAL CHEMISTRY.

Whether the analyst is concerned with a single sample or, as in process analytical chemistry, an entire chemical process (for example, the human body, a manufacturing process, or an ecosystem), chemometrics can assist in the experimental design, instrument response, optimization, standardization, and calibration as well as in the various steps involved in going from measurements (data), to chemical information, to knowledge of the chemical system under study. [B.Ko.]

Chemoreception The ability of organisms to detect changes in the chemical composition of their exterior or interior environment. It is a characteristic of every living cell, from the single-celled bacteria and protozoa to the most complex multicellular organisms. Chemoreception allows organisms to maintain homeostasis, react to stimuli, and communicate with one another. *See* HOMEOSTASIS.

At the single-cell level, bacteria orient toward or avoid certain chemical stimuli (chemotaxis); algal gametes release attractants which allow sperm to find oocytes in a dilute aqueous environment; and unicellular slime molds are drawn together to form colonial fruiting bodies by use of aggregation pheromones. *See* CELLULAR ADHESION; TAXIS.

In multicellular organisms, both single cells and complex multicellular sense organs are used to homeostatically maintain body fluids (interoreceptors) as well as to monitor the external environment (exteroreceptors). The best-studied interoreceptors are perhaps the carotid body chemoreceptors of higher vertebrates, which monitor the levels of oxygen, carbon dioxide, and hydrogen ions in arterial blood. The best-studied exteroreceptors are those associated with taste (gustation) and smell (olfaction). Internal communication is also effected by chemical means in multicellular organisms. Thus both hormonal and neural control involve the perception, by cells, of control chemicals (hormones and neurotransmitters, respectively). *See* CAROTID BODY; CHEMICAL SENSES; OLFACTION; SENSE ORGAN; TASTE; TONGUE.

The basic mechanism underlying chemoreception is the interaction of a chemical stimulus with receptor molecules in the outer membrane of a cell. These molecules are believed to be proteins which, because of their three-dimensional shapes and chemical properties, will have the right spatial and binding "fit" for interaction with only a select group of chemicals (the same basic mechanism by which enzymes are specific for various substrates). The interaction between a chemical stimulus and a receptor molecule ultimately leads to structural changes in membrane channels. The net result is usually a change in membrane conductance (permeability) to specific ions which changes both the internal chemical composition of the cell and the charge distribution across the cell membrane. In single-celled organisms, this may be sufficient to establish a membrane current which may elicit responses such as an increase or decrease in ciliary movement. In multicellular organisms, it usually results in changes in the rate of release of hormones or the stimulation of neurons. *See* CELL MEMBRANES.

The basic characteristics of all chemoreceptors are specificity (the chemicals that they will respond to); sensitivity (the magnitude of the response for a given chemical stimulus); and range of perception (the smallest or largest level of stimulus that the receptor can discriminate). Specificity is a consequence of the types of proteins found in the membrane of a receptor cell. Each cell will have a mosaic of different receptor molecules, and each receptor molecule will show different combinations of excitatory or inhibitory responses to different molecules. In an excitatory response, there is a net flux of positive ions into the cell (depolarization); for an inhibitory response, there is a net flux of negative ions into the cell (hyperpolarization). The stronger the stimulus—that is, the more of the chemical present—the more receptors affected, the greater the change in conductance, and the larger the membrane current. In animals with nervous systems, these changes in conductance of primary sensory cells can lead to one of two events. In some receptors, if the current is excitatory and sufficient in magnitude (threshold), an action potential will be generated at a spike-initiating zone on the neuron. Other receptors respond by releasing a neurotransmitter that acts on a second-order neuron which is excitable and therefore can generate action potentials. *See* BIOPOTENTIALS AND IONIC CURRENTS.

The sensitivity of a chemoreceptor reflects both the amount of chemical substance required to initiate a change in membrane potential or discharge of the receptor cell, and the change in potential or discharge for any given change in the level of the chemical stimulus. There are real limits as to the extent of change in membrane conductance or firing frequency. Thus, for more sensitive cells, there is a smaller range over which they can provide information about the change in concentration of any given chemical before it has reached its maximum conductance or discharge rate and has saturated.

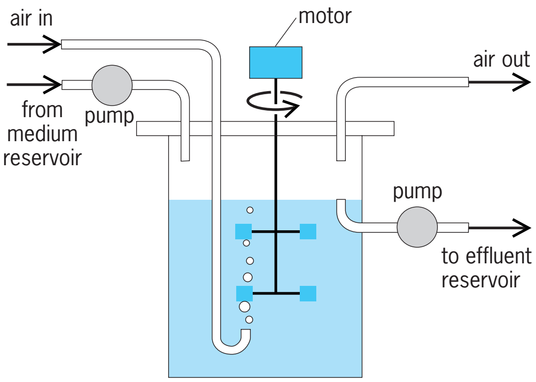
In animals, the responsiveness of some chemoreceptors can be either enhanced or attenuated by other neural input. These influences come in the form of efferent inputs from the central nervous system, from neighboring receptors, or even from recurrent branches of the chemoreceptor's own sensory axons. The net effect is either (1) to increase the acuity of the receptors (excitatory input brings the membrane potential of the receptor cell closer to threshold, requiring less chemical stimulus to elicit a response); or (2) to extend the range of responsiveness of the receptors (inhibitory input lowers the membrane potential of the receptor cell, requiring more chemical stimulus to bring the cell to threshold). For example, chemical sensitivity is greatly heightened in most animals when they are hungry.

Any given chemoreceptor cell can have any combination of receptor proteins, each of which may respond to different chemical molecules. Thus, chemoreceptor cells do not exhibit a unitary specificity to a single chemical substance, but rather an action spectrum to various groups of chemicals. The ability of animals to distinguish such a large number of different, complex, natural chemical stimuli resides in the ability of higher centers in the nervous system to "recognize" the pattern of discharge of large groups of cells. Sensory quality does not depend on the activation of a particular cell or group of cells but on the interaction of cells with overlapping response spectra.

Despite the common, basic mechanism underlying chemoreception in all organisms, there is a great diversity in the design of multicellular chemoreceptive organs, particularly in animals. The complex structures of most of these organs reflect adaptations that serve to filter and amplify chemical signals. Thus, the antennae in many insects, and the irrigated protective chambers, such as the olfactory bulb of fishes and nasal passages of mammals, increase the exposure of chemoreceptor cells to the environment. At the same time, they allow the diffusion distances between chemoreceptive cells and the environment to be reduced, thereby increasing acuity. In terms of filtering, they may serve to convert turbulent or dispersed stimuli into temporal patterns that can be more easily interpreted. The extent to which such structural adaptations are seen in various organisms tends to reflect the relative importance of chemoreception to the organism, which, to a large extend, reflects the habitat in which the organism lives. *See* CHEMICAL ECOLOGY. [W.Mil.]

Chemostat An apparatus (see illustration) for the continuous cultivation of microorganisms or plant cells. The nutrients required for cell growth are supplied continuously to the culture vessel by a pump connected to a medium reservoir. The cells in the vessel grow continuously on these nutrients. Residual nutrients and cells are removed from the vessel (fermenter) at the same rate by an overflow, thus maintaining the culture in the fermenter at a constant volume.

An important feature of chemostat cultivation is the dilution rate, defined as the volume of nutrient medium supplied per hour divided by the volume of the culture. During chemostat cultivation, an equilibrium is established (steady state) at which the growth rate of the cells equals the dilution rate. The higher the dilution rate, the faster the organisms are allowed to grow. Above a given dilution rate the cells will not be able to grow any faster, and the culture will be washed out of the fermenter. The chemostat thus offers the opportunity to study the properties of organisms at selected growth rates. *See* FERMENTATION.



Schematic representation of chemostat apparatus.

The nutrient medium which is fed to the fermenter contains an excess of all growth factors except one, the growth-limiting nutrient. The concentration of the cells (biomass) in the fermenter is dependent on the concentration of the growth-limiting nutrient in the medium feed. Upon entering the fermenter, the growth-limiting nutrient is consumed almost to completion, and only minute amounts of it may be found in the culture and the effluent. Initially, when few cells have been inoculated in the growth vessel, even the growth-limiting nutrient is in excess. Therefore, the microorganisms can grow at a rate exceeding their rate of removal. This growth of cells causes a fall in the level of the growth-limiting nutrient, gradually leading to a lower specific growth rate of the microorganisms. Once the specific rate of growth balances the removal of cells by dilution, a steady state is established in which both the cell density and the concentration of the growth-limiting nutrient remain constant. Thus the chemostat is a tool for the cultivation of microorganisms almost indefinitely in a constant physiological state.

To achieve a steady state, parameters other than the dilution rate and culture volume must be kept constant (for example, temperature and pH). The fermenter is stirred to provide a homogeneous suspension in which all individual cells in the culture come into contact with the growth-limiting nutrient immediately, and to achieve optimal distribution of air (oxygen) in the fermenter when aerobic cultures are in use.

Laboratory chemostats usually contain 0.5 to 10.5 quarts (0.5 to 10 liters) of culture, but industrial chemostat cultivation can involve volumes up to 343,000 gal (1300 m^3) for the continuous production of microbial biomass.

The chemostat can be used to grow microorganisms on very toxic nutrients since, when kept growth-limiting, the nutrient concentration in the culture is very low. The chemostat can be used to select mutants with a higher affinity to the growth-limiting nutrient or, in the case of a mixed population, to select the species that are optimally adapted to the growth limitation and culture conditions. The chemostat is of great use in such fields as physiology, ecology, and genetics of microorganisms. *See* BACTERIAL GENETICS; BACTERIAL PHYSIOLOGY AND METABOLISM; MICROBIOLOGY.

[J.Gi.]

Chemostratigraphy A subdiscipline of stratigraphy and geochemistry that involves correlation and dating of marine sediments and sedimentary rocks through the use of trace-element concentrations, molecular fossils, and certain isotopic ratios that can be measured on components of the rocks. The isotopes used in chemostratigraphy can be divided into three classes: radiogenic (strontium, neodymium, osmium), radioactive (radiocarbon, uranium, thorium, lead), and stable (oxygen, carbon, sulfur). Trace-element concentrations (that is, metals such as nickel, copper, molybdenum, and vanadium) and certain organic molecules (called biological markers or bio-markers) are also employed in chemostratigraphy. *See* DATING METHODS; ROCK AGE DETERMINATION.

Radiogenic isotopes are formed by the radioactive decay of a parent isotope to a stable daughter isotope. The application of these isotopes in stratigraphy is based on natural cycles of the isotopic composition of elements dissolved in ocean water, cycles which are recorded in the sedimentary rocks. *See* ISOTOPE; RADIOISOTOPE.

The elements hydrogen, carbon, nitrogen, oxygen, and sulfur owe their isotopic distributions to physical and biological processes that discriminate between the isotopes because of their different atomic mass. The use of these isotopes in stratigraphy is also facilitated by cycles of the isotopic composition of seawater, but the isotopic ratios in marine minerals are also dependent on water temperature and the mineral-forming processes. *See* SEAWATER.

Certain organic molecules that can be linked with a particular source (called biomarkers) have become useful in stratigraphy. The sedimentary distributions of biomarkers reflect the biological sources and inputs of organic matter (such as that from algae, bacteria, and vascular higher plants), and the depositional environment.

Certain trace metals, such as nickel, copper, vanadium, magnesium, iron, uranium, and molybdenum, are concentrated in organic-rich sediments in proportion to the amount of organic carbon. Although the processes controlling their enrichment are complex, they generally form in an oxygen-poor environment (such as the Black Sea) or at the time of global oceanic anoxic events, during which entire ocean basins become oxygen poor, resulting in the death of many organisms; hence large amounts of organic carbon are preserved in marine sediments. The trace-metal composition of individual stratigraphic units may be used as a stratigraphic marker, or "fingerprint." *See* GEOCHEMISTRY; MARINE SEDIMENTS; STRATIGRAPHY; URANIUM. [B.L.I.; D.J.DeP.]

Chemotaxonomy The use of biochemistry in taxonomic studies. Living organisms produce many types of natural products in varying amounts, and quite often the biosynthetic pathways responsible for these compounds also differ from one taxonomic group to another. The distribution of these compounds and their biosynthetic pathways correspond well with existing taxonomic arrangements based on more traditional criteria such as morphology. In some cases, chemical data have contradicted existing hypotheses, which necessitates a reexamination of the problem or, more positively, chemical data have provided decisive information in situations where other forms of data are insufficiently discriminatory. *See* ANIMAL SYSTEMATICS.

Modern chemotaxonomists often divide natural products into two major classes: (1) micromolecules, that is, those compounds with a molecular weight of 1000 or less, such as alkaloids, terpenoids, amino acids, fatty acids, flavonoid pigments and other phenolic compounds, mustard oils, and simple carbohydrates; and (2) macromolecules, that is, those compounds (often polymers) with a molecular weight over 1000, including complex polysaccharides, proteins, and the basis of life itself, deoxyribonucleic acid (DNA).

A crude extract of a plant can be separated into its individual components, especially in the case of micromolecules, by using one or more techniques of chromatography, including paper, thin-layer, gas, or high-pressure liquid chromatography. The resulting chromatogram provides a visual display or "fingerprint" characteristic of a plant species for the particular class of compounds under study.

The individual, separated spots can be further purified and then subjected to one or more types of spectroscopy, such as ultraviolet, infrared, or nuclear magnetic resonance or mass spectroscopy (or both), which may provide information about the structure of the compound. Thus, for taxonomic purposes, both visual patterns and structural knowledge of the compounds can be compared from species to species. *See* SPECTROSCOPY.

Because of their large, polymeric, and often crystalline nature, macromolecules (for example, proteins, carbohydrates, DNA) can be subjected to x-ray crystallography, which gives some idea of their three-dimensional structure. These large molecules can then be broken down into smaller individual components and analyzed by using techniques employed for micromolecules. In fact, the specific amino acid sequence of portions or all of a cellular respiratory enzyme, cytochrome *c*, has been elucidated and used successfully for chemotaxonomic comparisons in plants and especially animals. *See* X-RAY CRYSTALLOGRAPHY.

Cyctochrome *c* is a small protein or polypeptide chain consisting of approximately 103–112 amino acids, depending on the animal or plant under study. About 35 of the amino acids do not vary in type or position within the chain, and are probably necessary to maintain the structure and function of the enzyme. Several other amino acid positions vary occasionally, and always with the same amino acid substitution at a particular position. Among the remaining 50 positions scattered throughout the chain, considerable substitution occurs, the number of such differences between organisms indicating how closely they are related to one another. When such substitutional patterns were subjected to computer analysis, an evolutionary tree was obtained showing the degree of relatedness among the 36 plants and animals examined. This evolutionary tree is remarkably similar to evolutionary trees or phylogenies constructed on the basis of the actual fossil record for these organisms. Thus, the internal biochemistry of living organisms reflects a measure of the evolutionary changes which have occurred over time in these plants and animals. Since each amino acid in a protein is the ultimate product of a specific portion of the DNA code, the substitutional differences in this and other proteins in various organisms also reflect a change in the nucleotide sequences of DNA itself. *See* GENETIC CODE; PHYLOGENY.

In the case of proteins, it is often not necessary to know the specific amino acid sequence of a protein, but, rather, to observe how many different proteins, or forms of a single protein, are present in different plant or animal species. The technique of electrophoresis is used to obtain a pattern of protein bands of spots much like the chemical fingerprint of micromolecules. Because each amino acid in a protein carries a positive, negative, or neutral ionic charge, the total sum of charges of the amino acids constituting the protein will give the whole protein a net positive, negative, or neutral charge.

By using other techniques of molecular biology, such as DNA hybridization and genetic cloning, the specific gene function of individual fragments may be identified. Their nucleotide sequences can be determined and then compared for different taxa. Such data may prove useful at several different taxonomic levels. *See* GENETIC ENGINEERING.

While the organellar DNA does not contain the number of genetic messages of the organism that nuclear DNA does, and its transmission from parent to offspring may vary somewhat depending on the organism, the convenient size of organellar DNA and its potential for direct examination of the genetic code suggest that it is a potent macromolecular approach to chemosystematics. *See* GENETIC CODE. [D.E.G.]

Chemotherapy Chemotherapy is defined as the use of chemicals to treat any disease, but the term has come to be applied most commonly to the use of drugs to treat cancer. Cancer is an abnormal growth or proliferation of cells that tends to invade locally or spread to distant parts of the body. Several treatment modalities can be used for cancer. Surgery physically removes the abnormal growth, whereas radiation and chemotherapy are directed at killing, or slowing the growth of, cancerous cells.

Paul Ehrlich, a German physician and 1908 Nobel Laureate in Medicine, is generally credited with pioneering the field of chemotherapy and coining the word. However, his efforts were directed toward discovering antibiotics for infections rather than cancer drugs. The first extensively utilized chemotherapy was nitrogen mustard, which was used in the mid-1940s by Alfred Gilman and Frederick S. Philips for the treatment of lymphomas and chronic leukemias. *See* LEUKEMIA.

The second group of useful anticancer drugs developed were folic acid antagonists. All actively growing cells require a chemical metabolite called folic acid to grow and divide. The antagonists were designed to inhibit a cancer cell's ability to produce folic acid, and therefore they are toxic. The third group of chemotherapeutic agents was designed to have a toxic effect on the cell's deoxyribonucleic acid (DNA). The development of these drugs was based on the theory that tumor growth might be stopped with chemicals that antagonize nucleic acids which are necessary for cancer cell growth and division. Antitumor antibiotics became recognized as potential chemotherapeutic agents in 1954, when actinomycin D was studied. They differ from antimicrobial antibiotics in that their spectrum of cytotoxicity includes human cells rather than bacteria and fungi. Since the mid-1950s, many new drugs have been developed. The availability of the techniques of molecular biology and a greater understanding of the genetic abnormalities of cancer are resulting in more effective therapies which tend to be more specific for cancer cells. Drugs which inhibit angiogenesis (blood vessel formation) or which target promoting (oncogenes) or suppressing (tumor suppressor) genes are being tested.

Chemotherapeutic drugs come from various sources. They may be extracted from nature, such as from bacteria, fungi, plants, or trees, or they may be chemically synthesized. They may also be semisynthetic, meaning that the process starts with a complex natural compound that is then modified chemically. They may also be produced using modern recombinant DNA technology.

Chemotherapy is used when a cancer has spread to multiple sites and cannot be removed surgically or treated with radiation therapy. It can also be used after all detectable tumor has been eradicated (complete remission) in order to destroy suspected undetectable residual tumor. This type of treatment is called adjuvant, intensification, or consolidation chemotherapy. Adjuvant therapy is effective in breast and colon cancer, and consolidation in acute leukemia, for example. Neoadjuvant chemotherapy is used to shrink a tumor prior to surgery or radiation. The results of treatment depend upon how much chemotherapy is given, how many times it is applied, and how effective it is against the tumor. These facts are derived from a basic principle of chemotherapy that a uniform dose of a drug will destroy a constant fraction rather than a constant number of tumor cells regardless of the size of the tumor or number of cells present (fractional cell kill hypothesis). Regrowth eventually occurs, but each subsequent dose of chemotherapy brings about a further decline in tumor cell number until eventually, in optimal circumstances, the number of tumor cells is low enough for the body to eliminate them by other mechanisms, resulting in a chemotherapy cure. *See* ONCOLOGY.

Although the different groups of chemotherapeutic agents have different mechanisms of toxicity for cells, the cellular death response is almost always apoptosis, or programmed cell death. In this process a death signal is generated from within the damaged cells. This initiates a series of energy-requiring choreographed cellular events leading to cellular suicide.

The goal of therapy should be determined in all patients who will receive chemotherapy. The possibilities include cure, prolongation of life but not a cure, or palliation (alleviating symptoms) but no prolongation of life. The choice of chemotherapy depends not only upon the type of tumor and the drug efficacy but, most importantly, upon the patient. Also, it must be decided whether the chemotherapy will improve the quality of life of the patient and not just shrink the tumor. Age and the general condition of the patient influence the outcome. Those patients who are more active are more likely to have a favorable outcome to chemotherapy.

The amount of chemotherapy given in each dose is usually based on the size of the body surface in square meters or occasionally just on body weight. The dose must be appropriate for the size of the patient because toxicity often occurs at doses only slightly higher than those needed for therapy. The response of a cancer to a drug is determined by measuring the size of the cancer directly or the amount of marker substances produced by some tumors. A complete response is defined as disappearance of the tumor. A partial response is a decrease in the multiplication product of the two largest diameters by at least 50%. Less than this is considered a failure unless there is an improvement in symptoms. The ultimate measure of response is whether the patients have a prolongation of quality life, which may require observation over a long period of time.

Chemotherapeutic drugs have side effects that are specific for the agent and may include transient or permanent damage to almost any organ system of the body. Chemotherapeutic drugs cause side effects because in addition to destroying the actively dividing cancer cells they damage actively growing normal cells. Common sites of damage are the bone marrow resulting in increased risk for infection, anemia, and bleeding; the gastrointestinal tract resulting in vomiting and diarrhea; the hair follicles causing hair loss; and the kidneys resulting in renal failure. Today, cancer specialists have many ways of preventing or diminishing these toxicities, such as red blood cell transfusions for anemia, drugs to prevent nausea and vomiting, and growth factors which may improve anemia (erythropoietin) or shorten the time of either low white blood counts (granulocyte-colony stimulating factor) or of low platelet counts (thrombopoietin).

Cells can become resistant to drugs of different groups. The general mechanism is referred to as multiple drug resistance. This resistance is due to an acquired ability of the cells to pump these drugs out before they can cause irreversible damage. Most successful modern chemotherapeutic regimens are combinations of drugs. The use of more than one drug increases the chance of a cancer being sensitive to treatment since it is possible that a cancer cell resistant to one drug will be sensitive to another. Drugs can also be combined with other general types of treatment.

There has been a good deal of interest in the specific phase of the cell division cycle that is affected by chemotherapy in the hope that this information could be used to develop more effective cures for cancer. This may eventually lead to effective cell cycle-based drug strategies. Some of the proteins that control the cell cycle (for example, cyclins) might become targets for drug action. Techniques are being developed to ameliorate toxicity so that it may become possible to give higher doses of chemotherapeutic agents. *See* CANCER (MEDICINE); CELL CYCLE; CELL DIVISION.

[C.P.Bu.]

Cherry The two principal cherries of commerce are the sweet cherry (*Prunus avium*) and the sour cherry (*P. cerasus*). Both are of ancient origin and seem to have come from the region between the Black and Caspian seas. Cherries of minor importance are the dwarf or western sand cherries (*P. besseyi*) of the plains region of North America; the Duke cherries, which are supposedly natural hybrids between the sweet and sour cherry; and the Padus cherries, which bear their small fruits in long clusters or racemes rather than in short fascicles.

Sweet cherries may be divided into two groups: firm-fleshed types known as Bigarreaus, represented by the Napoleon (also called the Royal Anne), and soft-fleshed types known as Hearts, represented by the Black Tartarian. Sour cherries may also be divided into two groups, clear-juice or Amarelle types, represented by the Montmorency, and colored-juice or Morello types, represented by the English Morello.

In North America the principal sweet commercial varieties are the Napoleon (white), Bing, Lambert, Van, Schmidt, and Windsor (dark). The principal commercial variety of sour cherry is the Montmorency. *See* FRUIT; ROSALES.

[R.P.L.]

Chert A hard, dense sedimentary rock composed of fine-grained silica (SiO_2). Chert is characterized by a semivitreous to dull luster and a splintery to conchoidal fracture, and is most commonly gray, black, reddish brown, or green. Chert is also used as a field term to describe silica-rich rocks which may be impure; common impurities include carbonates, iron and manganese oxides, and clay minerals. When impurities change the texture of the rock to the extent that it is less dense and hard than chert, and has the appearance of unglazed porcelain, the rock is then called porcellanite or siliceous shale. The term flint is synonymous with chert, but its use has become restricted to archeological artifacts and to nodular chert that occurs in chalk. The term chert, however, is preferred for the nodular deposits. Jasper refers to red or yellow quartz chert associated with iron ore or containing iron oxide. Novaculite is a white chert of great purity and uniform grain size, and is composed chiefly of quartz; the term is mostly restricted to descriptions of Paleozoic cherts in Oklahoma and Arkansas. Chert synonyms that have become obsolete include silexite, petrosilex, phthanite, and hornstone. *See* JASPER.

Chert occurs mainly in three forms: bedded sequences, nodular, and massive. Bedded chert (called ribbon chert if beds show pinch-and-swell structure) consists of rhythmically interlayered beds of chert and shale; chert and carbonates; or in some pre-Phanerozoic formations, alternations of chert and siderite or hematite. Bedded sequences can be hundreds of feet thick stratigraphically and cover areas of hundreds of square miles. Individual beds are commonly $\frac{1}{2}$–8 in. (1–20 cm) thick. Chert nodules and lenses occur primarily in chalk, limstone, and dolomite. Nodules and lenses vary in size from $\frac{1}{2}$ in. to 30 ft (1 cm to 9 m). Fossils and sedimentary structures characteristic of the host rock are preserved within the nodules. Massive cherts occur in the interstices between basalt pillows, and as the basal member of bedded chert that overlies pillow basalts in ophiolites. *See* BASALT; CHALK; DOLOMITE ROCK; LIMESTONE.

When a supply of silica is available, chert forms in four ways: by replacement of mainly carbonate rock; by deposition from turbidity currents composed primarily of biogenic silica; by increasing the deposition of silica relative to terrigenous input, commonly by increased productivity of biogenic silica; and by precipitation of silica from water under either hydrothermal or low-temperature hypersaline conditions. *See* TURBIDITY CURRENT.

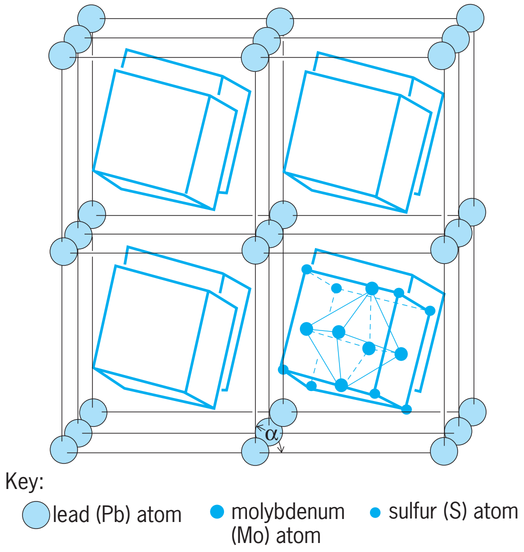
[J.R.He.]

Chestnut Any of seven species of deciduous, nut-bearing trees of the genus *Castanea* Corden Fagales native to the Northern Hemisphere and introduced throughout the world. The nuts are actually fruits, with the shells enclosing cotyledons. Trees bear both male and female flowers in late spring but must be cross-pollinated for nut production. Nuts are borne in a spiny involucre or bur that opens to release the nuts in late fall. *See* FAGALES.

Japanese chestnuts (*C. crenata*) and Chinese chestnuts (*C. mollissima*) are grown in Asia and the United States for their nuts, and many cultivars have been selected. European chestnuts (*C. sativa*) are an important food source, both cooked whole and ground into flour. They are native to the Caucasus mountains, and distributed throughout southern Europe. American chestnuts (*C. dentata*) have smaller nuts than Asian or European species and are usually sweeter. Only American trees served as an important source of lumber, because of the length of their unbranched trunks; all chestnut species have been used as a source of tannin for the leather-tanning industry. American and Chinese chinquapins (*C. pumila* and *C. henryi*) have very small nuts that are an important source of food for wildlife. All of the species can be crossed, and hybrids have been selected primarily as orchard cultivars.

[S.L.A.]

Chevrel phases A series of ternary molybdenum chalcogenide compounds. They were reported by R. Chevrel, M. Sergent, and J. Prigent in 1971. The compounds have the general formula $M_xMo_6X_8$, where M represents any one of a large number



Crystal structure of $PbMo_6S_8$. Each lead atom Is surrounded by eight Mo_6S_8 units, the structure of which is shown In the lower right-hand part of the figure. The rhombohedral angle α Is Indicated.

(nearly 40) of metallic elements throughout the periodic table; x has values between 1 and 4, depending on the M element; and X is a chalcogen (sulfur, selenium or tellurium). The Chevrel phases are of great interest, largely because of their striking superconducting properties.

Most of the ternary molybdenum chalcogenides crystallize in a structure in which the unit cell, that is, the repeating unit of the crystal structure, has the overall shape of a rhombohedron with a rhombohedral angle close to 90°. The building blocks of the Chevrel-phase crystal structure are the M elements and Mo_6X_8 molecular units or clusters. Each Mo_6X_8 unit is a slightly deformed cube with X atoms at the corners, and Mo atoms at the face centers. One of these structures, that of $PbMo_6S_8$, is shown in the illustration. *See* CRYSTAL; CRYSTALLOGRAPHY.

Several of the Chevrel-phase compounds have relatively high values of the superconducting transition temperature, T_c, the maximum being about 15 K (−433°F) for $PbMo_6S_8$. The Chevrel-phase $PbMo_6S_8$ has a value of the upper critical magnetic field near absolute zero $H_{c2}(O)$ of about 60 teslas (600 kilogauss), which was the largest value observed prior to the discovery of high-temperature ceramic superconductors in 1986. A number of Chevrel-phase compounds of the form RMo_6X_8, where R is a rare-earth element with a partially filled 4f electron shell and X is S or Se, display magnetic order at low temperatures in addition to superconductivity. *See* SUPERCONDUCTIVITY. [M.B.Ma.]

Chevrotain Any of four species of mammals which constitute the family Tragulidae in the order Artiodactyla. These animals, also known as mouse deer, are the smallest ruminants, growing to a maximum height of 12 in. (30 cm) at the shoulder. The chevrotain lacks horns or antlers. There are two well-developed toes on the feet, and the upper canines of the male are elongate and protrude from the mouth as small tusks. The chevrotain is a shy animal which leads a solitary life except during the breeding season. After a gestation period of 120 days, one or two young are born. The water chevrotain (*Hyemoschus aquaticus*) is found in west-central Africa along the banks of rivers in Sierra Leone through Cameroon to the Congo. The other species are all members of the genus *Tragulus*, and range through the forested areas of Sumatra into Borneo and Java. These are the Indian chevrotain (*T. meminna*), the larger Malay chevrotain (*T. napu*), and the lesser Malay chevrotain (*T. javanicus*). They are differentiated by the pattern of markings (stripes or spots) on their coats. *Tragulus javanicus* has a coat of uniform color.

The Eocene fossil traguloid, *Archaeomeryx*, which was unearthed in Mongolia, shows many general similarities to the modern chevrotains. The main line of evolutionary development of the traguloids occurred in Eurasia. *See* ARTIODACTYLA. [C.B.C.]

Chickenpox and shingles Chickenpox (varicella) and shingles (herpes zoster) are two different forms of disease caused by the varicella-zoster virus, which is a deoxyribonucleic acid (DNA) virus closely related to herpes simplex and *Epstein-Barr viruses*. Initial infection causes varicella, a common childhood infection characterized by fever, malaise, and a rash consisting of dozens to hundreds of small fluid-filled lesions (vesicles) that are individually surrounded by reddened skin. Successive crops of lesions appear that eventually ulcerate and crust over during the two-week course of the disease. The virus is spread from person to person by the highly infectious respiratory secretions and lesion drainage. Varicella is rarely a serious disease in normal children but can be severe in immunocompromised individuals or in the rare adult who escaped childhood infection. Primary infection results in immunity to a new varicella-zoster virus, but the original virus lies dormant in nerve ganglia cells. *See* EPSTEIN-BARR VIRUS; HERPES.

At some time in their life, approximately 10% of the population suffers subsequent reactivation of latent virus, which spreads to the skin overlying the affected nerve and causes a localized eruption of vesicles called herpes zoster. The vesicles are similar in appearance and in infectiousness to varicella lesions. This syndrome is usually well tolerated, although elderly persons may develop chronic pain at the site of reactivation. Herpes zoster in immunocompromised individuals may be prolonged or may disseminate to vital organs.

Varicella or herpes zoster in a normal host is self-limited and does not typically require antiviral therapy. In individuals with underlying immune disorders, treatment with the antiviral drug acyclovir decreases the duration and severity of disease. *See* ANIMAL VIRUS; VIRUS INFECTION, LATENT, PERSISTENT, SLOW. [F.P.H.]

Chicle A gummy exudate used in the manufacture of chewing gum. It is contained in the bark of a tall evergreen tree, *Achras zapota* (Sapotaceae), a native of Mexico and Central America. The latex is collected and carefully boiled to remove excess moisture. When the water content is reduced to 33%, the chicle is poured off and molded into blocks. The product is an amorphous, pale-pink powder, insoluble in water, and forming a sticky paste when heated. In the manufacture of chewing gum, the chicle is cleaned, filtered, and sterilized, and various flavoring materials and sugar are added. [P.D.St./E.L.C.]

Chicory A perennial herb, *Cichorium intybus* (Compositae), with a long taproot, a coarse branching stem, and a basal rosette of numerous leaves. Although the plant is a native of Europe, it has become a common weed in the United States. It is used as a salad plant or for greens. The roasted root is also used as an adulterant of coffee. *See* CAMPANULALES. [P.D.St./E.L.C.]

Child-Langmuir law A law governing space-charge-limited flow of electron current between two plane parallel electrodes in vacuum when the emission velocities of the electrons can be neglected. It is often called the three-halves power law, and is expressed by the equation below.

$$j\,(\mathrm{A/cm}^2) = 2.33 \times 10^{-6}\,\frac{V\,(\mathrm{volts})^{3/2}}{d\,(\mathrm{cm})^2}$$

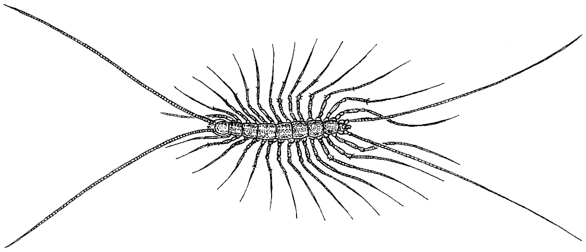
Here V is the potential difference between the two electrodes, d their separation, and j the current density at the collector electrode, or anode. The potential difference V is the applied voltage reduced by the difference in work function of the collector and emitter. The Child-Langmuir law applies, to a close approximation, to other electrode geometries as well. Thus for coaxial cylinders with the inner cylinder the cathode, it leads to a deviation from the true value of the current density of 13% at most. *See* SPACE CHARGE. [E.G.R.]

Chilopoda An order of the group Myriapoda commonly known as the centipedes. Like all myriapods, centipedes are ground dwellers whose spatial movements are restricted largely by a dependence upon high environmental moisture. Unlike the others, centipedes are evidently exclusively carnivorous and predatory, a way of life reflected in their great agility or fleetness and especially in the extraordinary modification of the first trunk appendages into a pair of usually massive raptorial pincers, the prehensors. Each prehensor contains a poison gland from which venom is conducted through a terminal claw into the victim's body. The poison immobilizes or kills arthropods and even some small vertebrates, but so far as is known it seems only harmlessly painful to human beings.

Excluding the last two or three trunk segments, each segment bears a single pair of functional legs. The genital ducts open at the posterior end of the body. Spiracles open laterally or dorsally; tracheal and circulatory systems are present and often elaborate. The antennae are unbranched; the eyes, when present, are either of the compound type or appear as simple ocelli. The mandibles have a partially free and movable gnathal portion. There are two pairs of maxillae.

In terms of families, genera, and individuals, the Diplopoda, or millipedes, are most abundant in the tropics, but this is not true of centipedes as a group, for whereas certain orders are basically tropical (Scutigeromorpha, Scolopendromorpha), one order, the Lithobiomorpha, is essentially temperate, and the Geophilomorpha is abundant in both zones. In general, centipedes seem less affected by temperature and more sensitive to environmental moisture than are millipedes.

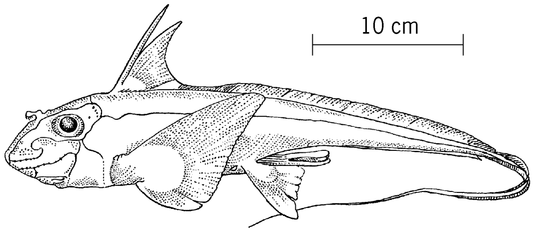
The class is divisible into two subclasses, the Notostigmophora and the Pleurostigmophora. The notostigmophorous centipedes comprise a single order, Scutigeromorpha. Its members, which are peculiar in embodying primitive as well as highly advanced characters, are signalized by possession of dorsal respiratory openings (stomata), of compound-type eyes, of long flagellate, multisegmental antennae, and of long thin legs with multisegmental tarsi. The order includes the common house centipedes, *Scutigera coleoptrata*, one of which is shown in the illustration.



***Scutigera coleoptrata*, the house centipede. (*After R. E. Snodgrass, A Textbook of Arthropod Anatomy, copyright 1952 by Cornell University Press; reprinted with permission*)**

The Pleurostigmophora, in contrast, have lateral respiratory openings, spiracles. They are reducible into four orders: Lithobiomorpha, Craterostigmomorpha, Scolopendromorpha, and Geophilomorpha. [R.E.Cr.]

Chimaeriformes The only order of the chondrichthyan subclass Holocephali. The chimaeriforms (ratfishes) are a distinctive group of marine bottom-feeding fishes that chiefly inhabit the deeper layers of the Atlantic and Pacific oceans. During the winter months some species move into coastal waters, and a few species may be restricted to this environment.



Modern chimaeriform *Chimaera*. (*After H. B. Bigelow and W. C. Schroeder, Fishes of the Western North Atlantic, pt. 2, Sears Foundation for Marine Research, 1953*)

Like the elasmobranchs, the ratfishes have a cartilaginous skeleton (partly calcified), a urea retention mechanism, and clasper organs in the male for internal fertilization. Unlike the elasmobranchs, however, they have the upper jaw fused to the braincase, a complete hyoid arch that is not involved in jaw suspension, four gill slits opening into a common outer chamber covered by an opercular skin fold, a single branchial opening on each side of the head, no spiracle in the adult, dental plates rather than teeth, a persistent notochord surrounded by calcified centra, and a narrow, tapering tail. *See* ELASMOBRANCHII.

The main line of chimaeriform evolution apparently began with Mississippian to Permian forms called menaspoids. By the beginning of the Jurassic the menaspoids had been replaced by their presumed descendants, the myracanthoids. Modem ratfishes (see illustration) appeared during the Middle Jurassic. They are characterized by a laterally compressed head with a variably developed rostrum, which is frequently exotically shaped, and an ethmoidal canal. The dorsal fin spine is made up almost entirely of lamellar bone. The pectoral fins are dibasal and fairly large, and the caudal fin is tapered to almost whiplike proportions. Placoid scales cover the body, in contrast to the more complicated compound scales of the primitive chimaeriforms.

The living ratfishes are divided into three families: the Chimaeridae, the Rhinochimaeridae, and the Callorhinchidae, which can be readily distinguished by the shape of the rostrum. Some 28 species are recognized. Most of them feed on mollusks and crustaceans and occasionally on smaller fishes. *See* CHONDRICHTHYES. [B.S.]

Chimera An individual animal or plant made up of cells derived from more than one zygote or otherwise genetically distinct.

Animals. Although some chimeras do arise naturally, most are produced experimentally, either by mixing cells of very early embryos or by tissue grafting in late embryos or adults. Experimental chimeras have been used to study a number of biological questions, including the origin and fate of cell lineages during embryonic development, immunological self-tolerance, tumor susceptibility, and the nature of malignancy.

Two techniques used to form chimeras by mixing embryo cells are aggregation and injection.

Aggregation chimeras are produced by a technique that involves removing the zonae pellucidae from around 8–16 cell embryos of different strains of mice and pushing the morulae together so that the cells can aggregate. After a short period of laboratory culture, during which the aggregate develops into a single large blastocyst, the embryo is returned to a hormone-primed foster mother. Chimeric offspring are recognized in several ways. If derived from embryos of pigmented and albino strains, they may have stripes of pigmented skin and patches of pigment in the eye. Internal chimerism can be detected by use of chromosomal markers or genetically determined enzyme variants. Chimeras accept skin grafts from the two component strains, but reject grafts from third-party strains.

Injection chimeras are produced by a technique in which a blastocyst of the host mouse strain of mouse embryos is removed from its zona pellucida and held on a suction pipette. Cells of the donor strain are injected through a fine glass needle, either into the blastocoele cavity or into the center of the inner cell mass (the group of cells from which the fetus is derived). After a short period of culture, the blastocyst is returned to a foster mother.

Another kind of cell—the pluripotent stem cell of mouse teratocarcinomas—was found to give rise to normal tissues in adult chimeras after injection into the mouse blastocyst. Teratocarcinomas are tumors consisting of a disorganized mixture of adult and embryonic tissues. They develop spontaneously from germ cells in the gonads of certain mouse strains, or from cells in early embryos transplanted to ectopic sites. All the differentiated tissues in the tumor arise from pluripotent stem cells known as embryonal carcinoma (EC) cells. When embryonal carcinoma cells are injected into a genetically marked host blastocyst, they continue to divide and participate in normal development, and give rise to fully differentiated cells in all tissues of the adult, including skin, muscle, nerve, kidney, and blood. Embryonal carcinoma cells from several sources, including spontaneous and embryo-derived tumors and cultured lines selected to carry specific mutations or even human chromosomes, have contributed to normal chimeras. However, embryonal carcinoma cells from some other sources fail to integrate, but produce teratocarcinomas in the newborn animal or adult. The fact that certain embryonal carcinoma cells give rise to tumors when injected under the skin or into the body cavity, but behave normally in the blastocyst, has been used to support the idea that cancers can develop not only as a result of gene mutations but also as a result of disturbances in environmental factors controlling normal cell differentiation (epigenetic theory of cancer).

Animals that have accepted skin or organ grafts are technically chimeras. Radiation chimeras are produced when an animal is exposed to x-rays, so that blood-forming stem cells in the bone marrow are killed and then replaced by a bone marrow transplant from a genetically different animal. Lymphoid cells in the process of differentiating from stem cells in the donor marrow recognize the recipient as "self" and do not initiate an immune response against the host cells. *See* TRANSPLANTATION BIOLOGY.

Naturally occurring chimeras in humans are not rare and are most easily recognized when some cells are XX and others XY. Such individuals are usually hermaphrodite and probably result from fertilization of the egg by one sperm and the second polar body by another, with both diploid cells then contributing to the embryo (the small polar bodies normally degenerate). Blood chimeras are somewhat more common in animals such as cattle where the blood vessels in placentas of twins fuse, so that blood cells can pass from one developing fetus to the other. [B.Hog.]

Plants. In modern botanical usage a chimera is a plant consisting of two or more genetically distinct kinds of cells. Chimeras can arise either by a mutation in a cell in some part of the plant where cells divide or by bringing together two different plants so that their cells multiply side by side to produce a single individual. They are studied not only because they are interesting freaks or ornamental, but also because they help in the understanding of many of the developmental features of plants that would otherwise be difficult to investigate.

The first type of chimera to be used in this way resulted from grafting. Occasionally a bud forms at the junction of the scion and stock incorporating cells from both, and it sometimes happens that the cells arrange themselves so that shoots derived from the bud will contain cells from both plants forever.

Flowering plants have growing points (apical meristems) where the outer cells are arranged in layers parallel to the surface. This periclinal layering is due to the fact that the outer cells divide only anticlinally, that is, by walls perpendicular to the surface of the growing point. In many plants there are two such tunica layers and, because cell divisions are confined to the anticlinal planes, each layer remains discrete from the other and from the underlying nonlayered tissue called the corpus. The epidermis of leaves, stems, and petals is derived from the outer layer of the growing point. *See* APICAL MERISTEM.

With a periclinal chimera it is possible to trace into stems, leaves, and flowers which tissues are derived from each layer in the growing point. For leaves, this can also be done with variegated chimeras where the genetic difference between the cells rests in the plastids resulting from mutation whose effect is to prevent the synthesis of chlorophyll. Tracts of cells whose plastids lack this pigment appear white or yellow. A common form of variegated chimera has leaves with white margins and a green center (see illustration). The white margin is derived from the second layer of the tunica, and the green center is derived from inner cells of the growing point. The white leaf tissue overlies the green in the center of the leaf, but does not mask the green color. Chimeras with green leaf margins and white centers are usually due to a genetically green tunica proliferating abnormally at the leaf margin in an otherwise white leaf.

Since the somatic mutation that initiates chimeras would normally occur in a single cell of a growing point or embryo, it often happens that it is propagated into a tract of mutant cells to form a sector of the plant. If the mutation resulted in a failure to form green pigment, the tract would be seen as a white stripe. Such chimeras are called sectorial, but they are normally unstable because there is no mechanism to isolate the mutant sector and, in the flux that occurs in a meristem of growing and dividing cells, one or other of the two sorts of cells takes over its self-perpetuating layer in the growing point. The sectorial chimera therefore becomes nonchimerical or else a periclinal chimera.

However, in one class of chimera an isolating mechanism can stabilize the sectorial arrangement. This propagates stripes of mutant tissue into the shoot, but because the tunica and corpus are discrete from each other, the plant is not fully sectored and is called a mericlinal chimera. Many chimeras of this type have

Variegated *Pelargonium*, a periclinal chimera whose second tunica layer is genetically white and whose corpus is genetically green.

a single tunica layer; those with green and white stripes in the leaves have the mutant cells in sectors of the corpus. They are always plants with leaves in two ranks, and consequently the lateral growth of the growing point occurs by cell expansion only in the plane connecting alternate leaves. This results in the longitudinal divisions of the corpus cells being confined to planes at right angles to the plane containing the leaves. A mutation in one cell therefore can result in a vertical sheet of mutant cells which, in the case of plastid defect, manifests itself as a white stripe in every future leaf.

The growing points of roots may also become chimerical, but in roots there is no mechanism to isolate genetically different tissues as there is in shoots, and so chimeras are unstable.

Since the general acceptance of the existence of organisms with genetically diverse cells, many cultivated plants have been found to be chimeras. Flecks of color often indicate the chimerical nature of such plants. Color changes in potato tubers occur similarly because the plants are periclinal chimeras. *See* SOMATIC CELL GENETICS. [F.A.L.C.]

Chimney A vertical hollow structure of masonry, steel, or reinforced concrete, built to convey gaseous products of combustion from a building or process facility. A chimney should be high enough to furnish adequate draft and to discharge the products of combustion without causing local air pollution. The height and diameter of a chimney determine the draft. For adequate draft, small industrial boilers and home heating systems depend entirely upon the enclosed column of hot gas. In contrast, stacks, which are chimneys for large power plants and process facilities, usually depend upon force-draft fans and induced-draft fans to produce the draft necessary for operation, and the chimney is used only for removal of the flue gas. *See* FAN.

For fire safety, chimneys for residential construction and for small buildings must extend at least 3 ft (0.9 m) above the level where they pass through the roof and at least 2 ft (0.6 m) higher than any ridge within 10 ft (3 m) of them. Some stacks extend as high as 500 ft (150 m) above ground level, thus providing supplementary natural draft.

A chimney or stack must be designed to withstand lateral loads from wind pressure or seismic forces (earthquakes), as well as vertical loads from its own weight. Small chimneys used in residential construction are commonly made of brick or unreinforced masonry, while stacks are usually made of steel. Tall steel chimneys of small diameter cannot economically be made self-supporting and must be guyed. Concrete chimneys may be plain or reinforced. Except for rectangular flues and chimneys commonly used in residential construction, masonry chimneys are usually constructed of perforated radial brick molded to suit the diameter of the chimney. *See* BRICK; LOADS, DYNAMIC; MASONRY; MORTAR; REINFORCED CONCRETE; STAINLESS STEEL; STEEL; TRUSS. [J.Ve.]

Chinchilla The name given to two species of rodents which, together with four species of viscachas, compose the family Chinchillidae. The two species of chinchilla are *Chinchilla brevicaudata* and *C. lanigar*. These animals resemble the squirrel in size and shape and are characterized by long, muscular hindlimbs, with elongate feet bearing four toes, and short forelimbs. Blunt claws occur on the flexible fingers. Chinchillas are gregarious, nocturnally active animals and are found in arid, mountainous regions where they feed principally on vegetation. They often seek shelter in burrows or rock crevices, so that their capture is difficult. The female, which is larger than the male, bears one to six offspring twice each year after a gestation period of 105–111 days.

These animals are native to several areas of South America and are widely bred on farms in North America and Europe for their fur, which is long, fine, and expensive. *See* RODENTIA. [C.B.C.]

Chinook A mild, dry, extremely turbulent westerly wind on the eastern slopes of the Rocky Mountains and closely adjoining plains. The term is an Indian word which means “snow-eater,” appropriately applied because of the great effectiveness with which this wind reduces a snow cover by melting or by sublimation. The chinook is a particular instance of a type of wind known as a foehn wind. Foehn winds, initially studied in the Alps, refer to relatively warm, rather dry currents descending the lee slope of any substantial mountain barrier. The dryness is an indirect result of the condensation and precipitation of water from the air during its previous ascent of the windward slope of the mountain range. The warmth is attributable to adiabatic compression, turbulent mixing with potentially warmer air, and the previous release of latent heat of condensation in the air mass and to the turbulent mixing of the surface air with the air of greater heat content aloft. In winter the chinook wind sometimes impinges upon much colder stagnant polar air along a sharp front located in the foothills of the Rocky Mountains or on the adjacent plain. Small horizontal oscillations of this front have been known to produce several abrupt temperature rises and falls of as much as 45–54°F (25–30°C) at a given location over a period of a few hours. Damaging winds sometimes occur as gravity waves, which are triggered along the interface between the two air masses. *See* FRONT; ISENTROPIC SURFACES; PRECIPITATION (METEOROLOGY); WIND; WIND STRESS. [F.S.; H.B.B.]

Chipmunk A member of the tribe Marmotini in the rodent family Sciuridae. There are 18 species. The eastern chipmunk (*Tamias striatus*) is found in wooded areas of eastern Canada and the United States. The western species, although quite similar to the eastern form, are included in the separate genus *Eutamias*.

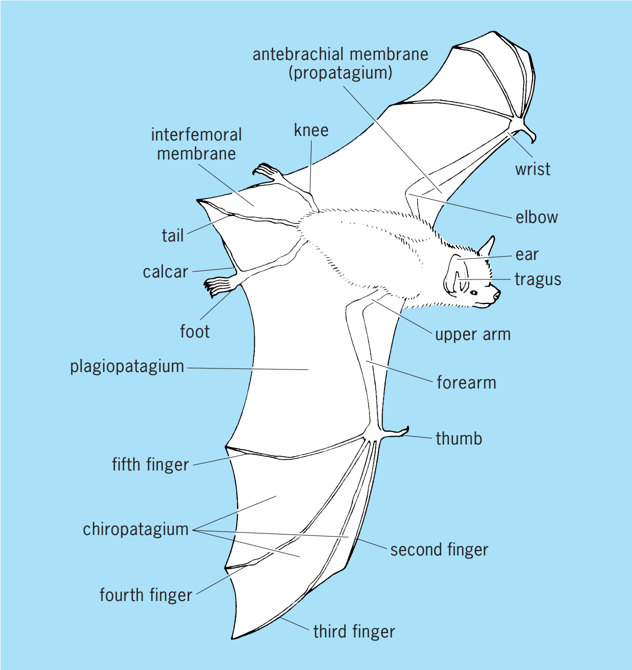
These rodents are intermediate between the squirrels and marmots, having lost the typical bushy tail, tufted ears, and silky fur of the squirrel. They are diurnal animals, active in collecting food such as nuts, grains, and seeds. They fill their large cheek pouches with gathered food to carry it to storage places for the winter.

The animals construct extensive burrows of several chambers at the bottom of a downward sloping entry tunnel, which is about 3 ft (1 m) long. The chambers, used for hoarding food and for nesting, are below the frost line. While chipmunks are not true hibernators, they tend to remain in their underground chambers during the winter months. In the early spring they emerge from the burrows and mating occurs. After a gestation period of 5 weeks six or more young are born, blind and helpless. *See* RODENTIA. [C.B.C.]

Chiroptera An order of mammals (bats) in which the front limbs are modified as wings, thus making the chiropterans the only truly flying mammals. Bats form the second largest order of living mammals (16 families, 171 genera, some 840 species). They range from the limit of trees in the Northern Hemisphere to the southern tips of Africa, New Zealand, and South America, but most species are confined to the tropics. On many oceanic islands they are the only native land mammals.

The wing is formed by webs of skin running from the neck to the wrist (propatagium, or antebrachial membrane), between the greatly elongated second, third, fourth, and fifth fingers (chiropatagium), and from the arm and hand to the body (usually the side) and hindlegs (plagiopatagium). There is also usually a web between the hindlegs (uropatagium, or interfemoral membrane) in which the tail, if present, is usually embedded for at least part of its length (see illustration). The 16 living families may be briefly characterized as follows.

Pteropodidae are in general the most primitive of living bats and are placed in the suborder Megachiroptera, characterized by more primitive ears and shoulder joints. Most still retain a claw on the second digit (absent in all other bats, suborder Microchiroptera), and few have developed an echolocation (sonar) mechanism, found in all Microchiroptera. The teeth, however,



Features of the bat. (*From R. Peterson, Silently by Night, McGraw-Hill, 1964*)

are highly modified for eating fruit or nectar. The family, with 38 genera and 149 species, is widely distributed in the tropics and subtropics of the Eastern Hemisphere. While some species are quite small, the family includes the largest of all bats, with wingspreads of up to $5^1/_2$ ft (1.65 m).

Rhinopomatidae is an insect-eating family, with one genus and two species, found chiefly in arid regions of northern Africa and southern Asia. These bats are characterized by long wirelike tails and rudimentary nose leaves.

Emballonuridae is an insectivorous family that includes 12 genera with 45 species found in the tropics of both Eastern and Western hemispheres. Like the Pteropodidae, these bats have well-developed bony processes behind the eye sockets. The tail extends only partly across the uropatagium.

Noctilionidae, a tropical American family, is represented by two species in one genus, including a highly specialized fish-eating species. Fish are detected by echolocation and gaffed by the long clawed feet.

Nycteridae are insect eaters, with 1 genus and 12 species found in Africa and southern Asia. These bats have an extensive basin behind the nose, which is partly bridged over by flaps of skin, leaving a mere slit between them.

The four genera of the Megadermatidae (with five species) occur in tropical Africa, southeastern Asia and adjoining islands, and northern Australia. Some species are insect-eating; others feed on small vertebrates, including other bats.

Rhinolophidae are insect-eating bats that are widely distributed in the Eastern Hemisphere. They are remarkable for their extremely complex nose leaves. There are 11 genera represented by 129 species.

Phyllostomatidae includes 120 species (in 50 genera) of tropical and subtropical bats. They possess simple nose leaves and a tremendous variety in structure, reflecting an equal diversity in food habits. Primitively insect-eating, many have become fruit or nectar feeders, and a few are predators on small vertebrates, including other bats.

Desmodontidae are the true vampires, essentially confined to the mainland of tropical America. The teeth and tongue are highly modified for taking of blood. This family includes three genera with three species.

Natalidae (one genus and four species) are tropical American insect-eating species with large funnellike ears.

Furipteridae is an insect-eating family, confined to tropical South America, and represented by two species in two genera. The thumb is reduced in size and largely enclosed in the wing membrane.

Thyropteridae includes two species (in one genus), confined to the tropical American mainland. The large suction disks on the thumbs and hindfeet enable them to roost on the smooth inner surfaces of large rolled-up leaves.

Myzopodidae, with a single species, is confined to Madagascar, eats insects, and has suckers on the thumbs and feet rather like those of the Thyropteridae.

Vespertilionidae, a nearly cosmopolitan family with 279 species in 34 genera, occur almost everywhere that bats occur. Almost all are insect-eating and a few catch fish. In all, the tail is long, extending to the edge of the uropatagium. Most have no special facial modifications. A few have very large ears or small simple nose leaves. In spite of its many species, the family shows little structural diversity. Echolocation, present in all families of bats except the Pteropodidae, is perhaps most highly developed here and is used for catching insects as well as avoiding obstacles.

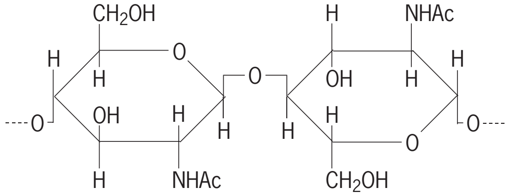
Mystacinidae, with a single insect-eating species, is confined to New Zealand. It has a short tail, not reaching the edge of the uropatagium, and stout hindlegs and body.

Molossidae is widely distributed in the tropics and subtropics. Feeding on insects, they have long tails which extend beyond their uropatagia. The body and hindlegs are stoutly built. The family includes 81 species in 10 genera.

Bats have a poor fossil record, but have been distinct at least since the Eocene, some 50,000,000 years ago. *See* BAT; MAMMALIA. [K.F.K.]

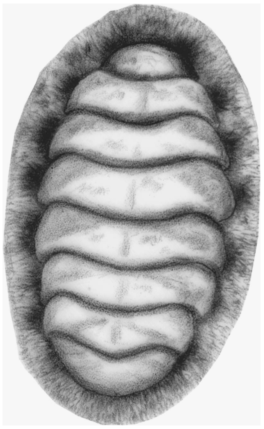
Chitin A polysaccharide found abundantly in nature. Chitin forms the basis of the hard shells of crustaceans, such as the crab, lobster, and shrimp. The exoskeleton of insects is also chitinous, and the cell walls of certain fungi contain this substance.

Chitin is a long, unbranched molecule consisting entirely of *N*-acetyl-D-glucosamine units linked by β-1,4 bonds (see illustration). It may be thought of as cellulose in which the hydroxyl groups on the second carbon are replaced with $NHCOCH_3$ groups. Chitin is considered to be synthesized in nature by an enzyme which is capable of effecting a glycosyl transfer of the *N*-acetyl-D-glucosamine from uridinediphosphate-*N*-acetyl-D-glucosamine to a preformed chitodextrin acceptor, forming the polysaccharide. This stepwise enzymic transfer results in the production of the long chain of β-*N*-acetyl-D-glucosamine units, which is insoluble chitin. *See* CELLULOSE; OPTICAL ACTIVITY; POLYSACCHARIDE. [W.Z.H.]



β-*N*-acetyl-D-glucosamine unit of chitin.

Chiton A member of the class Polyplacophora in the phylum Mollusca. Chitons are also called loricates or coat-of-mail shells. All chitons are marine and, except for a few deep-sea forms, all live in the low intertidal and upper sublittoral, typically on wave-swept rocks. The flattened elliptical body bears eight articulated shell plates dorsally on the mantle and a ventral suctorial foot, features which are clearly adapted for life adhering to hard and uneven surfaces in the lower littoral zone (see illustration).



Dorsal view of a mossy chiton (*Mopalia muscosa*) showing the eight articulated plates of the shell and the pallial girdle with calcareous spicules.

Normally, chitons can resist the strongest surf action but, in the unlikely natural event of a chiton being washed off its rock (or if removed by a human collector), the articulated shell allows it to curl up to protect the soft foot and gills of its underside. Chiton species living on both sides of the Atlantic are relatively small (0.4–1.2 in. or 1–3 cm long) and unobtrusive. Only four genera have living species offshore and in deeper waters (to 20,000 ft or 6000 m), but they may be related to the earliest fossil chitons. *See* MOLLUSCA; POLYPLACOPHORA. [W.D.R.-H.]

Chlamydia A genus of bacteria with a growth cycle differing from that of all other microorganisms. Chlamydiae grow only in living cells and cannot be cultured on artificial media. Although capable of synthesizing macromolecules, they have no system for generating energy; the host cell's energy system fuels the chlamydial metabolic processes. The genome is relatively small; the genomes of *C. pneumoniae* and *C. trachomatis* have been completely sequenced.

The chlamydial infectious particle, called the elementary body, is round and about 350–450 nanometers in diameter. It enters a susceptible host cell and changes to a metabolically active and larger (approximately 800–1000 nm in diameter) reticulate body that divides by binary fission. The entire growth cycle occurs within a vacuole that segregates the chlamydia from the cytoplasm of the host cell. The reticulate bodies change back to elementary bodies, and then the cell lyses and the infectious particles are released. The growth cycle takes about 48 h.

Human diseases are caused by three species of *Chlamydia*. *Chlamydia trachomatis* is almost exclusively a human pathogen, and one of the most common. Infections occur in two distinct epidemiologic patterns. In many developing countries, *C. trachomatis* causes trachoma, a chronic follicular keratoconjunctivitis. It is the world's leading cause of preventable blindness, affecting approximately 500 million people. In areas where this condition is highly endemic, virtually the entire population is infected within the first few years of life. Most active infections are found in childhood. By age 60, more than 20% of a population can be blinded as a result of trachoma. *See* EYE DISORDERS.

Chlamydia trachomatis is the most common sexually transmitted bacterial pathogen; an estimated 3–4 million cases occur each year in the United States, and there are close to 90 million worldwide. The most common manifestation is nongonococcal urethritis in males. The cervix is the most commonly infected site in women. Ascending infections can occur in either sex, resulting in epididymitis in males or endometritis and salpingitis in females. Chlamydial infection of the fallopian tube can cause late consequences such as infertility and ectopic pregnancy, even though the earlier infection is asymptomatic. The infant passing through the infected birth canal can acquire the infection and may develop either conjunctivitis or pneumonia. A more invasive form of *C. trachomatis* causes a systemic sexually transmitted disease called lymphogranuloma venereum. *See* SEXUALLY TRANSMITTED DISEASES.

Chlamydia psittaci is virtually ubiquitous among avian species and is a common pathogen among lower mammals. It is economically important in many countries as a cause of abortion in sheep, cattle, and goats. It causes considerable morbidity and mortality in poultry. *Chlamydia psittaci* can infect humans, causing the disease psittacosis. Psittacosis can occur as pneumonia or a febrile toxic disease without respiratory symptoms.

Chlamydia pneumoniae appears to be a human pathogen with no animal reservoir. It is of worldwide distribution and may be the most common human chlamydial infection. It appears to be an important cause of respiratory disease.

Azithromycin is the drug of choice for uncomplicated chlamydial infection of the genital tract. Two therapeutic agents require longer treatment regimens: doxycycline, a tetracycline antibiotic, is the first alternate treatment; erythromycin may be used for those who are tetracycline-intolerant, as well as for pregnant women or young children. *See* MEDICAL BACTERIOLOGY. [J.S.]

Chlorine A chemical element, Cl, atomic number 17 and atomic weight 35.453. Chlorine exists as a greenish-yellow gas at ordinary temperatures and pressures. It is second in reactivity only to fluorine among the halogen elements, and hence is never found free in nature, except at the elevated temperatures of volcanic gases. It is estimated that 0.045% of the Earth's crust is chlorine. It combines with metals, nonmetals, and organic materials to form hundreds of chlorine compounds, the most important of which are discussed here. *See* PERIODIC TABLE.

Chlorine and its common acid derivative, hydrochloric (or muriatic) acid, were probably noted by experimental investigators as early as the thirteenth century. C. W. Scheele identified chlorine as "dephlogisticated muriatic acid" in 1774, and H. Davy proved that a new element had been found in 1810. Extensive production started 100 years later. During the twentieth century, the amount of chlorine used has been considered a measure of industrial growth.

Physical properties. The atomic weight of naturally occurring chlorine is 35.453 (based on carbon at 12). It is formed of stable isotopes of mass 35 and 37; radioactive isotopes have been made artificially. The diatomic gas has a molecular weight of 70.906. The boiling point of liquid chlorine (golden-yellow in color) is −33.97°C (−29.15°F) at 760 mm Hg (10^2 kilopascals) and the melting point of solid chlorine (tetragonal crystals) is −100.98°C (−149.76°F). The critical temperature is 144°C (292°F); the critical pressure is 78.7 atm; the critical volume is 1.745 ml/g; and density at the critical point is 0.573 g/ml. Thermodynamic properties include heat of sublimation at 7370 ± 10 cal/mole at 0 K, heat of evaporation at 4882 cal/mole at −33.97°C, heat of fusion at 1531 cal/mole, vapor heat capacity at a constant pressure of 1 atm of 8.32 cal/(mole °C) at 0°C (32°F) and 8.46 cal/(mole °C) at 100°C (212°F). Chlorine forms solid hydrates, $Cl_2 \cdot 6H_2O$ (pale-green crystals) and $Cl_2 \cdot 8H_2O$. It hydrolyzes in water as shown in reaction (1).

$$Cl_2 + H_2O \rightarrow HClO + HCl \qquad (1)$$

Chemical properties. Chlorine is one of four closely related chemical elements which have been called the halogen elements. Fluorine is more active chemically, and bromine and iodine are less active. Chlorine replaces iodine and bromine from their salts. It enters into substitution and addition reactions with both organic and inorganic materials. Dry chlorine is somewhat inert, but moist chlorine unites directly with most of the elements. *See* HALOGEN ELEMENTS.

Compounds. Sodium chloride, NaCl, is used directly as mined (rock salt), or as found on the surface, or as brine. It may also be dissolved, purified, and reprecipitated for use in foods or when chemical purity is required. Its main uses are in the production of soda ash and chlorine products. Farm use, refrigeration, dust and ice control, water treatment, food processing, and food preservation are other uses. Calcium chloride, $CaCl_2$, is usually obtained from brines or as a by-product of chemical processing. Its main uses are in road treatment, coal treatment, concrete conditioning, and refrigeration. *See* Halite.

Wet chlorine reacts with metals to form chlorides, most of which are soluble in water. It also reacts with sulfur and phosphorus and with other halogens as in reactions (2).

$$\begin{aligned} H_2 + Cl_2 &\rightarrow 2HCl \\ 2Fe + 3Cl_2 &\rightarrow 2FeCl_3 \\ 2S + Cl_2 &\rightarrow S_2Cl_2 \\ S + Cl_2 &\rightarrow SCl_2 \\ S + 2Cl_2 &\rightarrow SCl_4 \\ P_4 + 6Cl_2 &\rightarrow 4PCl_3 \\ P_4 + 10Cl_2 &\rightarrow 4PCl_5 \\ Br_2 + Cl_2 &\rightarrow 2BrCl \\ 2F_2 + Cl_2 &\rightarrow ClF + ClF_3 \end{aligned} \qquad (2)$$

The oxides of chlorine, dichlorine monoxide, Cl_2O, chlorine monoxide, ClO, chlorine dioxide, ClO_2, chlorine hexoxide, Cl_2O_6, and chlorine heptoxide, Cl_2O_7, are all made indirectly. Cl_2O is commonly called chlorine monoxide also. Chlorine dioxide, a green gas, has become increasingly important in commercial bleaching of cellulose, water treatment, and waste treatment.

Hydrogen chloride, HCl, is a colorless, pungent, poisonous gas which liquefies at 82 atm at 51°C (124°F). It boils at −85°C (−121°F) at 1 atm (10^2 kPa). Its major production is as the by-product of many organic chlorinations. It can be made by direct reaction of chlorine and hydrogen in an open combustion chamber submerged in cooled, aqueous hydrochloric acid solution. It is used as a strong acid and as a reducing agent.

Aluminum chloride, $AlCl_3$, is an anhydrous, white, deliquescent, hexagonal crystalline substance. Either scrap aluminum or the oxide (bauxite) may be chlorinated. Aluminum chloride is a catalyst for production of cumene, styrene, and isomerized butane. Of the aluminum chloride uses in anhydrous form, ethylbenzene production uses 25%, dyes 30%, detergents 15%, ethyl chloride 10%, drugs 8%, and miscellaneous production 12%. Hydrated and liquid forms are also available, 50% of which are used in drug and cosmetic production.

Ferric chloride, $FeCl_3$, is a solid composed of dark, hexagonal crystals. Much chlorine from chemical processes is converted to ferric chloride, which is then used for the manufacture of salts, pigments, pharmaceuticals, and dyes and for photoengraving, preparation of catalysts, and waste and sewage treatment.

Natural occurrence. Because many inorganic chlorides are quite soluble in water, they are leached out of land areas by rain and ground water to accumulate in the sea or in lakes that have no outlets. Seawater contains 18.97 g of chloride ion per kilogram (3% sodium chloride). Solar evaporation produces large deposits of salts in landlocked areas. Similar evaporation in the past is responsible for vast underground deposits of rock salt and brines in Michigan, central New York, the Gulf Coast of Texas, Stassfurt in Germany, and elsewhere. These deposits are mainly of sodium chloride, the supply of which is unlimited for practical purposes. Other rocks and minerals in the Earth's surface average slightly over 0.03% chloride. *See* Halogen minerals; Saline evaporite.

Manufacture. The first electrolytic process was patented in 1851 by Charles Watt in Great Britain. In 1868 Henry Deacon produced chlorine from hydrochloric acid and oxygen at 400°C (750°F) with copper chloride absorbed in pumice stone as a catalyst. The electrolytic cells now used may be classified for the most part as diaphragm and mercury types. Both make caustic (NaOH or KOH), chlorine, and hydrogen. The economics of the chlor-alkali industry mainly involve the balanced marketing or internal use of caustic and chlorine in the same proportions as obtained from the electrolytic cell process.

Uses. Chlorine is an excellent oxidizing agent. Historically, the use of chlorine as a bleaching agent in the paper, pulp, and textile industries and as a germicide for drinking water preparation, swimming pool purification, and hospital sanitation has made community living possible. Chlorine is used to produce bromine from bromides found in brines and seawater. The automotive age increased the production of bromine tremendously for the manufacture of ethylene dibromide for use in gasoline. Compounds of chlorine are used as bleaching agents, oxidizing agents, solvents, and intermediates in the manufacture of other substances. *See* Herbicide. [J.Do.; F.W.Ko.; R.W.B.]

Chlorite One of a group of layer silicate minerals, usually green in color, characterized by a perfect cleavage parallel to (001). The cleavage flakes are flexible but inelastic, with a luster varying from pearly or vitreous to dull and earthy. The hardness on the cleavage is about 2.5. The specific gravity of chlorate varies between 2.6 and 3.3 as a function of composition.

Chlorite is a common accessory mineral in low- to medium-grade regional metamorphic rocks and is the dominant mineral in chlorite schist. It can form by alteration of ferromagnesian minerals in igneous rocks and is found occasionally in pegmatites and vein deposits. It is a common constituent of altered basic rocks and of alteration zones around metallic ore bodies. Chlorite also can form by diagenetic processes in sedimentary rocks. *See* Authigenic minerals; Clay minerals; Diagenesis; Silicate minerals. [S.W.Ba.]

Chloritoid A hydrous iron aluminum silicate mineral with an ideal formula of $Fe_2^{2+}Al_4O_2(SiO_4)_2(OH)_4$. Chloritoid occurs as platy, black or dark green crystals, rarely more than a few millimeters in size. Its density ranges from 3.46 to 3.80 g/cm^3, and its hardness on the Mohs scale is 6.5. *See* Hardness scales.

Chloritoid is increasingly being recognized as a constituent in rocks that formed under high-pressure conditions. It is found in association with glaucophane in blueschist-facies metamorphic rocks, and with amphibole and pyroxene in eclogite-facies metamorphic rocks. These are rocks that formed under conditions thought to prevail at the base of the Earth's crust or in the mantle. Experimental studies of metamorphism of basalt under these conditions indicate the formation of chloritoid at pressures exceeding 2300 MPa (23 kbar) and at a temperature of 650°C (1200°F). In these high-pressure occurrences of chloritoid, the chloritoid is rich in magnesium, having a value of $Mg/(Mg + Fe)$ ranging from 0.38 to 0.40. *See* Metamorphic rocks. [T.C.L.]

Chloromonadida An order of the class Phytamastigophorea, also known as the Chloromonadina. These poorly known flagellates are grass-green or colorless, somewhat flattened, and have two equal flagella, one anterior, the other trailing. All known genera are free-swimming, although *Reckertia* and *Thaumatomastix* form pseudopodia. They vary in size from 30 to 100 micrometers. Chromatophores are small disks, stigmas are lacking, and fat is the storage product. Trichocysts are found in three genera. The nucleus is large, with nucleoli and chromosomes visible during interphase. One or two anterior vacuoles are present and a reservoir seems to be present in *Trentonia* and *Gonyostomum*. Life cycles are unknown, but longitudinal division occurs. The taxonomic position of the class is poorly defined. *See* Phytamastigophorea. [J.B.L.]

Chlorophyceae A large and diverse class of plants, commonly called green algae, in the chlorophyll *a-b* phyletic line (Chlorophycota). Estimated number of taxa varies widely;

560 genera and 8600 species are conservative estimates. *See* Chlorophycota.

The green algae exhibit great morphological diversity while sharing fundamental biochemical and ultrastructural features. Their photosynthetic pigments are similar to those in higher plants and include chlorophyll *a* and *b*, α-, β-, and γ-carotene, and various xanthophylls. Chloroplasts vary in number and shape, but always have two membranes, two to five thylakoids per lamella, and usually one or more pyrenoids. A cell wall, which may be calcified, is usually present, often contains cellulose, hydroxyproline glycosides, xylan, and mannan. The chief food reserve is starch, stored in the chloroplast as granules which often sheathe a pyrenoid. Motile cells usually have two or four apically inserted smooth flagella of approximately equal length. *See* Cell plastids; Chlorophyll; Photosynthesis.

Almost all somatic cell types known for algae occur among the Chlorophyceae, the exceptions being rhizopodial unicells and complex multicellular thalli differentiated into macroscopic organs. Ultrastructural studies have revealed differences in details of nuclear and cell division, cell coverings, plasmodesmata, pyrenoids, and flagellar structure that are correlated among themselves and with certain traditional characters to a degree that strongly suggests that the ulotrichine line is polyphyletic, with desmoschisis having evolved at least four times. Moreover, these studies suggest that the ultimate ancestral green flagellate was prasinophycean (asymmetrical and covered with scales) rather than *Chlamydomonas*-like. Integration of these studies and inferences suggests four phyletic lines: chlorophycean, ulvophycean, charophycean, and pleurastrophycean.

In addition to the four phyletic lines, each of which includes monads as well as multicellular algae, there is a residual group of primitive green flagellates for which the name Micromonadophyceae has been proposed. These monads are scaly or secondarily naked and have one to four flagella arising from an apical pit or lateral depression. The interzonal mitotic spindle persists during cytokinesis. This group corresponds to the class Prasinophyceae in the present classification. For the sake of consistency, however, Prasinophyceae and Charophyceae are treated elsewhere in this work as separate classes. *See* Algae; Charophyceae; Prasinophyceae. [P.C.Si.; R.L.Moe]

Chlorophycota A division of the plant kingdom (also known as Chlorophyta or Chlorophycophyta) comprising all algae that have chlorophyll *a* and *b* except the Euglenophyceae, and that in all other respects are so different as to suggest a separate origin of their photosynthetic pigments. Three classes, Charophyceae (charophytes), Chlorophyceae (green algae), and Prasinophyceae, are recognized. *See* Algae; Charophyceae; Chlorophyceae; Prasinophyceae. [P.C.Si.; R.L.Moe]

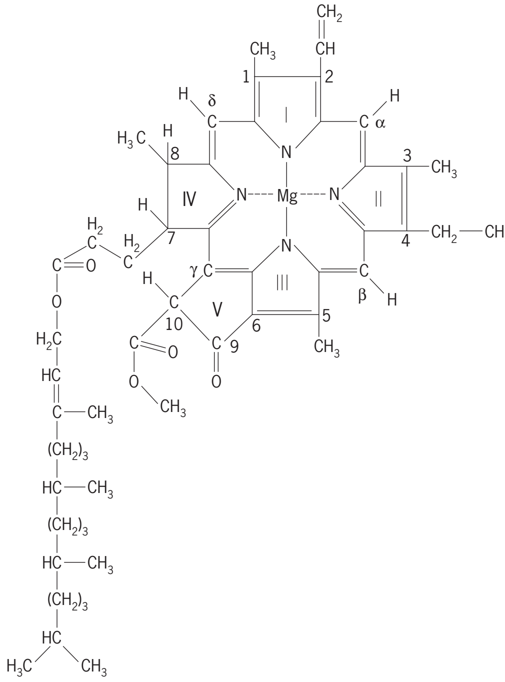
Chlorophyll The generic name for the intensely colored green pigments which are the photoreceptors of light energy in photosynthesis. These pigments belong to the tetrapyrrole family of organic compounds.

Five closely related chlorophylls, designated *a* through *e*, occur in higher plants and algae. The principal chlorophyll (Chl) is Chl *a*, found in all oxygen-evolving organisms; photosynthetic bacteria, which do not evolve O_2, contain instead bacteriochlorophyll (Bchl). Higher plants and green algae contain Chl *b*, the ratio of Chl *b* to Chl *a* being 1:3. Chlorophyll *c* (of two or more types) is present in diatoms and brown algae. Chlorophyll *d*, isolated from marine red algae, has not been shown to be present in the living cell in large enough quantities to be observed in the absorption spectrum of these algae. Chlorophyll *e* has been isolated from cultures of two algae, *Tribonema bombycinum* and *Vaucheria hamata*. In higher plants the chlorophylls and the above-mentioned pigments are contained in lipoprotein bodies, the plastids. *See* Carotenoid; Cell plastids; Photosynthesis.

Chlorophyll molecules have three functions: They serve as antennae to absorb light quanta; they transmit this energy from one chlorophyll to another by a process of "resonance transfer;" and finally, this chlorophyll molecule, in close association with enzymes, undergoes a chemical oxidation (that is, an electron of high potential is ejected from the molecule and can then be used to reduce another compound). In this way the energy of light quanta is converted into chemical energy.

The chlorophylls are cyclic tetrapyrroles in which four 5-membered pyrrole rings join to form a giant macrocycle. Chlorophylls are members of the porphyrin family, which plays important roles in respiratory pigments, electron transport carriers, and oxidative enzymes. *See* Porphyrin.

It now appears that the chlorophyll *a* group may be made up of several chemically distinct Chl *a* species. The structure of monovinyl cholorophyll *a*, the most abundant of the Chl *a* species, is shown in the illustration.



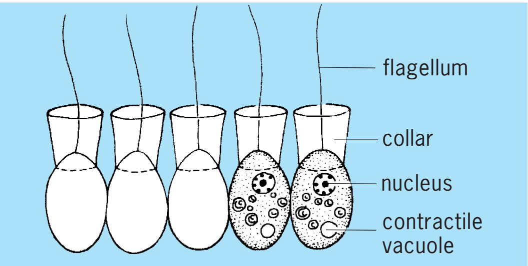
Structure of chlorophyll *a* ($C_{55}H_{72}O_5N_4Mg$).

The two major pigments of protoplasm, green chlorophyll and red heme, are synthesized from ALA (δ-aminolevulinic acid) along the same biosynthetic pathway to protoporphyrin. ALA is converted in a series of enzymic steps, identical in plants and animals, to protoporphyrin. Here the pathway branches to form (1) a series of porphyrins chelated with iron, as heme and related cytochrome pigments; and (2) a series of porphyrins chelated with magnesium which are precursors of chlorophyll. *See* Hemoglobin.

Chlorophylls reemit a fraction of the light energy they absorb as fluorescence. Irrespective of the wavelength of the absorbed light, the emitted fluorescence is always on the long-wavelength side of the lowest energy absorption band, in the red or infrared region of the spectrum.

The fluorescent properties of a particular chlorophyll are functions of the structure of the molecule and its immediate environment. Thus, the fluorescence spectrum of chlorophyll in the living plant is always shifted to longer wavelengths relative to the fluorescence spectrum of a solution of the same pigment. This red shift is characteristic of aggregated chlorophyll. [G.; S.Gr.; G.P.]

Choanoflagellida An order of the class Zoomastigophorea, superclass Mastigophora, subphylum Sarcomastigophora, in the phylum Protozoa. They are principally small, single-celled or colonial, structurally simple, colorless flagellates distinguished by having the anterior end surrounded by a thin protoplasmic collar, within which is an ingestive area for particu-



A linear colony of the choanoflagellate, *Desmarella moniliformis.*

late matter, for example, bacteria. A single flagellum arises from the center of this collar (see illustration). They are widespread in fresh and salt water and are common in inshore waters. *See* PROTOZOA; SARCOMASTIGOPHORA; ZOOMASTIGOPHOREA. [J.B.La.]

Choke (electricity)

An inductor that is used to prevent electric signals and energy from being transmitted along undesired paths or into inappropriate parts of an electric circuit or system. Power-supply chokes prevent alternating-current components, inherent to a power supply, from entering the electronic equipment. Radio-frequency chokes (RFCs) prevent radio-frequency signals from entering audio-frequency circuits. The printed circuit boards used in virtually all electronic equipment such as computers, television sets, and high-fidelity audio systems typically have one or more chokes. The purposes of these chokes are the (1) attenuation of spurious signals generated in the equipment itself so that these signals will not be transmitted to other parts of the circuit or beyond the overall system to other electronic devices; (2) prevention of undesired signals or electrical noise generated in other parts of the system from adversely affecting circuit performance; and (3) prevention of ripple from the power supply from degrading system behavior. Waveguide chokes keep microwave energy from being transmitted to the wrong part of a waveguide system. *See* ELECTRICAL NOISE; ELECTRONIC POWER SUPPLY; PRINTED CIRCUIT; RIPPLE VOLTAGE; WAVEGUIDE.

In its simplest form, a choke or an inductor is a coil of wire (usually copper) wound around and insulated from a core, which may or may not be ferromagnetic. Ferromagnetic cores tend to increase inductance, reduce physical size, and reduce electromagnetic coupling between circuit elements, and they may increase power loss and resultant heating. Such cores often lead to nonlinear or swinging chokes, commonly found in power supplies, where the nonlinearity may be an advantage. *See* INDUCTANCE; INDUCTOR. [E.C.Jo.]

Choked flow

Fluid flow through a restricted area whose rate reaches a maximum when the fluid velocity reaches the sonic velocity at some point along the flow path. The phenomenon of choking exists only in compressible flow and can occur in several flow situations. *See* COMPRESSIBLE FLOW.

Through varying-area duct. Choked flow can occur through a convergent flow area or nozzle attached to a huge reservoir. Flow exits the reservoir through the nozzle if the back pressure is less than the reservoir pressure. When the back pressure is decreased slightly below the reservoir pressure, a signal from beyond the nozzle exit is transmitted at sonic speed to the reservoir. The reservoir responds by sending fluid through the nozzle. Further, the maximum velocity of the fluid exists at the nozzle throat where the area is smallest.

When the back pressure is further decreased, fluid exits the reservoir more rapidly. Eventually, however, the velocity at the throat reaches the sonic velocity. Then the fluid velocity at the throat is sonic, and the velocity of the signal is also sonic. Therefore, further decreases in back pressure are not sensed by the reservoir, and correspondingly will not induce any greater flow to exit the reservoir. The nozzle is thus said to be choked, and the mass flow of fluid is a maximum. *See* MACH NUMBER; NOZZLE; SOUND; SUPERSONIC DIFFUSER.

With friction. Choked flow can also occur through a long constant-area duct attached to a reservoir. As fluid flows through the duct, friction between the fluid and the duct wall reduces the pressure acting on the fluid. As pressure is reduced, other fluid properties are affected, such as sonic velocity, density, and temperature. The maximum Mach number occurs at the nozzle exit, and choked flow results when this Mach number reaches 1.

With heat addition. A reservoir with a constant-area duct attached may also be considered in the case that the flow through the duct is assumed to be frictionless but heat is added to the system along the duct wall. *See* FLUID FLOW; GAS DYNAMICS. [W.S.J.]

Cholera

A severe diarrheal disease caused by infection of the small bowel of humans with *Vibrio cholerae*, a facultatively anaerobic, gram-negative, rod-shaped bacterium. Cholera is transmitted by the fecal-oral route. Cholera has swept the world in seven pandemic waves. These involved the Western Hemisphere several times in the 1800s, and again in Peru in 1991. Whereas previous cholera outbreaks were associated with high mortality rates, through understanding of its pathophysiology it can now be said that no one should die of cholera who receives appropriate treatment soon enough.

Cholera produces a secretory diarrhea caused by the protein cholera enterotoxin (CTX). The toxin causes hypersecretion of chloride and bicarbonate and inhibition of sodium absorption in host membranes leading to the secretion of the large volumes of isotonic fluid which constitute the diarrhea of severe cholera. Treatment consists of replacing the fluids and electrolytes lost in the voluminous cholera stool. This can be done intravenously or orally. Appropriate antibiotics can also be used. The incubation period may be less than one day or up to several days; properly treated, the patient should recover in 4 or 5 days. The disease produces immunization, and convalescents rarely get cholera again. *See* DIARRHEA.

Despite the fact that the cholera bacteria were first discovered by Robert Koch in 1883 and a cholera vaccine was introduced 3 years later, there is still no effective, economical, and nonreactogenic vaccine. Use of a killed whole-cell vaccine administered parenterally (via injection) was eliminated because of expense, reactogenicity, and lack of efficacy. Experimental vaccines currently being evaluated include genetically engineered living attentuated preparations administered orally (or intranasally), killed whole-cell vaccines administered orally, and conjugated vaccines (polysaccharide and toxin antigens) administered parenterally. Efforts are also being made to include cholera antigens transgenically in edible plants.

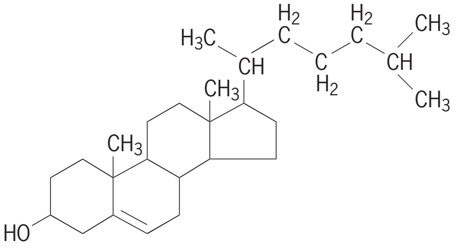
A complicating feature is the fact that of approximately 150 recognized serogroups of *V. cholerae*, until 1992 only two, classical (first described by Koch) and El Tor (recognized later), of serogroup O1 have been responsible for all epidemic cholera. In 1992 a recently recognized serogroup, O139, caused epidemic cholera in India and Bangladesh and, for a time, replaced the resident El Tor vibrios. O139 and El Tor are antigenically distinct, so a new vaccine will be required for O139. The emergence of O139 raises the specter that other serogroups of *V. cholerae* may acquire virulence and epidemicity.

The best ways to avoid cholera are by chlorination of water, sanitary disposal of sewage, and avoidance of raw or improperly cooked seafood, which may have become infected by ingesting infected plankton in epidemic areas. [R.A.Fin.]

Cholesterol

A cyclic hydrocarbon alcohol commonly classified as a lipid because it is insoluble in water but soluble in a number of organic solvents. It is the major sterol in all vertebrate cells and the most common sterol of eukaryotes. In vertebrates, the highest concentration of cholesterol is in the myelin sheath that surrounds nerves and in the plasma membrane that surrounds all cells. *See* Lipid.

Cholesterol can exist either in the free (unesterified) form (see structure below) or in the esterified form, in which a fatty acid is bound to the hydroxyl group of cholesterol by an ester bond. The free form is found in membranes. Cholesteryl esters are normally found in lipid droplets either within the cells of steroidogenic tissues, where it can be converted to free cholesterol and then to steroid hormones, or in the middle of spherical lipid-protein complexes, called lipoproteins, that are found in blood. *See* Cell membranes.



Cholesterol, together with phospholipids and proteins, is important in the maintenance of normal cellular membrane fluidity. At physiological temperatures, the cholesterol molecule interacts with the fatty acids of the membrane phospholipids and causes increased packing of the lipid molecules and hence a reduction of membrane fluidity. Thus, all vertebrate cells require cholesterol in their membranes in order for the cell to function normally. Cholesterol is also important as a precursor for a number of other essential compounds, including steroid hormones, bile acids, and vitamin D. *See* Lipid metabolism; Steroid.

Cellular cholesterol is obtained both from the diet, following its absorption in the intestine, and from synthesis within all cells of the body. Foods that are particularly high in cholesterol include eggs, red meat, and organs such as liver and brain. About 40–50% of the dietary cholesterol is absorbed from the intestine per day. In contrast, plant sterols are very poorly absorbed. Cholesterol synthesis occurs in all vertebrate cells but is highest in the liver, intestine, and skin, and in the brain at the time of myelination.

Cholesterol and cholesteryl esters are essentially insoluble in water. In order to transport these compounds around the body in the blood, the liver and intestine produce various lipid-protein complexes, called lipoproteins, which serve to solubilize them. Lipoproteins are large, complex mixtures of cholesterol, cholesteryl esters, phospholipids, triglycerides (fats), and various proteins. The major lipoproteins include chylomicrons, very low density lipoprotein (VLDL), low-density lipoprotein, and high-density lipoprotein (HDL).

Total plasma cholesterol levels of less than 200 mg/100 ml are considered desirable. Values of 200–239 or greater than 239 mg per 100 ml are considered, respectively, borderline high or high risk values, indicating the potential for a heart attack. High levels of low-density lipoprotein in the plasma are associated with increased risk of atherosclerosis, ("hardening of the arteries"), which involves deposition of cholesterol and other lipids in the artery wall. Diets low in cholesterol and saturated fats often result in a reduction in total plasma and LDL cholesterol levels. Such changes in blood cholesterol levels are thought to be beneficial and to reduce the incidence of heart attacks. *See* Arteriosclerosis. [P.A.E.]

Choline A compound, trimethyl-β-hydroxyethylammonium hydroxide, used by the animal organism as a precursor of acetylcholine and as a source of methyl groups. It is a strongly basic hygroscopic substance with the formula

$$(CH_3)_3\equiv\overset{+}{N}-CH_2-CH_2OH$$

Choline deficiency in animals is associated with fatty livers, poor growth, and renal lesions. It is a lipotropic agent. There is no direct evidence of disease in humans due to choline deficiency, although there have been suggestions that some of the liver, kidney, or pancreas pathology seen in various nutritional deficiency states may be related to choline insufficiency. Choline is found in acetylcholine, which is necessary for nerve impulse propagation, and in phospholipids.

Humans eat 50–600 mg of choline per day, but only excrete 2–4 mg. Thus, conventional tests are of no value in studying choline requirements, and no knowledge of human choline requirements exists. *See* Acetylcholine. [S.N.G.]

Chondrichthyes A class of vertebrates comprising the cartilaginous, jawed fishes. The Chondrichthyes have traditionally included the subclasses Elasmobranchii (sharks, skates, and rays) and Holocephali (ratfishes). A classification scheme for the Chondrichthyes follows; for detailed information see separate articles on each group listed.

- Class Chondrichthyes
  - Subclass Elasmobranchii
    - Order: Cladoselachii
      - Pleurocanthodii
      - Selachii
      - Batoidea
  - Subclass Holocephali
    - Order Chimaeriformes

A group of Devonian armored fishes, the Placodermi, has usually been regarded as ancestral to the Chondrichthyes, but this derivation is not certain. Another group of primitive jawed fishes called acanthodians, which are considered by many as ancestral to the higher bony fishes, exhibit certain primitive elasmobranch-like features. In any case it is probable that the elasmobranchs and ratfishes arose independently of each other sometime during the Silurian or Early Devonian. *See* Acanthodii; Placodermi.

The most distinctive feature shared by the elasmobranchs and ratfishes is the absence of true bone. In both groups the endoskeleton is cartilaginous; in some cases it may be extensively calcified. Because even calcified cartilage is rarely preserved, the fossil record of the Chondrichthyes is represented mainly by teeth and spines, with only occasional associated skeletons. *See* Skeletal system.

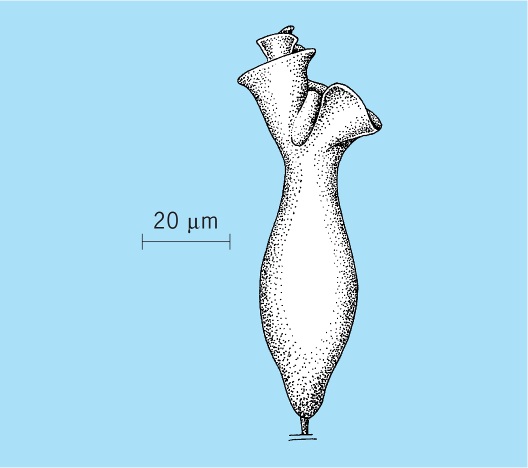
Other characteristics of the Chondrichthyes include placoid scales, clasper organs on the pelvic fins of males for internal fertilization, a urea-retention mechanism, and the absence of an air (swim) bladder. Both groups have primarily always been marine predators, although they have repeatedly invaded fresh water throughout their long history. The elasmobranchs have probably always fed as they do today, on other fishes as well as on soft and hard-bodied invertebrates. The ratfishes have most likely concentrated on invertebrates, although modern forms occasionally also feed on smaller fishes. *See* Ray; Scale (zoology); Shark; Swim bladder. [B.S.]

Chondrostei The most archaic of three organizational levels (infraclasses) of the subclass Actinopterygii, or rayfin fishes. Chondrosteans of the order Palaeonisciformes appeared first in the Lower Devonian, and by Middle Devonian were abundant contemporaries of the early crossopterygians and lungfishes, representative of the other two subclasses of bony fishes. Palaeonisciformes were diversified and abundant in sturgeons (order Acipenseriformes), which persist in the modern fauna as highly specialized and in some ways degenerate chondrosteans.

Even more like the palaeonisciforms than the sturgeons are the surviving African fishes of the order Polypteriformes, which are known only since the Eocene but are probably much older. *See* ACIPENSERIFORMES; PALAEONISCIFORMES; POLYPTERIFORMES.

Primitive chondrosteans were mostly small- or moderate-sized fishes with a heavy armor of rhomboidal, enameled scales. The heterocercal tail was preceded on the midline, above and below, by series of enlarged fulcral scales. There was usually a spiracle behind the eye. The head was heavily plated and relatively inflexible, with the maxilla firmly bound to the cheek bones. Feeding was accomplished largely by biting and gulping, aided by simple conical teeth. *See* ACTINOPTERYGII; SCALE (ZOOLOGY). [R.M.B.]

Chonotrichida An order of the Holotrichia. This is a small group of curious, vase-shaped ciliates, commonly found as ectocommensals on marine crustaceans. They attach to their hosts by a short, secreted stalk, and their bodies are practically devoid of ciliature. *Spirochona* (see illustration) is a common example of this order. *See* HOLOTRICHIA; PROTOZOA. [J.O.C.]



***Spirochona*, an example of a chonotrichid.**

Chopping The act of interrupting an electric current, beam of light, or beam of infrared radiation at regular intervals. This can be accomplished mechanically by rotating a vibrating mirror in the path of the beam to deflect it away from its intended source at regular intervals. A current can be chopped with an electromagnetic vibrator having contacts on its moving armature. A current can also be chopped electronically by passing it through a multivibrator or other switching circuit. Chopping is generally used to change a direct-current signal into an alternating-current signal that can more readily be amplified. *See* MULTIVIBRATOR.

Chopping has been increasingly used inside analog integrated circuits. Solid-state switches and capacitors are used to chop operational amplifiers, greatly improving their offset voltages. Chopping is also used in analog large-scale-integrated switched-capacitor filters as a means for reducing their undesirable $1/f$ (inverse-frequency) noise. *See* AMPLIFIER; INTEGRATED CIRCUITS; OPERATIONAL AMPLIFIER; SWITCHED CAPACITOR. [E.J.S.]

Chordata The highest phylum in the animal kingdom, which includes the lancelets or amphioxi (Cephalochordata), the tunicates (Urochordata), the acorn worms and pterobranchs (Hemichordata), and the vertebrates (Craniata) comprising the lampreys, sharks and rays, bony fish, amphibians, reptiles, birds, and mammals. Members of the first three groups, the lower chordates, are small and strictly marine. The vertebrates are free-living; the aquatic ones are primitively fresh-water types with marine groups being advanced; and the members include animals of small and medium size, as well as the largest of all animals. *See* CEPHALOCHORDATA; HEMICHORDATA; TUNICATA; VERTEBRATA.

The typical chordate characteristics are the notochord, the dorsal hollow nerve cord, the pharyngeal slits, and a postanal tail. The notochord appears in the embryo as a slender, flexible rod filled with gelatinous cells and surrounded by a tough fibrous sheath, and contains, at least in some forms, transverse striated muscle fibers; it lies above the primitive gut. In lower chordates and the early groups of vertebrates, the notochord persists as the axial support for the body throughout life, but it is surrounded and gradually replaced by segmental vertebrae in the higher fish.

The dorsal hollow nerve cord grows from a specialized band of ectoderm along the middorsal surface of the embryo by a folding together of two parallel ridges. The anterior end enlarges slightly in larval tunicates and somewhat more in lancelets, but enlarges greatly in the vertebrates to form the brain. Vertebral evolution is characterized by continual enlargement of the brain. *See* NERVOUS SYSTEM (VERTEBRATE).

Paired slits develop as outpocketings of the posterior end of the mouth on the sides of the embryonic pharynx, a part of the digestive system, and are retained in all aquatic chordates. Pharyngeal slits originated as adaptations for filter feeding but soon became the primary respiratory organ, as blood vessels line the fine filaments on the margins of each slit. Water passing over the gills serves for gas exchange in addition to the original filter-feeding function, which was soon lost in the vertebrates. Internal gills were lost with the origin of tetrapods; larval and some adult amphibians possess external gills which are different structures. The pharyngeal slits in embryonic tetrapods close early in life, with the pharyngeal pouches becoming the site for development of glands, for example, the thyroid and the tonsils. *See* RESPIRATORY SYSTEM.

The chordate tail is part of the skeletal support, muscles, and nervous system which continues posteriad to the anus or posterior opening of the digestive system. It is a feature not found in any other animal group and serves to increase the force available to the animal for locomotion.

Much controversy still exists about the limits, origin, and affinities of the chordates. For example, opinions differ considerably as to whether the Hemichordata and the Pogonophora are related to the Chordata, although there is no question that the Hemichordata are closely related and part of the pharyngeal-slit filter-feeding radiation; the Hemichordata are here considered as members of the phylum Chordata, not as a separate phylum. Almost all workers agree that the Echinodermata are the closest relatives of the Chordata because of evidence ranging from embryonic development to biochemical resemblances, but there is dispute over which group is the more primitive. *See* ECHINODERMATA; POGONOPHORA.

The Chordata apparently arose from a group of elongated, segmented worms with three sets of body musculature (longitudinal, circular, and transverse) and transverse septa. The first change was the evolution of a segmented coelom, associated with improved locomotion; these animals possessed a hydrostatic skeleton and moved with a sinusoidal or peristaltic locomotion. The first chordate feature to appear was the notochord, which provided a stronger skeleton and permitted the reduction of the transverse and circular muscles. A notochord resulted in a fixed body length and the loss of peristaltic locomotion. The dorsal longitudinal muscles enlarged, and with this modification came the evolution of the dorsal hollow nerve cord. Having a notochord for support rather than a hydrostatic skeleton permitted the appearance of pharyngeal slits through the lateral walls of the anterior parts of the body, which served for increased filter feeding and subsequently for respiration. The presence of the notochord also permitted the appearance of a postanal tail and increased force for locomotion.

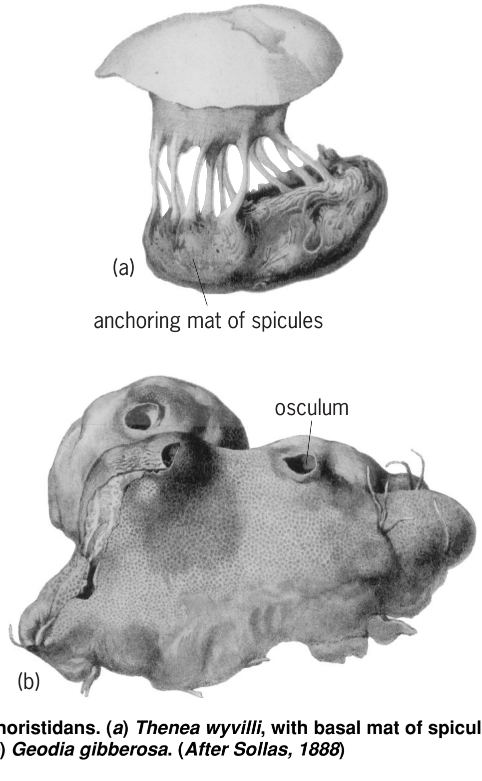
The earliest chordate with all of the typical features of the phylum probably looked much like the present-day lancelet or amphioxus (Cephalochordata), which burrows in shifting sands and needs considerable force to move through the heavy sand. Presumably all other chordates developed from this ancestral type, with their differing characteristics evolving because of conditions of their differing habitats. [W.J.B.]

Chorion The outermost of the several extraembryonic membranes in amniotes (reptiles, birds, and mammals) enclosing the embryo and all of its other membranes. The chorion, or serosa, is composed of an outer layer of ectodermal cells and an inner layer of mesodermal cells, collectively the somatopleure. Both layers are continuous with the corresponding tissue of the embryo. The chorion arises in conjunction with the amnion, another membrane that forms the outer limb of the somatopleure which folds up over the embryo in reptiles, birds, and some mammals. The chorion is separated from the amnion and yolk sac by a fluid-filled space, the extraembryonic coelom, or body cavity. In those mammals in which the amnion forms by a process of cavitation in a mass of cells, instead of by folding, the chorion forms directly from the trophoblastic capsule, the extraembryonic ectoderm, which becomes gradually underlain by extraembryonic mesoderm.

In reptiles and birds the chorion fuses with another extraembryonic membrane, the allantois, to form the chorioallantois, which lies directly below the shell membranes. An extensive system of blood vessels develops in the mesoderm of this compound membrane which serves as the primary respiratory and excretory organ for gaseous interchanges. In all mammals above the marsupials, the chorion develops special fingerlike processes (chorionic villi) extending outward from its surface. To a varying degree in different species of mammals, the villous regions of the chorion come into more or less intimate contact with the uterine mucosa, or uterine lining, of the mother, thereby forming the various placental types. *See* Allantois; Amniota; Fetal membrane; Germ layers. [N.T.S.]

Choristida An order of sponges of the class Demospongiae, subclass Tetractinomorpha, in which at least some of the megascleres are tetraxons, usually triaenes. Monaxonid spicules may occur as well. Microsclere types are chiefly asters, streptasters, or sigmas. A well-developed cortex comprising an outer gelatinous layer and an inner fibrous layer is often present.

Many choristidan sponges are radially symmetrical; spherical or ellipsoidal shapes are common. Others are encrusting or massive; very few form branching colonies. Some species have basal tufts or mats of long, thin spicules which anchor them in mud or sand on the sea bottom (see illustration). Choristidans are common in tidal regions and shallow waters of all seas, and some species extend down to depths of at least 11, 500 ft (3500 m). *See* Demospongiae. [W.D.H.]



Choristidans. (*a*) *Thenea wyvilli*, with basal mat of spicules. (*b*) *Geodia gibberosa*. (*After Sollas, 1888*)

Chromadorida An order of nematodes in which the amphid manifestation is variable but within superfamilies some constancy is apparent. The various amphids are reniform, transverse elongate loops, simple spirals, or multiple spirals not seen in any other orders or subclasses. The cephalic sensilla are in one or two whorls at the extreme anterior. In all taxa the cuticle shows some form of ornamentation, usually punctations that are apparent whether the cuticle is smooth or annulated. When developed, the stoma is primarily esophastome and is usually armed with a dorsal tooth, jaws, or protrusible rugae. The corpus of the esophagus is cylindrical; the isthmus is not seen; and the postcorpus, in which the heavily cuticularized lumen forms the cresentic valve, is distinctly expanded. The esophagointestinal valve is triradiate or flattened. The females usually have paired reflexed ovaries.

There are four chromadorid superfamilies: Choanolaimoidea, Chromadoroidea, Comesomatoidea, and Cyatholaimoidea. Choanolaimoidea are distinguished by a complex stoma in two parts. The group occupies marine habitats; some species are predaceous, but for many the feeding habits are unknown. Chromadoroidea comprise small to moderate-sized free-living forms that are mainly marine but are also found in fresh water and soil. Known species either are associated with algal substrates or are nonselective deposit feeders in softbottom sediments. Comesomatoidea, containing only the family Comesomatidae, are found in marine habitats, but the feeding habits are unknown. Cyatholaimoidea are found in marine, terrestrial, and fresh-water environments. *See* Nemata. [A.R.M.]

Chromatic aberration The type of error in an optical system in which the formation of a series of colored images occurs, even though only white light enters the system. Chromatic aberrations are caused by the fact that the refraction law determining the path of light through an optical system contains the refractive index, which is a function of wavelength. Thus the image position and the magnification of an optical system are not necessarily the same for all wavelengths, nor are the aberrations the same for all wavelengths. *See* Aberration (optics); Refraction of waves. [M.J.H.]

Chromatography A physical separation method in which the components of a mixture are separated by differences in their distribution between two phases, one of which is stationary (stationary phase) while the other (mobile phase) moves through it in a definite direction. The substances must interact with the stationary phase to be retained and separated by it.

Retention results from a combination of reversible physical interactions that can be characterized as adsorption at a surface, absorption in an immobilized solvent layer, and electrostatic interactions between ions. When the stationary phase is a porous medium, accessibility to its regions may be restricted and a separation can result from size differences between the sample components. More than one interaction may contribute simultaneously to a separation mechanism. The general requirements are that all interactions must be reversible, and that the two phases can be separated (two immiscible liquids, a gas and a solid, and so forth) in such a way that a distribution of sample components between phases and mass transport by one phase can be established. *See* Absorption; Adsorption.

Reversibility of the interactions can be achieved by purely physical means, such as by a change in temperature or by competition; the latter condition is achieved by introducing substances into the mobile phase that have suitable properties to ensure reversibility for the interactions responsible for retention of the sample components. Since this competition with the sample components is itself selective, it provides a general approach to adjusting the outcome of a chromatographic experiment to obtain a desired separation. It is an absolute requirement that a difference in the distribution constants for the sample components in the chromatographic system exist for a separation to be possible.

Methods. A distinction between the principal chromatographic methods can be made in terms of the properties of the mobile phase and configuration of the stationary phase. In gas chromatography the mobile phase is an inert gas, in supercritical fluid chromatography the mobile phase is a fluid (dense gas above its critical pressure and temperature), and in liquid chromatography the mobile phase is a liquid of low viscosity. The stationary phase can be a porous, granular powder with a narrow particle-size distribution packed into a tube (called a column) as a dense homogeneous bed. This configuration is referred to as a packed column and is nearly always used in liquid chromatography and is commonly used in supercritical fluid and gas chromatography. Alternatively, the stationary phase can be distributed as a thin film or layer on the wall of an open tube of capillary dimensions, leaving an open space through the center of the column. This configuration is referred to as an open tubular column (or incorrectly as a capillary column); and it is commonly used in gas chromatography, frequently used in supercritical fluid chromatography, but rarely used in liquid chromatography.

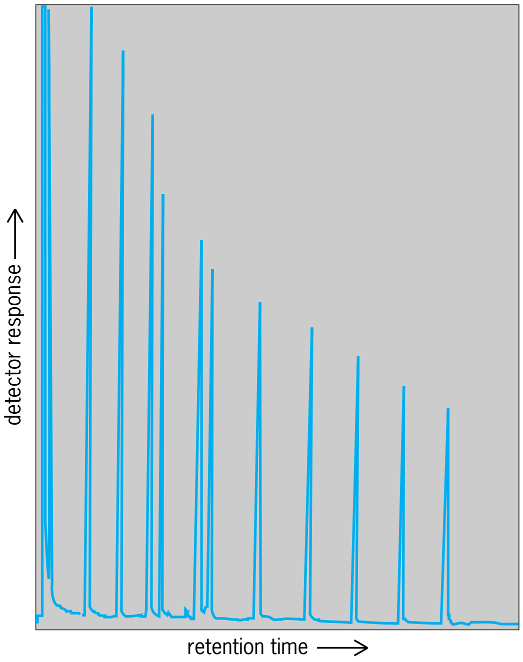
Thin-layer chromatography is a form of liquid chromatography in which the stationary phase is spread as a thin layer over the surface of a glass or plastic supporting structure. The stationary phase must be immobilized on the support by using a binder to impart the desired mechanical strength and stability to the layer. The samples are applied to the layer as spots or bands near the bottom edge of the plate. The separation is achieved by contacting the bottom edge of the plate below the line of samples with the mobile phase, which proceeds to ascend the layer by capillary action. This process is called development and is performed in a chamber, with the lower edge of the layer in contact with the mobile phase and the remaining portion of the layer in contact with solvent vapors from the mobile phase. The chamber may be a simple device such as a covered jar or beaker or a more elaborate device providing control of the mobile-phase velocity and elimination or control of the vapor phase. Thin-layer chromatography is the most popular form of planar chromatography having virtually replaced paper chromatography in laboratory practice. *See* GAS CHROMATOGRAPHY; GEL PERMEATION CHROMATOGRAPHY; LIQUID CHROMATOGRAPHY; SUPERCRITICAL-FLUID CHROMATOGRAPHY.

Uses. Chromatographic methods provide a means of analyzing samples (to determine component identity and relative amount), of isolating significant quantities of purified material for further experimentation or commerce, and for determining fundamental physical properties of either the samples or the mobile or stationary phases (for example, diffusion coefficients, solubilities, or thermodynamic properties). There are virtually no boundaries to the sample types that can be separated. Examples include organic and inorganic compounds in the form of fixed gases, ions, polymers, as well as other species. Applications are found in all areas of technological development, making chromatography one of the most widely used laboratory procedures in chemistry. Depending on intent, chromatography can be applied to trace quantities at the limit of detector response (for example, 10^{-15} g) or to kilogram amounts in preparative separations.

Instrumentation. Modern chromatographic methods are instrumental techniques in which the optimal conditions for the separation are set and varied by electromechanical devices external to the column or layer. Separations are largely automated, with important features of the instrumentation being control of the flow and composition of the mobile phase, introduction of the sample onto the stationary phase, and on-line detection of the separated components. In column chromatography the sample components are detected in the presence of the mobile phase after they have exited the stationary phase. In thin-layer chromatography the sample components are detected in the presence of the stationary phase, resulting in different detection strategies.

Instrument requirements differ by the needs of the method employed. Gas chromatography, for example, employs a mobile phase of constant composition at a few atmospheres of column inlet pressure and variation in the temperature of the column to effect a separation. Liquid chromatography uses a pump to select or vary the composition of the mobile phase with a high column inlet pressure (typically a few hundred atmospheres) and a constant temperature for the separation. These differences in optimized separation conditions result in different equipment configurations for each chromatographic method.

Interpretation. The results of a chromatographic experiment are summarized in a chromatogram (see illustration), a two-dimensional record of the detector response to the sample components (y axis) plotted against the residence time of the components in column chromatography or migration distance in planar chromatography (x axis). Individual compounds or mixtures of unseparated compounds appear as peaks in the chromatogram. These peaks are ideally symmetrical and occur at positions in the chromatogram that are characteristic of their identity, with a distribution around the mean position (apex of the peak) that is characteristic of the kinetic properties of the chromatographic system. The area inscribed by the peak is proportional to the amount of substance separated in the chromatographic system.



Typical chromatogram obtained by gas chromatography.

Information readily extracted from the chromatogram includes an indication of sample complexity (the number of observed peaks), qualitative substance identification (determined by peak position), relative composition of the sample (peak dimensions; area or height), and a summary of the kinetic characteristics of the chromatographic system (peak shapes). [C.F.P.]

Chromatophore A pigmented structure found in many animals, generally in the integument. The term is usually restricted to those structures that bring about changes in color or brightness. A majority of chromatophores are single cells that are highly branched and contain pigment granules that can disperse or aggregate within the cell. However, in coleoid cephalopod mollusks (all mollusks except *Nautilus*), the chromatophores function as miniature organs, and changes in the dispersion of pigment are brought about by muscles. Although the mode of action of the two types of chromatophore is completely different, the effect is the same: pigment either is spread out over a large area of the body or is retracted into a small area.

The movement of pigment takes place in many chromatophores simultaneously, so that the effect is a change in the quality of light reflected from the surface of the animal. The color change functions as a camouflage from predator or prey, but it may also serve for regulating temperature, protecting against harmful radiation, and in signaling. Light stimulates the responses of chromatophores, generally indirectly via the eyes and central nervous system.

Single-cell chromatophores are found in some annelids, insects, and echinoderms. They are much more conspicuous in crustaceans (shrimps and prawns), in fishes (especially in bony fish and teleosts), in anuran amphibians (frogs and toads), and in a few reptiles. The chromatophores may be uniformly distributed in the skin (chameleons), or they may occur in patches (flounders) or lines (around the abdomen in shrimps). Chromatophores of various colors may be distributed unevenly across the body, and occur at different depths in the skin.

Chromatophores produce their colors by reflection after absorption of light. Generally, the light comes from above, but it may come from below after reflection from an underlying structure. The most common type of chromatophore contains melanin (and is, therefore, often called a melanophore), which absorbs all wavelengths so that the chromatophore appears black; other types have red (erythrophores) or yellow (xanthophores) pigments. These pigments generally derive from carotenoids in vertebrates.

Chromatophores contain pigment granules that move within them, giving them an appearance that ranges from spotted to fibrous on the five-stage scale that is widely used to measure the degree of chromatophore expansion. If the pigment within the particular cell is black or brown, the integument takes on a dark appearance when most of the chromatophores are in the last stage of dispersion (stage 5). If the pigment color is yellow or cream, the animal tends to look paler if all the chromatophores are at that stage.

In crustaceans, elasmobranch fishes, anurans, and lizards, control of the chromatophores is thought to be exclusively hormonal. Such hormonal control is true also of some teleosts; in others the control is part hormonal and part neural; while in still others control is purely neural, as in the chameleon. Where nerves are involved, the speed of the response is faster, the chromatophores responding in minutes rather than hours. *See* NEUROSECRETION.

Each cephalopod chromatophore organ comprises an elastic sac containing pigment granules. Attached to the sac is a set of 15–25 radial muscles that are striated and contract rapidly. Associated with the radial muscles are axons from nerve cell bodies that lie within the brain. Active nerve cells cause the radial muscles to contract and the chromatophore sac expands; when the nerves are inactive, energy stored in the elastic sac causes the chromatophore to retract as the muscles relax. The chromatophores receive only nerve impulses, and there is no evidence that they are influenced by hormones. The chromatophores are ultimately controlled by the optic lobe of the brain under the influence of the eyes.

Two consequences follow from the fact that cephalopod chromatophores are under the direct control of the brain. First, color change is instantaneous. Second, patterns can be generated in the skin in a way impossible in other animals. Thus, cephalopods can use the chromatophores not just to match the background in general color but to break up the body visually (disruptive coloration) so that a predator does not see the whole animal. Because the chromatophores are neurally controlled and patterns can be produced in the skin, they can also be used for signaling. *See* PIGMENTATION; PROTECTIVE COLORATION. [J.B.M.]

Chromite The only ore mineral of chromium. Chromite is jet black to brownish black, has a submetallic luster. It belongs to the spinel group of minerals and has cubic symmetry. Naturally occurring chromite has the general formula $(Mg,Fe^{2+})(Cr,Al,Fe^{3+})_2O_4$ and ranges from 15 to 64 wt % Cr_2O_3, with minor amounts of nickel, titanium, zinc, cobalt, and manganese. The specific gravity of chromite ranges from 4 to 5, depending on its composition. Pure chromite, $Fe^{2+}Cr_2O_4$, is extremely rare in nature and has been found only in meteorites.

Chromite has a variety of uses. Chromium is extracted from it to make stainless steel and other alloys for which resistance to oxidation and corrosion is important. Chromium is also used as a plating and tanning agent. The mineral chromite is made into refractory lining for steel-making furnaces. *See* CHROMIUM; SPINEL; STAINLESS STEEL. [B.R.L.]

Chromium A chemical element, Cr, atomic number 24, and atomic weight 51.996, which is the weighted average for several isotopes weighing 50 (4.31%), 52 (83.76%), 53 (9.55%), and 54 (2.38%). The orbital arrangement of the electrons is $1s^2$, $2s^2$, $2p^6$, $3s^2$, $3p^6$, $3d^5$, $4s^1$. The stability of the half-filled *d* shell doubtless accounts for this rather unusual arrangement. In the crust of the Earth, chromium is the twenty-first element in abundance, which ranks it along with vanadium, zinc, nickel, and copper. Traces of chromium are present in the human body; in fact, it is essential to life. *See* PERIODIC TABLE.

The element was discovered in 1797 and isolated the following year by the French chemist L. N. Vauquelin. It was named chromium because of the many colors of its compounds. It occurs in nature largely as the mineral chromite ($FeO \cdot Cr_2O_3$), which is a spinel, but the ore is usually contaminated with Al^{3+}, Fe^{3+}, Mn^{2+}, and Mg^{2+}. Smaller quantities are found as the yellow mineral crocoite ($PbCrO_4$).

As a transition metal, chromium exists in all oxidation states from 2− to 6+. The chemistry of its aqueous solutions, at least in the 3+ (chromic) state, is complicated by the fact that the compounds exist in many isomeric forms, which have quite different chemical properties.

Pure chromium metal has a bluish-white color, reflects light well, and takes a high polish. When pure, it is ductile, but even small amounts of impurities render it brittle. The metal melts at about 1900°C (3452°F) and boils at 2642°C (4788°F). Chromium shows a wide range of oxidation states; the compounds in which the metal is in a low oxidation state are powerful reducing agents, whereas those in which it shows a high oxidation state are strong oxidizing agents.

The bright color and resistance to corrosion make chromium highly desirable for plating plumbing fixtures, automobile radiators and bumpers, and other decorative pieces. Unfortunately, chrome plating is difficult and expensive. It must be done by electrolytic reduction of dichromate in sulfuric acid solution. This requires the addition of six electrons per chromium ion. This reduction does not take place in one step, but through a series of steps, most of which are not clearly understood. The current efficiency is low (maybe 12%), and the chromium plate contains microscopic cracks and other flaws, and so it does not adequately protect the metal under it from corrosion. It is customary, therefore, to first plate the object with copper, then with nickel, and finally, with chromium.

In alloys with iron, nickel, and other metals, chromium has many desirable properties. Chrome steel is hard and strong and resists corrosion to a marked degree. Stainless steel contains roughly 18% chromium and 8% nickel. Some chrome steels can be hardened by heat treatment and find use in cutlery; still others are used in jet engines. Nichrome and chromel consist largely of nickel and chromium; they have low electrical conductivity and resist corrosion, even at red heat, so they are used for heating coils in space heaters, toasters, and similar devices. Other important alloys are Hastelloy C (Cr, Mo, W, Fe, Ni), used in chemical equipment which is in contact with HCl, oxidizing acids, and hypochlorite. Stellite [Co, Cr, Ni, C, W (or Mo)], noted for its hardness and abrasion resistance at high temperatures, is used for lathes and engine valves, and Inconel (Cr, Fe, Ni) is used in heat treating and in corrosion-resistant equipment in the chemical industry. *See* ALLOY; HEAT TREATMENT (METALLURGY); STAINLESS STEEL.

Several chromium compounds are used as paint pigments—chrome oxide green (Cr_2O_3), chrome yellow ($PbCrO_4$), chrome orange ($PbCrO_4 \cdot PbO$), molybdate orange (a solution of $PbSO_4$, $PbCrO_4$, and $PbMoO_4$), chrome green (a mixture of $PbCrO_4$ and Prussian blue), and zinc yellow (potassium zinc chromate). Several of these, particularly zinc yellow, are used to inhibit corrosion. The gems ruby, emerald, and alexandrite owe their colors to traces of chromium compounds. *See* CORROSION; EMERALD; PAINT; RUBY.

Dichromates are widely used as oxidizing agents, as rust inhibitors on steel, and as wood preservatives. In the last application, they kill fungi, termites, and boring insects. The wood can still be painted and glued, and retains its strength. Other chromium compounds find use as catalysts, as drilling muds, and in photochemical reactions. The last are important in the printing industry. A metal plate is coated with a colloidal material (for example, glue, shellac, or casein) containing a dichromate. On exposure to strong light under a negative image, the dichromate is reduced to Cr^{3+}, which reacts with the colloid, hardening it and making it resistant to removal by washing. The unexposed material is washed off, and the metal plate is etched with acid to give a printing plate. *See* PRINTING.

Chromium is essential to life. A deficiency (in rats and monkeys) has been shown to impair glucose tolerance, decrease glycogen reserve, and inhibit the utilization of amino acids. It has also been found that inclusion of chromium in the diet of humans sometimes, but not always, improves glucose tolerance. Certain chromium(III) compounds enhance the action of insulin.

On the other hand, chromates and dichromates are severe irritants to the skin and mucous membranes, so workers who handle large amounts of these materials must be protected against dusts and mists. Continued breathing of the dusts finally leads to ulceration and perforation of the nasal septum. Contact of cuts or abrasions with chromate may lead to serious ulceration. Even on normal skin, dermatitis frequently results. Cases of lung cancer have been observed in plants where chromates are manufactured. [J.C.Ba.]

Chromophycota A division of the plant kingdom (also known as Chromophyta) comprising nine classes of algae: Bacillariophyceae (diatoms), Chrysophyceae (golden or goldenbrown algae), Cryptophyceae, Dinophyceae (dinoflagellates), Eustigmatophyceae, Phaeophyceae (brown algae), Prymnesiophyceae, Raphidophyceae, and Xanthophyceae (yellow-green algae). Some of these classes are closely related, while others stand so far apart that they are sometimes assigned to their own divisions. The chief unifying character is the presence of chlorophyll *c* rather than chlorophyll *b* as a complement to chlorophyll *a* (although only chlorophyll *a* is present in Eustigmatophyceae). The chloroplasts are usually brown or yellowish because of large amounts of β-carotene and various xanthophylls, many of which are restricted to one or more classes. In most classes, motile cells bear two unequal flagella, one of which may be almost completely reduced and at least one of which bears two rows of hairlike appendages. Algae range in size and complexity from unicellular flagellates to gigantic kelps. *See* ALGAE; BACILLARIOPHYCEAE; CHRYSOPHYCEAE; CRYPTOPHYCEAE; DINOPHYCEAE; EUSTIGMATOPHYCEAE; PHAEOPHYCEAE; PRYMNESIOPHYCEAE; RAPHIDOPHYCEAE; XANTHOPHYCEAE. [P.C.Si.; R.L.Moe]

Chromosome Any of the organized components of each cell which carry the individual's hereditary material, deoxyribonucleic acid (DNA). Chromosomes are found in all organisms with a cell nucleus (eukaryotes) and are located within the nucleus. Each chromosome contains a single extremely long DNA molecule that is packaged by various proteins into a compact domain. A full set, or complement, of chromosomes is carried by each sperm or ovum in animals and each pollen grain or ovule in plants. This constitutes the haploid (n) genome of that organism and contains a complete set of the genes characteristic of that organism. Sexually reproducing organisms in both the plant and animal kingdoms begin their development by the fusion of two haploid germ cells and are thus diploid ($2n$), with two sets of chromosomes in each body cell. These two sets of chromosomes carry virtually all the thousands of genes of each cell, with the exception of the tiny number in the mitochrondria (in animal), and a few plant chloroplasts. *See* DEOXYRIBONUCLEIC ACID (DNA); GENE.

Chromosomes can change their conformation and degree of compaction throughout the cell cycle. During interphase, the major portion of the cycle, chromosomes are not visible under the light microscope because, although they are very long, they are extremely thin. However, during cell division (mitosis or meiosis), the chromosomes become compacted into shorter and thicker structures that can be seen under the microscope. At this time they appear as paired rods with defined ends, called telomeres, and they remain joined at a constricted region, the centromere, until the beginning of anaphase of cell division. *See* CELL CYCLE; MEIOSIS; MITOSIS.

Chromosomes are distinguished from one another by length and position of the centromere. They are metacentric (centromere in the middle of the chromosome), acrocentric (centromere close to one end), or telocentric (centromere at the end, or telomere). The centromere thus usually lies between two chromosome arms, which contain the genes and their regulatory regions, as well as other DNA sequences that have no known function. In many species, regional differences in base composition and in the time at which the DNA is replicated serve as the basis for special staining techniques that make visible a series of distinctive bands on each arm, and these can be used to identify the chromosome.

Compaction. Each nucleus in the cell of a human or other mammal contains some 6 billion base pairs of DNA which, if stretched out, would form a very thin thread about 6 ft (2 m) long. This DNA has to be packaged into the chromosome within a nucleus that is much smaller than a printed dot (Fig. 1). Each chromosome contains a single length of DNA comprising a specific portion of the genetic material of the organism. Tiny stretches of DNA, about 140 base pairs long and containing acidic phosphate groups, are individually wrapped around an octamer consisting of two molecules of each of the four basic histone proteins H2a, H2b, H3, and H4. This arrangement produces small structures called nucleosomes and results in a sevenfold compaction of the DNA strand. Further compaction is achieved by binding the histone protein H1 and several nonhistone proteins, resulting in a supercoiled structure in which the chromosome is shortened by about 1600-fold in the interphase nucleus and by about 8000-fold during metaphase and anaphase, where the genetic material must be fully compacted for transport to the two daughter cells. At the point of maximum compaction, human chromosomes range in size from about 2 to 10 micrometers in length, that is, less than 0.0004 in. *See* NUCLEOSOME.

Number and size. Each diploid ($2n$) organism has a characteristic number of chromosomes in each body (somatic) cell, which can vary from two in a nematode worm and one species of

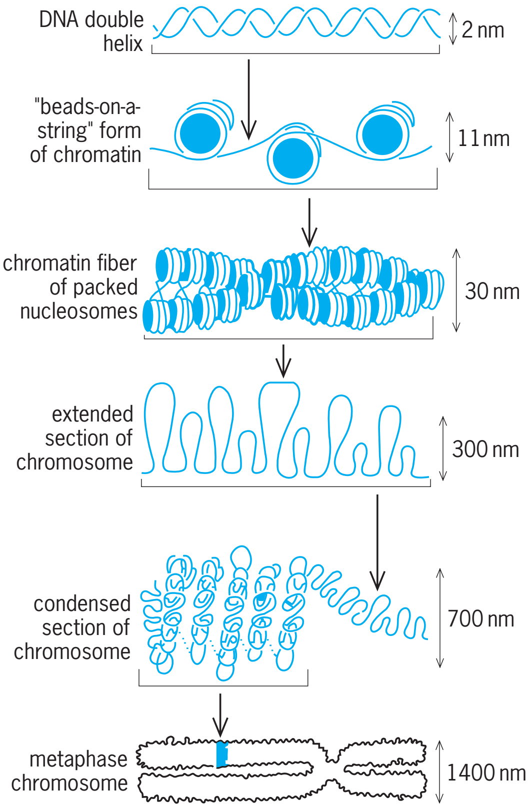


Fig. 1. Organization of DNA into chromosomes. (*From B. Alberts et al., Molecular Biology of the Cell, 2d ed., Garland Publishing, 1989*)

ant, to hundreds in some butterflies, crustaceans, and plants. The diploid number of chromosomes includes a haploid (*n*) set from each parent. Many one-celled organisms are haploid throughout most of their life cycle. The human diploid number is 46.

There is some relationship between the number of chromosomes and their size. Some of the chromosomes in certain classes of organisms with large numbers of chromosomes are very tiny, and have been called microchromosomes. In birds and some reptiles, there are about 30–40 pairs of microchromosomes in addition to 5–7 or so pairs of regular-sized macrochromosomes. The number of microchromosomes is constant in any species carrying them, and only their size distinguishes them from the widespread macrochromosomes. At least seven microchromosomes in birds have been shown to contain genes, and all are thought to.

In some species of insects, plants, flatworms, snails, and rarely vertebrates (such as the fox), the number of chromosomes can vary because of the presence of a variable number of accessory chromosomes, called B chromosomes. It is not clear what role, if any, B chromosomes play, but they appear to be made primarily of DNA that neither contains functional genes nor has much effect on the animal or plant even when present in multiple copies.

Structure. A telomere caps each end of every chromosome and binds specific proteins that protect it from being digested by enzymes (exonucleases) present in the same cell. Most important, the telomere permits DNA replication to continue to the very end of the chromosome, thus assuring its stability. The telomere is also involved in attachment of the chromosome ends to the nuclear membrane and in pairing of homologous chromosomes during meiosis. The structure of telomeric DNA is very similar in virtually all eukaryotic organisms except the fruit fly (*Drosophila*). One strand of the DNA is rich in guanine and is oriented toward the end of the chromosome, and the other strand is rich in cytosine and is oriented toward the centromere. In most organisms, the telomere consists of multiple copies of a very short DNA repeat.

The centromere is responsible for proper segregation of each chromosome pair during cell division. The chromatids in mitosis and each pair of homologous chromosomes in meiosis are held together at the centromere until anaphase, when they separate and move to the spindle poles, thus being distributed to the two daughter cells. The kinetochore, which is the attachment site for the microtubules that guide the movement of the chromosomes to the poles, is organized around the centromere. The molecular structures of centromeres in most species are still unclear. The repetitive DNA making up and surrounding the centromere is called heterochromatin because it remains condensed throughout the cell cycle and hence stains intensely.

One or more pairs of chromosomes in each species have a region called a secondary constriction which does not stain well. This region contains multiple copies of the genes that transcribe, within the nucleolus, the ribosomal RNA (rRNA). The number of active rRNA genes may be regulated, and an organism that has too few copies of the rRNA genes may develop abnormally or not survive. *See* RIBOSOMES.

Staining. Staining with quinacrine mustard produces consistent, bright and less bright fluorescence bands (Q bands) along the chromosome arms because of differences in the relative amounts of CG (cytosine-guanine) or AT (adenine-thymine) base pairs. The distinctive Q-band pattern of each chromosome makes it possible to identify every chromosome in the human genome. Quinacrine fluorescence can also reveal a difference in the amount or type of heterochromatin on the two members of a homologous pair of chromosomes, called heteromorphism or polymorphism. Such differences can be used to identify the parental origin of a specific chromosome, such as the extra chromosome in individuals who have trisomy 21. Two other methods involve treating chromosomes in various ways before staining with Giemsa. Giemsa or G-band patterns are essentially identical to Q-band patterns; reverse Giemsa or R-band patterns are the reverse, or reciprocal, of those seen with Q or G banding. In humans, most other mammals, and birds (macrochromosomes only), the Q-, G-, and R-banding patterns are so distinctive that each chromosome pair can be individually identified, making it possible to construct a karyotype, or organized array of the chromosome pairs from a single cell (Fig. 2). The chromosomes are identified on the basis of the banding patterns, and the pairs are arranged and numbered in some order, often based on length. In the human karyotype, the autosomes are numbered 1 through 22, and the sex chromosomes are called X and Y. The short arm of a chromosome is called the p arm, and the long arm is called the q arm; a number is assigned to each band on the arm.

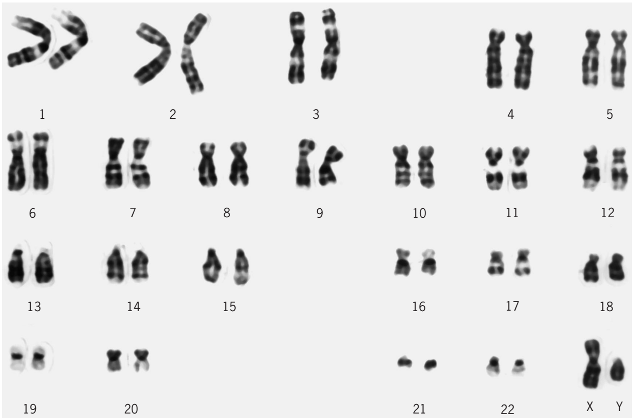

Fig. 2. G-banded metaphase karyotype of a human male cell. Every chromosome pair can be identified by its banding pattern. Chromosome 1 is about 12 μm long.

Thus, band 1q23 refers to band 23 on the long arm of human chromosome 1.

Imprinting. A chromosome carries the same complement of genes whether it is transmitted from the father or the mother, and most of these genes appear to be functionally the same. However, a small number of mammalian genes are functionally different depending on whether they were transmitted by the egg or by the sperm. This phenomenon is known as imprinting. It appears to be caused by the inactivation of certain genes in sperm or ova, probably by methylation of cytosine residues within the regulatory (promotor) region of the imprinted gene. As a result of imprinting, normal development of the mammalian embryo requires the presence of both a maternal and a paternal set of chromosomes. Parthenogenesis, the formation of a normal individual from two sets of maternal chromosomes, is therefore not possible in mammals.

Sex chromosomes. In most mammals, the sex of an individual is determined by whether or not a Y chromosome is present because the Y chromosome carries the male-determining *SRY* gene. Thus XX and the rare XO individuals are female, while XY and the uncommon XXY individuals are male. In contrast, sex in the fruit fly depends on the balance of autosomes (non-sex chromosomes) and X chromosomes. Thus, in diploids, XX and the rare XXY flies are female, while XY and the rare XO flies are male. In both mammals and fruit flies, males are the heterogametic sex, producing gametes that contain either an X or a Y chromosome; and females are the homogametic sex, producing only gametes containing an X. In birds and butterflies, however, females are the heterogametic sex and males the homogametic sex. Other sex-determining systems are used by some classes of organisms, while sex in some species is determined by a single gene or even by environmental factors such as temperature (some turtles and alligators) or the presence of a nearby female (*Bonellia*, a marine worm) rather than by a chromosome-mediated mechanism.

More than 900 gene loci have been mapped to the human X chromosome. If the genes on both X chromosomes were fully expressed in female mammalian cells, then male cells, which have only one X, would exhibit only half as much gene product as female cells. However, dosage compensation is achieved, because genes on only one X chromosome are expressed, and genes on any additional X chromosomes are inactivated. This X inactivation randomly occurs during an early stage in embryonic development, and is transmitted unchanged to each of the daughter cells. Mammalian females are therefore mosaics of two types of cells, those with an active maternally derived X and those with an active paternally derived X. Species other than mammals do not show this type of dosage compensation mechanism for sex-linked genes, and some show none at all.

The Y chromosome is one of the smallest chromosomes in the genome in most mammalian species. Usually the mammalian Y chromosome has a very high proportion of heterochromatin, as does the large Y chromosome in *Drosophila*. Very few genes are located on the Y chromosome in mammals or in *Drosophila*, and most of these genes are concerned with either sex determination or the production of sperm. In some species of insects and other invertebrates, no Y chromosome is present, and sex in these species is determined by the X:autosome balance (XX female, XO male). *See* CELL NUCLEUS; GENETICS; HUMAN GENETICS; SEX DETERMINATION; SEX-LINKED INHERITANCE. [O.J.M.; D.A.Mi.]

Chromosome aberration

Any numerical or structural change in the usual chromosome complement of a cell or organism.

Heteroploidy. Numerical changes (heteroploidy) are of two types, polyploidy and aneuploidy. Polyploidy is a change in the number of chromosome sets. Triploidy (3*n*), for example, occurs in about 1% of human pregnancies, but it is almost always an embryonic lethal condition. *See* MEIOSIS; MITOSIS; POLYPLOIDY.

Aneuploidy is a change in the number of chromosomes from the diploid (2*n*) number (usually found in the somatic cells of sexually reproducing organisms) or the haploid (*n*) number (usually found in germ cells and the haplophase of some unicellular organisms.) It usually involves a single chromosome, and any chromosome in the complement can be involved. Aneuploidy is the result of aberrant segregation of one or more chromosomes during meiosis or mitosis. If malsegregation or nondisjunction occurs during meiosis, one daughter cell receives two copies of the chromosome and the other daughter cell receives none. Fertilization of such an aneuploid germ cell by a euploid gamete will produce a zygote that has either three copies (trisomy) or one copy (monosomy) of the chromosome. Malsegregation of a chromosome can also take place during a mitotic division in a somatic cell, producing trisomic or monosomic cells in an otherwise euploid individual. This outcome is important primarily in the origin and progression of some forms of cancer.

The most common trisomy of autosomes (non-sex chromosomes) in human liveborns is trisomy 21, or Down syndrome, which is a major cause of mental retardation and congenital heart disease. Individuals with trisomy 18 and trisomy 13 also occur but are much less common. Most autosomal trisomies are lethal to embryos, leading to spontaneous abortion. The incidence of trisomy for any autosome increases exponentially with maternal age. *See* CHROMOSOME; DOWN SYNDROME.

In humans, there are more types of aneuploidy involving the sex chromosomes than the autosomes. The most common is XO, occurring in about 1% of pregnancies. Although 99% of XO fetuses die early in pregnancy, the other 1% (about 1 in 10,000 liveborn females) survive. Adults who are XO tend to be short, with some webbing of the neck. They rarely develop secondary sexual characteristics or have children because the germ cells essential for ovarian development are usually absent. These features are characteristic of Turner syndrome. Trisomy for the human X chromosome, commonly called XXX, is not associated with embryonic death or congenital malformations. The reason is that in all mammals only a single X chromosome is active in each somatic cell. *See* HUMAN GENETICS.

In contrast to autosomal trisomy, sex chromosome aneuploidy increases only slightly with maternal age, and the extra X chromosome comes from the mother in only about 60% of the cases. An additional X chromosome can be present in either egg or sperm; additional Y chromosomes can be present only in sperm. The XXX and XXY individuals display minimal phenotypic manifestations of their increased number of chromosomes. Individuals who are XYY generally are indistinguishable from XY individuals. The presence of a Y chromosome leads to male sex differentiation no matter how many X chromosomes are present, because of the presence of a single, critical gene, called *SRY*, on the Y chromosome. A mutation of this gene has been found in some XY individuals who developed as females.

Structural abnormalities. Structural abnormalities (chromosome mutations) involve the gain, loss, or rearrangement of chromosome segments after the continuity of the deoxyribonucleic acid (DNA) strand in one or more chromosomes is disrupted. A deletion involves the loss of a chromosome segment and the genes it carries. A terminal deletion involves the loss of a segment extending from the point of disruption (breakpoint) to the end of the same arm of a chromosome, and it is relatively uncommon. An interstitial deletion involves the loss of the segment between two breakpoints in one arm of a chromosome. The effect of such a loss depends on the genes that are included in the missing segment.

When one break occurs in each arm of a chromosome, the broken ends of the internal centromeric fragment may join, resulting in the formation of a stable ring chromosome. Each of the two end segments lacks a centromere, and such acentric fragments are lost during cell division. Ring chromosomes are subject to reduction in size, as well as doubling. An individual who has a ring chromosome may thus show phenotypic effects not only of deletion but of duplication of part of the chromosome. A duplication more commonly occurs in other ways. For example, a chromosome segment can undergo tandem or inverted duplication at the usual chromosome site, or the second copy of the segment may be carried on another chromosome.

An inversion is generated by disrupting the DNA strand in a chromosome at two breakpoints and rejoining the broken ends with the interstitial segment in the opposite orientation. This process will invert the order of the genes on the segment.

A translocation involves the interchange of one or more chromosome segments between two or more chromosomes. If a translocation breakpoint disrupts a gene, the gene's function will be blocked or abnormal, and such can have deleterious effects on development or function. Sometimes a normally silent gene is activated by a chromosome rearrangement that places it next to a strong promoter of gene expression, and this change is important as a cause of cancer. If a translocation does not block the function of an essential gene or activate a normally silent gene, the individual carrying the rearrangement will be normal.

Structural aberrations can occur spontaneously or be induced by agents that break chromosomes, such as x-rays, radioactive substances, ultraviolet rays, and certain chemicals. The most frequent cause may be the presence of enormous numbers of a few types of short interspersed elements (SINES), that is, DNA sequences that occur once every few thousand base pairs throughout the genome of most metazoans, including humans. These elements predispose to the occurrence of errors during DNA replication or genetic recombination at meiosis that can lead to the deletion or duplication of the region between two nearby interspersed repeats on one chromosome. They may also play a role in the formation of inversions and, possibly, translocations. *See* GENE AMPLIFICATION; MUTAGENS AND CARCINOGENS; MUTATION.

Another cause of structural aberrations is also inherent in the genome: the great abundance of short repeats of a 2-, 3-, or 4-base-pair unit. Some trinucleotide repeats, such as $(CGG)_n$ or $(CAG)_n$, can undergo expansion during meiotic and mitotic cell divisions. This expansion sometimes affects gene function and leads to disease. The most common type of X-linked mental retardation in humans is the result of heritable expansions, in the *FMR-1* gene, of a specific trinucleotide repeat, $(CGG)_n$, where the number of expansions (n) is increased from the normal 8–20 or so to 50–200 or more. For unknown reasons, this expanded region tends to undergo breakage under some conditions, and this particular form of mental retardation is called the fragile X syndrome. There are dozens, if not hundreds, of similar fragile sites in the human and other genomes. [O.J.M.; D.A.Mi.]

Chromosphere A complex structure of warm gas above the visible surface, or photosphere, of the Sun and most stars. The term "chromosphere" was first applied to the red ring and large prominences seen at the edge of the eclipsed Sun with the unaided eye. Emission in the Balmer-alpha line of hydrogen at 653-nanometer wavelength accounts for the red color. The chromosphere is transparent in visible light, but is opaque and bright in the ultraviolet continuum and in strong lines of abundant elements, including hydrogen, helium (first observed during the 1868 solar eclipse), oxygen, calcium, and magnesium. Gas temperatures range from 3500 to 30,000 K (5800 to 54,000°F) and densities are between 10^9 and 10^{12} particles per cubic centimeter. *See* SUN.

The solar chromosphere extends from roughly 500 km (300 mi) above the photosphere to where hydrogen becomes fully ionized and the gas temperature rises rapidly to more than 10^6 K (1.8×10^6 °F) in the corona. High-resolution images of the Sun taken in strong emission lines reveal a filamentary structure consisting of many magnetic loops. In the chromospheric network at the edges of 30,000-km-wide (19,000-mi) supergranule cells, the magnetic field is strong, the gas is dense and hot, and the chomosphere may be only 500 km (300 mi) thick. Here the magnetic heating rate is 10 or more times higher than average. Thin gas jets called spicules are clustered in the network. In the center of supergranule cells, where the magnetic field is weak, the chromospheric gas cools to 3500 K (5800°F) and extends upward several thousand kilometers. *See* SUPERGRANULATION.

Stars with effective temperatures less than about 8000 K (14,000°F; the Sun is 5770 K or 9930°F) show the same emission lines as the solar chromosphere and are thus thought to have analogous regions. [J.L.L]

Chronic fatigue immune dysfunction syndrome A condition resulting in massive, debilitating fatigue accompanied by diverse symptoms including memory loss, diminished powers of concentration, sleep disorder, headaches, low-grade fever, muscle and joint pains, and intolerance to change of temperature. This condition is also known as postviral fatigue, chronic fatigue syndrome, and myalgic encephalomyelitis. It is often associated with stress.

The severity of the disease varies considerably: Some patients are bedridden while others suffer only mildly debilitating symptoms. The cause of the disease is unknown, although there are hypotheses relating it to an abnormal immune response due to concurrent stress and a previous infection, perhaps viral. The Epstein-Barr virus, Human Herpes virus 6, Cytomegaloinclusion virus, Coxsackie virus, various stealth viruses, and a retrovirus have been implicated. All of these viruses are common, and the general population is frequently exposed to them. The disease is not life-threatening and is not considered infectious. However, if a viral cause is proven, there would be an infective phase during or immediately after the initial incubation of the virus. There is no definitive diagnostic test for chronic fatigue immune dysfunction syndrome (CFIDS); thus it is necessary to rule out the possibility of another disease that produces fatigue. While the majority of individuals with confirmed CFIDS have a positive antibody to one or more of the implicated viruses, the viruses are so common that antibody titers may be suggestive but are not diagnostic. *See* ANTIBODY; EPSTEIN-BARR VIRUS; HERPES; INFECTION.

There is no standard method of treatment. However, some believe that treatment based on reversal of the abnormal immune response is helpful. Some individuals affected by CFIDS improve with time; most who are not treated remain functionally impaired for several years. [D.En.]

Chronograph A device for recording the epoch of an event. In its older form the astronomical chronograph includes a drum rotated at constant speed and a pen actuated by an electromagnet. A spiral line is traced on paper on the drum. Signals from a clock produce a set of time marks and signals made by an observer produce other marks, so that the epoch of the events observed can be determined.

Modem chronographs are of the digital printing type. In one form rotating type wheels carry numbers. In another form the time is accumulated electronically, and when a signal is given the output is printed by keys. *See* TIME-INTERVAL MEASUREMENT. [W.M.]

Chronometer A large, strongly built watch especially designed for precise timekeeping on ships at sea. The name is sometimes loosely applied to any fine watch.

The features that distinguish a chronometer from a watch are (1) a heavy balance wheel, the axis of which is kept always vertical; (2) a balance spring wound in cylindrical shape, instead of a nearly flat helix; (3) a special escapement; and (4) a fusee, by means of which the power of the mainspring is made to work through a lever arm of continuously changing length, being shortest when the spring is tightly wound and longest when it has run down, thus regulating the transmitted power so that it is approximately constant at all times.

Oceangoing ships during a voyage formerly relied completely on chronometers keeping Greenwich mean time as a means for determining longitude. The broadcasting of radio time signals that became widespread in the decade 1920–1930 has made Greenwich mean time available to mariners at almost any time of day, and chronometers are no longer indispensable for determining longitude at sea. *See* CLOCK. [G.M.C.]

Chrysoberyl A mineral having composition $BeAl_2O_4$ and crystallizing in the orthorhombic system. The hardness is 8.5 (Mohs scale) and the specific gravity is 3.7–3.8. The luster is vitreous and the color various shades of green, yellow, and brown. There are two gem varieties of chrysoberyl. Alexandrite, one of the most prized of gemstones, is an emerald green but in transmitted or in artificial light is red. Cat's eye, or cymophane, is a green chatoyant variety with an opalescent luster. When cut en cabochon, it is crossed by a narrow beam of light. This property results from minute tabular cavities that are arranged in parallel position.

Chrysoberyl is a rare mineral found most commonly in pegmatite dikes and occasionally in granitic rocks and mica schists. Gem material is found in stream gravels in Ceylon and Brazil. The alexandrite variety is found in the Ural Mountains. In the United States chrysoberyl is found in pegmatites in Maine, Connecticut, and Colorado. *See* BERYLLIUM; GEM. [C.S.Hu.]

Chrysocolla A silicate mineral, composition $CuSiO_3 \cdot 2H_2O$. Small acicular crystals have been observed, but it ordinarily occurs in impure cryptocrystalline crusts and masses with conchoidal fracture. The hardness varies from 2 to 4 on Mohs scale, and the specific gravity varies from 2.0 to 2.4. The luster is vitreous and it is normally green to greenish-blue, but may be brown to black when impure. Chrysocolla is a secondary mineral occurring in the oxidized zones of copper deposits, where it is associated with malachite, azurite, native copper, and cuprite. It is a minor ore of copper. *See* SILICATE. [C.S.Hu.]

Chrysomonadida An order of the class Phytamastigophorea. Chrysomonads, also known as Chrysomonadina, are usually small flagellates. They are yellow to brown because of phycocrysin in the usual one or two chromatophores, but some lack chromatophores. Many species form diagnostic siliceous cysts. Palmelloid colonies (*Hydrurus*) consist of a tough, gelatinous matrix holding many nonflagellate cells. Starch is not formed, but fats are, and the refractive carbohydrate leucosin is common. The flagella are usually two, rarely three, and are subequal. Nuclei are small. *See* PHYTAMASTIGOPHOREA. [J.B.L.]

Chrysophyceae A relatively large and diverse class of algae in the chlorphyll *a*–*c* phyletic line (Chromophycota). In protozoological classification, these organisms constitute an order, Chrysomonadida, of the class Phytomastigophora. Some workers align Chrysophyceae (golden or golden-brown algae) with Bacillariophyceae (diatoms) and Xanthophyceae (yellow-green algae) in the division Chrysophyta. *See* CHROMOPHYCOTA.

Chrysophytes typically are flagellate unicells, either free-living or attached, and solitary or colonial. There are, however, ameboid and plasmodial forms, solitary or colonial nonflagellate cells, filaments, and blades. Fresh-water forms, which are usually found in cold clear water, are more common than marine forms.

Asexual reproduction in unicellular forms is by longitudinal binary fission, autospores (nonflagellate cells that are miniatures of the parent), or zoospores, and in multicellular forms by fragmentation or zoospores. *See* ALGAE; BACILLARIOPHYCEAE; BICOSOECIDA; CHOANOFLAGELLIDA; CHRYSOMONADIDA; XANTHOPHYCEAE. [P.C.Si.; R.L.Moe]

Chrysotile Chrysotile is a fibrous mineral with a tubular morphology for each fibril. It is a member of the serpentine mineral group, as are antigorite and lizardite. Chrysotile aggregates make up serpentine asbestos, which is the most important type of commercially mined asbestos. Russia and Canada are the main producing countries. Chrysotile displays interesting properties such as being thermally and electrically insulating, sound insulating, chemically inert, fire-resistant, mechanical energy-absorbing, and flexible with enough high tensile strength to be woven. There are hundreds of applications for chrysotile including fire retarder in buildings, roofing tiles, brake pads, weavable material for refractory clothes, filters, and fibers in fibrocement and road surfaces. *See* ASBESTOS; SERPENTINE; SERPENTINITE.

Intensive inhalation of long and thin asbestos fibers over a considerable time period can induce pulmonary deseases such as asbestosis and lung cancers, as well as pleural diseases such as plaques, fibrosis, and mesothelioma. Such health hazards have drastically reduced the use of chrysotile, which is strictly regulated by law in western countries. *See* RESPIRATORY SYSTEM DISORDERS. [A.J.Ba.]

Chytridiomycetes A monophyletic group of true fungi in the subdivision Mastigomycotina. The zoospore has a single, posteriorly directed, whiplash-type of flagellum; a few species are polyflagellated. The Chytridiomycetes are generally regarded as primitive and are probably representative of the ancestral group for the true fungi, but they have also been classified within the Kingdom Protista and Kingdom Protoctista.

The thallus may be unicellular, colonial, or filamentous and consists of a single reproductive body (monocentric) or many reproductive bodies (polycentric). The asexual reproductive body comprises a zoosporangium that releases zoospores. The five orders are classified primarily on differences in zoospore ultrastructure and include the Chytridiales, Spizellomycetales, Blastocladiales, Monoblepharidales, and Neocallimastigales.

Chytrids are cosmopolitan in distribution and are found in environments from the tundra to the equatorial rainforests, in alkaline or acid soil, in peat bogs, and in fresh or brackish water. Many are saprobes, but some are parasites of microflora and fauna such as algae and rotifers. Some are of interest because they destroy mosquitoes and others are parasites of vascular plants and are of economic concern as vectors of plant viruses. The Neocallimastigales are obligate anaerobes in the rumen and digestive tract of herbivores, where they are important in the breakdown of cellulose and hemicellulose fiber. *See* EUMYCOTA; FUNGI; MASTIGOMYCOTINA. [D.J.S.B.]

Ciconiiformes An order of predominantly long-legged, long-necked wading birds including herons, ibises, spoonbills, storks, and their allies, and also the hawklike New World vultures which were previously placed in the Falconiformes.

The order Ciconiiformes is divided into four suborders and seven families: Ardeae, with the family Ardeidae (herons; 62 species); Balaenicipites, with the family Balaenicipitidae (shoe-billed stork; 1 species); Ciconiae, with the families Scopidae (hammerhead; 1 species), Threskiornithidae (ibises and spoonbills; 33 species), and Ciconiidae (storks; 17 species); and Cathartae, containing the families Teratornithidae (Miocene to Pleistocene of South and North America) and Cathartidae (New World vultures; 7 species).

The herons, shoe-billed stork, hammerhead, ibises and spoonbills, and storks are mainly wading birds with strong legs, living in marshes and other wet areas. They feed on fish, amphibians, and other animals, which are caught in various ways depending on the structure of the bill. Some of the storks are scavengers. Most species are colonial and nest in mixed, often huge, colonies in trees or on the ground, as well as a few on cliff ledges. All are strong fliers, usually having to cover a long distance between the nesting site and feeding areas; some are excellent soarers.

The New World vultures are placed in a separate suborder to emphasize their specialization as scavengers. These vultures are large soaring birds; the Andean condor has the largest wing span of any living land bird. Vultures locate their food from the air either by sight or by smell; these abilities differ in the several species. Vultures may be solitary or hunt in loose flocks; larger concentrations may exist during the winter. They nest solitarily, with the nest placed on the ground or on a cliff ledge. The one to three young remain in the nest until they can fly. *See* AVES.

[W.J.B.]

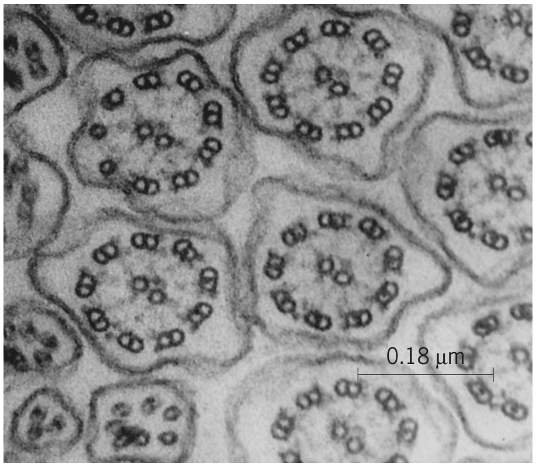
Cilia and flagella Centriole-based, motile cell extensions. These organelles are usually indistinguishable in fine structure as seen with the electron microscope, but quantitatively there are many (several hundred) cilia, and few or fewer (usually one or two) flagella, on one cell. Bacterial or prokaryotic flagella are entirely different organelles that are not considered in this article, which concerns only eukaryotic flagella.

Flagella move with undulatory motion in which successive bending waves progress along the length of the organelle, whereas cilia move with flexural motion consisting of a planar effective stroke, with the organelle extended perpendicular to the cell body, followed by a nonplanar curving recovery stroke, with the organelle pulled parallel to the cell body. Both organelles function to move water past the cell. Their action may bring food and oxygen into an animal, or it may propel the cell to a new environment.

The words cilium (eyelash) and flagellum (whip) are accurate descriptions of the appearance of these cell organelles when they are seen under the light microscope. Cilia are present on protozoa, such as *Paramecium*, and on metazoan cells of many different tissue types. A flagellum is present on human sperm; in fact, the sperm of most animals possess a flagellum, and, correspondingly, male gametes of many lower plants are flagellated. In addition, many ordinary types of cells of vertebrates, for example, from the thyroid, the kidney, or the pituitary gland, possess modified nonmotile derivatives that resemble cilia. *See* CILIOPHORA; EPITHELIUM; SPERM CELL.

Relative to cell size, both cilia and flagella are very long organelles. Flagella may be over 50 micrometers long. Certain compound cilia, such as the comb plates of ctenophores, are macroscopic structures, visible to the naked eye. Usually, however, cilia range from 10 to 15 μm in length.

The electron microscope reveals that the cilium or flagellum is really an internal organelle since it is bounded by the cell membrane and enclosed at the tip. The main internal structure of the cilium is the axoneme. Under the electron microscope, a single axoneme appears to contain a fixed pattern of microtubules. The microtubules are not simple single units; rather, nine doublet microtubules are found on the periphery of the axoneme surrounding two central elements. This is the so-called 9 + 2 pattern (see illustration). Each peripheral doublet is composed of one complete and one partial microtubule. The microtubules are themselves composed of subunits arranged into microfibers or protofilaments.



Electron micrograph of cilia showing 9 + 2 pattern of axoneme. (*From P. Satir, Studies on Cilia, II: Examination of the distal region of the ciliary shaft and the role of the filaments in motility, J. Cell Biol., 26:805–834, 1965*)

At the base of the cilium or flagellum there is a basal body, or kinetosome, that is similar to, and sometimes derived from, a centriole. The basal body may have extensions of various sorts attached to it, notably a basal foot that indicates effective stroke direction and prominent striated rootlet fibers in many cilia. Ordinarily, the ciliary axoneme originates and grows in a membrane protrusion which forms just above the basal body, either at the cell surface or deeper inside the cytoplasm. The basal body remains attached to the cell membrane throughout morphogenesis by a structure that extends from the microtubules to the membrane, where it is seen as a ciliary necklace. *See* CENTRIOLE.

[P.S.; I.Gi.]

Ciliatea The single class of the subphylum Ciliophora. This group has the characteristics of those defined for the subphylum. This protozoan class is divided into the subclasses Holotrichia, Peritrichia, Suctoria, and Spirotrichia. *See* CILIOPHORA; HOLOTRICHIA; PERITRICHIA; SPIROTRICHIA; SUCTORIA.

[J.O.C.]

Ciliophora A subphylum of the Protozoa. The ciliates are a fairly homogeneous group of highly differentiated, unicellular organisms. Over 5000 species have been described, and many more surely exist but remain to be discovered. Typically, ciliates are larger than most other protozoans, ranging from 10 to 3000 micrometers (about 1/2500 to 1/8 in.). Some larger species are easily visible to the naked eye. The majority of them are free-living forms, found abundantly in a variety of fresh- and salt-water habitats, although a few entire groups live in association with other organisms, generally as harmless ecto- or endocommensals. Their principal value to humans is as experimental animals in a host of biological investigations.

A classification scheme for the ciliates is given below. It is widely recognized as the most reasonable and useful classification currently available. Separate articles appear on each group listed. Subordinal divisions of some orders are commonly recognized by protozoologists.

Subphylum Ciliophora
  Class Ciliatea
    Subclass Holotrichia
      Order: Gymnostomatida
        Trichostomatida
        Chonotrichida
        Apostomatida
        Astomatida
        Hymenostomatida
        Thigmotrichida
    Subclass Peritrichia
      Order Peritrichida
    Subclass Suctoria
      Order Suctorida
    Subclass Spirotrichia
      Order: Heterotrichida
        Oligotrichida
        Tintinnida
        Entodiniomorphida
        Odontostomatida
        Hypotrichida

The usual ciliate life cycle is fairly simple. An individual feeds and undergoes binary fission, and the resulting filial products repeat the process. Some commensal or parasitic forms have a more complicated life history. Some ciliates, including free-living species, have a cystic stage in their cycle. As in other kinds of Protozoa this stage often serves as a protective phase during adverse environmental conditions, such as desiccation or lack of food. It also may be important in distribution, and thus possibly in preservation, of the species.

Six major characteristics aid in distinguishing the Ciliophora from other protozoan groups. Not all of these are entirely unique, but when taken together they are definitely distinctive of ciliates: mouth, ciliation, infraciliature, nuclear apparatus, fission, and reproduction.

Most Ciliophora possess a true mouth or cytostome often associated with a buccal cavity containing compound ciliary organelles. However, some ciliates are completely astomatous, that is, mouthless. Nutrition is heterotrophic in ciliates.

The Ciliophora possess simple cilia or compound ciliary organelles, often in abundance, in at least one stage of their life cycle. Morphologically, cilia are relatively short and slender hairlike structures, whose ultrastructure is known, from electron microscope studies, to be composed of nine peripheral and two central fibrils. Membranes and membranelles are characteristically associated with the mouth or buccal areas and serve to bring food into the oral opening, although they sometimes aid in locomotion as well. *See* CILIA AND FLAGELLA.

Infraciliature is present, without exception, at a subpellicular level in the cortex. The infraciliature consists essentially of basal bodies, or kinetosomes, associated with cilia and ciliary organelles at their bases, plus certain more or less interconnecting fibrils.

Ciliophora possess two kinds of nuclei, and at least one of each is usually present. The smaller, or micronucleus, contains recognizable chromosomes and behaves much as the single nucleus in cells of metazoan organisms. The larger, or macronucleus, is considered indispensable in controlling metabolic functions, and is recognized as having genic control over all phenotypic characteristics of ciliates.

Ciliophora exhibit a type of binary fission commonly known as transverse division. In ciliates the splitting results in two filial organisms, the anterior or proter and the posterior or opisthe which, geometrically speaking, show homothety with respect to identical structures possessed by each. Thus, homothetogenic is both a broader and most exact descriptive term.

Ciliophora lack true sexual reproduction. Ciliates do not show syngamy, with fusion of free gametes. Processes such as conjugation are considered to be sexual phenomena, since meiosis and chromosome recombination are involved, but not sexual reproduction. In addition to conjugation, certain ciliates exhibit forms of sexual phenomena known as autogamy and cytogamy. *See* PROTOZOA; REPRODUCTION (ANIMAL). [J.O.C.]

Cinchona A genus of trees belonging to the madder family (Rubiaceae), occurring indigenously in the cool, cloud forests of the Andes from Colombia to Peru. Many species have been described, most of which may be variants of *Cinchona pubescens* or *C. officinalis*. The bark contains several alkaloids, the most important of which is quinine. This bitter substance is the most specific drug used in the treatment of malaria. The great demand for quinine and the wasteful methods used in collecting the materials threatened extinction of the plants; therefore cultivation was begun. Now there are extensive cinchona plantations in India, Java, Sri Lanka, Australia, and Jamaica. *See* QUININE; RUBIALES. [P.D.St.; E.L.C.]

Cinematography The process of producing the illusion of a moving picture. Cinematography includes two phases: the taking of the picture with a camera and the showing of the picture with a projector. The camera captures the action by taking a series of still pictures at regular intervals; the projector flashes these pictures on a screen at the same frequency, thus producing an image on the screen that appears to move. This illusion is possible only because of the persistence of vision of the human eye. The still pictures appear on the screen many times a second, and although the screen is dark equally as long as it is lighted by the projected image, they do not seem to be a series of pictures but appear to the viewer to be one continuous picture. *See* CAMERA; MAGNETIC RECORDING; OPTICAL PROJECTION SYSTEMS; OPTICAL RECORDING; PHOTOGRAPHIC; PHOTOGRAPHY; STEREOPHONIC SOUND.

Cameras. Still photographs are taken by motion picture cameras (movie cameras) at the rate of 24 per second, even faster at times. The photographs are sharp and clear, and if they were superimposed on one another would be found to be extremely uniform with respect to position. This last feature is essential in order to have the image appear steady on the screen.

The lens on a motion picture camera collects the light from the scene being photographed and focuses it on the photographic emulsion in the camera aperture. The focal lengths most often used on 35-mm cameras are between 30 and 50 mm. Other lenses in common use vary from wide-angle (14.5 to 25 mm), through long-focal-length (60 to 250 mm), to telephoto (300 to 1000 mm). Variable-focal-length lenses (zoom lenses) are useful to cinematographers and directors and are used extensively not only for filming sport events but also in making feature films, documentaries, and television films. *See* FOCAL LENGTH; TELEPHOTO LENS; ZOOM LENS.

To protect the lens from extraneous light and prevent lens flare, a lens shade must be used. On a motion picture camera this shade is called a matte box. It completely surrounds the lens and acts as a lens shade, but it also has slots to hold various types of filters (such as diffusion, fog, color correcting, and polarizing), and optically flat glass for use when needed. These items are used by cinematographers for the many effects required in making a professional motion picture.

The shutter in a motion picture camera rotates and exposes the film according to its angle of opening. When the shutter is open to its widest angle, the film receives its maximum exposure. Many cameras have variable shutters; that is, the angle of opening can be changed while the camera is running. The shutter in a motion picture camera is almost always located between the lens and the film.

The aperture called the gate is the passageway through which the film is channeled while it is being exposed. It consists of the aperture plate, which is in front of the film and masks the frame, or picture; the pressure plate, which is in back of the film and holds it firmly against the aperture plate; and the edge guides, which keep the film stable laterally.

The film chamber holds the unexposed film at one end and collects the exposed film at the other. Although some motion picture cameras have an interior film chamber, it is usually a separate piece of equipment called the film magazine.

The part of the pull-down mechanism called the intermittent movement pulls the film down through the gate of the camera one frame at a time; in a conventional 35-mm camera, each frame is four perforations high. Some wide-screen cameras have frames five or six perforations high. The pull-down claw engages the perforations and pulls the film down into place to be exposed. Most modern cameras have registration pins which engage the film while the picture is being taken. This ensures that the film is perfectly still and is in exactly the same position as each frame is being exposed. This feature is especially important in special effects photography where independently photographed images are superimposed.

When sound is being recorded, cameras must be absolutely quiet. In the early days of sound, cameras were put in enclosures called blimps. Almost all modern cameras are self-blimped, which enhances their portability. The Mitchell BNC (Blimped News Camera) was the first such camera (see illustration), and remains the industry standard.

All sound is recorded on sprocketless 0.25-in. (6-mm) tape. Since tape is an elastic medium, some sort of “sync” pulse must be put on the tape in order to synchronize the recorded sound with the picture when they are put together in a “married” print. The sync pulse is usually an inaudible 1-V, 60-Hz (in Europe, 50 Hz) pulse put on the tape at the time of recording. This

Mitchell studio camera (BNC).

pulse can be one generated at the camera and sent to the sound recorder, which is exactly 60-Hz when the camera is running precisely 24 frames/s.

There are two types of sound tracks, optical and magnetic on the prints seen by the audience. All 35-mm have optical sound tracks. Until the mid-1990s, all sound tracks were recorded in analog fashion. Developments in the technology, however, have enabled optical sound tracks to be recorded digitally, permitting optical sound tracks to provide sound quality comparable to a digital compact disk.

Film. The film used in the standard motion-picture camera is 35 mm (wide) and is perforated along both edges. Motion-picture film consists of a cellulose acetate base approximately 0.006 in. (0.15 mm) thick and coated with a light-sensitive emulsion. In color film, several layers of emulsion are applied; each of three of the layers is sensitive to one of the three primary colors of light: blue, green, and red. The film is made in large rolls about 54 in. (1.37 m) wide and as long as several thousand feet. It is slit into 35-mm strips, perforated, and packed in lightproof bags and cans in rolls 100, 200, 400, and 1000 ft (30, 60, 120, and 300 m) in length.

There are two different types of film: negative film, from which a print is made in order to see the original subject in its true likeness, and reversal film, in which a negative is first formed in the original film and from this a positive is formed in the same piece of film. In the negative film two pieces of film are necessary to get a picture that can be projected; in the reversal film only one piece of film is required, making it a much less expensive process. In professional work, the original, that is, the film used in the camera, is never used for projection. A work print is made in order to edit the film and the original negative is assembled to conform to the edited work print. Master positives are then struck from the original negative, and the master positives are used, in turn, to produce duplicate negatives. The release prints are made from the duplicate negatives, and during this process the sound tracks are added. The original film is all-important and is kept in a vault at the laboratory; it is used only for making prints.

Projectors. The projector system in a modern motion picture theater has five main assemblies: the optical sound head, which reproduces optical (photographically recorded) sound; the projector head, which projects the image onto the screen; the lamphouse, which furnishes the illumination for the picture; the shutter; and the platter system, which feeds the film through the projector head. On some projectors, there is a second sound head for the reproduction of magnetic (magnetically recorded) sound.

With the development of digital optical sound, most projectors are now equipped with a charge-coupled-device (CCD) line array to read the digital track. The analog optical track, which is still present as a backup system, is now read by a light-emitting diode (LED) array in lieu of the traditional exciter lamp. An alternate dual-system approach has a time-code track on the film that is read to synchronize the picture with the sound track played back from a compact disk machine. *See* CHARGE-COUPLED DEVICES; LIGHT-EMITTING DIODE.

Current screen formats. Films for theatrical release have now been standardized in two basic formats in the United States. With rare exceptions all films for theatrical presentation are now shot either in the 2.35:1 aspect ratio (ratio of film width to height), using the 35-mm frame, or in the 1.85:1 aspect ratio, which is achieved by cropping the standard 35-mm frame top and bottom. In Europe, the popular aspect ratio is 1.66:1. [E.M.DiG.]

Cinnabar

A mineral of composition HgS, crystallizing in the hexagonal system. Crystals are rare, usually of rhombohe-dral habit and often in penetration twins. Cinnabar most commonly occurs in fine, granular, massive form. It has perfect prismatic cleavage, a Mohs hardness of 2.0–2.5, and a density of 8.09. It has either an adamantine luster and vermilion red color or a dull luster and brownish-red color.

Cinnabar is deposited from hydrothermal solutions in veins and as impregnations near recent volcanic rocks and hot springs. It is the principal ore of mercury. Notable occurrences are Almaden, Spain; Idria, Italy; near Belgrade, Yugoslavia; Kweichow and Hunan provinces, China; Soviet Turkistan; New Almaden and New Idria, California; Terlingua, Texas; and several localities in Utah, Nevada, New Mexico, Oregon, and Idaho. *See* MERCURY (ELEMENT). [L.Gr.]

Cinnamon

An evergreen shrub or small tree, *Cinnamomum zeylanicum*, of the laurel family (Lauraceae). A native of Ceylon, the plant is now in cultivation in southern India, Burma, parts of Malaya, West Indies, and South America. The bark is removed from suckers that grow up from the roots, dried, and packaged for shipping. Cinnamon is a very important spice for flavoring foods. It is used in confectionery, gums, incense, dentrifrices, and perfumes. Cinnamon oil is used in medicine and as a source of cinnamon extract. *See* MAGNOLIALES. [P.D.St./E.L.C.]

Circle

The curve that is the locus of points in a plane with equal distance (radius) from a fixed point (center). In elementary mathematics, circle often refers to the finite portion of the plane bounded by a curve (circumference) all points of which are equidistant from a fixed point of the plane, that is, a circular disk. Circles are conic sections and are defined analytically by certain second-degree equations in cartesian coordinates. The ancient Greeks formulated the problem of "squaring the circle," that is, to construct, with compasses and unmarked straightedge only, a square whose area is equal to that of a given circle. It was not until 1882 that this was shown to be impossible, when F. Lindemann proved that the ratio of the length of a circle to its diameter (denoted by π) is not the root of any algebraic equation with integer coefficients. Electronic computers have calculated π to over 10^{12} decimal places.

The area of a circle (circular disk) with radius r is πr^2; the length (circumference) is $2\pi r$. The area enclosed by a circle is greater than that bounded by any other curve of the same length. *See* ANALYTIC GEOMETRY; CONIC SECTION. [L.M.Bl.]

Circuit (electricity)

A general term referring to a system or part of a system of conducting parts and their interconnections through which an electric current is intended to flow. A circuit is made up of active and passive elements or parts and their interconnecting conducting paths. The active elements are the sources of electric energy for the circuit; they may be batteries, direct-current generators, or alternating-current generators. The passive elements are resistors, inductors, and capacitors. The electric circuit is described by a circuit diagram or map showing the active and passive elements and their connecting conducting paths.

Devices with an individual physical identity, such as amplifiers, transistors, loudspeakers, and generators, are often represented by equivalent circuits for purposes of analysis. These equivalent circuits are made up of the basic passive and active elements listed above.

Electric circuits are used to transmit power as in high-voltage power lines and transformers or in low-voltage distribution circuits in factories and homes; to convert energy from or to its electrical form as in motors, generators, microphones, loudspeakers, and lamps; to communicate information as in telephone, telegraph, radio, and television systems; to process and store data and make logical decisions as in computers; and to form systems for automatic control of equipment.

Electric circuit theory includes the study of all aspects of electric circuits, including analysis, design, and application. In electric circuit theory the fundamental quantities are the potential differences (voltages) in volts between various points, the electric currents in amperes flowing in the several paths, and the parameters in ohms or mhos which describe the passive elements. Other important circuit quantities such as power, energy, and time constants may be calculated from the fundamental variables. For a discussion of these parameters *See* Admittance; Conductance; Electrical impedance; Electrical resistance; Reactance; Susceptance; Time constant.

Electric circuit theory is often divided into special topics, either on the basis of how the voltages and currents in the circuit vary with time (direct-current, alternating-current, nonsinu-soidal, digital, and transient circuit theory) or by the arrangement or configuration of the electric current paths (series circuits, parallel circuits, series-parallel circuits, networks, coupled circuits, open circuits, and short circuits). Circuit theory can also be divided into special topics according to the physical devices forming the circuit, or the application and use of the circuit (power, communication, electronic, solid-state, integrated, computer, and control circuits). *See* Alternating current; Circuit (electronics); Coupled circuits; Direct-current; Electric transient; Integrated circuits; Negative-resistance circuits; Open circuit; Parallel circuit; Series circuit; Short circuit.
[C.F.G.]

Circuit (electronics) An interconnection of electronic devices, an electronic device being an entity having terminals which is described at its terminals by electromagnetic laws. Most commonly these are voltage-current laws, but others, such as photovoltaic relationships, may occur.

Some typical electronic devices are represented as shown in Fig. 1, where a resistor, a capacitor, a diode, transistors, an operational amplifier, an inductor, a transformer, voltage and current sources, and a ground are indicated. Other devices (such as vacuum tubes, switches, and logic gates) exist, in some cases as combinations of the ones mentioned. The interconnection laws are (1) the Kirchhoff voltage law, which states that the sum of voltages around a closed loop is zero, and (2) the Kirchhoff current law, which states that the sum of the currents into a closed surface is zero (where often the surface is shrunk to a point, the node, where device terminals join). Figure 2 represents an electronic circuit which is the interconnection of resistors (R, R_{B1}, R_{B2}, R_E, R_L), capacitors (C), a battery voltage source (V_{CC}), a current source (i_s), a bipolar transistor (T), and a switch (S). Functionally Fig. 2 represents a high-pass filter when S is open, and an oscillator when S is closed and the current source is removed. *See* Amplifier; Battery; Capacitor; Current sources and mirrors; Diode; Electric filter; Electronic switch; Inductor; Kirchhoff's laws of electric circuits; Logic circuits; Operational amplifier; Oscillator; Resistor; Transformer; Transistor; Vacuum tube.

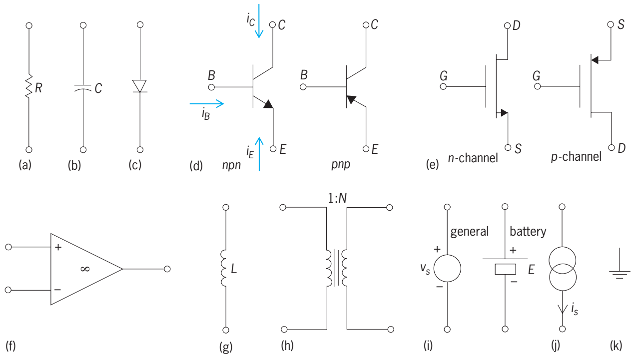


Fig. 1. Representation of some typical electronic devices. (*a*) Resistor. (*b*) Capacitor. (*c*) Diode. (*d*) Bipolar junction transistors (BJTs). (*e*) Metal oxide semiconductor field-effect transistors (MOSFETs). (*f*) Operational amplifier. (*g*) Inductor. (*h*) Transformer. (*i*) Voltage sources. (*j*) Current source. (*k*) Ground.

The devices in an electronic circuit are classified as being either passive or active. The passive devices change signal energy, as is done dynamically by capacitors and statically by transformers, or absorb signal energy, as occurs in resistors, which also act to convert voltages to currents and vice versa. The active devices, such as batteries, transistors, operational amplifiers, and vacuum tubes, can supply signal energy to the circuit and in many cases amplify signal energy by transforming power supply energy into signal energy. Often, though, they are used for other purposes, such as to route signals in logic circuits. Transistors can be considered the workhorses of modern electronic circuits, and consequently many types of transistors have been developed, among which the most widely used are the bipolar junction transistor (BJT), the junction field-effect transistor (JFET), and the metal oxide silicon field-effect transistor (MOSFET). *See* Electronic power supply.

Fortunately, most of these transistors occur in pairs, such as the *npn* and the *pnp* bipolar junction transistors, or the *n*-channel and the *p*-channel MOSFETs, allowing designers to work symmetrically with positive and negative signals and sources. This statement may be clarified by noting that transistors can be characterized by graphs of output current i versus output voltage v that are parametrized by an input current (in the case of the bipolar junction transistor) or input voltage (in the MOSFET and JFET cases). Typically, the curves for an *npn* bipolar junction transistor or an *n*-channel field-effect transistor are used in the first quadrant of the output i-v plane, while for a *pnp* bipolar junction transistor or a *p*-channel field-effect transistor the same curves show up in the third quadrant. Mathematically, if $i = f(v)$ for an *npn* bipolar junction transistor or *n*-channel field-effect

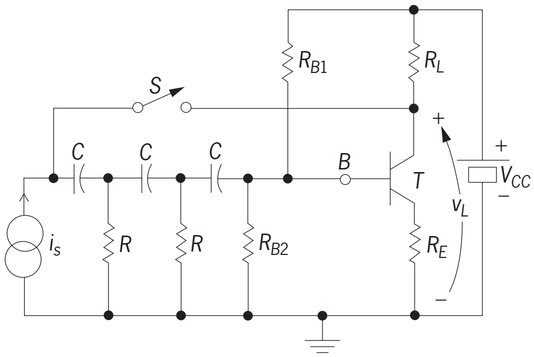

Fig. 2. Diagram of electronic circuit.

device, then $i = -f(-v)$ for a *pnp* bipolar junction transistor or *p*-channel field-effect device when the controlling parameters are also changed in sign.

Transistors. Transistors are basic to the operation of electronic circuits. Bipolar transistors have three terminals, designated as the base *B*, the collector *C*, and the emitter *E*. These terminals connect to two diode junctions, *B-C* and *B-E*, these forming back-to-back diodes. The *B-E* junction is often forward-biased, in which case its voltage is about 0.7 V, while the *B-C* junction is reverse-biased for linear operation.

Besides biasing of the junctions for linear operation, any state of the two junctions can occur. For example, both junctions might be forward-biased, in which case the transistor is said to be in saturation and acts nearly as a short circuit between *E-C*, while if the junctions are simultaneously back-biased the transistor is said to be cut off and acts as an open circuit between all terminals. The transistor can be controlled between saturation and cutoff to make it act as an electronically controlled switch. This mode of operation is especially useful for binary arithmetic, as used by almost all digital computers, where 0 and 1 logic levels are represented by the saturation and cutoff transistor states.

MOSFETs have three regions of operation: cutoff, saturated, and resistive. The MOSFET also has three terminals, the gate *G*, the drain *D*, and the source *S*. A key parameter characterizing the MOSFET is a threshold voltage V_{th}. When the *G-S* voltage is below the threshold voltage, no drain current flows and the transistor is cut off.

The MOSFET is a versatile device, acting as a voltage-controlled current source in the saturation region and approximately as a voltage-controlled resistor in the resistive region. It can also be electronically controlled between cutoff and the resistive region to make it act as a switch, while for small signals around an operating point in the saturation region it acts as a linear amplifier. Another feature of the MOSFET is that, besides the categories of *n*-channel and *p*-channel devices, there are also enhancement- and depletion-mode devices of each category. In practice, for electronic circuit considerations, an *n*-channel device has $V_{th} > 0$ for enhancement-mode devices and $V_{th} < 0$ for depletion-mode devices, while the signs are reversed for *p*-channel devices.

Biasing of circuits. Since active devices usually supply signal energy to an electronic circuit, and since energy can only be transformed and not created, a source of energy is needed when active devices are present. This energy is usually obtained from batteries or through rectification of sinusoidal voltages supplied by power companies. When inserted into an electronic circuit, such a source of energy fixes the quiescent operation of the circuit; that is, it allows the circuit to be biased to a given operating point with no signal applied, so that when a signal is present it will be processed properly. To be useful, an electronic circuit produces one or more outputs; often inputs are applied to produce the outputs. These inputs and outputs are called the signals and, consequently, generally differ from the bias quantities, though often it is hard to separate signal and bias variables. Biasing of electronic circuits is an important, nontrivial, and often overlooked aspect of their operation. *See* BIAS (ELECTRONICS).

Analog versus digital circuits. Electronic circuits are also classified as analog or digital. Analog circuits work with signals that span a full range of values of voltages and currents, while digital circuits work with signals that are at prescribed levels to represent numerical digits. Analog signals generally are used for continuous-time processes, while digital ones most frequently occur where transitions are synchronized via a clock. However, there are situations where it is desirable to transfer between these two classes of signals, that is, where analog signals are needed to excite a digital circuit or where a digital signal is needed to excite an analog circuit. For example, it may be desired to feed a biomedically recorded signal, such as an electrocardiogram into a digital computer, or it may be desired to feed a digital computer output into an analog circuit, such as a temperature controller. For such cases, there are special electronic circuits, called analog-to-digital and digital-to-analog converters. *See* ANALOG-TO-DIGITAL CONVERTER; DIGITAL-TO-ANALOG CONVERTER.

Feedback. An important concept in electronic circuits is that of feedback. Feedback occurs when an output signal is fed around a device to contribute to the input of the device. Consequently, when positive feedback occurs, that is, when the output signal returns to reinforce itself upon being fed back, it can lead to the generation of signals which may or may not be wanted. Circuit designers need to be conscious of all possible feedback paths that are present in their circuits so that they can ensure that unwanted oscillations do not occur. In the case of negative feedback, that is, when the output signal returns to weaken itself, then a number of improvements in circuit performance often ensue; for example, the circuit can be made less sensitive to changes in the environment or element variations, and deleterious nonlinear effects can be minimized. *See* CONTROL SYSTEMS; FEEDBACK CIRCUIT.

Digital circuits. The digital computer is based on digital electronic circuits. Although some of the circuits are quite sophisticated, such as the microprocessors integrated on a single chip, the concepts behind most of the circuits involved in digital computers are quite simple compared to the circuits used for analog signal processing. The most basic circuit is the inverter; a simple realization based upon the MOS transistor is shown in Fig. 3*a*. The upper (depletion-mode) transistor acts as a load "resistor" for the lower (enhancement-mode) transistor, which acts as a switch, turning on (into its resistive region) when the voltage at point *A* is above threshold to lower the voltage at point *B*. Adding the output currents of several of these together into the same load resistor gives a NOR gate, a two-input version of which is shown in Fig. 3*b*; that is, the output is high, with voltage at V_{DD}, if and only if the two inputs are low. Placing the drains of several of the enhancement-mode switches in series yields the NAND gate, a two-input version of which is shown in Fig. 3*c*; that is, the output is low if and only if both inputs are high. From the circuits of Fig. 3, the most commonly used digital logic circuits can be constructed. Because these circuits are so simple, digital circuits and digital computers are usually designed on the basis of negation logic, that is, with NOR and NAND rather than OR and AND circuits. *See* DIGITAL COMPUTER; INTEGRATED CIRCUITS; MICROPROCESSOR.

Conversion. Because most signals in the real world are analog but digital computers work on discretizations, it is necessary to convert between digital and analog signals. As mentioned above, this is done through digital-to-analog and analog-to-digital converters. Most approaches to digital-to-analog conversion use summers, where the voltages representing the digital bits are applied to input resistors, either directly or indirectly through switches gated on by the digital bits which change the input resistance fed by a dc source.

One means of doing analog-to-digital conversion is to use a clocked counter that feeds a digital-to-analog converter, whose output is compared with the analog signal to stop the count when the digital-to-analog output exceeds the analog signal. The counter output is then the analog-to-digital output. The comparator for such an analog-to-digital converter is similar to an open-loop operational amplifier (which changes saturation level when one of the differential input levels crosses the other). Other types of analog-to-digital converters, called flash converters, can do the conversion in a shorter time by use of parallel operations, but they are more expensive.

Other circuits. The field of electronic circuits is very broad and there are a very large number of other circuits besides those discussed above. For example, the differential is a key element in operational amplifier design and in biomedical data acquisition devices which must also be interfaced with specialized electronic sensors. Light-emitting and -detecting diodes allow

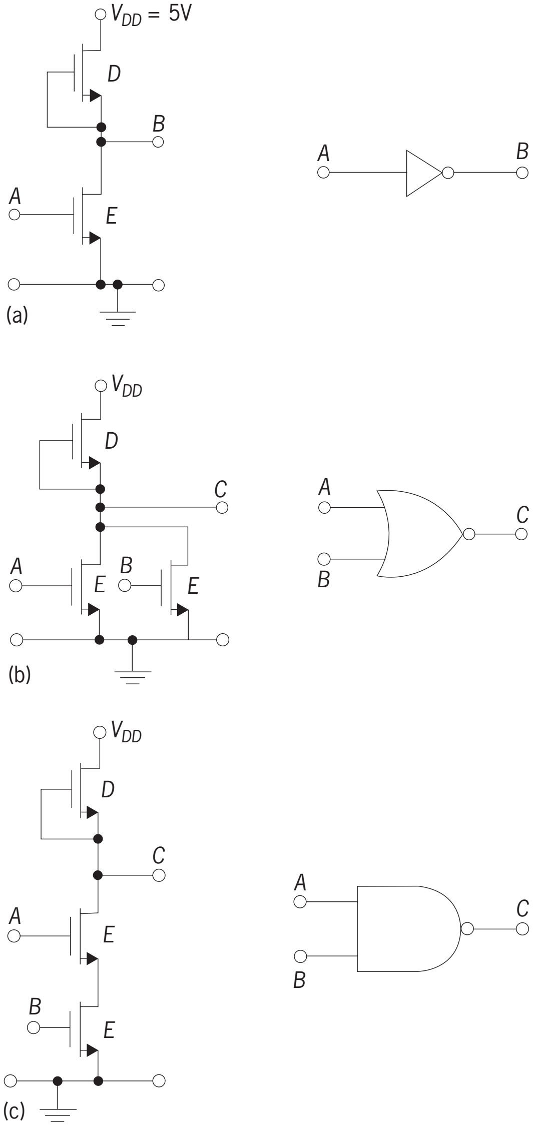

Fig. 3. Digital logic gates and their symbols. *D* = depletion-mode transistor; *E* = enhancement-mode transistor. (*a*) Inverter. (*b*) NOR gate. (*c*) NAND gate.

for signals to be transmitted and received at optical frequencies. Liquid crystals are controlled by electronic circuits and are useful in digital watches, flat-panel color television displays, and electronic shutters. *See* BIOMEDICAL ENGINEERING; ELECTRONIC DISPLAY; LIGHT-EMITTING DIODE; LIQUID CRYSTALS; OPTICAL DETECTORS; TRANSDUCER.

Design. Because some circuits can be very complicated, and since even the simplest circuits may have complicated behavior, the area of computer-aided design (CAD) of electronic circuits has been extensively developed. A number of circuit simulation programs are available, some of which can be run on personal computers with good results. These programs rely heavily upon good mathematical models of the electronic devices. Fortunately, the area of modeling of electronic devices is well developed, and for many devices there are models that are adequate for most purposes. But new devices are constantly being conceived and fabricated, and in some cases no adequate models for them exist. Thus, many of the commerical programs allow the designer to read in experimentally obtained data for a device from which curve fitting techniques are used to allow an engineer to proceed with the design of circuits incorporating the device. Reproducibility and acceptability of parts with tolerances are required for the commerical use of electronic circuits. Consequently, theories of the reliability of electronic circuits have been developed, and most of the computer-aided design programs allow the designer to specify component tolerances to check out designs over wide ranges of values of the elements. Finally, when electronic circuits are manufactured they can be automatically tested with computer-controlled test equipment. Indeed, an area that will be of increasing importance is design for testability, in which decisions on what to test are made by a computer using knowledge-based routines, including expert systems. Such tests can be carried out automatically with computer-controlled data-acquisition and display systems. *See* CIRCUIT (ELECTRICITY); COMPUTER-AIDED DESIGN AND MANUFACTURING; EXPERT SYSTEMS; RELIABILITY, AVAILABILITY, AND MAINTAINABILITY; ROBOTICS. [R.W.Ne.]

Circuit breaker A device to open or close an electric power circuit either during normal power system operation or during abnormal conditions. A circuit breaker serves in the course of normal system operation to energize or deenergize loads. During abnormal conditions, when excessive current develops, a circuit breaker opens to protect equipment and surroundings from possible damage due to excess current. These abnormal currents are usually the result of short circuits created by lightning, accidents, deterioration of equipment, or sustained overloads.

Formerly, all circuit breakers were electromechanical devices. In these breakers a mechanism operates one or more pairs of contacts to make or break the circuit. The mechanism is powered either electromagnetically, pneumatically, or hydraulically. The contacts are located in a part termed the interrupter. When the contacts are parted, opening the metallic conductive circuit, an electric arc is created between the contacts. This arc is a high-temperature ionized gas with an electrical conductivity comparable to graphite. Thus the current continues to flow through the arc. The function of the interrupter is to extinguish the arc, completing circuit-breaking action.

In oil circuit breakers, the arc is drawn in oil. The intense heat of the arc decomposes the oil, generating high pressure that produces a fluid flow through the arc to carry energy away. At transmission voltages below 345 kV, oil breakers used to be popular. They are increasingly losing ground to gas-blast circuit breakers such as air-blast breakers and SF_6 circuit breakers.

In air-blast circuit breakers, air is compressed to high pressures. When the contacts part, a blast valve is opened to discharge the high-pressure air to ambient, thus creating a very-high-velocity flow near the arc to dissipate the energy. In SF_6 circuit breakers, the same principle is employed, with SF_6 as the medium instead of air. In the "puffer" SF_6 breaker, the motion of the contacts compresses the gas and forces it to flow through an orifice into the neighborhood of the arc. Both types of SF_6 breakers have been developed for ehv (extra high voltage) transmission systems.

Two other types of circuit breakers have been developed. The vacuum breaker, another electromechanical device, uses the rapid dielectric recovery and high dielectric strength of vacuum. A pair of contacts is hermetically sealed in a vacuum envelope. Actuating motion is transmitted through bellows to the movable contact. When the contacts are parted, an arc is produced and supported by metallic vapor boiled from the electrodes. Vapor particles expand into the vacuum and condense on solid surfaces. At a natural current zero the vapor particles disappear, and the arc is extinguished. Vacuum breakers of up to 242 kV have been built.

The other type of breaker uses a thyristor, a semiconductor device which in the off state prevents current from flowing but which can be turned on with a small electric current through a third electrode, the gate. At the natural current zero, conduction ceases, as it does in arc interrupters. This type of breaker does not require a mechanism. Semiconductor breakers have been built to carry continuous currents up to 10,000 A. [T.H.L.]

Circuit testing (electricity) The testing of electric circuits to determine and locate any of the following circuit conditions: (1) an open circuit, (2) a short circuit with another conductor in the same circuit, (3) a ground, which is a short circuit between a conductor and ground, (4) leakage (a high-resistance path across a portion of the circuit, to another circuit, or to ground), and (5) a cross (a short circuit or leakage between conductors of different circuits). Circuit testing for complex systems often requires extensive automatic checkout gear to determine the faults defined above as well as many quantities other than resistance.

In cable testing, the first step in fault location is to identify the faulty conductor and type of fault. This is done with a continuity tester, such as a battery and flashlight bulb or buzzer (Fig. 1), or an ohmmeter.

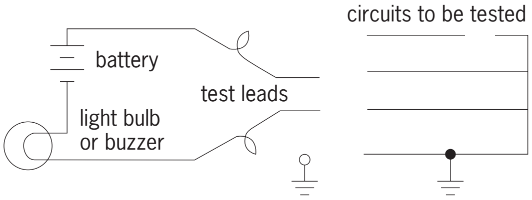

Fig. 1. Simple continuity test setup.

Useful for locating faults in relatively low-resistance circuits, the Murray loop is shown in Fig. 2 with a ground fault in the circuit under test. A known "good" conductor is joined to the faulty conductor at a convenient point beyond the fault but at a known distance form the test connection. One terminal of the test battery is grounded. The resulting Wheatstone bridge is then balanced by adjusting R_B until a null is obtained, as indicated by the detector in Fig. 2. Ration R_A/R_B is then known. For a circuit having a uniform ratio of resistance with lenght, circuit resistance is directly proportional to circuit lenght. Therefore, the distance to the fault is determined from the producer given by Eqs. (1)–(3). From Eq. (3) and a knowledge of total length l of the circuit, once ratio r has been measured, the location of the fault x is determined.

$$R_C \propto l + (l - x) \quad R_D \propto x \tag{1}$$

$$R_A/R_B = r = R_C/R_D = (2l - x)/x \tag{2}$$

$$x = 2l/(r - 1) \tag{3}$$

The Varley loop test is similar to the Murray loop test except for the inclusion of the adjustable resistance R. The Varley loop is used for fault location in high-resistance circuits.

An alternating-current capacitance bridge can be used for locating an open circuit as shown in Fig. 3. One test terminal is connected to the open conductor and the other terminal to a conductor of known continuity in the cable. All conductors associated with the test are opened at a convenient point beyond the fault but at a known distance from the test connection. An audio oscillator supplies the voltage to the bridge, which is balanced by adjusting R_B for a null as detected by the earphones. Measured ratio R_A/R_B equals the ratio of capacitances between the lines and the grounded sheath. Because each capacitance is proportional to the length of line connected to the bridge, the location of the open circuit can be determined from Eq. (4).

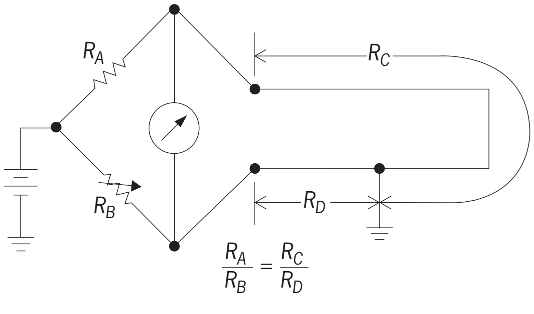

Fig. 2. Murray loop for location of ground fault.

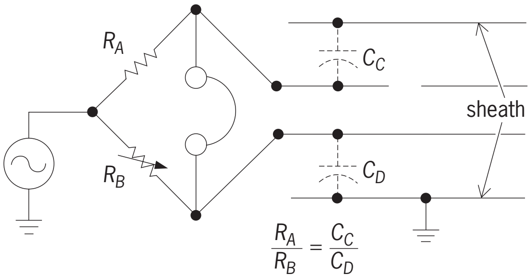

Fig. 3. Alternating-current capacitance bridge used in location of an open circuit in one conductor.

$$R_A/R_B = C_C/C_D \tag{4}$$

See CIRCUIT (ELECTRICITY). [C.E.A.]

Circulation Those processes by which metabolic materials are transported from one region of an organism to another. Ultimately, the essential gases, nutrients, and waste products of metabolism are exchanged across cell membranes by diffusion. Diffusion is the movement of material, by random motion of molecules, from a region of high concentration to one of low concentration. The amount of material moved from one place to another depends on the difference in concentrations and on the distance between the two points. The greater the distance, the less movement of material per unit time for a given difference in concentration. Consequently, in all but the smallest animals, convection (or bulk circulation) of materials to the cell must be employed to supplement diffusion.

Protoplasmic movement aids diffusion at the intracellular level. In multicellular animals, however, either the external medium or extracellular body fluids, or both, are circulated. In sponges and coelenterates, water is pumped through definite body channels by muscular activity or, more often, by cilia or flagella on the cells lining the channels.

Coelenterates have a body wall derived from two cell layers; an outer ectoderm is separated from an inner endoderm by a noncellular gelatinous material (mesoglea). All higher animals have bodies consisting of three cell layers, with the ectoderm being separated from the endoderm by a cellular layer of mesoderm. The mesoderm proliferates and separates to develop a fluid-filled body cavity or coelom. The coelom separates the ectoderm (together with an outer layer of mesoderm) from the endoderm (which has an inner layer of mesoderm). Coelomic fluid is moved around by body movements or ciliary activity, but in larger animals this movement is usually inadequate to supply the metabolic requirements of the organs contained within the coelom. These needs are provided for by pumping a fluid, blood, to them through vessels, the blood vascular system. *See* BLOOD.

When the blood is in a separate compartment from the rest of the extracellular fluid, the vascular system is described as closed. The two principal components of such systems are hearts and blood vessels. In such a system, the blood is circulated by a pump, the heart, through special channels, blood vessels; it comes into close association with the tissues only in the capillaries, fine vessels with walls only one cell thick. In some tissues or regions, larger blood spaces may exist, called sinuses. A closed vascular system is found in most annelids (segmented worms and leeches), cephalopod mollusks (squids and octopods), holothurian echinoderms (sea cucumbers), and vertebrates. *See* BLOOD VESSELS; HEART (VERTEBRATE).

In vertebrates, a functional but anatomically closed connection exists between the extracellular spaces (between the cells) and the blood vascular system in the form of lymph channels. Lymph is derived from the noncellular component of blood (plasma), modified in its passage through the tissues, and is conducted to the veins by blind-ending lymphatic vessels, which are separate from blood vessels and coelomic space. *See* LYMPHATIC SYSTEM.

In most arthropods (crustaceans, insects), most mollusks (shellfish), and many ascidians (sea squirts), the extracellular spaces are confluent with the blood system. In these animals, blood is pumped through a limited network of vessels into a body cavity called a hemocoel. After bathing the tissues, blood (called hemolymph in these organisms) collects in sinuses and returns to the heart. This is the open vascular system. In animals with open circulatory systems, the coelom is much reduced. [D.R.J.]

Circulation disorders The function of the circulatory system is to transport and distribute substances either used or produced by cells or both. Excluded are those materials that are discharged directly from sweat glands, digestive glands, and renal tubule cells. Included, however, are nutritive and metabolic substances, hormones, waste products, water, and heat.

Disturbances in the normal pattern of circulation can either result in or from disease conditions. An example is edema, which is an abnormal accumulation of fluid in the cells, tissue spaces, or cavities of the body. There are three main factors in the formation of generalized edema and a fourth which plays a role in the formation of local edema. They are the permeability of the capillary wall, the colloid osmotic pressure of the plasma proteins, and the hydrostatic pressure in the capillaries. The fourth factor, which is of importance in local edema formation, is lymphatic obstruction.

Increased permeability of the capillary walls plays an important role in the formation of inflammatory edema, the edema of severe infections, metabolic intoxications, asphyxia, anaphylactic reactions, secondary shock, and acute nephritis. *See* EDEMA.

A deficiency of circulating blood volume, both cellular elements and fluid, is called oligemia. This may be the result of an acute blood loss or it may be of a chronic nature, such as an anemia combined with dehydration. Anemia, or oligochromemia, is a deficiency of circulating red cell volume or, more specifically, hemoglobin content. It can result from a variety of causes. *See* ANEMIA; BLOOD.

Pancytopenia, or oligocythemia, is a deficiency of all circulating blood cellular elements. This is usually the result of a deficiency of the blood-forming tissue, the bone marrow.

The decrease of blood flow to an organ or tissue is known as ischemia. This can be sudden as when a vessel is ligated, when a thrombus or blood clot forms, or when an embolus comes to lodge in the vessel. A gradual occlusion can follow arteriosclerotic changes in the vessel wall. The effect of a sudden occlusion depends to a great extent on the collateral circulation to the organ or tissue involved. If an adequate collateral circulation comes to be established, the tissue survives; if not, it dies and an infarct results. *See* INFARCTION.

An excess of blood is referred to as plethora. This increase may be the result of an increase in the size or the number of red blood cells. The increase in red cell volume may be a polycythemia vera, or true polycythemia, which is a primary increase in the number of red blood cells with no regard to the needs of the organism. Polycythemia, or erythrocytosis, is usually a secondary increase in red cells following conditions of chronic hypoxia. Serous plethora is an increase in the watery part of the blood.

Hyperemia, or congestion, refers to an excess of blood within an organ or tissue. This condition may be localized or generalized. Active hyperemia, caused by an active dilatation of arterioles and capillaries, occurs under certain physiological conditions, such as in the muscle when there is an increased need for blood during exercise. It also occurs in pathological states such as inflammation. Passive hyperemia, a condition which results in an accumulation of blood in the venous system, may be generalized or localized and can result from any obstruction or hindrance to the outflow of blood from the venous circuit. Diseases of the lungs such as emphysema, fibrosis, or pulmonary hypertension of any origin can result in right ventricular failure and generalized congestion. Localized venous congestion results when a main vein from a region is occluded either by a thrombus or some extrinsic pressure such as a tumor or enlarged lymph nodes.

The escape of blood from within the vascular system is hemorrhage. This process can be the result of trauma to, or disease of, the vessel wall. The causes of hemorrhage other than trauma can be divided into three main groups. In the first group are those conditions in which there is a disease process affecting the vessel wall, such as arteriosclerosis or aneurysm formation. In the second group are conditions in which there is an acute process affecting the vessel wall such as in septicemia, poisoning by heavy metals, or even anoxia. The third group consists of those conditions in which there is a defect in the blood itself, which results in hemorrhage. Apoplexy, or stroke, is an acute vascular lesion of the brain. This can be the result of hemorrhage of, thrombosis in, or embolism to a cerebral vessel. *See* HEMORRHAGE.

Thrombosis is the formation of a thrombus, a solid body formed during life and composed of the elements of the blood: platelets, fibrin, red cells, and leukocytes. Thrombosis may occur on a vessel wall anywhere that the endothelium is damaged. However, because the platelets release thromboplastinogen, which activates the clotting mechanism, thrombosis and blood coagulation may occur together. *See* THROMBOSIS.

The sudden blocking of an artery or vein by a clot or other substance which has been brought to its place by the blood current is an embolism. The material carried in the circulation in this process is an embolus. Emboli may be composed of thrombi, fat, air, tumor cells, masses of bacteria or parasites, bone marrow, amniotic fluid, or atheromatous material from the vessel wall. *See* EMBOLISM. [R.A.V.]

Cirque A cliffed rock basin, shaped like half a bowl, at the head of a mountain valley. Cirques may be shallow if glacier erosion is slight, but may be 1600–2600 ft (500–800 m) from the top of the headwall to the cirque floor if erosion is deep. Cirques occur in glaciated mountains all over the world. Some cirques used repeatedly by glaciers over long periods of years are excavated profoundly. Many cirques contain small glaciers today that were inherited from a huge cirque cut by glaciers long ago. Well-formed cirques have steep rock walls and floors that slope down-valley or back toward the base of the headwall. Some cirques are cup-shaped rock basins holding rainwater; a lake formed in them is a tarn. If glacial deposits, such as till or a small moraine on the cirque floor, form a depression for a lake the lake is known as a moraine-dammed lake. [S.E.Wh.]

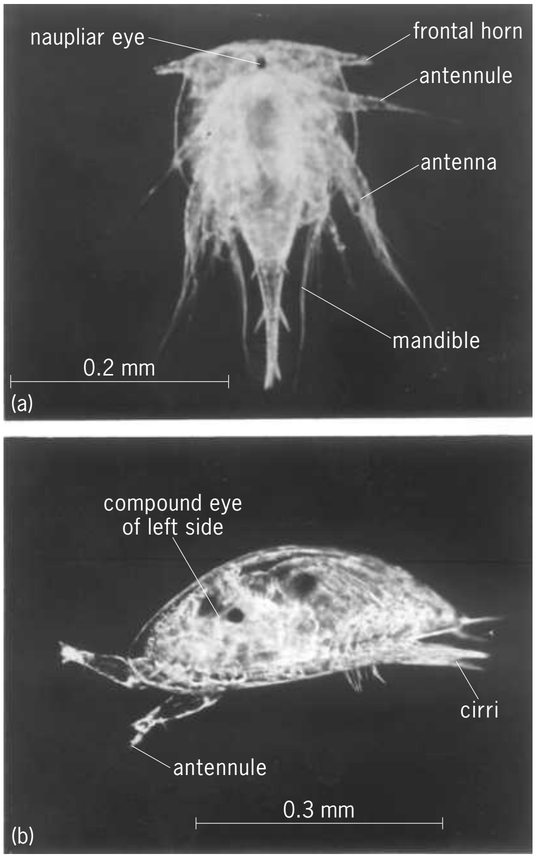
Cirrhosis A liver disease characterized by a marked increase in fibrous connective tissue, resulting in a firm, nodular, distorted liver.

There are numerous causes of cirrhosis. In the United States the majority of cases are caused by excessive alcohol consumption, and the condition is referred to as alcoholic cirrhosis. Cirrhosis may occur as a result of the healing of severe fulminant hepatitis or chronic active hepatitis. Some cases are caused by obstruction of the bile duct by calculi (stones) and are referred to as secondary biliary cirrhosis. Primary biliary cirrhosis is primarily a disease of middle-aged women and is caused by an autoimmune destruction of bile ducts. Autoimmune hepatitis, sometimes referred to as lupoid hepatitis and characteristically seen in young women and associated with serum autoantibodies, may progress to cirrhosis. Relatively few cases of cirrhosis are caused by genetically determined deficiencies in certain substances. *See* ALCOHOLISM; HEPATITIS.

The signs and symptoms of cirrhosis are nonspecific and frequently related to the complications. As the liver becomes fibrotic, there is obstruction of the blood flow through the liver. This results in portal hypertension, an increase in blood pressure within the portal vein and its tributaries. The obstructed hepatic blood flow also causes congestion of the spleen, leading to a markedly enlarged spleen (splenomegaly). Also, most people with cirrhosis eventually develop fluid in their abdomen (ascites) and are at an increased risk of developing a spontaneous intraabdominal infection. In addition to obstruction of blood flow, the bile ducts within the liver are distorted and frequently partially obstructed by the increased connective tissue. This results in jaundice, a yellow discoloration of all tissues and organs, including the skin. Some individuals with advanced cirrhosis develop renal failure, a condition referred to as hepatorenal syndrome. Also, there is a definite increase in liver cell cancer in cirrhotic persons. The liver may be slightly enlarged, but as the disease progresses it usually becomes smaller due to progressive loss of liver cells. *See* JAUNDICE.

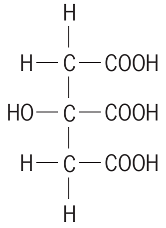
The therapy of cirrhosis is aimed primarily at preventing or reducing the complications. Bleeding esophageal varices (collateral venous channels) are a frequent serious complication of cirrhosis. Various techniques are used to control the bleeding. In some individuals with severe portal hypertension, vascular shunts are made to reduce the pressure in the portal vein by bypassing the liver. Most frequently the portal vein is surgically connected to the inferior vena cava so that some of the blood in the portal vein does not pass through the liver. *See* CARDIOVASCULAR SYSTEM; LIVER DISORDERS. [S.P.H.]

Cirripedia A subclass of the Crustacea, permanently attached when adult, and called barnacles. The carapace forms a complete covering or mantle over the rest of the body and is usually strengthened by calcareous plates. The body within the mantle consists of a mouth region and thorax. The abdomen is usually vestigial. Typically the mouth appendages are paired mandibles with palps, maxillulae, and maxillae. The thorax bears six pairs of biramous appendages (cirri) composed of numerous segments, each with a considerable armament of setae. Compound eyes occur only in the larvae, there is no heart, and typically adults are hermaphroditic. The eggs are incubated in the mantle cavity and hatch into free-swimming nauplius larvae (illus. *a*). By successive molts a further five nauplius larvae follow. The sixth nauplius (or metanauplius) molts into an entirely different larval form, the cypris (illus. *b*), which is characteristic of all Cirripedia. The Cirripedia are divided into four orders: Thoracica, Acrothoracica, Ascothoracica, and Rhizocephala. Only the Thoracica, the goose barnacles, and acorn barnacles are at all conspicuous, and only the latter of any economic significance. *See* ACROTHORACICA; ASCOTHORACICA; BARNACLE; RHIZOCEPHALA; THORACICA. [H.G.St.]



Larval stages of *Balanus*. (*a*) Nauplius. (*b*) Cypris. (*Photographs by D. P. Wilson*)

Citric acid A hydroxytricarboxylic acid, general formula $C_6H_8O_7$, with the structure shown here. It is available primarily as anhydrous material but also as the monohydrate. The major commercial salts are sodium and potassium, with calcium, diammonium, and ferric ammonium (complex) also available. *See* ACID AND BASE.



$$\begin{array}{rcl} & \mathrm{H} & \\ & | & \\ \mathrm{H}- & \mathrm{C} & -\mathrm{COOH} \\ & | & \\ \mathrm{HO}- & \mathrm{C} & -\mathrm{COOH} \\ & | & \\ \mathrm{H}- & \mathrm{C} & -\mathrm{COOH} \\ & | & \\ & \mathrm{H} & \end{array}$$

Citric acid is a relatively strong organic acid, and is very soluble in water. Citric acid and its salts are widely used because they are nontoxic, safe to handle, and easily biodegraded.

Citric acid occurs in relatively large quantities in citrus fruits. It also occurs in other fruits, in vegetables, and in animal tissues and fluids either as the free acid or as citrate ion. It is an integral part of the Krebs (citric acid) cycle involving the metabolic conversion of carbohydrates, fats, and proteins in most living organisms. *See* CITRIC ACID CYCLE.

Today, essentially all of the commercial citric acid is produced by fermentation. Processes employed are surface or submerged fermentation by mold (*Aspergillus niger*) and submerged fermentation by yeast (*Candida guilliermondii, C. lipolytica*), using a variety of substrates including sucrose, molasses, corn syrup, enzyme-treated starch, and normal paraffins. Citric acid is recovered from the fermentation broth by solvent extraction or more commonly by precipitation as calcium citrate, followed by treatment with sulfuric acid to convert the calcium citrate to calcium sulfate and citric acid. The calcium sulfate is removed by filtration, and the citric acid solution is further purified. Crystallization of citric acid from a hot aqueous solution (above the transition temperature of 36.6°C or 97.9°F) yields anhydrous citric acid; crystallization from a cold solution yields the monohydrate. Although total chemical syntheses for citric acid have been published, they have never achieved commercial success. *See* FERMENTATION; INDUSTRIAL MICROBIOLOGY.

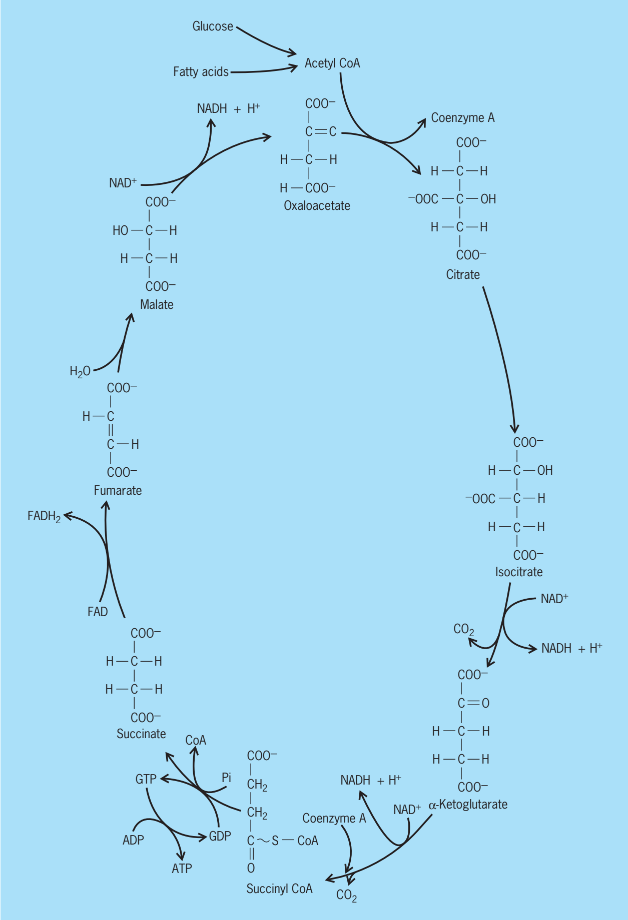
Citric acid is widely used in the food and pharmaceutical industries. In foods it is used primarily to produce a tart taste and to complement fruit flavors in carbonated beverages, beverage powders, fruit-flavored drinks, jams and jellies, candy, sherbets, water ices, and wine. It is also used to reduce pH in certain canned foods to make heat treatment more effective, and in conjunction with antioxidants to chelate trace metals and retard enzymatic activity. *See* FOOD MANUFACTURING.

In pharmaceuticals, citric acid provides the acid source in effervescent tablets in addition to being used to adjust pH, impart a tart taste, and chelate trace metals. It is also used as a blood anticoagulant. *See* Pharmaceutical chemistry.

Citric acid, because of its low toxicity, relative noncorrosiveness, and biodegradability, is also being used for applications normally reserved for the strong mineral acids. These include preoperational and operational cleaning of iron and copper oxides from boilers, nuclear reactors, and heat exchangers; passivation of stainless steel tanks and equipment; and etching of concrete floors prior to coating. It is also used as a dispersant to retard settling of titanium dioxide slurries and as a sequestering and pH control agent in the textile industry. *See* Textile chemistry. [F.Sa.]

Citric acid cycle In aerobic cells of animals and certain other species, the major pathway for the complete oxidation of acetyl coenzyme A (the thioester of acetic acid with coenzyme A); also known as the Krebs cycle or tricarboxylic acid cycle. Reduced electron carriers generated in the cycle are reoxidized by oxygen via the electron transport system; water is formed, and the energy liberated is conserved by the phosphorylation of adenosine diphosphate (ADP) to adenosine triphosphate (ATP). Reactions of the cycle also function in metabolic processes other than energy generation. The role of the cycle in mammalian tissues will be emphasized in this article. *See* Adenosine diphosphate (ADP); Coenzyme; Enzyme.

The first step in the cycle involves the condensation of the acetyl portion of acetyl coenzyme A (CoA) with the four-carbon compound oxaloacetate to form citrate, a tricarboxylate containing six carbons (see illustration). A shift of the hydroxyl group of citrate to an adjacent carbon results in the formation of D-threo-isocitrate, which in turn is oxidized to the five-carbon compound α-ketoglutarate and carbon dioxide (CO_2). In a second oxidative decarboxylation reaction, α-ketoglutarate, in the presence of CoA, is converted to succinyl CoA and another molecule of CO_2. In the subsequent formation of the four-carbon compound succinate and CoA, the energy in the thioester bond of succinyl CoA is conserved by the formation of guanosine triphosphate (GTP) from guanosine diphosphate (GDP) and inorganic phosphate. Fumarate is formed from succinate by the removal of two atoms of hydrogen, and the unsaturated compound is then hydrated to L-malate. The dehydrogenation of malate forms oxaloacetate, the starting four-carbon compound of the metabolic cycle. Thus, beginning with the two-carbon acetyl group, one completion of the cycle results in the formation of two molecules of carbon dioxide.



Citric acid cycle.

The oxidation of acetyl CoA to CO_2 in the cycle occurs without direct reaction with molecular oxygen. The oxidations occur at dehydrogenation reactions in which hydrogen atoms and electrons are transferred from intermediates of the cycle to the electron carriers nicotinamide adenine dinucleotide (NAD^+) and flavin adenine dinucleotide (FAD). The electrons from NADH and $FADH_2$ are transferred to molecular oxygen via a series of electron transport carriers, with regeneration of NAD^+ and FAD. The energy liberated in the electron transport chain is partially conserved by the formation of ATP from ADP and inorganic phosphate, by a process called oxidative phosphorylation. The energy generated as oxygen accepts electrons from the reduced coenzymes generated in one turn of the cycle results in the maximal formation of 11 molecules of ATP. Because GTP obtained by phosphorylation of GDP at the succinyl CoA to succinate step of the cycle is readily converted to ATP by nucleotide diphosphokinase, the yield is 12 molecules of ATP per molecule of acetyl CoA metabolized. *See* Nicotinamide adenine dinucleotide (NAD).

The electron transport and oxidative phosphorylation systems and the enzymes required for the citric acid cycle are located in the mitochondria of cells, which are the major source of ATP for energy-consuming reactions in most tissues. The citric acid cycle does not occur in all cells. For example, mature human red blood cells do not contain mitochondria and the cycle is absent. In these cells, ATP is formed by the anaerobic conversion of glucose to lactate (anaerobic glycolysis). *See* Mitochondria; Phosphate metabolism.

Acetyl CoA is formed from carbohydrates, fats, and the carbon skeleton of amino acids. The origin of a precursor and the extent of its utilization depend on the metabolic capability of a specific tissue and on the physiological state of the organism. For example, most mammalian tissues have the capacity to convert glucose to pyruvate in a reaction called glycolysis. Pyruvate is then taken up from cellular cytosol by mitochondria and oxidatively decarboxylated to acetyl CoA and carbon dioxide by pyruvate dehydrogenase. Acetyl CoA is also the end product of fatty acid oxidation in mitochondria. However, the fatty acid oxidation pathway occurs in fewer tissues than does glycolysis or the citric acid cycle. The amino acids follow varied pathways for forming compounds that can enter the citric acid cycle. *See* Amino acids.

In addition to the cycle's role in yielding catabolic energy, portions of it can supply intermediates for synthetic processes, such as the synthesis of the fatty acid moiety of triglycerides from glucose (lipogenesis), and formation of glucose from the carbon skeletons of certain amino acids, lactate, or glycerol (gluconeogenesis). *See* Biological oxidation; Carbohydrate metabolism; Cell (biology); Glucose; Glycogen; Lipid metabolism; Metabolism. [G.E.W.P.]

Citron *Citrus medica*, a species of true citrus. Commercially, citrons are grown almost exclusively in the Mediterranean area, principally in Italy, Sicily, Corsica, Greece, and Israel. The tree is evergreen, as are all citrus, and frost-tender. It is thorny, straggly, shrubby, and tends to be short-lived.

The fruit is scarcely edible fresh, having a very thick skin with little flesh and that lacking in juice. However, it is very fragrant and was valued in ancient times for its aroma and its fragrant peel oil, used in perfumes and as a moth repellent. It is grown commercially only as a source of candied peel for use in cakes and confections. The actual candying is usually done in the importing country, the citron peel being exported in brine.

Confusion sometimes arises due to "citron" also being used for a small, wild, inedible melon in the United States and for lemons (*C. limon*) in France. *See* FRUIT, TREE. [W.G.]

Citronella A tropical grass, *Cymbopogon nardus*, from the leaves of which oil of citronella is distilled. This essential oil is pale yellow, inexpensive, and much used in cheap perfumes and soaps. It is perhaps best known as an insect repellent. A large acreage is devoted to the cultivation of this grass in Java and Ceylon. *See* CYPERALES. [P.D.St./E.L.C.]

Civet Any of 18 species of carnivores assigned to the family Viverridae. Also included in this family are genets, linsangs, and mongooses. *See* MONGOOSE.

Civets are small to medium size with a pointed muzzle, long head, slender body, and long, bushy tail. They have short limbs and nonretractile claws; they are digitigrade, that is, they walk on their toes. The Indian civet (*Viverra zibetha*) and the smaller African civet are two better-known species.

Civets are nocturnal and remain hidden in brush areas during the day. They have well-developed perianal glands, from which a scented substance used in perfumery is secreted. *See* CARNIVORA; SCENT GLAND. [C.B.C.]

Civil engineering A branch of engineering that encompasses the conception, design, construction, and management of residential and commercial buildings and structures, water supply facilities, and transportation systems for goods and people, as well as control of the environment for the maintenance and improvement of the quality of life. Civil engineering includes planning and design professionals in both the public and private sectors, contractors, builders, educators, and researchers.

The civil engineer holds the safety, health, and welfare of the public paramount. Civil engineering projects and systems should conform to governmental regulations and statutes; should be built economically to function properly with a minimum of maintenance and repair while withstanding anticipated usage and weather; and should conserve energy and allow hazard-free construction while providing healthful, safe, and environmentally sound utilization by society.

Civil engineers play a major role in developing workable solutions to construct, renovate, repair, maintain, and upgrade infrastructure. The infrastructure includes roads, mass transit, railroads, bridges, airports, storage buildings, terminals, communication and control towers, water supply and treatment systems, storm water control systems, wastewater collection, treatment and disposal systems, as well as living and working areas, recreational buildings, and ancillary structures for civil and civic needs. Without a well-maintained and functioning infrastructure, the urban area cannot stay healthy, grow, and prosper.

Because the desired objectives are so broad and encompass an orderly progression of interrelated components and information to arrive at the visually pleasing, environmentally satisfactory, and energy-frugal end point, civil engineering projects are actually systems requiring the skills and inputs of many diverse technical specialties, all of which are subsets of the overall civil engineering profession.

Some of the subsets that civil engineers can specialize in include photogrammetry, surveying, mapping, community and urban planning, and waste management and risk assessment. Various engineering areas that civil engineers can specialize in include geotechnical, construction, structural, environmental, water resources, and transportation engineering. *See* CIVIL ENGINEERING; COASTAL ENGINEERING; CONSTRUCTION ENGINEERING; ENGINEERING; ENGINEERING GEOLOGY; ENVIRONMENTAL ENGINEERING; HIGHWAY ENGINEERING; LAND-USE PLANNING; PHOTOGRAMMETRY; RIVER ENGINEERING; SURVEYING; TOPOGRAPHIC SURVEYING AND MAPPING; TRANSPORTATION ENGINEERING. [G.Pa.]

Cladding An old jewelry art, now employed on an industrial scale to add the desirable surface properties of an expensive metal to a low-cost or strong base metal. In the process a clad metal sheet is made by bonding or welding a thick facing to a slab of base metal; the composite plate is then rolled to the desired thickness. The relative thickness of the layers does not change during rolling. Cladding thickness is usually specified as a percentage of the total thickness, commonly 10%.

Gold-filled jewelry has long been made by this process: the surface is gold, the base metal bronze or brass with the cladding thickness usually 5%. The process is used to add corrosion resistance to steel and to add electrical or thermal conductivity, or good bearing properties, to strong metals. Corrosion-resistant pure aluminum is clad to a strong duralumin base, and many other combinations of metals are widely used in cladding; a development includes a technique for cladding titanium to steel for jet-engine parts.

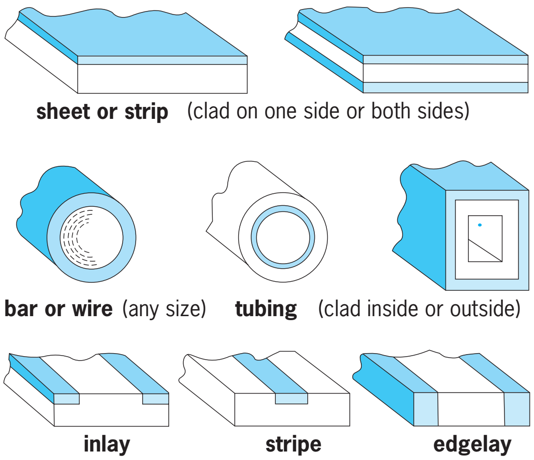
Cladding supplies a combination of desired properties not found in any one metal. A base metal can be selected for cost or structural properties, and another metal added for surface protection or some special property such as electrical conductivity. Thickness of the cladding can be made much heavier and more durable than obtainable by electroplating.

Cladding can be added to both sides of a sheet or strip of base metal. Tubing can be supplied with a clad surface on inside or outside; round and rectangular wire can be clad similarly (see illustration).

For some forms of electrical contacts, the composite materials are bonded side by side, or silver is inset as a stripe on one side or along the edges. This construction can place solid silver just where it is needed to form an electrical contact with no waste of costly metal.

A related form of cladding is found in thermostatic bimetals in which equal thicknesses of low- and high-expansion metals are bonded together. With a change in temperature, differing expansion rates of the two metals cause the composite material to bend and thus operate values in automobile cooling systems, or electrical contacts in room thermostats.

Clad wires with properly chosen proportions of materials of different thermal-expansion rates can match the thermal expan-

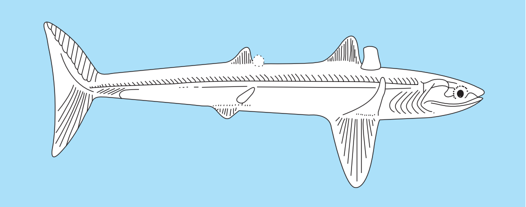


Types of cladding.

sion of types of glass used for vacuum-tight seals for conductors in lamp bulbs and hermetically sealed enclosures.

In making parts from clad metal, the composite material can be bent, drawn, spun, or otherwise formed just the same as the base metal without breaking the bond. The maximum service temperature is limited by the melting point of the material at the juncture of the two metals. *See* ELECTROPLATING OF METALS; METAL COATINGS. [R.W.C.]

Cladoselachii An order of extinct elasmobranch fishes including the oldest and most primitive of sharks. Best known is Cladoselache (see illustration), of which complete specimens, including even muscle and other soft tissues, have been obtained from shales in the region of Cleveland, Ohio. Primitive features are broad-based paired fins, amphistylic jaw support, and absence of claspers. *See* ELASMOBRANCHII. [A.S.R.]



***Cladoselache* of the Late Devonian.**

Clarification The removal of small amounts of fine, particulate solids from liquids. The purpose is almost invariably to improve the quality of the liquid, and the removed solids often are discarded. The particles removed by a clarifier may be as large as 100 micrometers or as small as 2 micrometers. Clarification is used in the manufacture of pharmaceuticals, beverages, and fiber and film polymers; in the reconditioning of electroplating solutions; in the recovery of dry-cleaning solvent; and for the purification of drinking water and waste water. The filters in the feed line and lubricating oil system of an internal combustion engine are clarifiers.

The methods of clarification include gravity sedimentation, centrifugal sedimentation, filtration, and magnetic separation. Clarification differs from other applications of these mechanical separation techniques by the low solid content of the suspension to be clarified (usually less than 0.2%) and the substantial completion of the particle removal. *See* FILTRATION; MAGNETIC SEPARATION METHODS; MECHANICAL SEPARATION TECHNIQUES; SEDIMENTATION (INDUSTRY); THICKENING. [S.A.M.]

Classical field theory The mathematical discipline that studies the behavior of distributions of matter and energy when their discrete nature can be ignored; also known as continuum physics or continuum mechanics. The discrete nature of matter refers to its molecular nature, and that of energy to the quantum nature of force fields and of the mechanical vibrations that exist in any sample of matter. The theory is normally valid when the sample is of laboratory size or larger, and when the number of quanta present is also very large. *See* PHONON; PHOTON; QUANTUM MECHANICS.

Classical field theories can be formulated by the molecular approach, which seeks to derive the macroscopic (bulk) properties by taking local averages of microscopic quantities, or by the phenomenological approach, which ignores the microscopic nature of the sample and uses properties directly measurable with laboratory equipment. Although the microscopic treatment sometimes yields profounder insights, the phenomenological approach can use partial differential equations since neglecting the microscopic structure allows quantities such as density and pressure to be expressed by continuously varying numbers.

Examples of classical field theories include the deformation of solids, flow of fluids, heat transfer, electromagnetism, and gravitation. Solving the equations has produced a vast body of mathematics. Computers have aided in special calculations, but many mathematicians are working on the analytical theory of partial differential equations, and new results continue to be produced. *See* DIFFERENTIAL EQUATION. [D.P.]

Classical mechanics The science dealing with the description of the positions of objects in space under the action of forces as a function of time. Some of the laws of mechanics were recognized at least as early as the time of Archimedes (287?–212 B.C.). In 1638, Galileo stated some of the fundamental concepts of mechanics, and in 1687, Isaac Newton published his *Principia*, which presents the basic laws of motion, the law of gravitation, the theory of tides, and the theory of the solar system. This monumental work and the writings of J. D'Alembert, J. L. Lagrange, P. S. Laplace, and others in the eighteenth century are recognized as classic works in the field of mechanics. Jointly they serve as the base of the broad field of study known as classical mechanics, or Newtonian mechanics. This field does not encompass the more recent developments in mechanics, such as statistical, relativistic, or quantum mechanics.

In the broad sense, classical mechanics includes the study of motions of gases, liquids, and solids, but more commonly it is taken to refer only to solids. In the restricted reference to solids, classical mechanics is subdivided into statics, kinematics, and dynamics. Statics considers the action of forces that produce equilibrium or rest; kinematics deals with the description of motion without concern for the causes of motion; and dynamics involves the study of the motions of bodies under the actions of forces upon them. For some of the more important areas of classical mechanics *see* BALLISTICS; COLLISION (PHYSICS); DYNAMICS; ENERGY; FORCE; GRAVITATION; KINEMATICS; LAGRANGE'S EQUATIONS; MASS; MOTION; PRECESSION; RIGID-BODY DYNAMICS; STATICS; WORK. [N.S.G.]

Classification, biological A human construct for grouping organisms into hierarchical categories. The most inclusive categories of any classification scheme are called kingdoms, which are delimited so that organisms within a single kingdom are more related to each other than to organisms grouped in the other kingdoms. Classification (grouping) is a part of biological systematics or taxonomy, science that involves naming and sorting organisms into groups.

Historically, organisms have been arranged into kingdoms based on practical characteristics, such as motility, medicinal properties, and economic value for food or fiber. In the nineteenth and twentieth centuries, advances such as electron and light microscopy, biochemistry, genetics, ethology, and greater knowledge of the fossil record provided new evidence upon which to construct more sophisticated classification schemes. Proposals were made to assign organisms into four, five, and even thirteen kingdoms. Earlier two-kingdom and three-kingdom systems were devised without awareness of the profound distinction between prokaryotes and eukaryotes, which Edouard Chatton (1937) recognized as a fundamental evolutionary discontinuity. Prokaryotic cells do not have either a nucleus or any other internal membrane-bounded structures, the so-called organelles. By contrast, eukaryotic cells have both a nucleus and organelles. The deoxyribonucleic acid (DNA) of eukaryotes is combined with protein to form chromosomes. All bacteria are prokaryotes. Plants, fungi, animals, and protoctists are eukaryotes. *See* EUKARYOTAE; PROKARYOTAE.

By the late 1990s, biologists widely accepted a system that classifies all organisms into five kingdoms based on key characteristics of function and structure. These are Superkingdom Prokarya [Kingdom Bacteria (Monera) with two subkingdoms, Archaea and Eubacteria] and Superkingdom Eukarya with four kingdoms, Protoctista (or Protozoa in some classification schemes), Fungi, Animalia, and Plantae. Key charactistics used to classify organisms into these categories include the mode by which the organism obtains its nutrients; presence or absence of an embryo; and whether and how the organism achieves motility.

Cladistics may be defined as an approach to grouping organisms that classifies them according to the time at which branch points occur along a phylogenetic tree. Such a phylogenetic tree is represented by a diagram called a cladogram. In this approach, classification is based on a sequence of phylogenetic branching. In a cladogram, the phylogenetic tree branches dichotomously and repeatedly, reflecting cladogenesis (production of biological diversity by evolution of new species from parental species).

Modern classification is based on evidence derived from developmental pattern, biochemistry, molecular biology, genetics, and detailed morphology of extant organisms and their fossils. Because information is drawn from such diverse sources, and because 10–30 million (possibly 100 million) species are probably alive today, informed judgments must be made to integrate the information into classification hierarchies. Only about 1.7 million species have been formally classified in the taxonomic literature of biology to date. Thus, as new evidence about the evolutionary relationships of organisms is weighed, it must be anticipated that biological classification schemes will continue to be revised. *See* ANIMAL SYSTEMATICS; BACTERIAL TAXONOMY; PLANT TAXONOMY; VIRUS CLASSIFICATION. [K.V.S.]

Clathrate compounds Well-defined addition compounds formed by inclusion of molecules in cavities existing in crystal lattices or present in large molecules. The constituents are bound in definite ratios, but these are not necessarily integral. The components are not held together by primary valence forces, but instead are the consequence of a tight fit which prevents the smaller partner, the guest, from escaping from the cavity of the host. Consequently, the geometry of the molecules is the decisive factor.

Inclusion compounds can be subdivided into (1) lattice inclusion compounds (inclusion within a lattice which, as such, is built up from smaller single molecules); (2) molecular inclusion compounds (inclusion into larger ring molecules with holes); and (3) inclusion compounds of macromolecules. The best-known lattice inclusion compounds are the urea and thiourea channel inclusion compounds, which are formed by mixing hydrocarbons, carboxylic acids, or long-chain fatty alcohols with solutions of urea. Other representatives of lattice inclusion compounds are the choleic acids, which are adducts of deoxycholic acid with fatty acids, and other lipoic substances. Some aromatic compounds form an open crystal lattice which can accommodate smaller gas and solvent molecules (clathrates in the stricter sense of the word). The gas hydrates are inclusion compounds of gases in a somewhat expanded ice lattice. The gas or solvent molecules are inserted into definite places within the ice lattice and are surrounded by water molecules on all sides.

Crown ether compounds are cyclic or polycyclic polyether compounds capable of including another atom in the center of the ring. In this way, sodium or potassium compounds can be solubilized in organic solvents. Similarly, a series of ionophore antibiotics can complex inorganic cations.

Some clay minerals are made up of distinct silicate layers. Between these layers some free space may exist in the shape of channels. Smaller hydrocarbon molecules can be accommodated reversibly within these channels. This phenomenon is used in some technical separation processes for separating hydrocarbons (molecular sieves). Furthermore, ion-exchange processes used for water deionization are based on similar minerals. *See* CLAY MINERALS; MOLECULAR SIEVE.

Enzymes are believed to accommodate their substrates in active sites, pockets, or clefts prior to the chemical reaction which then changes the chemical structures of the substrates. These binding processes are identical to those of low-molecular-weight inclusion compounds. [F.Cr.; W.S.; D.G.]

Clathrinida An order of sponges in the subclass Calcinea of the class Calcarea. These sponges have an asconoid structure and lack a true dermal membrane or cortex. The spongocoel is lined with choanocytes. This order contains the family Clathrinidae; *Clathrina, Ascute*, and *Dendya* are examples. *See* CALCAREA. [W.D.H.]

Clavaxinellida An order of sponges of the class Demospongiae, subclass Tetractinomorpha, with monaxonid megascleres arranged in radial or plumose tracts. In the suborder Epipolasina, monactinal or diactinal megascleres are arranged in a radial pattern. Spongin is rare.

Clavaxinellidan sponges vary greatly in shape, from radially symmetrical species which are spherical in shape to encrusting or massive species and upright branching types. They occur in tidal and shallow waters of all seas and extend down to depths of at least 18,000 ft (5500 m). Sponges comparable to existing clavaxinellidans occur scattered through the fossil record from Cambrian strata upward. *See* DEMOSPONGIAE. [W.D.H.]

Clay The finest-grain particles in a sediment, soil, or rock. Clay is finer than silt, characterized by a grain size of less than approximately 4 micrometers. However, the term clay can also refer to a rock or a deposit containing a large component of clay-size material. Thus clay can be composed of any inorganic materials, such as clay minerals, allophane, quartz, feldspar, zeolites, and iron hydroxides, that possess a sufficiently fine grain size. Most clays, however, are composed primarily of clay minerals. *See* CLAY MINERALS; FELDSPAR; QUARTZ; ZEOLITE.

Although the composition of clays can vary, clays can share several properties that result from their fine particle size. These properties include plasticity when wet, the ability to form colloidal suspensions when dispersed in water, and the tendency to flocculate (clump together) and settle out in saline water. *See* COLLOID.

Clays, together with organic matter, water, and air, are one of the four main components of soil. Clays can form directly in a soil by precipitation from solution (neoformed clays); they can form from the partial alteration of clays already present in the soil (transformed clays); or they can be inherited from the underlying bedrock or from sediments transported into the soil by wind, water, or ice (inherited clays). *See also* SOIL.

The type of clays neoformed in a soil depends on the composition of the soil solution, which in turn is a function of climate, drainage, original rock type, vegetation, and time. Generally, neoformed clays that have undergone intense leaching, such as soils formed under wet, tropical climates, are composed of the least soluble elements, such as ferric iron, aluminum, and silicon. These soils contain clays such as gibbsite, kaolinite, goethite, and amorphous oxides and hydroxides of aluminum and iron. Clays formed in soils that are found in dry climates or in soils that are poorly drained can contain more soluble elements, such as sodium, potassium, calcium, and magnesium, in addition to the least soluble elements. These soils contain clays such as smectite, chlorite, and illite, and generally are more fertile than those formed under intense leaching conditions. *See* CHLORITE; GOETHITE; ILLITE; KAOLINITE.

Examples of clays formed by the transformation of other clays in a soil include soil chlorite and soil vermiculite, the first formed by the precipitation of aluminum hydroxide in smectite interlayers, and the second formed by the leaching of interlayer potassium from illite. Examples of inherited clays in a soil are illite and chlorite-containing soils formed on shales composed of these minerals. *See* SHALE.

Clays also occur abundantly in sediments and sedimentary rocks. For example, clays are a major component of many marine sediments. These clays generally are inherited from adjacent continents, and are carried to the ocean by rivers and wind, although some clays (such as smectite and glauconite) are neoformed abundantly in the ocean. Hydrothermal clays can form abundantly where rock has been in contact with hot water or steam. Illite and chlorite, for example, form during the deep burial of sediments, and smectite and chlorite form by the reaction of hot, circulating waters at ocean ridges. *See* MARINE SEDIMENTS; SEDIMENTARY ROCKS.

Various clays possess special properties which make them important industrially. For example, bentonite, a smectite formed primarily from the alteration of volcanic ash, swells; is readily dispersible in water; and possesses strong absorptive powers, including a high cation exchange capacity. These properties lead to uses in drilling muds, as catalysts and ion exchangers, as fillers and absorbents in food and cosmetics, and as binders for taxonite and fertilizers. Other important uses for clays include the manufacture of brick, ceramics, molding sands, decolorizers, detergents and soaps, medicines, adhesives, liners for ponds and landfills, lightweight aggregate, desiccants, molecular sieves, pigments, greases, paints, plasticizing agents, emulsifying, suspending, and stabilizing agents, and many other products. *See* BENTONITE; CATALYSIS; CLAY, COMMERCIAL; ION EXCHANGE; REFRACTORY. [D.D.E.]

Clay, commercial Clays utilized as raw material in manufacturing, which are among the most important nonmetallic mineral resources. The value of clays is related to their mineralogical and chemical composition, particularly the clay mineral constituents kaolinite, montmorillonite, illite, chlorite, and attapulgite. The presence of minor amounts of mineral or soluble salt impurities in clays can restrict their use. The more common mineral impurities are quartz, mica, carbonates, iron oxides and sulfides, and feldspar. In addition, many clays contain some organic material. *See* CLAY MINERALS.

Kaolinitic clays. Clays containing a preponderance of the clay mineral kaolinite are known as kaolinitic clays. Several commercial clays are composed predominantly of kaolinite. These are china clays, kaolines, ball clays, fireclays, and flint clays. The terms china clay and kaolin are used interchangeably in industry. *See* KAOLINITE.

China clays are high-grade white kaolins found in the southeastern United States, England, and many other countries. Many grades of kaolin are used in the manufacture of ceramics, paper, rubber, paint, plastics, insecticides, adhesives, catalysts, and ink. By far the largest consumer of white kaolins is the paper industry, which uses them to make paper products smoother, whiter, and more printable. The kaolin is used both as a filler in the sheet to enhance opacity and receptivity to ink and as a thin coating on the surface of the sheet to make it smoother and whiter for printing. *See* CERAMICS; PORCELAIN; POTTERY.

Ball clays are composed mainly of the mineral kaolinite but usually are much darker in color than kaolin. The term ball clay is used for a fine-grained, very plastic, refractory bond clay. Most ball clays contain minor amounts of organic material and the clay mineral montmorillonite, and are finer grained than china clays. This fineness, together with the montmorillonite and organic material, gives ball clays excellent plasticity and strength. For these reasons and because they fire to a light-cream color, ball clays are commonly used in whitewares and sanitary ware.

The term fireclay is used for clays that will withstand temperatures of 2730°F (1500°C) or higher. Such clays are composed primarily of the mineral kaolinite. Fireclays are generally light to dark gray in color, contain minor amounts of mineral impurities such as illite and quartz, and fire to a cream or buff color. Most fireclays are plastic, but some are nonplastic and very hard; these are known as flint clays. Fireclays are used primarily by the refractories industry. The foundry industry uses fireclay to bind sands into shapes in which metals can be cast. *See* REFRACTORY.

Diaspore clay. This clay is composed of the minerals diaspore and kaolinite. Diaspore is a hydrated aluminum oxide with an Al_2O_3 content of 85% and a water content of 15%. Diaspore clay is used almost exclusively by the refractories industry in making refractory brick. However, after calcination, it is sometimes used as an abrasive material.

Mullite. Mullite is a high-temperature conversion product of many aluminum silicate minerals, including kaolinite, pinite, topaz, dumortierite, pyrophyllite, sericite, andalusite, kyanite, and sillimanite. Mullite is used in refractories to produce materials of high strength and great refractoriness. Mullite does not spall, withstands the shock of heating and cooling exceptionally well, and is resistant to slag erosion. It is used in making spark plugs, laboratory crucibles, kiln furniture, saggars, and other special refractories.

Bentonites. Those clays that are composed mainly of the clay mineral montmorillonite and are formed by the alteration of volcanic ash are known as bentonites. The term bentonite is a rock term, but in industrial usage it has become almost synonymous with swelling clay. Bentonites are used in many industries; the most important uses are as drilling muds and catalysts in the petroleum industry, as bonding clays in foundries, as bonding agents for taconite pellets, and as adsorbents in many industries. *See* BENTONITE; MONTMORILLONITE; OIL AND GAS WELL DRILLING.

Attapulgite clays. Attapulgite is a hydrated magnesium aluminum silicate with a needlelike shape. Each individual needle is exceedingly small, about 1 micrometer in length and approximately 0.01 micrometer across. Attapulgite is used as a suspending agent, and gives high viscosity because of the interaction of the needles. Some commercial uses are as an oil well drilling fluid, in adhesives as a viscosity control, in oil base foundry sand binders, as thickeners in latex paints, in liquid suspension fertilizers, and as a suspending agent and thickener in pharmaceuticals.

Properties. Most clays become plastic when mixed with varying proportions of water. Plasticity of a material can be defined as the ability of the material to undergo permanent deformation in any direction without rupture under a stress beyond that of elastic yielding. Clays range from those which are very plastic, called fat clay, to those which are barely plastic, called lean clay. The type of clay mineral, particle size and shape, organic matter, soluble salts, adsorbed ions, and the amount and type of nonclay minerals are all known to affect the plastic properties of a clay.

Green strength and dry strength properties are very important because most structural clay products are handled at least once and must be strong enough to maintain shape. Green strength is the strength of the clay material in the wet, plastic state. Dry strength is the strength of the clay after it has been dried.

Both drying and firing shrinkages are important properties of clay used for structural clay products. Shrinkage is the loss in volume of a clay when it dries or when it is fired. Drying shrinkage is high in most very plastic clays and tends to produce cracking and warping. It is low in sandy clays or clays of low plasticity and tends to produce a weak, porous body. Firing shrinkage depends on the volatile materials present, the types of crystalline phase changes that take place during firing, and the dehydration characteristics of the clay minerals.

The temperature range of vitrification, or glass formation, is a very important property in structural products. Vitrification is due to a process of gradual fusion in which some of the more easily melted constituents begin to produce an increasing amount of liquid which makes up the glassy bonding material in the final fired product. The degree of vitrification depends on the duration of firing as well as on the temperature attained.

Color is important in most structural clay products, particularly the maintenance of uniform color. The color of a product is influenced by the state of oxidation of iron, the state of division of the iron minerals, the firing temperature and degree of vitrification, the proportion of alumina, lime, and magnesia in the clay material, and the composition of the fire gases during the burning operation. [H.H.Mu.]

Structural uses. All types of clay and shale are used in the structural products industry but, in general, the clays that are used are considered to be relatively low grade. Clays that are used for conduit tile, glazed tile, and sewer pipe are underclays and shales that contain large proportions of kaolinite and illite. The semirefractory plastic clays found directly beneath the coal seams make the best raw material for the above mentioned uses. Brick and drain tile can be made from a wide variety of clays depending on their location and the quality of product desired. Clays used for brick and drain tile must be plastic enough to be shaped. In addition, color and vitrification range are very important. For common brick, drain tile, and terra-cotta, shales and surface clays are usually suitable, but for high-quality face bricks, shales and underclays are used. Geographic location is a prime factor in the type of clay used for structural clay products because, in general, these products cannot be shipped great distances without excessive transportation costs. Many raw materials of questionable quality are utilized in certain areas because no better raw material is available nearby. *See* BRICK; TILE.

The cement industry uses large quantities of impure clays and shales. Clays are used to provide alumina and silica to the charge for the cement kiln. Generally, a suitable clay can be found in the area in which the cement is being manufactured. *See* CEMENT; POTTERY; REFRACTORY.

Clay minerals

Fine-grained, hydrous, layer silicates that belong to the larger class of sheet silicates known as phyllosilicates. Their structure is composed of two basic units. (1) The tetrahedral sheet is composed of silicon-oxygen tetrahedra linked to neighboring tetrahedra by sharing three corners to form a hexagonal network. The fourth corner of each tetrahedron (the apical oxygen) points into and forms a part of the adjacent octahedral sheet. (2) The octahedral sheet is usually composed of aluminum or magnesium in sixfold coordination with oxygen from the tetrahedral sheet and with hydroxyl. Individual octahedra are linked laterally by sharing edges. Tetrahedral and octahedral sheets taken together form a layer, and individual layers may be joined to each other in a clay crystallite by interlayer cations, by van der Waals and electrostatic forces, or by hydrogen bonding.

Clay minerals are classified by their arrangement of tetrahedral and octahedral sheets. Thus, 1:1 clay minerals contain one tetrahedral and one octahedral sheet per clay layer; 2:1 clay minerals contain two tetrahedral sheets with an octahedral sheet between them; and 2:1:1 clay minerals contain an octahedral sheet that is adjacent to a 2:1 layer.

Ionic substitutions may occur in any of these sheets, thereby giving rise to a complex chemistry for many clay minerals. For example, cations small enough to enter into tetrahedral coordination with oxygen, cations such as Fe^{3+} and Al^{3+}, can substitute for Si^{4+} in the tetrahedral sheet. Cations such as Mg^{2+}, Fe^{2+}, Fe^{3+}, Li^{+}, Ni^{2+}, Cu^{2+}, and other medium-sized cations can substitute for Al^{3+} in the octahedral sheet. Still larger cations such as K^{+}, Na^{+}, and Cs^{+} can be located between layers and are called interlayer cations. F^{-} may substitute for $(OH)^{-}$ in some clay minerals. *See* COORDINATION CHEMISTRY.

Clay minerals and related phyllosilicates are classified further according to whether the octahedral sheet is dioctahedral or trioctahedral. In dioctahedral clays, two out of three cation positions in the octahedral sheet are filled, every third position being vacant. This type of octahedral sheet is sometimes known as the gibbsite sheet, with the ideal composition $Al_2(OH)_6$. In trioctahedral clay minerals, all three octahedral positions are occupied, and this sheet is called a brucite sheet, composed ideally of $Mg_3(OH)_6$.

Clay minerals can be classified further according to their polytype, that is, by the way in which adjacent 1:1, 2:1, or 2:1:1 layers are stacked on top of each other in a clay crystallite. For example, kaolinite shows at least four polytypes: *b*-axis ordered kaolinite, *b*-axis disordered kaolinite, nacrite, and dickite. Serpentine shows many polytypes, the best-known of which is chrysotile, a mineral that is used to manufacture asbestos products. *See* KAOLINITE; SERPENTINE.

Finally, clays are named on the basis of chemical composition. For example, two types of swelling clay minerals are the 2:1, dioctahedral smectites termed beidellite and montmorillonite. The important difference between them is in the location of ionic substitutions. In beidellite, charge-building substitutions are located in the tetrahedral sheet; in montmorillonite, the majority of these substitutions are located in the octahedral sheet.

Because clay minerals are composed of only two types of structural units (octahedral and tetrahedral sheets), different types of clay minerals can articulate with each other, thereby giving rise to mixed-layer clays. The most common type of mixed-layer clay is mixed-layer illite/smectite, which is composed of an interstratification of various proportions of illite and smectite layers. The interstratification may be random or ordered. The ordered mixed-layer clays may be given separate names. For example, a dioctahedral mixed-layer clay containing equal proportions of illite and smectite layers that are regularly interstratified is termed potassium rectorite. A regularly interstratified trioctahedral mixed-layer clay mineral containing approximately equal proportions of chlorite and smectite layers is termed corrensite.

A primary requirement for the formation of clay minerals is the presence of water. Clay minerals form in many different environments, including the weathering environment, the sedimentary environment, and the diagenetic-hydrothermal environment. Clay minerals composed of the more soluble elements (for example, smectite and sepiolite) are formed in environments in which these ions can accumulate (for example, in a dry climate, in a poorly drained soil, in the ocean, or in saline lakes), whereas clay minerals composed of less soluble elements (for example, kaolinite and halloysite) form in more dilute water such as that found in environments that undergo severe leaching (for example, a hilltop in the wet tropics), where only sparingly soluble elements such as aluminum and silicon can remain. Illite and chlorite are known to form abundantly in the diagenetic-hydrothermal environment by reaction from smectite. *See* CHLORITE; CLAY; CLAY, COMMERCIAL; HALLOYSITE; ILLITE; LITHOSPHERE; SEPIOLITE; SILICATE MINERALS. [D.D.E.]

Clear-air turbulence

Turbulence above the boundary layer but not associated with cumulus convection. The atmosphere is a fluid in turbulent motion. That turbulence of a scale sensed by humans in aircraft is primarily associated with the boundary layer within a kilometer or so of the Earth, where it is induced by the surface roughness, or in regions of deep convection such as cumulus cloud development or thunderstorms. However, aircraft occasionally encounter turbulence when flying at altitudes well above the surface and far from convective clouds. This phenomenon has been given the rather unsatisfactory name of clear-air turbulence (CAT).

What is primarily sensed in CAT by the human is vertical acceleration. This acceleration will depend on the person's location in the plane, the speed of flight relative to the air, and the response characteristics of the airframe. A plane with a wing that generates aerodynamic lift more efficiently or an air-frame with less weight per unit wing area will respond more strongly to a given gust magnitude.

CAT is encountered in the atmosphere with a probability depending on flight altitude, geographical location, season of the year, and meteorological conditions. Given this variability and the small scale of the phenomenon, it is difficult to establish reliable statistics on the frequency of its occurrence. Although CAT may be encountered in unexpected meteorological contexts, there are highly favored locations for its occurrence. One is in the vicinity of the jet stream, particularly in ridges and troughs where the wind direction is turning sharply. A second and even more common location of occurrence is in the lee of a mountain range when a strong air flow is distorted by being forced over the range. In this situation a gravity lee wave is generated, which propagates to stratospheric heights. At various altitudes and distances from the mountain, this wave may break, and as many as a dozen or more CAT patches, light to severe, may be formed. Despite knowledge of these favored meteorological areas, it is not possible to forecast with confidence the precise location of a CAT patch. Warning forecasts for substantial portions of routes are typically given to pilots when CAT conditions prevail. *See* JET STREAM.

Aside from the practical implications of CAT for air transport, this phenomenon plays a role of undetermined magnitude in the dissipation of the kinetic energy of the atmosphere. *See* UPPER ATMOSPHERE DYNAMICS. [M.G.W.; L.J.E.]

Cleavage (embryology) The subdivision of eggs into cells called blastomeres. It occurs in eggs activated by fertilization or parthenogenetic agents. Cleavages follow one another so rapidly that there is little opportunity for daughter cells to grow before they divide again. Consequently the size of blastomeres diminishes progressively, although many times unequally, during cleavage. By contrast, the nucleus of each daughter cell enlarges following each cleavage with the result that the ratio of the volume of the nucleus to the volume of cytoplasm (the nucleoplasmic ratio) progressively increases. The cleavage period is said by some authorities to terminate when the nucleoplasmic ratios of various blastomeres attain values characteristic of adult tissues. Cells continue to divide thereafter, but each daughter cell then undergoes a period of growth prior to its division with the result that the nucleoplasmic ratio tends to remain approximately constant for each cell type following termination of cleavage. According to others, cleavage terminates with formation of the definitive blastula. Cleavage appears to be an essential step in development. Although some differentiation occurs in eggs of certain animals when cleavage is blocked experimentally, it is limited and infrequent. *See* BLASTULATION.

Cleavage does more than merely subdivide the substance of the egg quantitatively into smaller units, the blastomeres, which are then of such a size that they can readily undergo the subsequent events of blastulation, gastrulation, and interaction that are involved in formation of tissues and organs. Sooner or later, cleavage segregates different cytoplasmic areas into different blastomeres, thus subdividing the substance of the egg qualitatively. These qualitative cytoplasmic differences among blastomeres are then sufficient to account for the initial establishment of different lines of differentiation in the progeny of different blastomeres, even though the genetic content of all blastomeres is identical. *See* CELL LINEAGE. [R.L.W.]

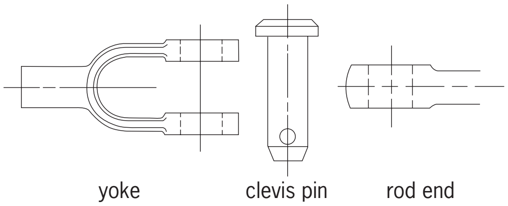
Cleft lip and cleft palate Two of the most common congenital anomalies in humans, resulting from incomplete closure of the lip and palate during early embryonic life. During the first trimester of pregnancy, the face and mouth are formed by the fusion of several different parts. The lip is fully fused 6 or 7 weeks after fertilization. The palate, which forms the roof of the mouth and separates the oral cavity from the nasal cavity, is fully fused 10 weeks after fertilization. If fusion fails to occur or breaks down, an opening, or cleft, occurs in the lip, the palate, or both. Although cleft lip and cleft palate are associated with separate embryologic events, that is, are separated by a long time on the embryonic time scale, both often occur in an affected individual.

Clefts of the lip may occur on one side (unilateral), or both sides (bilateral). When they occur in the exact midline of the lip, they are often associated with severe anomalies of the brain. The cleft usually extends through the lip and nostril floor. The underlying dental arch is also typically involved.

Clefts are the only major abnormality in approximately half of newborns who have them. In the other half, they occur as a part of a pattern of multiple anomalies (a syndrome). It has been determined that most clefts are associated with genetic factors. *See* HUMAN GENETICS.

Because of the combination of esthetic, structural, and functional requirements for total repair of clefts, that is, surgical, dental, ear, hearing, and speech, the care of children with clefts has usually been managed by comprehensive teams of specialists, including plastic surgeons, speech pathologists, audiologists, geneticists, otolaryngologists, oral surgeons, orthodontists, and pediatricians. *See* CONGENITAL ANOMALIES. [R.Sh.]

Clevis pin A fastener with a head at one end and a hole at the other used to join a clevis to a rod. A clevis is a yoke with a hole formed or attached at one end of a rod (see illustration).



Clevis pin which joins yoke to rod end.

When an eye or hole of a second rod is aligned with the hole in the yoke, a clevis pin can be inserted to join the two. A cotter pin can then be inserted in the hole of the clevis pin to hold it in, yet the fastening is readily detachable. This joint is used for rods in tension where some flexibility is required. [P.H.B.]

Client-server system A computing system that is composed of two logical parts: a server, which provides services, and a client, which requests them. The two parts can run on separate machines on a network, allowing users to access powerful server resources from their personal computers. *See* LOCAL-AREA NETWORKS; WIDE-AREA NETWORKS.

Client-server systems are not limited to traditional computers. An example is an automated teller machine (ATM) network. Customers typically use ATMs as clients to interface to a server that manages all of the accounts for a bank. This server may in turn work with servers of other banks (such as when withdrawing money at a bank at which the user does not have an account). The ATMs provide a user interface and the servers provide services, such as checking on account balances and transferring money between accounts.

To provide access to servers not running on the same machine as the client, middleware is usually used. Middleware serves as the networking between the components of a client-server system; it must be run on both the client and the server. It provides everything required to get a request from a client to a server and to get the server's response back to the client. Middleware often facilitates communication between different types of computer systems. This communication provides cross-platform client-server computing and allows many types of clients to access the same data.

The server portion almost always holds the data, and the client is nearly always responsible for the user interface. The application logic, which determines how the data should be acted on, can be distributed between the client and the server. The part of a system with a disproportionately large amount of application logic is termed "fat"; a "thin" portion of a system is a part with less responsibility delegated to it. Fat server systems, such as groupware systems and web servers, delegate more responsibility for the application logic to the server, whereas fat client systems, such as most database systems, place more responsibility on the client. *See* HUMAN-COMPUTER INTERACTION.

The canonical client-server model assumes two participants in the system. This is called a two-tiered system; the application logic must be in the client or the server, or shared between the two. It is also possible to have the application logic reside in a third layer separate from the user interface and the data, turning the system into a three-tier system. Complete separation is rare in actual systems; usually the bulk of the application logic is in the middle tier, but select portions of it are the responsibility of the client or the server.

The three-tier model is more flexible than the two-tier model because the separation of the application logic from the client and the server gives application logic processes a new level of autonomy. The processes become more robust since they can operate independently of the clients and servers. Furthermore, decoupling the application logic from the data allows data from multiple sources to be used in a single transaction without a breakdown in the client-server model. This advancement in client-server architecture is largely responsible for the notion of distributed data. *See* DISTRIBUTED SYSTEMS (COMPUTERS).

Standard web applications are the most common examples of three-tier systems. The first tier is the user interface, provided via interpretation of Hyper Text Markup Language (HTML) by a web browser. The embedded components being displayed by the browser reside in the middle tier, and provide the application logic pertinent to the system. The final tier is the data from a web server. Quite often this is a database-style system, but it could be a data-warehousing or groupware system. *See* WORLD WIDE WEB. [S.M.L.]

Climate history The long-term records of precipitation, temperature, wind, and all other aspects of the Earth's climate. The climate, like the Earth itself, has a history extending over several billion years. Climatic changes have occurred at time scales ranging from hundreds of millions of years to centuries and decades. Processes in the atmosphere, oceans, cryosphere (snow cover, sea ice, continental ice sheets), biosphere, and lithosphere (such as plate tectonics and volcanic activity) and certain extraterrestrial factors (such as the Sun) have caused these changes of climate.

The present climate can be described as an ice age climate, since large land surfaces are covered with ice sheets (for example, Antartica and Greenland). The origins of the present ice age may be traced, at least in part, to the movement of the continental plates. With the gradual movement of Antarctica toward its present isolated polar position, ice sheets began to develop there about 30 million years ago. For the past several million years, the Antarctic ice sheet reached approximately its present size, and ice sheets appeared on the lands bordering the northern Atlantic Ocean. During the past million years of the current ice age, about 10 glacial-interglacial cycles have been documented. Changes in the Earth's orbital parameters, eccentricity, obliquity, and longitude of perihelion are thought to have initiated, or paced, these cycles through the associated small changes in the seasonal and latitudinal distribution of solar radiation. The most recent glacial period ended between about 15,000 and 6000 years ago with the rapid melting of the North American and European ice sheets and an associated rise in sea level, and the atmospheric concentration of carbon dioxide.

The climates of the distant geologic past were strongly influenced by the size and location of continents and by large changes in the composition of the atmosphere. For example, around 250 million years ago the continents were assembled into one supercontinent, Pangaea, producing significantly different climatic patterns than are seen today with widely distributed continents. In addition, based upon models of stellar evolution, it is hypothesized that the Sun's radiation has gradually increased by 10–20% over the past several billion years and, if so, this has contributed to a significant warming of the Earth. *See* CONTINENTS, EVOLUTION OF; GLACIAL EPOCH; PALEOCLIMATOLOGY.

Instrumental records of climatic variables such as temperature and precipitation exist for the past 100 years in many locations and for as long as 200 years in a few locations. These records provide evidence of year-to-year and decade-to-decade variability, but they are completely inadequate for the study of century-to-century and longer-term variability. Even for the study of short-term climatic fluctuations, instrumental records are incomplete, because most observations are made from the continents (covering only 29% of the Earth's surface area). Aerological observations, which permit the study of atmospheric mass, momentum and energy budgets, and the statistical structure of the large-scale circulation, are available only since about the mid-1960s. Again there is a bias toward observations over the continents. It is only with the advent of satellites that global monitoring of the components of the Earth's radiation budget (clouds; planetary albedo, from which the net incoming solar radiation can be estimated; and the outgoing terrestrial radiation) became possible. *See* METEOROLOGICAL SATELLITES.

Evidence of climatic changes prior to instrumental records comes from a wide variety of sources. Tree rings, banded corals, and pollen and trace minerals retrieved from laminated lake sediments and ice sheets yield environmental records for past centuries and millennia. Advanced drilling techniques have made it possible to obtain long cores from ocean sediments that provide geologic records of climatic conditions going back hundreds of millions of years. *See* DENDROCHRONOLOGY; PALYNOLOGY.

Many extraterrestrial and terrestrial processes have been hypothesized to be possible causes of climatic fluctuations. These include solar irradiance, variations in orbital parameters, motions of the lithosphere, volcanic activity, internal variations of the climate system, and human activities. It is likely that all of the natural processes have played a role in past climatic changes. Also, the climatic response to some particular causal process may depend on the initial climatic state, which in turn depends upon previous climatic states because of the long time constants of lithosphere, oceans, and cryosphere. True equilibrium climates may not exist, and the climate system may be in a continual state of adjustment.

Because of the complexity of the real climate system, simplified numerical models of climate are being used to study particular processes and interactions. Some models treat only the global-average conditions, whereas others, particularly the dynamical atmosphere and ocean models, simulate detailed patterns of climate. These models will undoubtedly be of great importance in attempts to understand climatic processes and to assess the possible effects of human activities on climate. *See* CLIMATE MODELING; CLIMATIC PREDICTION; CLIMATOLOGY. [J.E.K.]

Climate modeling Construction of a mathematical model of the climate system of the Earth capable of simulating its behavior under present and altered conditions. The Earth's climate is continually changing over time scales ranging from millions of years to a few years. Since the climate is determined by the laws of classical physics, it should be possible in principle to construct such a model. The advent of a worldwide weather observing system capable of gathering data for validation and the development and widespread routine use of digital computers have made this undertaking possible.

The Earth's average temperature is determined mainly by the balance of radiant energy absorbed from sunlight and the radiant energy emitted by the Earth system. About 30% of the incoming radiation is reflected directly to space, and 72% of the remainder is absorbed at the surface. The radiation is absorbed unevenly over the Earth, which sets up thermal contrasts that in turn induce convective circulations in the atmosphere and oceans. Climate models attempt to calculate from mathematical algorithms the effects of these contrasts and the resulting motions in order to understand better and perhaps predict future climates in some probabilistic sense. *See* SOLAR RADIATION; TERRESTRIAL RADIATION.

Climate models differ in complexity, depending upon the application. The simplest models are intended for describing only the surface thermal field at a fairly coarse resolution. These mainly thermodynamical formulations are successful at describing the seasonal cycle of the present climate, and have been used in some simulations of past climates, for example, for different continental arrangements millions of years ago. At the other end of the spectrum are the most complex climate models, which are extensions of the models in weather forecasts. These models aim at simulating seasonal and even monthly averages just shortly into the future, based upon conditions such as the temperatures of the tropical-sea surfaces. Intermediate to these extremes are models that attempt to model climate on a decadal basis, and these are used mainly in studies of the impact of hypothesized anthropogenically induced climate change. *See* WEATHER FORECASTING AND PREDICTION.

Attempts at modeling climate have demonstrated the extreme complexity and subtlety of the problem. This is due largely to the many feedbacks in the system. One of the simplest and yet most important feedbacks is that due to water vapor. If the Earth is perturbed by an increase in the solar radiation, for example, the first-order response of the system is to increase its temperature. But an increase in air temperature leads to more water vapor evaporating into the air; this in turn leads to increased absorption of space-bound long-wave radiation from the ground (greenhouse effect), which leads to an increased equilibrium temperature. Water vapor feedback is not the only amplifier in the system. Another important one is snowcover: a cooler planet leads to more snow and hence more solar radiation reflected to space, since snow is more reflecting of sunlight than soil or vegetation. Other, more subtle mechanisms that are not yet well understood include those involving clouds, oceans, and the biosphere.

While water vapor and snowcover feedback are fairly straightforward to model, the less understood feedbacks differ in their implementations from one climate model to another. These differences as well as the details of their different numerical formulations have led to slight differences in the sensitivity of the various models to such standard experimental perturbations as doubling carbon dioxide in the atmosphere. All models agree that the planetary average temperature should increase if carbon dioxide concentrations are doubled. However, the predicted response in planetary temperatures ranges from 4.5 to 9°F (2.5 to 5.0°C). Regional predictions of temperature or precipitation are not reliable enough for detailed response policy formulation. Many of the discrepancies are expected to decrease as model resolution increases (more grid points), since it is easier to include such complicated phenomena as clouds in finer-scale formulations and coupling with dynamic models of the ocean. Similarly, it is anticipated that some observational data (such as rainfall over the oceans) that are needed for validation of the models will soon be available from satellite sensors. *See* METEOROLOGICAL SATELLITES. [R.E.D.; E.S.S.]

Climate modification Alteration of the Earth's climate by human activities. This can occur on various scales. For example, conventional agriculture alters the microclimate in the lowest few meters of air, causing changes in the evapotranspiration and local heating characteristics of the air-surface interface. These changes lead to different degrees of air turbulence over the plants and to different moisture and temperature distributions in the local air. An example at a larger scale is that the innermost parts of cities are several degrees warmer than the surrounding countryside, and have slightly more rainfall. These changes are brought about by the differing surface features of urban land versus natural countryside and the ways that cities dispose of water (for example, storm sewers). The urban environment prevents evaporation cooling of surfaces in the city. The modified surface texture of cities (horizontal and vertical planes of buildings and streets versus gently rolling surfaces over natural forest or grassland) leads to a more efficient trapping of solar heating of the near-surface air. The scales of buildings and other structures also lead to a different pattern of atmospheric boundary-layer turbulence, modifying the stirring efficiency of the atmosphere. *See* MICROMETEOROLOGY; URBAN CLIMATOLOGY.

At the next larger scale, human alteration of regional climates is caused by changes in the Earth's average reflectivity to sunlight. For example, the activities of building roads and highways and deforestation alter the amount of sunshine that is reflected to space as opposed to being absorbed by the surface and thereby heating the air through contact. Such contact heating leads to temperature increases and evaporation of liquid water at the surface. Vapor wakes from jet airplanes are known to block direct solar radiation near busy airports by up to 20%. Human activities also inject dust, smoke, and other aerosols into the air, causing sunlight to be scattered back to space. Dust particles screen out sunlight before it can enter the lower atmosphere and warm the near-surface air. *See* AIR POLLUTION; SMOG. [G.R.N.]

One of the most important and best understood features of the atmosphere is the process that keeps the Earth's surface much warmer than it would be with no atmosphere. This process involves several gases in the air that trap infrared radiation, or heat, emitted by the surface and reradiate it in all directions, including back to the surface. The heat-trapping gases include water vapor, carbon dioxide (CO_2), methane (CH_4), and nitrous oxide (N_2O). These gases constitute only a small fraction of the atmosphere, but their heat-trapping properties raise the surface temperature of the Earth by a large amount, estimated to be more than 55°F (30°C). Human activities, however, are increasing the concentrations of CO_2, CH_4, and N_2O in the atmosphere, and in addition industrially synthesized chemicals—chlorofluorocarbons (CFCs) and related compounds—are being released to the air, where they add to the trapping of infrared radiation. Carbon dioxide is released to the air mainly from fossil fuel use, which also contributes to the emissions of CH_4 and N_2O. Agricultural and industrial processes add to the emissions of these gases. These concentration increases add to the already powerful heat-trapping capability of the atmosphere, raising the possibility that the surface will warm above its past temperatures, which have remained roughly constant, within about 3°F (1.7°C) for the past 10,000 years. Treaties are in existence that control internationally the production and use of many of the CFCs and related compounds, so their rate of growth has slowed, and for some a small decrease in atmospheric concentration has been observed. Large emissions of sulfur dioxide in industrial regions are thought to result in airborne sulfate particles that reflect sunlight and decrease the amount of heating in the Northern Hemisphere. *See* ATMOSPHERE; GREENHOUSE EFFECT. [J.Fi.]

Climatology The scientific study of climate. Climate is the expected mean and variability of the weather conditions for a particular location, season, and time of day. The climate is often described in terms of the mean values of meteorological variables such as temperature, precipitation, wind, humidity, and cloud cover. A complete description also includes the variability of these quantities, and their extreme values. The climate of a region often has regular seasonal and diurnal variations, with the climate for January being very different from that for July at most locations. Climate also exhibits significant year-to-year variability and longer-term changes on both a regional and global basis.

The goals of climatology are to provide a comprehensive description of the Earth's climate over the range of geographic scales, to understand its features in terms of fundamental physical principles, and to develop models of the Earth's climate for sensitivity studies and for the prediction of future changes that may result from natural and human causes. *See* CLIMATE HISTORY; CLIMATE MODELING; CLIMATE MODIFICATION; CLIMATIC PREDICTION; WEATHER. [D.L.Ha.]

Clinical immunology A branch of clinical pathology concerned with the role of the immune defense system in disease. The subject encompasses diseases where a malfunction of the immune system itself is the basic cause, together with diseases where some external agent is the initiating factor but an excessive response by the immune system produces the actual tissue damage. It also extends to the monitoring of the normal immune response in infectious diseases and to the use of immunological techniques in disease diagnosis. *See* ALLERGY; AUTOIMMUNITY; CLINICAL PATHOLOGY; HYPERSENSITIVITY; IMMUNOLOGICAL DEFICIENCY.

Many features of the immune system make it prone to shift from protecting the body to damaging it. This complex system not only must distinguish between the body's own cells and a foreign invader but must also recognize and eliminate the body's own cells if they are damaged or infected with a virus. The recognition receptors used to make this fine distinction between "self" and "not self" are not encoded in the genes. Rather, they are assembled following random rearrangement of information carried in small gene segments. During their development, immune system cells are subjected to a selective process, those bearing potentially useful receptors being preserved while those bearing dangerous, self-reactive receptors are eliminated. This process is closely balanced, and some potentially self-reactive cells often persist. *See* CELLULAR IMMUNOLOGY.

There are several approaches to suppressing excessive immune reactivity. Desensitization, or modifying the nature of the response by injecting small amounts of the foreign antigen, is sometimes used to treat allergic states. In contrast, there are few therapies for enhancing immune responses. Bone marrow transplantation is used to restore the immune system in some immunodeficiency diseases. Passive transfer of preformed antibody protects against some infections, and transfusion of immunoglobulin is used to treat immunoglobulin deficiencies. However, vaccination or immunization is one of the most effective of all medical procedures. *See* IMMUNOSUPPRESSION. [K.Sh.]

Clinical microbiology The adaptation of microbiological techniques to the study of the etiological agents of infectious disease. Clinical microbiologists determine the nature of infectious disease and test the ability of various antibiotics to inhibit or kill the isolated microorganisms. In addition to bacteriology, a contemporary clinical microbiologist is responsible for a wide range of microscopic and cultural studies in mycology, parasitology, and virology. The clinical microbiologist is often the most competent person available to determine the nature and extent of hospital-acquired infections, as well as public-health problems that affect both the hospital and the community. *See* ANIMAL VIRUS; HOSPITAL INFECTIONS; MEDICAL BACTERIOLOGY; MEDICAL MYCOLOGY; MEDICAL PARASITOLOGY; VIRUS.

Bacteriology. Historically, the diagnosis of bacterial disease has been the primary job of clinical microbiology laboratories. Many of the common ailments of humans are bacterial in nature, such as streptococcal sore throat, diphtheria, and pneumococcal pneumonia. The bacteriology laboratory accepts specimens of body fluids, such as sputum, urine, blood, and respiratory or genital secretions, and inoculates the specimens onto various solid and liquid growth media. Following incubation at body temperature, the microbiologist examines these agar plates and tubes and makes a determination as to the relative numbers of organisms growing from the specimen and their importance in the disease process. The microbiologist then identifies these alleged causes of disease and determines their pattern of antibiotic susceptibility to a few chosen agents.

Clinical microbiologists also microscopically examine these body fluids. They report on the presence of bacteria in body fluids and the cellular response to infection, such as the numbers or types of white blood cells observed in the specimen. [R.C.T.]

Nonculture methods. While direct microscopy and culture continue to be methodological mainstays in diagnostic microbiology laboratories, nonculture methods are growing in the variety of applications and the sophistication of the technology. For example, polyclonal antibodies raised in animals such as mice, sheep, goats, and rabbits, and monoclonal antibodies produced by hybridization technology are used to detect bacteria, fungi, parasites, or virus-infected cells by using direct or indirect fluorescent techniques. Additional methods include latex agglutination tests to detect particulate antigens and enzyme immunoassays to detect soluble antigens. *See* IMMUNOASSAY; MONOCLONAL ANTIBODIES.

Probes for deoxyribonucleic acid (DNA) or messenger ribonucleic acid (mRNA) are available for various applications. Probes are used for direct detection of organisms in clinical material and for culture confirmation.

Further increases in analytical sensitivity have been achieved by nucleic acid amplification techniques. In polymerase chain reaction (PCR), double-stranded DNA is denatured; oligonucleotide probes bind to homologous strands of single-stranded DNA, and the enzyme polymerase extends the probes using deoxyribonucleotides in the milieu. In ligase chain reaction (LCR), the enzyme ligase fills the 3-nucleotide gap between two probes that attach to homologous, target, single-stranded DNA. In nucleic acid sequence–based amplification (NASBA), reverse transcriptase is used to make double-stranded complementary DNA (cDNA) and the target RNA is digested by ribonuclease H.

Analysis of lipopolysaccharides and proteins by sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE) and cellular fatty acid analysis by gas-liquid chromatography have given way to nucleic acid–based methods. Restriction enzymes, which cut DNA at a constant position within a specific recognition site usually composed of four to six base pairs, are used to cut chromosomal DNA; the resulting fragments are compared by pulse field gel electrophoresis (PFGE) or ribotyping. Electrophoresis of isolated plasmid DNA is another method for comparing organisms. DNA sequencing can also compare segments of the DNA of organisms from the same genus and species.

DNA chip or microarray technology is expected to have a greater effect on medicine than either DNA sequencing or PCR. Over 30,000 small cDNA clones of expressed fragments of individual genes are spotted onto a thumbnail-sized glass chip. Fluorescein-labeled genomic or cDNA from the sample being evaluated is passed over the chip to allow hybridization. A laser measures the fluorescent emissions and a computer analyzes the data. [C.A.Sp.]

Clinical pathology The branch of general pathology directed to the diagnosis and monitoring of diseases through the examination of blood, body fluids, secretions, and tissue biopsy specimens for chemical, morphological, microbiological, and immunological abnormalities. A variety of test procedures and microscopic examinations are performed in clinical pathology laboratories, located within hospitals, clinics, and stand-alone facilities, either privately owned or operated under the auspices of local, state, and federal public health agencies. Clinical laboratories function to confirm a clinical impression, establish or rule out a diagnosis, monitor therapy, and help establish a prognosis. Under guidelines established by the Clinical Laboratory Improvement Act of 1988, laboratory services are divided into several levels of activities. Many of the less complicated waived tests may be performed in physicians' office laboratories; more complex tests can be performed only within hospital laboratories or in laboratories where sophisticated state-of-the-art equipment is available.

The clinical pathology laboratory is commonly divided into four major subdisciplines or sections: chemical pathology, hematology, immunohematology (blood bank), and microbiology. Each includes several subsections of activity.

Chemical pathology. The chemical constituents of serum, urine, and other body fluids are analyzed in the chemical pathology section of the laboratory. Chemical tests are then clustered into functional groups to help diagnose diseases of the heart, kidney, liver, gastrointestinal tract, and other organ systems. Simple and high-volume tests are usually performed in the routine chemistry laboratory; more complicated, labor-intensive tests are carried out in a special chemistry section.

In the toxicology subsection of the chemical pathology laboratory, the blood, urine, and other body fluids are analyzed for the presence of drugs and substances of abuse. An equally important application of toxicology testing is to measure the blood levels of therapeutic drugs to assure that concentrations are adequate to treat the disease but not so high as to cause toxic side effects.

Radioimmunoassay allows trace quantities of substances to be measured. This procedure involves adding radioactive chemical markers to properly prepared specimens and detecting their binding to the substances being measured.

Because the use of radioactive substances requires licensure of personnel presents problems in disposal of biohazard waste, and requires expensive analytic instruments, most laboratories have substituted one or more enzyme-linked immunoassay (ELISA) techniques, in which specific enzymes instead of radioisotopes are linked to protein markers.

Electrophoresis is used to separate and identify proteins and lipoproteins.

Urinalysis is still carried out by manual procedures in many laboratories, relying on reagent-impregnated filter paper strips for the detection of protein, glucose, ketones, hemoglobin, bilirubin, and other substances, and microscopic observations for casts, crystals, red and white blood cells, and bacteria. However, automated instruments are used in higher-volume laboratories. Specific gravity is measured by a mass gravity meter, and urine chemistries by standard reflectance spectrophotometry; microscopic analysis is facilitated with an automated intelligent microscopy system. *See* ELECTROPORESIS; IMMUNOASSAY; RADIOIMMUNOASSAY; SEROLOGY; TOXICOLOGY; URINALYSIS.

Hematology. The cornerstone of clinical laboratory work in hematology is the assessment of the cellular elements (red blood cells, white blood cells, and platelets) in blood samples. The blood cells may be enumerated, either by manual cell-counting techniques or by automated particle-sensing and -sizing instruments. Microscopic observation of stained peripheral blood smears is limited to assessing the morphology of atypical cells as they may appear in cases of dysplastic syndromes and overt leukemias. In complicated cases where the diagnosis of a hematologic disorder cannot be made by study of the peripheral blood smear, a bone marrow examination may be necessary. Special procedures are available by which specific markers on the surfaces of blood cells can be detected by using specific reactants, thereby providing a means for classifying leukemias and other hematologic disorders.

Flow cytometry is an extension of the particle-sensing principles used in the automated blood counting instruments. In the flow cytometer, cells are dispersed in fluid suspension and channeled through a narrow-bore tube; as each cell passes by a narrow laser light beam, an optical signal is translated into electronic pulses that are measured and analyzed in the computer processor. Signals may be scattered light that relates to the mass of each cell, or to the magnitude and type of fluorescence produced, which reflects the internal structures of cells depending upon the dyes used to stain the cells. Coagulation is an important subdiscipline of hematology involving the study of clotting and bleeding disorders. People especially prone to developing blood clots often receive anticoagulant drugs in order to “thin” the blood. The amount of anticoagulant given must be regulated, based on the results of a clotting test known as the prothrombin time. A test known as the partial thromboplastin time is also frequently performed in clinical laboratories to assist in the assessment of patients who have one of various bleeding disorders. The evaluation of platelets in the peripheral blood is also an important step in evaluating patients with coagulopathies. *See* BLOOD.

Immunohematology (blood bank). The primary function of the blood bank is to ensure that blood taken from a donor will be safe to give to a recipient (that is, will not produce a transfusion reaction or transmit an infectious disease). Blood from a recipient must be subjected to compatibility testing against the blood of each donor to ensure that no atypical reaction occurs. Donor-recipient blood compatibility must be established for both the ABO blood group system and the Rh system. The recipient’s plasma must also be subjected to an antibody screen to detect any atypical antibodies. If an atypical antibody is found, donor units must be carefully screened to select for transfusion only those with red cells lacking the antigens corresponding to the recipient’s atypical antibody. Transfusion therapy has become a highly advanced discipline. It requires the separation of whole blood into a variety of components—packed red blood cells, platelet concentrates, fresh-frozen plasma, and cryoprecipitate.

Donor recruitment programs to maintain an adequate supply of blood are provided by many blood banks. Other services include outpatient therapeutic transfusions; phlebotomy of individuals who have too many red blood cells; and plasmapheresis, a procedure where plasma or platelets can be separated from the withdrawn blood and the formed elements (red cells and platelets) can be immediately retransfused, eliminating the chance for inducing anemia or deficiencies of other blood components. *See* BLOOD GROUPS.

Microbiology. The primary task of the clinical microbiologist is to identify as quickly as possible any microorganism in a specimen that represents the possible causative agent of an infectious disease. Presumptive identification of microbes can be made by microscopically examining direct mounts of an appropriate portion of the specimen or thin smears that have been stained with one of a variety of dyes. Rapid presumptive diagnoses can also be made by directly testing specimens with a variety of immunological reagents.

The practice of general bacteriology still follows traditional culture methods that were introduced by Robert Koch before the turn of the century. Specimens are applied to the surface of a variety of agar culture media for the purpose of recovering in pure culture any bacterial species that may be clinically significant. Gram stains may determine the cellular morphology and staining characteristics of the bacteria, and a variety of rapid, direct tests can be performed to provide an early identification.

Bacterial identifications and antibiotic susceptibility tests may be performed in a variety of packaged systems. These systems typically use lyophilized, dried chemical substrates or antibiotics at various concentrations that are contained within microwells that are stamped into plastic polystyrene cards or trays. These cards or trays are placed in a 95°F (35°C) incubator after the microwells have been inoculated with a suspension of a pure culture of the bacterium to be identified.

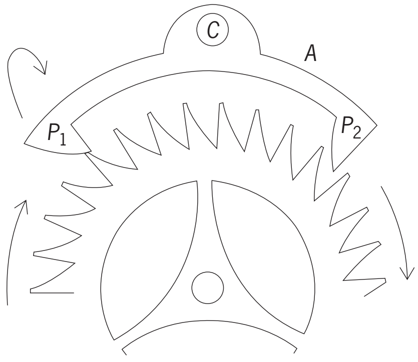
The availability of monoclonal antibodies and nucleic acid probes, in which a highly specific portion of antigen or a small segment of nucleic acid can be tagged with either a fluorescent or an enzyme-linked detector, revolutionized the ability to detect specific microbes in biologic specimens and rapidly confirm the results of a culture.

The laboratory identification of fungi and the diagnosis of fungal infections is similar to that described for the bacteria. Specimens are inoculated on special fungal media, the plates are incubated for periods as long as 4 weeks, and the growth of any mold or yeast is identified morphologically and biochemically. Nucleic acid probes are available to quickly confirm any fungus colony suspected of being one of the dangerous pathogens. The laboratory identification of parasites involves detecting microscopically the typical forms in body fluids and secretions. Viruses can live only in viable cells and, for the most part, can survive briefly outside human or animal hosts. Therefore, culture techniques must use embryonated eggs, cell culture suspensions, thin cell sheets called monolayers, or laboratory animals. Species of viruses are identified by observing their ability to produce certain cytopathic effects in the cells where they are growing or to cause recognizable diseases in laboratory animals.

Clinical immunology is that discipline in which infectious diseases are diagnosed by detecting antibodies in serum and other body fluids. In practice, immunologic and serologic techniques are used to diagnose an infectious disease when the agent may be too difficult to recover in culture. *See* CLINICAL MICROBIOLOGY; CULTURE; MONOCLONAL ANTIBODIES. [E.W.Ko.]

Clock A device for indicating the passage of time. Most clocks contain a means for producing a regularly recurring action. This article describes only mechanical clocks. *See* ATOMIC CLOCK; QUARTZ CLOCK; WATCH.

The recurring action of a mechanical clock depends on the swing of a pendulum, or the oscillation of a balance wheel and balance spring or hairspring, or the vibration of a tuning fork, mechanisms capable of repeating their cyclic movements with great regularity. A counting mechanism, consisting of a gear train with calibrated dial and indicating hands, sometimes with a striking mechanism, marks the number of oscillations that have occurred, although the graduations are in seconds, minutes, and hours. A weight or spring ordinarily supplies power to operate the oscillating and the counting mechanisms. However, temperature changes, accelerations, automatic windings, or electricity may provide the power.



Anchor escapement, common in domestic pendulum clocks. This escapement tends to compensate for changes in amplitude of the swing because of irregularly cut gears and varying lubrication.

Usually an escapement transmits power from the counting mechanism to the oscillating mechanism. The accuracy of a clock depends primarily on the escapement. The illustration depicts an anchor or recoil escapement. Anchor A is connected loosely to the pendulum and swings about C. At some time after midswing, a tooth of the wheel escapes from pallet P_1 or P_2, giving the pallet a push to maintain oscillation. The other pallet then checks another tooth, the curve of the pallet forcing the wheel slightly backward. The reaction helps to reverse the pendulum swing and to correct for circular error. [R.D'E.A.]

Clock paradox The phenomenon occurring in the special theory of relativity wherein two observers who start together with identical clocks and then undergo different motions can have different total elapsed time on their clocks when they rejoin later. This effect is a well-defined, mathematically consistent prediction of special relativity which has been verified by experiment but, historically, it has been referred to as a paradox because of erroneous reasoning in the manner in which the effect is commonly analyzed. The clock-paradox phenomenon arises because there is no notion of absolute simultaneity in the theory of special relativity.

The clock-paradox effect is illustrated by the following hypothetical example. (In the context of the example the effect usually is referred to as the twin paradox.) Two identical twins are separated as young adults. One of the twins remains on Earth and, for the purposes of the discussion, is assumed to undergo inertial motion. (In fact, in the context of general relativity, the twin on Earth would be viewed as accelerating—only freely falling observers would be viewed as inertial—but in this example the corrections made to the effect by performing a proper, general-relativistic analysis would be negligible.) The other twin is placed in a rocket ship which accelerates very rapidly away from Earth until it is receding from Earth at nearly the speed of light. After coasting for a while at this speed, the rocket ship turns around and accelerates very rapidly back toward Earth, so that it soon is traveling at nearly the speed of light. The rocket ship then lands on Earth and the twins rejoin. The twin on Earth is old (and everything else on Earth has aged considerably), but the twin in the rocket ship (and everything else therein) has barely aged at all.

The clock-paradox phenomenon has been observed directly in an experiment performed in 1971 by J. C. Hafele and R. E. Keating, who observed differences in elapsed times of atomically stabilized clocks flown in airplanes as compared with ones on the ground. In this experiment the special relativistic effect is so small, since the velocities achieved by airplanes are much smaller than c, that the tiny corrections due to general relativity cannot be neglected, so the experiment actually must be viewed as verifying the analogous clock effect in general relativity rather than purely the clock effect of special relativity. *See* RELATIVITY; SPACE-TIME. [R.M.Wal.]

Closed-caption television A service, primarily for deaf people, that allows individual viewers to display the dialog of a television program in a readable form on the television screen. In the United Kingdom the service is called subtitling. Closed-caption television was introduced in the United States in 1980. Legislative and regulatory actions are spurring the worldwide introduction and growth of captioned television service.

Captions for television programs can be prepared in three ways. (1) Off-line captioning is used when the television program has been prerecorded. (2) Live television broadcasts that are scripted in advance, such as presidential State of the Union speeches, employ a live display captioning method. Here the script is stored in a computer in advance of the broadcast. During the broadcast the script appears as roll-up captions at the bottom of the screen. (3) In live broadcasts, where a script is not available, real-time captions have to be generated during the broadcast. Highly skilled court reporters using a stenograph keyboard and an associated computer create the captions.

Prior to being broadcast, the captions are digitally encoded and inserted into the vertical blanking interval (VBI) of the television picture.

The world's terrestrial television systems are in the process of converting from analog to digital broadcasting. The International Telecommunications Union (ITU) recommendation on a digital video, audio, and ancillary data multiplex model has been adopted worldwide. Captions have been classified as an ancillary service and will be multiplexed with other ancillary services such as text services. *See* TELEVISION. [J.E.D.B.]

Closed-circuit television Television transmitted to a particular audience at specific locations via coaxial cables, telephone wires, fiber-optic strands, microwave radio systems, or communications satellites, as compared to open-circuit (broadcast) television intended for the general public. *See* Coaxial cable; Communications cable; Communications satellite; Microwave; Optical communications; Telephone service.

Closed-circuit television applications include information display, remote monitoring, instruction, cable television programming, and teleconferences and special events. *See* Cable television system; Teleconferencing.

Many types of closed-circuit television systems produce pictures intended for distant viewing. These images may include those taken from a space probe passing close to a distant planet, or pictures of blast furnaces or other industrial operations that could be hazardous to human observers. The low cost of modern video equipment makes practical the use of small cameras to observe sleeping children at home and to enjoy video images of people far away while chatting with them on the Internet.

Many universities and school systems employ television for teaching. Classrooms may be equipped with closed-circuit television cameras, recorders, and receivers. Lesson material is often presented via video tape recordings, CD-ROMs, or DVD recordings. In other cases, classroom receivers are supplied with signals from specially reserved broadcast channels, cable television channels, or satellite channels. Audio circuits installed at viewing locations sometimes allow two-way conversations between lecturer and students. *See* Compact disk; Magnetic recording.

The standardized television broadcast system used at present in the United States, Canada, Mexico, Japan, and some other countries was devised in the 1950s by the National Television Systems Committee (NTSC). Closed-circuit television systems are not required to use NTSC signals, but many do, mainly for economic reasons. If the transmission path to the viewer is of low quality, however, the signal can be modified to meet more closely the characteristics of the transmission system. For example, channel bandwidth can be reduced without loss of image resolution if the user accepts a rate lower than the normal 30 frames per second in the representation of image motion. This is called slow-scan closed-circuit television. Still-frame video images sometimes suffice.

Other applications require high image resolution, great sensitivity to light, the ability to respond to infrared or ultraviolet light, or very rugged system components. Closed-circuit television requirements for high-resolution display can be satisfied by increasing the number of image scanning lines and the overall video channel bandwidth. Industrial standards exist for high-resolution closed-circuit systems.

The digital revolution has affected the design of all kinds of television equipment. Video signals can be converted into digital form and processed by specialized computers, called digital signal processors. In closed-circuit television applications, digital processing can make transmission via the Internet practical and can also provide image enhancement. The advanced television systems now entering service make use of the advantages of digital signal processing to provide high-quality images to the home, to the classroom, and to industrial locations. *See* Data compression; Image processing; Television. [F.M.Re.]

Clostridium A genus of bacteria comprising large anaerobic spore-forming rods that usually stain gram-positive. Most species are anaerobes, but a few will grow minimally in air at atmospheric pressure.

The clostridia are widely distributed in nature, and are present in the soil and in the intestinal tracts of humans and animals. They usually live a saprophytic existence, and play a major role in the degradation of organic material in the soil and other nature environments. A number of clostridia release potent exotoxins and are pathogenic for humans and animals. Among the human pathogens are the causative agents of botulism (*Clostridium botulinum*), tetanus (*C. tetani*), gas gangrene (*C. perfringens*), and an antibiotic-associated enterocolitis (*C. difficile*). *See* Anaerobic infection; Botulism; Tetanus; Toxin.

Clostridial cells are straight or slightly curved rods, 0.3–1.6 micrometers wide and 1–14 μm long. They may occur singly, in pairs, in short or long chains, or in helical coils. The length of the cells of the individual species varies according to the stage of growth and growth conditions. Most clostridia are motile with a uniform arrangement of flagella. *See* Cilia and flagella.

The endospores produced by clostridia are dormant structures capable of surviving for prolonged periods of time, and have the ability to reestablish vegetative growth when appropriate environmental conditions are provided. The spores of clostridia are oval or spherical and are wider than the vegetative bacterial cell. Among the distinctive forms are spindle-shaped organisms, club-shaped forms, and tennis racket-shaped structures:

Clostridia are obligate anaerobes: they are unable to use molecular oxygen as a final electron acceptor and generate their energy solely by fermentation. Clostridia exhibit varying degrees of intolerance of oxygen. Some species are sensitive to oxygen concentrations as low as 0.5%, but most species can tolerate concentrations of 3–5%. The sensitivity of clostridia to oxygen restricts their habitat to anaerobic environments; habitats that contain large amounts of organic matter provide optimal conditions for their growth and survival.

A primary property of all species of *Clostridium* is their inability to carry out a dissimilatory reduction of sulfate. Most species are chemoorganotrophic. The substrate spectrum for the genus as a whole is very broad and includes a wide range of naturally occurring compounds. Extracellular enzymes are secreted by many species, enabling the organism to utilize a wide variety of complex natural substrates in the environment. [H.P.W.]

Cloud Suspensions of minute droplets or ice crystals produced by the condensation of water vapor (the ordinary atmospheric cloud). Other clouds, less commonly seen, are composed of smokes or dusts. *See* Air pollution; Dust storm.

If water vapor is cooled sufficiently, it becomes saturated, that is, in equilibrium with a plane surface of liquid water (or ice) at the same temperature. Further cooling in the presence of such a surface causes condensation upon it. In the atmosphere, even in the apparent absence of any surfaces, there are invisible motes upon which the condensation proceeds at barely appreciable cooling beyond the state of saturation. Consequently, when atmospheric water vapor is chilled sufficiently, such motes, or condensation nuclei, swell into minute waterdroplets and form a visible cloud.

The World Meteorological Organization (WMO) uses a classification which divides clouds into low-level (base below about 1.2 mi or 2 km), middle-level (about 1.2–4 mi or 2–7 km), and high-level (4–8 mi or 7–14 km) forms within the middle latitudes. The names of the three basic forms of clouds are used in combination to define 10 main characteristic forms, or “genera.”

1. Cirrus are high white clouds with a silken or fibrous appearance.
2. Cumulus are detached dense clouds which rise in domes or towers from a level low base.
3. Stratus are extensive layers or flat patches of low clouds without detail.
4. Cirrostratus is cirrus so abundant as to fuse into a layer.
5. Cirrocumulus is formed of high clouds broken into a delicate wavy or dappled pattern.
6. Stratocumulus is a low-level layer cloud having a dappled, lumpy, or wavy structure.
7. Altocumulus is similar to stratocumulus but lies at intermediate levels.
8. Altostratus is a thick, extensive, layer cloud at intermediate levels.

9. Nimbostratus is a dark, widespread cloud with a low base from which prolonge drain or snow falls.
10. Cumulonimbus is a large cumulus which produces a rain or snow shower.

See CLOUD PHYSICS. [F.H.Lu.]

Cloud physics The study of the physical and dynamical processes governing the structure and development of clouds and the release from them of snow, rain, and hail (collectively known as precipitation).

The factors of prime importance are the motion of the air, its water-vapor content, and the numbers and properties of the particles in the air which act as centers of condensation and freezing. Because of the complexity of atmospheric motions and the enormous variability in vapor and particle content of the air, it seems impossible to construct a detailed, general theory of the manner in which clouds and precipitation develop. However, calculations based on the present conception of laws governing the growth and aggregation of cloud particles and on simple models of air motion provide reasonable explanations for the observed formation of precipitation in different kinds of clouds.

Clouds are formed by the lifting of damp air which cools by expansion under continuously falling pressure. The relative humidity increases until the air approaches saturation. Then condensation occurs on some of the wide variety of aerosol particles present; these exist in concentrations ranging from less than 2000 particles/in.^{3} (100/cm^3) in clean, maritime air to perhaps 10^7/in.^{3} (10^6/cm^3) in the highly polluted air of an industrial city. A portion of these particles are hygroscopic and promote condensation at relative humidities below 100%; but for continued condensation leading to the formation of cloud droplets, the air must be slightly supersaturated. Among the highly efficient condensation nuclei are the salt particles produced by the evaporation of sea spray, but it appears that particles produced by human-made fires and by natural combustion (for example, forest fires) also make a major contribution. Condensation onto the nuclei continues as rapidly as the water vapor is made available by cooling of the air and gives rise to droplets of the order of 0.0004 in. (0.01 mm) in diameter. These droplets, usually present in concentrations of several thousand per cubic inch, constitute a nonprecipitating water cloud.

Cloud droplets are seldom of uniform size. Droplets arise on nuclei of various sizes and grow under slightly different conditions of temperature and supersaturation in different parts of the cloud. A droplet appreciably larger than average will fall faster than the smaller ones, and so will collide and fuse (coalesce) with some of those which it overtakes.

The second method of releasing precipitation can operate only if the cloud top reaches elevations where temperatures are below 32°F (0°C) and the droplets in the upper cloud regions become supercooled. At temperatures below −40°F (−40°C) the droplets freeze automatically or spontaneously; at higher temperatures they can freeze only if they are infected with special, minute particles called ice nuclei. As the temperature falls below 32°F (0°C), more and more ice nuclei become active, and ice crystals appear in increasing numbers among the supercooled droplets. Such a mixture of supercooled droplets and ice crystals is unstable. After several minutes the growing crystals will acquire definite falling speeds, and several of them may become joined together to form a snowflake. In falling into the warmer regions of the cloud, however, the snowflake may melt and reach the ground as a raindrop.

The deep, extensive, multilayer-cloud systems, from which precipitation of a usually widespread, persistent character falls, are generally formed in cyclonic depressions (lows) and near fronts. Although the structure of these great raincloud systems, which are being explored by aircraft and radar, is not yet well understood, radar signals from these clouds usually take a characteristic form which has been clearly identified with the melting of snowflakes.

Precipitation from shower clouds and thunderstorms, whether in the form of raindrops, pellets of soft hail, or true hailstones, is generally of greater intensity and shorter duration than that from layer clouds and is usually composed of larger particles. The clouds themselves are characterized by their large vertical depth, strong vertical air currents, and high concentrations of liquid water, all these factors favoring the rapid growth of precipitation elements by accretion.

The development of precipitation in convective clouds is accompanied by electrical effects culminating in lightning. The mechanism by which the electric charge dissipated in lightning flashes is generated and separated within the thunderstorm has been debated for more than 200 years, but there is still no universally accepted theory. However, the majority opinion holds that lightning is closely associated with the appearance of the ice phase, and the most promising theory suggests that the charge is produced by the rebound of ice crystals or a small fraction of the cloud droplets that collide with the falling hail pellets. *See* LIGHTNING.

The various stages of the precipitation mechanisms raise a number of interesting and fundamental problems in classical physics. Worthy of mention are the supercooling and freezing of water; the nature, origin, and mode of action of the ice nuclei; and the mechanism of ice-crystal growth which produces the various snow crystal forms.

The maximum degree to which a sample of water may be supercooled depends on its purity, volume, and rate of cooling. The freezing temperatures of waterdrops containing foreign particles vary linearly as the logarithm of the droplet volumes for a constant rate of cooling. This relationship, which has been established for drops varying between 10 micrometers and 1 centimeter in diameter, characterizes the heterogeneous nucleation of waterdrops and is probably a consequence of the fact that the ice-nucleating ability of atmospheric aerosol increases logarithmically with decreasing temperature.

Measurements made with large cloud chambers on aircraft indicate that the most efficient nuclei, active at temperatures above 14°F (−10°C), are present in concentrations of only about 10 in a cubic meter of air, but as the temperature is lowered, the numbers of ice crystals increase logarithmically to reach concentrations of about 1 per liter at −4°F (−20°C) and 100 per liter at −22°F (−30°C). Since these measured concentrations of nuclei are less than one-hundredth of the numbers that apparently are consumed in the production of snow, it seems that there must exist processes by which the original number of ice crystals are rapidly multiplied, Laboratory experiments suggest the fragmentation of the delicate snow crystals and the ejection of ice splinters from freezing droplets as probable mechanisms.

The most likely source of atmospheric ice nuclei is provided by the soil and mineral-dust particles carried aloft by the wind. Laboratory tests have shown that, although most common minerals are relatively inactive, a number of silicate minerals of the clay family produce ice crystals in a supercooled cloud at temperatures above −4°F (−18°C). A major constituent of some clays, kaolinite, which is active below 16°F (−9°C), is probably the main source of highly efficient nuclei.

The fact that there may often be a deficiency of efficient ice nuclei in the atmosphere has led to a search for artificial nuclei which might be introduced into supercooled clouds in large numbers. In general, the most effective ice-nucleating substances, both natural and artificial, are hexagonal crystals in which spacings between adjacent rows of atoms differ from those of ice by less than 16%. The detailed surface structure of the nucleus, which is determined only in part by the crystal geometry, is of even greater importance.

Collection of snow crystals from clouds at different temperatures has revealed their great variety of shape and form. This multiple change of habit over such a small temperature range is remarkable and is thought to be associated with the fact that water molecules apparently migrate between neighboring faces on an ice crystal in a manner which is very sensitive to the temperature. The temperature rather than the supersaturation of the environment is primarily responsible for determining the basic shape of the crystal, though the supersaturation governs the growth rates of the crystals, the ratio of their linear dimensions, and the development of dendritic forms.

The presence of either ice crystals or some comparatively large waterdroplets (to initiate the coalescence mechanism) appears essential to the natural release of precipitation. Rainmaking experiments are conducted on the assumption that some clouds precipitate inefficiently, or not at all, because they are deficient in natural nuclei; and that this deficiency can be remedied by "seeding" the clouds artificially with dry ice or silver iodide to produce ice crystals, or by introducing waterdroplets or large hygroscopic nuclei. *See* PRECIPITATION (METEOROLOGY); WEATHER MODIFICATION. [B.J.M.]

Clove The unopened flower bud of a small, conical, symmetrical, evergreen tree, *Eugenia caryophyllata*, of the myrtle family (Myrtaceae). The cloves are picked by hand and dried. Cloves, one of the most important and useful spices, are strongly aromatic and have a pungent flavor. They are used as a culinary spice for flavoring pickles, ketchup, and sauces, in medicine, and for perfuming the breath and air. The essential oil distilled from cloves has even more uses. The chief clove-producing countries are Tanzania, Indonesia, Mauritius, and the West Indies. *See* MYRTALES. [P.D.St./E.L.C.]

Clover A common name used loosely to designate the true clovers, sweet clovers, and other members of the plant family Leguminosa.

True clovers. The true clovers are herbaceous annual or perennial plants of the genus *Trifolium*, order Rosales. There are approximately 250 species in the world. Collectively they represent the most important genus of forage legumes in agriculture. Most clovers are highly palatable and nutritious to livestock. The name clover is often applied to members of legume genera other than *Trifolium*. *See* ROSALES.

Clovers are used for hay, pasture, silage, and soil improvement. Certain kinds may be used for all purposes whereas others, because of their low growth, are best suited for grazing. All kinds, when well grown in thick stands, are good for soil improvement. Thoroughly inoculated plants add 50–200 lb of nitrogen per acre (62–252 kg per hectare) when plowed under for soil improvement, the amount added depending on growth, thickness of stand, and length of growing season. *See* NITROGEN CYCLE.

All the clover species of agricultural importance in the United States are introduced (exotic) plants. Some of the species most widely used are: red clover (*T. pratense*), alsike clover (*T. hybridum*), white clover (*T. repens*), crimson clover (*T. incarnatum*), subclover (*T. subterraneum*), strawberry clover (*T. fragiferum*), persian clover (*T. resupinatum*), and large hop clover (*T. campestre*, or *procumbens*). Other clovers of regional importance, mostly adapted to specific environmental conditions, are rose clover (*T. hirtum*), berseem clover (*T. alexandrinum*), ball clover (*T. nigrescens*), lappa clover (*T. lappaceum*), big-flower clover (*T. michelianum*), and arrowleaf clover (*T. vesiculosum*).

Red clover is composed of two forms, medium and mammoth, producing two and one hay cuts, respectively. The large purplish-red flower heads are round. An upright-growing perennial, red clover generally persists for 2 years in the northern United States, but behaves as a winter annual in the South. There are several varieties and strains of red clover such as Kenland, Pennscott, Lakeland, Dollard, and Chesapeake. These produce higher yields of forage and are more persistent than common red clover.

Alsike clover is an upright-growing species that behaves like a biennial. The growth pattern, seeding methods, mixtures, and uses are similar to those of red clover. The flower heads are much like those of white clover in shape and size, but are slightly more pinkish. Alsike clover is more tolerant of wet, poorly drained soils than red clover and occurs widely in mountain meadows of the West.

White clover, an inhabitant of lawns and closely grazed pastures, is the most important pasture legume in the humid states. The flowers are generally white, but sometimes they are tinged with pink. There are three main types, large, intermediate, and small, with all gradations between. All types are nutritious and are relished by all classes of livestock and poultry. White clover is mainly grown with low-growing grasses, not being tolerant of the tall-growing kinds. For best growth of the clover, grass-clover mixtures should be grazed or cut frequently.

Crimson clover is used principally as a winter annual for pasture and as a soil-improving crop from the latitude of the Ohio River southward, and along the West Coast. Crimson clover is seeded alone, with small grains and grasses, or on grass turf. During the winter it may be grazed, although if it is too heavily grazed, regrowth is slow. The greatest return for soil improvement is obtained when the largest growth is plowed under. There are several varieties of crimson clover, including Dixie, Auburn, Autauga, Chief, Talladega, and many local strains. When used with Bermuda or other perennial summer-growing grasses, the fall growth of the grass must be closely grazed or clipped.

Subclover, a winter annual extensively used for grazing in the coastal sections of the Western states, is the basic pasture crop of the sheep and cattle industry of Australia. The Australian varieties Mount Barker, Tallarook, and Nangeela have proved to be best adapted to most conditions in the United States. Subclover appears to have considerable promise as a pasture legume under many conditions in the southern United States, but better adapted varieties are needed.

Sweet clover. Sweet clover is the common name for all but one species of legumes of the genus *Melilotus*, order Rosales. The exception is sour clover (*M. indica*). There are approximately 20 species of sweet clover. Some of the biennial species have an annual form. Sweet clovers are native to the Mediterranean region and adjacent countries, but several are widely scattered throughout the world, generally by chance introduction.

Sweet clover is used as a field crop in regions of the United States and Canada where the rainfall is 17 in. (42 cm) or more during the growing season, where the soil is neutral, or where limestone and other needed minerals are applied. It is grown either alone or in rotations with small grains and corn, and is used for grazing, soil improvement, and hay. Except for those of certain improved varieties, the plants are somewhat bitter because of the presence of coumarin. [E.A.H.]

Clupeiformes An order of teleost fishes of the subclass Actinopterygii that includes the herrings, sardines, anchovies, and their allies. The Recent clupeiforms are classified in 2 suborders, 3 (by some authorities as many as 6) families, 71 genera, and about 300 species.

The Clupeiformes are generalized teleosts. They are mostly silvery and compressed. A distinctive feature is the extension of the cephalic canal system onto the operculum; the lateral line is undeveloped on the trunk except in *Denticeps*. They lack fin spines, adipose fin, and gular plate. The middle of the belly often bears one or a series of strong scutes. The pelvic fin is abdominal in position, free from the shoulder girdle, and the pectoral fin is placed low on the side. The cycloid scales are usually thin and loosely attached. The upper jaw is bordered by premaxillae and maxillae, but the dentition is usually feeble.

Clupeiform fishes have left a rich fossil record, especially from the Upper Cretaceous to the early Tertiary, but appeared first in the Upper Jurassic. Some herrings and a few anchovies live in lowland rivers and lakes, and others such as the shad and alewife enter rivers to reproduce; but the majority of clupeiforms occur in bays or shore waters of tropical, temperate, or even northern seas, where they commonly make up enormous schools. None inhabits deep water. Most feed on plankton or other minute organisms. Thus they are efficient converters from the base of the food chain to fish flesh.

Some of the great fisheries of the world are based on the conversion of plankton by clupeiform fishes: the tremendous anchovy fishery off western South America; the California fisheries for anchovy and (until depleted) Pacific sardine; the menhaden fisheries of the western Atlantic; and the herring and sardine fisheries of northern seas. The catch is processed variously into oil, fertilizer, or fish meal or is prepared directly for human consumption. *See* ACTINOPTERYGII. [R.M.B.]

Clutch A machine element for the connection and disconnection of shafts in equipment drives. If both shafts to be connected can be stopped or made to move relatively slowly, a positive-type mechanical clutch may be used. If an initially stationary shaft is to be driven by a moving shaft, friction surfaces must be interposed to absorb the relative slippage until the speeds are the same. Likewise, friction slippage allows one shaft to stop after the clutch is released.

When positive connection of one shaft with another in a given position is needed, a positive clutch is used. This clutch is the simplest of all shaft connectors, sliding on a keyed shaft section or a splined portion and operating with a shift lever on a collar element. Because it does not slip, no heat is generated in this clutch. Interference of the interlocking portions prevents engagement at high speeds; at low speeds, if connection occurs, shock loads are transmitted to the shafting. Positive clutches may be of the square jaw type (Fig. 1) with two or more jaws of square section meshing together in the opposing clutches, or the spiral jaw type, a modification of the square-jaw clutch that permits more convenient engagement and provides a more gradual movement of the mating faces toward each other.

When the axial pressure of the clutch faces on each other serves to transmit torque instead of the mating shape of their parts, the clutch operates by friction. This friction clutch is usually placed between an engine and a load to be driven; when the friction surfaces of the clutch are engaged, the speed of the driven load gradually approaches that of the engine until the two speeds are the same. A friction clutch is necessary for connecting a rotating shaft of a machine to a stationary shaft so that it may be brought up to speed without shock and transmit torque for the development of useful work. The three common designs for friction clutches, combining axial and radial types, are cone clutches (Fig. 2), disk clutches, and rim clutches. In a cone clutch, the surfaces are sections of a pair of cones. The disk clutch consists essentially of one or more friction disks connected to a driven shaft by splines. A rim clutch has surface elements that apply pressure to the rim externally or internally.

In the overrunning type of clutch, the driven shaft can run faster than the driving shaft. This action permits freewheeling as the driving shaft slows down or another source of power is applied. Effectively this is a friction pawl-and-ratchet drive, wherein balls or rollers become wedged between the sleeve and recessed pockets machined in the hub (Fig. 3). The clutch does not slip when the second shaft is driven, and is released automatically when the second shaft runs faster than the driver. The centrifugal clutch employs centrifugal force from the speed of rotation. This type of clutch is not normally used because it becomes unwieldy and unsafe with increasing size. Clutch action is also produced by hydraulic couplings, with a smoothness not possible with a mechanical clutch. Automatic transmissions in automobiles represent a fundamental use of hydraulic clutches. *See* FLUID; COUPLING; TORQUE CONVERTER.

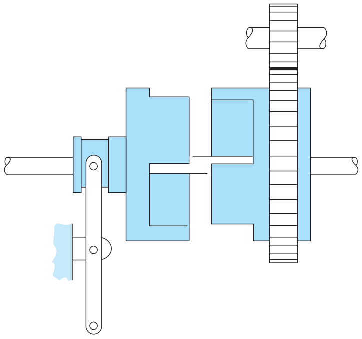


Fig. 1. Square-jaw-type positive clutch.

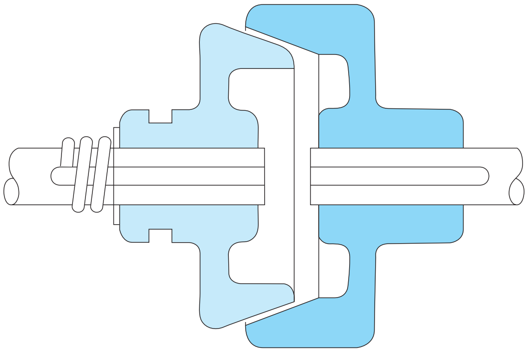

Fig. 2. Cone-type friction clutch.

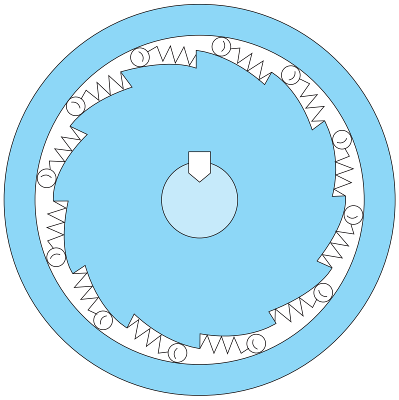

Fig. 3. Overrunning clutch with spring-constrained rollers or balls.

Magnetic coupling between conductors provides a basis for several types of clutches. The magnetic attraction between a current-carrying coil and a ferromagnetic clutch plate serves to actuate a disk-type clutch. Slippage in such a clutch produces heat that must be dissipated and wear that reduces the life of the clutch plate. Thus the electromagnetically controlled disk clutch is used to engage a load to its driving source. *See* BRAKE; COUPLING. [J.E.G.; J.J.R.]

Cnidospora A subphylum of spore-producing Protozoa containing the two classes Myxosporidea and Microsporidea. Cnidospora are parasites of cells and tissues of invertebrates, fishes, a few amphibians, and turtles. *See* MICROSPORIDEA; MYXOSPORIDEA.

A distinctive structure of this subphylum is the spore, which contains one or more protoplasmic masses called sporoplasms. The spore also contains one or more filaments which lie coiled within the spore proper or within one or more polar capsules.

When the spore is ingested by a new host, the filaments are extruded and at the same time the sporoplasm is released. The sporoplasm, now called an amebula, reaches the specific site of infection directly through the intestinal wall or by way of the bloodstream. The amebula becomes a stage in the life cycle which feeds and grows at the expense of the host. Asexual reproduction by repeated binary fission, multiple fission, internal and external budding, or plasmotomy results in cells which develop into sporonts and eventually into sporoblasts, producing one or more spores. *See* PROTOZOA; SPOROZOA. [R.F.N.]

Coal A brown to black combustible rock that originated by accumulation and subsequent physical and chemical alteration of plant material over long periods of time, and that on a moisture-free basis contains no more than 50% mineral matter. The plant debris accumulated in various wet environments, commonly called peat swamps, where dead plants were largely protected from decay by a high water table and oxygen-deficient water. The accumulating spongy, water-saturated, plant-derived organic material known as peat is the precursor of coal. Over time, many changes of the original vegetable matter are brought about by bacteria, fungi, and chemical agents. The process progressively transforms peat into lignite or brown coal, subbituminous coal, bituminous coal, and anthracite. This progression is known as the coalification series. The pressure exerted by the weight of the overlying sediment and the heat that increases with depth, as well as the length of exposure to them, determine the degree of coalification reached. *See* FOSSIL FUEL; KEROGEN; LIGNITE; PEAT.

Minable coal seams occur in many different shapes and compositions. Some coal seams can be traced over tens, even hundreds, of miles in relatively uniform thickness and structure. The extensively mined Herrin coal bed of the Illinois Basin and the Pittsburgh coal bed of the northern Appalachian Basin are examples. They are 6–8 ft (2–2.5 m) thick over thousands of square miles. These coals originated in peat swamps that developed on vast coastal plains during the Pennsylvanian Period. The German brown coal deposits near Cologne are characterized by very thick coal deposits (300 ft or 100 m). However, their lateral extent is much more limited than are the two examples from the United States. These peat deposits formed in a gradually subsiding structural graben bounded by major faults. Land lay to the south and the sea to the north. Only a relatively small portion of the subsiding graben block provided optimal conditions for peat accumulation over a long period of time. Thus each coal bed has its own depositional history that determined many of its characteristics. *See* CARBONIFEROUS; CRETACEOUS; PENNSYLVANIAN; TERTIARY.

Coal seams are commonly composed of a number of benches of alternating coal and more or less carbonaceous shale. The shale represents periods when the peat accumulation was interrupted by flooding from a river or the sea, or, more rarely, interrupted by volcanic ash deposition (tonsteins). The individual benches of a coal bed vary laterally in thickness and composition, sometimes quite rapidly. The degree of variability is related to the stability of conditions during accumulation. Fluvial and lacustrine depositional environments produce greater lateral variability than deltaic or coastal plain environments. *See* SHALE.

Both physical (pressure, heat) and chemical (biochemical, thermochemical) factors are influential in the transformation of peat into the other members of the coalification series. The boundaries between the members of the series are transitional and must be chosen somewhat arbitrarily. The term rank is used to identify the stage of coalification reached in the course of coal metamorphism. Rank is a fundamental property of coal, and its determination is essential in the characterization of a coal. Classification of coal by rank generally is based upon the chemical composition of the coal's ash-free or mineral-matter-free organic substance (see table), but parameters derived from empirical tests indicative of technological properties, such as agglomerating characteristics, are commonly used in several countries outside the United States in addition to coal rank parameters. *See* METAMORPHISM.

Coal rank increases with depth at differing rates from place to place, depending primarily on the rate of temperature increase with depth (geothermal gradient) at the time of coalification. Coal rank also changes laterally, even in the same coal seam, as former depth of burial and thus exposure to different pressure and temperature vary. Originally established vertical and regional coalification patterns can be significantly altered by various kinds of geologic events, such as the intrusion of large magma bodies at depth (plutonism), or renewed subsidence of a region. Volcanic activity may cause significant local anomalies in coal rank, but rarely leads to regional changes in coalification pattern. *See* MAGMA.

American Society for Testing and Materials classification of coals by rank (in box, ASTM standard D 388) and other related coal properties

ASTM class	ASTM group	1000 Btu/lb[1]	Agglomerating[2]	Volatile matter,[3] %	MJ/kg[1]	Maximum reflectance,[4] %	Moisture,[1] %	C,[3] %	O,[3] %	H,[3] %

[1] Moist, mineral-matter-free.

[2] Agglomerating coals form a button of cokelike residue in the standard volatile-matter determination that shows swelling or cell structure or supports a 500-g weight without pulverizing. The residue of nonagglomerating coal lacks these characteristics.

[3] Dry, mineral-matter-free.

[4] Reflectance of virinite under oil immersion.

[5] Well suited for rank discrimination in range indicated.

[6] Moderately well suited for rank discrimination.

SOURCE: Modified from Damberger et al., in B. R. Cooper and W. A. Ellingson (eds.), *The Science and Technology of Coal and Coal Utilization*, 1984.

Coal is used primarily for producing steam in electric power plants. Other important uses are by industry for producing steam and heat, and by the steel industry for coke making. Conversion of coal to synthetic liquid or gaseous fuels does not constitute a major use of coal worldwide or in most countries. *See* Coal chemicals; Coal gasification. [H.H.D.]

Coal balls Variously shaped nodules consisting of fossilized peat in which the individual cells and tissue systems of the plant parts are infiltrated by minerals, principally calcium carbonate, along with pyrite, dolomite, and occasionally silica. This type of fossilization, in which the cell walls are filled with minerals, is termed permineralization. Coal balls occur principally in Pennsylvanian (upper Carboniferous) bituminous and anthracite coals, but permineralized plants have also been reported in coals from as early as the Devonian and extending well into the Paleocene.

How coal balls formed is not well understood, but some are believed to represent accumulations of peat in which the plants were growing in low-lying swampy areas close to the sea. According to this model, seawater provided the high source of calcium carbonate in the permineralization processes.

Because the individual plant cells in coal balls have not been crushed, they offer a wealth of information to paleobiologists about the structure, morphology, and biology of the plants. *See* Coal paleobotany; Paleobotany. [T.N.T.]

Coal chemicals For about 100 years, chemicals obtained as by-products in the primary processing of coal to metallurgical coke have been the main source of aromatic compounds used as intermediates in the synthesis of dyes, drugs, antiseptics, and solvents. Although some aromatic hydrocarbons, such as toluene and xylene, are now obtained largely from petroleum refineries, the main source of others, such as benzene, naphthalene, anthracene, and phenanthrene, is still the by-product coke oven. Heterocyclic nitrogen compounds, such as pyridines and quinolines, are also obtained largely from coal tar. Although much phenol is produced by hydrolysis of monochlorobenzene and by decomposition of cumene hydroperoxide, much of the phenol, cresols, and xylenols are still obtained from coal tar.

Coke oven by-products are gas, light oil, and tar. Coke oven gas is a mixture of methane, carbon monoxide, hydrogen, small amounts of higher hydrocarbons, ammonia, and hydrogen sulfide. Most of the coke oven gas is used as fuel. Although several hundred chemical compounds have been isolated from coal tar, a relatively small number are present in appreciable amounts. These may be grouped as in the table. All the compounds in the table except the monomethylnaphthalenes are of some commercial importance.

The direct utilization of coal as a source of bulk organic chemicals has been the objective of much research and development. Oxidation of aqueous alkaline slurries of coal with oxygen under pressure yields a mixture of aromatic carboxylic acids. Because of the presence of nitrogen compounds and hydroxy acids, this mixture is difficult to refine. Hydrogenation of coal at elevated temperatures and pressures yields much larger amounts of tar acids and aromatic hydrocarbons of commercial importance than are obtained by carbonization. However, this operation is more costly than other sources of these chemicals. *See* Coke; Destructive distillation; Pyrolysis. [H.W.W.]

Coal tar chemicals

Compound	Fraction of whole tar, %	Use
Naphthalene	10.9	Phthalic acid
Monomethylnaphthalenes	2.5	
Acenaphthenes	1.4	Dye intermediates
Fluorene	1.6	Organic syntheses
Phenanthrene	4.0	Dyes, explosives
Anthracene	1.0	Dye intermediates
Carbazole (and other similar compounds)	2.3	Dye intermediates
Phenol	0.7	Plastics
Cresols and xylenols	1.5	Antiseptics, organic syntheses
Pyridine, picolines, lutidines, quinolines, acridine, and other tar bases	2.3	Drugs, dyes, antioxidants

Coal gasification The conversion of coal or coal char to gaseous products by reaction with steam, oxygen, air, hydrogen, carbon dioxide, or a mixture of these. Products consist of carbon monoxide, carbon dioxide, hydrogen, methane, and some other gases in proportions dependent upon the specific reactants and conditions (temperatures and pressures) employed within the reactors, and the treatment steps which the gases undergo subsequent to leaving the gasifier. Similar chemistry can also be applied to the gasification of coke derived from petroleum and other sources. The reaction of coal or coal char with air or oxygen to produce heat and carbon dioxide could be called gasification, but it is more properly classified as combustion. The principal purposes of such conversion are the production of synthetic natural gas as a substitute gaseous fuel and synthesis gases for production of chemicals and plastics. *See* Combustion.

In all cases of commercial interest, gasification with steam, which is endothermic, is an important chemical reaction. The necessary heat input is typically supplied to the gasifier by combusting a portion of the coal with oxygen added along with the steam. From the industrial viewpoint, the final product is either chemical synthesis gas (CSG), medium-Btu gas (MBG), or a substitute natural gas (SNG).

Each of the gas types has potential industrial applications. In the chemical industry, synthesis gas from coal is a potential alternative source of hydrogen and carbon monoxide. This mixture is obtained primarily from the steam reforming of natural gas, natural gas liquids, or other petroleum liquids. Fuel users in the industrial sector have studied the feasibility of using medium-Btu gas instead of natural gas or oil for fuel applications. Finally, the natural gas industry is interested in substitute natural gas, which can be distributed in existing pipeline networks. *See* Natural gas.

There has also been some interest by the electric power industry in gasifying coal by using air to provide the necessary heat input. This could produce low-Btu gas (because of the nitrogen present), which can be burned in a combined-cycle power generation system. *See* Electric power generation.

In nearly all of the processes, the general process is the same. Coal is prepared by crushing and drying, pretreated if necessary to prevent caking, and then gasified with a mixture of air or oxygen and steam. The resulting gas is cooled and cleaned of char fines, hydrogen sulfide, and carbon dioxide before entering optional processing steps to adjust its composition for the intended end use. [W.R.Ep.]

Coal liquefaction The conversion of most types of coal (with the exception of anthracite) primarily to petroleumlike hydrocarbon liquids which can be substituted for the standard liquid or solid fuels used to meet transportation, residential, commercial, and industrial fuel requirements. Coal liquids contain less sulfur, nitrogen, and ash, and are easier to transport and use than the parent (solid) coal. These liquids are suitable refinery feedstocks for the manufacture of gasoline, heating oil, diesel fuel, jet fuel, turbine fuel, fuel oil, and petrochemicals.

Liquefying coal involves increasing the ratio of hydrogen to carbon atoms (H:C) considerably—from about 0.8 to 1.5–2.0. This can be done in two ways: (1) indirectly, by first gasifying the coal to produce a synthesis gas (carbon monoxide and hydrogen) and then reconstructing liquid molecules by Fischer-Tropsch or methanol synthesis reactions; or (2) directly, by chemically adding hydrogen to the coal matrix under conditions of high pressure and temperature. In either case (with the exception of methanol synthesis), a wide range of products is obtained, from light hydrocarbon gases to heavy liquids. Even waxes, which are solid at room temperature, may be produced, depending on the specific conditions employed. [W.R.Ep.]

Coal mining The technical and mechanical activities involved in removing coal from the earth and preparing it for market. Coal mining in the industrialized countries is characterized by the integration of a number of complex systems into a production methodology that varies for surface versus underground mining. *See* COAL.

The basic systems of the production methodology are the following. (1) Extraction systems: the methods and techniques used to break out or "win" the coal. (2) Materials-handling systems: the transport of coal and waste products away from the active production area, and the transport of the necessary materials, equipment, supplies, and workers to service the extraction system. (3) Ventilation: the development and operation of an air distribution system to provide the quantity, quality, and velocity of air where and when needed, to meet health and safety requirements. (4) Ground control: the control of the behavior of underground and surface openings developed by the extraction of coal. (5) Reclamation: the restoration of the mined area to its approximate original state or to an approved state.

To properly plan, design, and engineer a production system, knowledge of the geology of the deposit and the chemical and physical properties of the coal must be assembled and assessed. Basic information on the geology of the deposit is obtained from surface prospecting and mapping, and borehole drilling. This information is used to determine the size and shape of the coal area, the geologic column above and below all minable seams, the continuity and persistence of geologic features throughout the deposit, the presence of water or methane gas, and other special conditions. Proximate chemical analyses are made to determine coal characteristics, which affect its utilization. Tests are made to determine the cleaning, grinding, and handling properties of the coal. Ultimate chemical analyses are made to determine the fundamental chemical constituents of the coal. Maps are drawn to summarize this information, and are used for scheduling and sequencing production. *See* ANALYTICAL CHEMISTRY; ENGINEERING GEOLOGY; PROSPECTING; ROCK MECHANICS; SOIL MECHANICS; SPECTROSCOPY.

When a coal seam lies close to the ground surface, a surface mining method is employed. Surface coal mines involve area mining or modified open pit mining, contour mining and mountaintop removal, and auger mining. Removal of overburden is called stripping, and hence the term "strip mining" is often applied to surface coal operations. Area mining is applicable in relatively flat to gently undulating terrain where coal seams are of considerable area and may be at various dips. Contour mining and mountaintop removal are used in hilly and mountainous country and can be modified to handle coal seams at any dip. Auger mining follows the other surface methods when overburden removal becomes uneconomic, and is generally limited to more or less horizontal coal seams. *See* SURFACE MINING.

When a coal seam does not lie close to the surface, it must be extracted by underground methods. The methods may be classified as room-and-pillar, longwall, and others. In each method, modifications to the basic techniques are needed to cope with varying geologic conditions and seam factors. Irregular seam thickness, steep dips, changing rock quality, seam partings, and other factors have a marked influence on the mine geometry and equipment specifications. In developing a particular extraction system, development openings and production openings must be driven. Development openings provide the primary access to various parts of the coal deposit and are called mains. In room-and-pillar mining, the production openings are the rooms driven in the panel and the extraction cuts made during pillar retrieval. In longwall mining, the production openings are the longwall faces. In general, the term "development" includes all openings and other work which precedes production. *See* MINING; UNDERGROUND MINING. [M.T.W.; T.M.Y.]

Coal paleobotany A special branch of the paleobotanical sciences concerned with the origin, composition, mode of occurrence, and significance of the fossil plant materials that occur in, or are associated with, coal seams. Information developed in this field of science provides knowledge useful to the biologist in attempting to describe the development of the plant world, aids the geologist in unraveling the complexities of coal measure stratigraphy in order to reconstruct the geography of past ages and to describe ancient climates, and has practical application in the coal, coke, and coal chemical industries. *See* PALEOBOTANY.

All coal seams consist of countless fragments of fossilized plant material admixed with varying percentages of mineral matter. The organic and inorganic materials initially accumulate in some type of swamp environment. In some instances, the fossilized plant fragments can be recognized as remnants of a plant of some particular family, genus, or species. When this is possible, information can be obtained on the vegetation extant at the time the source peat was formed, and such data aid greatly in reconstructing paleogeographies and paleoclimatic patterns.

Pollen grains and spores are more adequately preserved in coals than are most other plant parts. Recognition of this fact, coupled with an appreciation of the high degree to which these fossils are diagnostic of floral composition, has led to the rapid development of the paleobotanical subscience of palynology. Fruits, seeds, and identifiable woods also occur as coalified fossils. Occasionally, coal seams contain fossil-rich coal balls. Essentially all types of plant fossil, including entire leaves, cones, and seeds, are encountered in these discrete nodular masses. *See* COAL BALLS; PALYNOLOGY.

Coal seams generally are composed of several superposed sedimentary layers, each having formed under somewhat different environmental conditions. The coal petrologist and paleobotanist recognize these layers because of their distinctive textural appearance and because each consists of a particular association of organic and inorganic materials. Accordingly, each coal seam usually contains several types of coal. These coal types, or lithotypes, possess characteristic suites of physical properties, and knowledge of these properties is very profitably employed in manipulating coal composition in coal preparation and beneficiation plants. [W.Sp.]

Coalbed methane Coalbed methane production, sometimes referred to as coal degasification, is the process of extracting natural gas from underground coal formations (coal seams). This extraction is accomplished with production technology similar to that used in the conventional natural gas industry. The objectives of producing the natural gas from a coal seam are to improve mine safety, to sell the natural gas, or both. *See* COAL; NATURAL GAS.

Coalbed methane production is a leading form of unconventional production in terms of annual gas production and reserves. Other unconventional gas resources include low-permeability sandstones, Devonian shales, geopressured aquifers, and gas-hydrate reservoirs.

In 2001, coalbed methane production accounted for approximately 7.9% of the United States annual natural gas production and 9.6% of its total proven natural gas reserves. In addition, natural gas production from all of the unconventional gas resources accounted for approximately 26% of the total United States annual production.

The natural gas associated with coal is a by-product of the coalification process. Therefore, coal-seam reservoirs are different from conventional natural gas reservoirs; the coal seam is both the source rock and reservoir rock for the gas. The natural gas associated with coal is composed of low-molecular-weight hydrocarbon gases, predominantly methane, and inorganic gases, such as carbon monoxide, carbon dioxide, hydrogen sulfide, and oxygen.

The drilling technology used for coalbed methane wells is identical to the technology used for conventional natural gas wells. The production technologies do, however, differ in well completions. The well completion is the portion of the well that connects the wellbore to the reservoir. Specialized well completions are required for coalbed methane wells because of the unique mechanical properties of coal.

There are two well completions commonly used in coalbed methane wells: open-hole cavity completions and hydraulically stimulated completions. In the open-hole cavity completion, the well is injected with high-pressure gas and water and is then rapidly depressurized. This process is repeated several times to break down the coal in order to create a large effective well radius, or cavity, in the coal seam.

In the hydraulic stimulation process, a high-pressure fluid (usually a gelled liquid, foam, or gas) is injected into the well along with a proppant (generally sand). The injection of the fracturing fluid either creates and propagates a fracture from the well into the coal seam, or opens preexisting, near-wellbore fractures. The proppant is used to keep the fractures open once the well is put onto production. [G.R.K.]

Coastal engineering A branch of civil engineering concerned with the planning, design, construction, and maintenance of works in the coastal zone. The purposes of these works include control of shoreline erosion; development of navigation channels and harbors; defense against flooding caused by storms, tides, and seismically generated waves (tsunamis); development of coastal recreation; and control of pollution in nearshore waters. Coastal engineering usually involves the construction of structures or the transport and possible stabilization of sand and other coastal sediments.

The successful coastal engineer must have a working knowledge of oceanography and meteorology, hydrodynamics, geomorphology and soil mechanics, statistics, and structural mechanics. Tools that support coastal engineering design include analytical theories of wave motion, wave-structure interaction, diffusion in a turbulent flow field, and so on; numerical and physical hydraulic models; basic experiments in wave and current flumes; and field measurements of basic processes such as beach profile response to wave attack, and the construction of works. Postconstruction monitoring efforts at coastal projects have also contributed greatly to improved design practice.

Coastal structures can be classified by the function they serve and by their structural features. Primary functional classes include seawalls, revetments, and bulkheads; groins; jetties; breakwaters; and a group of miscellaneous structures including piers, submerged pipelines, and various harbor and marina structures.

Seawalls, revetments, and bulkheads are structures constructed parallel or nearly parallel to the shoreline at the land-sea interface for the purpose of maintaining the shoreline in an advanced position and preventing further shoreline recession. Seawalls are usually massive and rigid, while a revetment is an armoring of the beach face with stone rip-rap or artificial units. A bulkhead acts primarily as a land-retaining structure and is found in a more protected environment such as a navigation channel or marina. *See* REVETMENT.

A groin is a structure built perpendicular to the shore and usually extending out through the surf zone under normal wave and surge-level conditions. It functions by trapping sand from the alongshore transport system to widen and protect a beach or by retaining artificially placed sand.

Jetties are structures built at the entrance to a river or tidal inlet to stabilize the entrance as well as to protect vessels navigating the entrance channel.

The primary purpose of a breakwater is to protect a shoreline or harbor anchorage area from wave attack. Breakwaters may be located completely offshore and oriented approximately parallel to shore, or they may be oblique and connected to the shore where they often take on some of the functions of a jetty. [R.M.So.]

Coastal landforms The characteristic features and morphology of the land in the coastal zone. They are subject to processes of erosion and deposition as produced by winds, waves, tides, and river discharge. The interactions of these processes and the coastal environments produce a wide variety of landforms. Processes directed seaward from the land are dominated by the transport of sediment by rivers, but also include gravity processes such as landslides, rockfalls, and slumping. The dominant processes on the seaward side are wind, waves, and wave-generated currents. Mixed among these locations are tidal currents which also carry large volumes of sediment.

Subcontinental- to continental-scale coastal landform patterns are related to plate tectonics. The three major tectonic coastal types are leading-edge, trailing-edge, and marginal sea coasts. Leading-edge coasts are associated with colliding plate boundaries where there is considerable tectonic activity. Trailing-edge coasts are on stable continental margins, and marginal seas have fairly stable coasts with plate margins, commonly characterized by island arcs and volcanoes, that form their seaward boundaries. *See* CONTINENTAL MARGIN; PLATE TECTONICS.

The primary characteristics of leading-edge coasts is the rugged and irregular topography, commonly displaying cliffs or bluffs right up to the shoreline. Seaward, the topography reflects this with an irregular bottom and deep water near the shoreline. The geology is generally complex with numerous faults and folds in the strata of the coastal zone. These coasts tend to be dominated by erosion with only local areas of deposition, typically in the form of small beaches or spits between headlands. Waves tend to be large because of the deep nearshore water, and form wave-cut platforms, terraces, notches, sea stacks, and caves. *See* FRAME OF REFERENCE.

The most diverse suite of coastal landforms develops along trailing-edge coasts. These coasts are generally developed along the margin of a coastal plain, they are fed by well-developed and large river systems, and they are subjected to a low-to-modest wave energy because of the gently sloping adjacent continental shelf. The overall appearance is little topographic relief dominated by deposition of mud and sand. The spectrum of environments and their associated landforms includes deltas, estuaries, barrier islands, tidal inlets, tidal flats, and salt marshes. *See* BARRIER ISLANDS; COASTAL PLAIN; DELTA; FLOODPLAIN; SALT MARSH.

Marginal coastal settings are along a stable continental mass and are protected from open ocean processes, commonly an island arc system or other form of a plate boundary. The consequence is a coastal zone that tends to be subjected to small waves and where considerable mud is allowed to accumulate in the coastal zone. Many coastal landforms are present in much the same fashion as on the trailing-edge coasts. Marginal sea coasts tend to have large river deltas. Examples are the eastern margin of Asia along the Gulf of Korea and the China Sea, the entire Gulf of Mexico, and the Mediterranean Sea. *See* DEPOSITIONAL SYSTEMS AND ENVIRONMENTS; NEARSHORE PROCESSES. [R.A.D.]

Coastal plain An extensive, low-relief area that is bounded by the sea on one side and by some type of relatively high-relief province on the landward side. The geologic province of the coastal plain actually extends beyond the shoreline across the continental shelf. It is only during times of glacial melting and high sea level that much of the coastal plain is drowned. *See* CONTINENTAL MARGIN.

Coastal plains of the United States.

The coastal plain is a geologic province that is linked to the stable part of a continent on the trailing edge of a plate. The extent and nature of the coastal plains of the world range widely. Some are very large and old, whereas others are small and geologically young. For example, the Atlantic and Gulf coasts of the United States are among the largest in the world. (see illustration). In some areas the coastal plain is hundreds of kilometers wide and extends back about 100 million years. By contrast, local coastal plains in places like the east coast of Australia and New Zealand are only 1 or 2 million years old and extend only tens of kilometers landward from the shoreline.

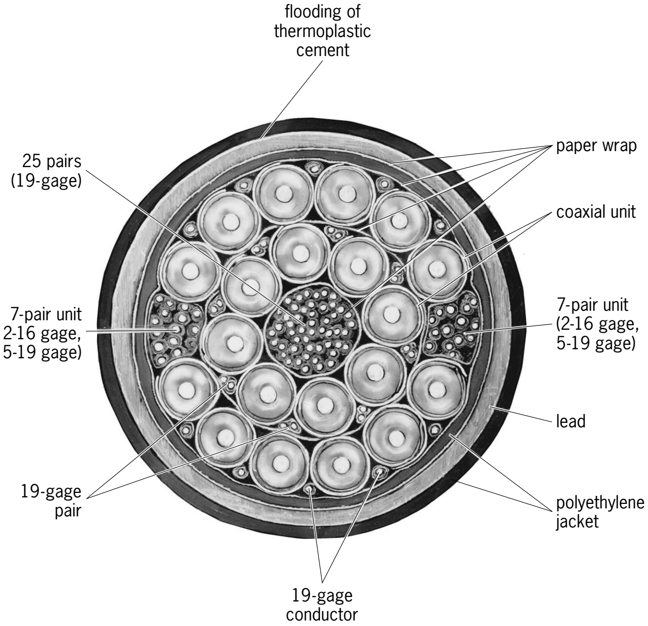
The typical character of a coastal plain is one of strata that dip gently and uniformly toward the sea. There may be low ridges that are essentially parallel to the coast and that have developed from erosion of alternating resistant and nonresistant strata. These strata are commonly a combination of mudstone, sandstone, and limestone, although the latter is typically a subordinate amount of the total. These strata resulted from deposition in fluvial, deltaic, and shelf environments as sea level advanced and retreated over this area. Coastal plain strata have been a source of considerable oil and gas as well as various economic minerals. Although the coastal plain province is typically stable tectonically, there may be numerous normal faults and salt dome intrusions. *See* COASTAL LANDFORMS; DELTA; GEOMORPHOLOGY; PLAINS. [R.A.D.]

Coati The name for three species of carnivorous mammals assigned to the raccoon family Procyonidae. The common or ring-tailed coati (*Nasua nasua*) ranges through the forests of Central and South America, the mountain coati (*Nasuella ovivacea*) is found only in South America, while *Nasua nelsoni* is confined to Cozumel Island in Central America.

The coatis are characterized by their elongated snouts, body, and tail, which is held erect when they walk (see illustration). They are adept at climbing trees in search of birds and lizards, and their diet also includes fruit, insects, and larvae. *Nasua nasua* roams in bands of females and young during the day in search of food. The males are excluded from the band except during the brief breeding season, when a single male is allowed to join. After mating, the male leaves and the female builds an isolated nest in a tree. Here, following a gestation period of 11 weeks, a litter of about five young are born and are cared for by the female away from the group. After about 1 month the female and her young rejoin the band. *See* CARNIVORA. [C.B.C.]

Common coati (*Nasua nasua*).

Coaxial cable An electrical transmission line comprising an inner, central conductor surrounded by a tubular outer conductor. The two conductors are separated by an electrically insulating medium which supports the inner conductor and keeps it concentric with the outer conductor. One version of coaxial cable has periodically spaced polyethylene disks supporting the inner conductor. This coaxial is a building block of multicoaxial cables used in L-carrier systems (see illustration). *See* TRANSMISSION LINES.



Construction of multicoaxial transmission line with twenty 0.375-in. (9.5-mm) coaxial units.

The symmetry of the coaxial cable and the fact that the outer conductor surrounds the inner conductor make it a shielded structure. At high frequencies, signal currents concentrate near the inside surface of the outer conductor and the outer surface of the inner conductor. This is called skin effect. The depth to which currents penetrate decreases with increasing frequency. Decreased skin depth improves the cable's self-shielding and increases transmission loss. This loss (expressed in decibels per kilometer) increases approximately as the square root of frequency because of the skin effect. *See* ELECTRICAL SHIELDING; SKIN EFFECT (ELECTRICITY).

Coaxial cables can carry high power without radiating significant electromagnetic energy. In other applications, coaxial cables carry very weak signals and are largely immune to interference from external electromagnetic fields.

A coaxial cable's self-shielding property is vital to successful use in broadband carrier systems, undersea cable systems, radio and TV antenna feeders, and community antenna television (CATV) applications.

Coaxial units are designed for different mechanical behavior depending upon the application. Widely used coaxials are classified as flexible or semirigid. [S.T.B.]

Cobalt A lustrous, silvery-blue metallic chemical element, Co, with an atomic number of 27 and an atomic weight of 58.93. Metallic cobalt was isolated in 1735 by the Swedish scientist G. Brandt, who called the impure metal cobalt rex, after the ore from which it was extracted. The metal was shown to be a previously unknown element by T. O. Bergman in 1780.

Cobalt is a transition element in the same group as rhodium and iridium. In the periodic table it occupies a position between iron and nickel in the third period. Cobalt resembles iron and nickel in both its free and combined states, possessing similar tensile strength, machinability, thermal properties, and electrochemical behavior. Constituting 0.0029% of the Earth's crust, cobalt is widely distributed in nature, occurring in meteorites, stars, lunar rocks, seawater, fresh water, soils, plants, and animals. *See* PERIODIC TABLE; TRANSITION ELEMENTS.

Cobalt and its alloys resist wear and corrosion even at high temperatures. The most important commercial uses are in making alloys for heavy-wear, high-temperature, and magnetic applications. Small amounts of the element are required by plants and animals. The artificially produced radioactive isotope of cobalt, ^{60}Co, has many medical and industrial applications.

Cobalt, with a melting point of 1495°C (2723°F) and a boiling point of 3100°C (5612°F), has a density (20°C; 68°F) of 8.90 g·cm^{-3}, an electrical resistivity (20°C) of 6.24 microhm·cm, and a hardness (diamond pyramid, Vickers; 20°C) of 225. It is harder than iron and, although brittle, it can be machined. The latent heat of fusion is 259.4 joules/g, and the latent heat of vaporization is 6276 J/g; the specific heat (15–100°C; 59–212°F) is 0.442 J/g · °C. Cobalt is ferromagnetic, with the very high Curie temperature of 1121°C (2050°F). The electronic configuration is $1s^2 2s^2 2p^6 3s^2 3p^6 3d^7 4s^2$. At normal temperatures the stable crystal form of cobalt is hexagonal close-packed, but above 417°C (783°F) face-centered cubic is the stable structure. Although the finely divided metal is pyrophoric in air, cobalt is relatively unreactive and stable to oxygen in the air, unless heated. It is attacked by sulfuric, hydrochloric, and nitric acids, and more slowly by hydrofluoric and phosphoric acids, ammonium hydroxide, and sodium hydroxide. Cobalt reacts when heated with the halogens and other nonmetals such as boron, carbon, phosphorus, arsenic, antimony, and sulfur. Dinitrogen, superoxo, peroxo, and mixed hydride complexes also exist. In its compounds, cobalt exhibits all the oxidation states from −I to IV, the most common being II and III. The highest oxidation state is found in cesium hexafluorocobaltate(IV), Cs_2CoF_6, and a few other compounds.

There are over 200 ores known to contain cobalt; traces of the metal are found in many ores of iron, nickel, copper, silver, manganese, and zinc. However, the commercially important cobalt minerals are the arsenides, oxides, and sulfides. Zaire is the chief producer, followed by Zambia. Russia, Canada, Cuba, Australia, and New Caledonia produce most of the rest. Zaire and Zambia together account for just over 50% of the world's cobalt reserves. Nickel-containing laterites (hydrated iron oxides) found in the soils of the Celebes, Cuba, New Caledonia, and many other tropical areas are being developed as sources of cobalt. The manganese nodules found on the ocean floor are another large potential reserve of cobalt. They are estimated to contain at least 400 times as much cobalt as land-based deposits. *See* MANGANESE NODULES.

Since cobalt production is usually subsidiary to that of copper, nickel, or lead, extraction procedures vary according to which of these metals is associated with the cobalt. In general, the ore is roasted to remove stony gangue material as a slag, leaving a speiss of mixed metal and oxides, which is then reduced electrolytically, reduced thermally with aluminum, or leached with sulfuric acid to dissolve iron, cobalt, and nickel, leaving metallic copper behind. Lime is used to precipitate iron, and sodium hypochlorite is used to precipitate cobalt as the hydroxide. The cobalt hydroxide can be heated to give the oxide, which in turn is reduced to the metal by heating with charcoal.

Cobalt ores have long been used to produce a blue color in pottery, glass, enamels, and glazes. Cobalt is contained in Egyptian pottery dated as early as 2600 B.C. and in the blue and white porcelain ware of the Ming Dynasty in China (1368–1644).

An important modern industrial use involves the addition of small quantities of cobalt oxide during manufacture of ceramic materials to achieve a white color. The cobalt oxide counteracts yellow tints resulting from iron impurities. Cobalt oxide is also used in enamel coatings on steel to improve the adherence of the enamel to the metal. Cobalt arsenates, phosphates, and aluminates are used in artists' pigments, and various cobalt compounds are used in inks for full-color jet printing and in reactive dyes for cotton. Cobalt blue (Thenard's blue), one of the most durable of all blue pigments, is essentially cobalt aluminate. Cobalt linoleates, naphthenates, oleates, and ethylhexoates are used to speed up the drying of paints, lacquers, varnishes, and inks by promoting oxidation. In all, about a third of the world's cobalt production is used to make chemicals for the ceramic and paint industries. *See* CERAMICS; DYE; INK; METAL COATINGS.

Cobalt catalysts are used throughout the chemical industry for various processes. These include hydrogenations and dehydrogenations, halogenations, aminations, polymerizations (for example, butadiene), oxidation of xylenes to toluic acid, production of hydrogen sulfide and carbon disulfide, carbonylation of methanol to acetic acid, olefin synthesis, denitrogenation and desulfurization of coal tars, reductions with borohydrides, and nitrile syntheses, and such important reactions as the Fisher-Tropsch method for synthesizing liquid fuels and the hydroformylation process. Cobalt catalysts have also been used in the oxidation of poisonous hydrogen cyanide in gas masks and in the oxidation of carbon monoxide in automobile exhausts. *See* CATALYTIC CONVERTER.

Although cobalt was not used in its metallic state until the twentieth century, the principal use of cobalt is as a metal in the production of alloys, chiefly high-temperature and magnetic types. Superalloys needed to stand high stress at high temperatures, as in jet engines and gas turbines, typically contain 20–65% cobalt along with nickel, chromium, molybdenum, tungsten, and other elements.

In parts of the world where soil and plants are deficient in cobalt, trace amounts of cobalt salts [for example, the chloride and nitrate of Co(II)] are added to livestock feeds and fertilizers to prevent serious wasting diseases of cattle and sheep, such as pining, a debilitating disease especially common in sheep. Symptoms of cobalt deprivation in animals include retarded growth, anemia, loss of appetite, and decreased lactation.

The principal biological role of cobalt involves corrin compounds (porphyrin-like macrocycles). The active forms contain an alkyl group (5′-deoxyadenosine or methyl) attached to the cobalt as well as four nitrogens from the corrin and a nitrogen from a heterocycle, usually 5,6-dimethylbenzimidazole. These active forms act in concert with enzymes to catalyze essential reactions in humans. However, the corrin compounds are not synthesized in the body; they must be ingested in very small quantities. Vitamin B_{12}, with cyanide in place of the alkyl, prevents pernicious anemia but is itself inactive. The body metabolizes the vitamin into the active forms. Although the cobalt in corrins is usually Co(III), both Co(II) and Co(I) are involved in enzymic processes. Roughly one-third of all enzymes are metalloenzymes. Cobalt(II) substitutes for zinc in many of these to yield active forms. Such substitution of zinc may account, in part, for the toxicity of cobalt. *See* ENZYME; VITAMIN B_{12}. [L.Ma.; P.A.Mar.]

Cobaltite A mineral having composition (Co,Fe)AsS. Cobaltite is one of the chief ores of cobalt. It crystallizes in the isometric system, commonly in cubes or pyritohedrons, resembling crystals of pyrite. There is perfect cubic cleavage. The luster is metallic and the color silver-white but with a reddish tinge. The hardness is 5.5 (Mohs scale) and the specific gravity is 6.33. Notable occurrences of cobaltite are at Skutterud, Norway; Lunaberg, Sweden; Ravensthorpe, Australia; and Cobalt, Ontario, Canada. *See* COBALT. [C.S.Hu.]

Coca Shrubs of the genus *Erythroxylum* in the coca family (Erythroxylaceae). The genus contains over 200 species, most in the New World tropics. Two species, *E. coca* and *E. novogranatense*, are cultivated for their content of cocaine and other alkaloids. Leaves of cultivated coca contain 14 alkaloids, chiefly cocaine, and significant amounts of vitamins and minerals. The cocaine content averages 0.5%, rarely exceeding 1.0%.

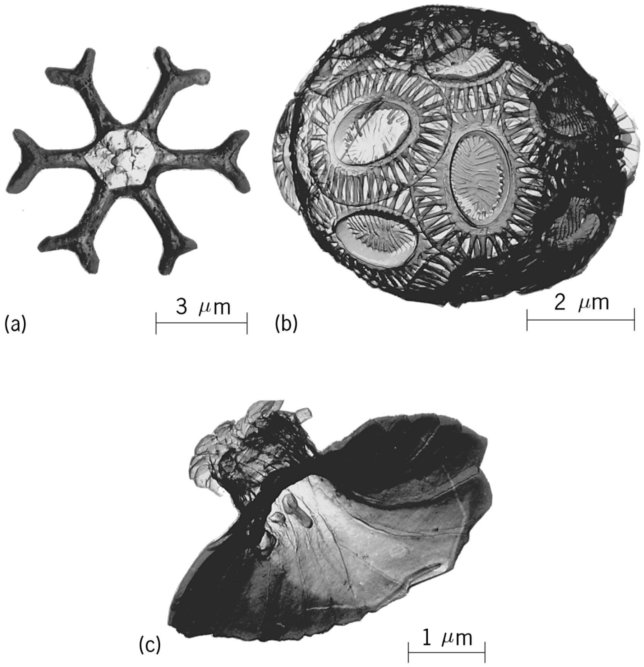
South American Indians "chew" coca as a mild stimulant by placing dried leaves in the mouth and masticating with various alkalies such as lime or plant ashes to promote the release of the alkaloids, which are swallowed. Coca is important in the folk medicine of Andean Indians, especially as a treatment for gastrointestinal disorders. It may regulate carbohydrate metabolism in a useful way and supplement an otherwise deficient diet. *See* COCAINE; COLA; LINALES. [A.T.W.]

Cocaine The principal alkaloid of coca leaves, a topical anesthetic and stimulant, and popular illicit drug. In 1884 C. Koller demonstrated cocaine's efficacy as an anesthetic in eye surgery, introducing the age of local anesthesia. For the next decade cocaine enjoyed the status of a wonder drug and panacea. It fell into disfavor with increasing reports of acute toxicity and long-term dependence. Today it is used as a topical anesthetic in the eye, nose, mouth, and throat; for injection anesthesia it has been replaced by synthetic drugs with fewer central nervous system effects. *See* COCA.

Cocaine increases heart rate and blood pressure and causes feelings of alertness and euphoria. It does not produce physical dependence, as alcohol and opiates do, but many people find it hard to use in a stable and moderate fashion if they have access to it in quantity. Although it is quite active orally, most users of illicit cocaine take it intranasally by snuffing; few inject it intravenously. Aside from local irritation of the nasal membranes, moderate users suffer few adverse effects. The soluble hydrochloride salt is the common form. Insoluble cocaine free base may be smoked, a practice that may be more harmful. *See* ALKALOID. [A.T.W.]

Coccidia A subclass of the class Telosporea. These protozoa are typically intracellular parasites of epithelial tissues in both vertebrates and invertebrates. The group is divided on the basis of life cycles into two orders, the Protococcida (in which there is only sexual reproduction) and the Eucoccida (in which there is both sexual and asexual reproduction). There are only a few species in Protococcida, and all are parasites in marine invertebrates. *See* EUCOCCIDA; PROTOCOCCIDA; TELOSPOREA. [E.R.B./N.D.L.]

Coccolithophorida A group of unicellular, biflagellate, golden-brown algae characterized by a covering of extremely small interlocking calcite plates called coccoliths. The Coccolithophorida are mainly classified by the shape of their coccoliths into two groups: the holococcoliths, with simple rhombic or hexagonal crystals arranged like a mosaic, and the heterococcoliths, with complex crystals arranged into boat, trumpet, basket, or collar-button shapes (see illustration). The Coccolithophorida are usually considered plants but possess also some animal characteristics. Botanists assign them to the class Haptophyceae of the phylum Chrysophyta, and zoologists to the class Phytamastigophorea of the phylum Protozoa. *See* PHYTAMASTIGOPHOREA; PROTOZOA.



Coccolithophorida: (*a*) *Discoaster*; (*b*) a coccosphere; (*c*) a heterococcolith. (*A. McIntyre, Lamont-Doherty Geological Observatory of Columbia University*)

Chiefly photosynthetic, although epiphytism, phagotrophism, and saprophytism have also been shown, the Coccolithophorida form a significant percentage of the nannoplankton of the tropic through subarctic-subantarctic waters of all oceans; a few brackish and fresh-water species also exist. Together with the diatoms they constitute the primary producers of the open ocean food chain. *See* PHYTOPLANKTON.

Coccoliths preserve well and have a fossil record dating back into the Jurassic, 180,000,000 years ago. Their long and involved evolutionary record makes them useful to geologists for dating ancient sediments. Because they live in surface waters, coccoliths are under direct climatic control. Thus many modern species with relatively long fossil records are excellent temperature indicators. *See* MICROPALEONTOLOGY. [A.McI.]

Cockroach Any of a group of insects (approximately 2500 species) of the family Blattidae, order Dictyoptera. This group is among the most primitive of the living and oldest of the fossilized insects, being found in abundance in the Carboniferous age. In general, cockroaches have a flat oval body, a darkened cuticle, and a thoracic shield which extends dorsally over the head. A pair of sensory organs, the whiplike antennae, are located on the head, and a much shorter pair of sensory organs, the cerci, are located at the end of the abdomen. Although some species are wingless, most have two pairs of wings but seldom fly. Most species are nocturnal and primarily live in narrow crevices and under stones and debris. Cockroaches are omnivorous, and a few species have adapted to the human environment, becoming household pests since they can chew foodstuffs, clothing, paper, and even plastic insulation. They also can emit a highly disagreeable odor.

Females deposit egg cases almost anywhere; each case contains several eggs from which the young nymphs hatch and go through several molts as they grow. At the final molt a winged, sexually mature adult will emerge. The time from egg to adult varies from species to species but can be longer than a year.

Cockroaches have been claimed as vectors for numerous human diseases. There is little evidence to support this claim; however, there is evidence that they can produce allergenic reactions in humans. Because of their large size, cockroaches have proved to be very useful animals for scientific research on general problems of insect behavior, physiology, and biochemistry. [C.R.F.]

Cocoa powder and chocolate Products derived from the seeds of the tropical tree *Theobroma cacao*, which grows within a narrow belt along both sides of the Equator. There are three basic varieties: Criollo, which was native to Central and South America; Forastero, which constitutes the bulk of the world supply and is mostly cultivated in West Africa and Brazil; and Trinitario, consisting of various hybrids. *See* Cacao.

The seeds, contained in pods which grow on the trunks and lower branches of the trees, are surrounded by a mucilaginous pulp. They are whitish in color and have no normal chocolate flavor. Each mature bean is about $\frac{3}{4}$–1 in. (2–2.5 cm) in length with an average weight not less than 0.04 oz (1 g). Good-quality beans show a brown or purplish-brown color and striations in the sliced cotyledon. Unfermented beans have a dense structure and slaty color. *See* Seed.

To develop a chocolate flavor, the beans are first subjected to a fermentation process. The next process is roasting in which the chocolate flavor is fully developed from the precursors, the shell loosened from the nib (cotyledon), and the moisture content reduced. After roasting, the shell is separated from the nib. The roasted nibs are ground at a temperature above the melting point of the cocoa butter constituent (93–95°F or 34–35°C) to produce a dark brown liquid called liquor, mass, or unsweetened chocolate. Finely ground liquor is the basis for manufacture of cocoa powder and chocolate.

To manufacture cocoa powder, liquor is subjected to hydraulic pressing, which separates some of the cocoa butter from the solid cocoa matters, resulting in compressed cocoa cakes. To make cocoa powder, these cakes are first mechanically broken into small pieces called kibbled cake and then put through pulverizers which, in conjunction with air separators, produce a very fine powder. Such cocoa powder is called natural cocoa. Commercial cocoa powders may have a residual cocoa butter content of 10–22%. They are used extensively as ingredients in cookies, biscuits, chocolate syrups and spreads, and vegetable fat coatings.

Dark, bitter, or sweet chocolate is manufactured from liquor (or nibs), sugar, and cocoa butter—the cocoa butter being obtained from cocoa powder manufacture. Cocoa butter is a very stable, natural fat; it melts just below body temperature and has a narrow melting range. It displays good contraction on solidifying from the liquid state, which enables chocolate to be molded into various shapes. Its melting properties impart good texture in the mouth and flavor release.

Milk chocolate is made from liquor, sugar, milk solids, and cocoa butter. The milk solids are derived from liquid milk, usually by a spray-drying process. Another milk product often used, called milk crumb, is prepared by concentrating and drying liquid milk in the presence of sugar and liquor. This gives a caramelized milk flavor. *See* Milk. [B.W.M.]

Coconut A large palm, *Cocos nucifera*, widely grown throughout the tropics and valuable for its fruit and fiber. Usually found near the seacoast, it requires high humidity, abundant rainfall, and mean annual temperature of about 85°F (29°C). Southern Florida, with mean temperature of 77°F (25°C), is at the limit of successful growth.

The fruit, 10 in. (25 cm) or more in length, is ovoid and obtusely triangular in cross section. The tough, fibrous outer husk encloses a spherical nut consisting of a hard, bony shell within which is a thin layer of fleshy meat or kernel. The meat is high in oil and protein and, when dried, is the copra of commerce.

Although many trees grow without special care, the crop lends itself to plantation culture with control of weeds, fertilization, and protection from diseases, insects, and animal pests. Palms begin to bear nuts the sixth year after planting and reach full bearing about the eighth year. Individual nuts mature about a year after blossoming and normally fall to the ground.

The oil from the dried coconut meats (copra) is widely used for margarine, soap, and industrial purposes. High-quality copra may be shredded for confectionery and the baking trade. The residue, after oil removal, is used for animal feed. Coconut husks are an important source of fiber called coir. Various grades of coir are used for ropes, mats and matting, and upholstery filling. *See* Coir.

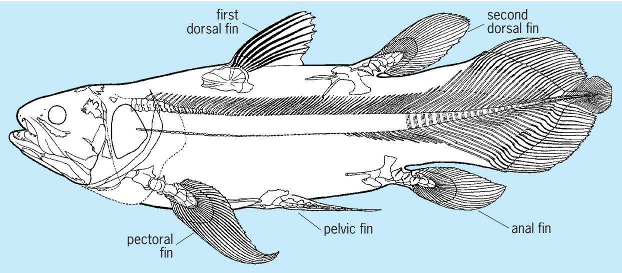
The coco palm is the most useful of all tropical plants to the native population. An important source of food and drink, it also furnishes building material, thatch, hats, dishes, baskets, and many other useful items. *See* Arecales. [L.H.MacD.]

Codfish Fish of a subfamily of the Gadidae in the order Gadiformes. Important commercially, these fish are found in cold waters, such as the Baltic and the North Atlantic. *Gadus morhua* is extensively fished off the Newfoundland banks and a circumpolar species, *Boreogadus saida*, the Arctic cod, is found around the ice pack during the summer. *G. macrocephalus*, a related species, occurs in the northern Pacific.

The cod is covered with cycloid scales, has a barbel under the chin, and has pelvic fins on the throat; there are two anal and three dorsal fins. Codfish average about 3 ft (0.9 m) in length and weigh 10–35 lb (4.5–15.7 kg). They live at depths of 100–1500 ft (30–450 m), where they feed on mollusks, small fish, crustaceans, and worms. Spawning occurs from January on to spring. The livers are processed for cod liver oil, which is rich in vitamins, and the swim bladder is made into isinglass. *See* Gadiformes. [C.B.C.]

Coelacanthiformes An order of lobefin fishes placed in the subclass Crossopterygii and well known as fossils. Members are easily recognized by the two dorsal fins, by the paired pectoral and pelvic fins, and the anal fin, and by their symmetrical caudal fin with small central prolongation (see illustration). The only living fish with such features is *Latimeria chalumnae*; it is also the only extant fish with an intracranial joint, which otherwise occurs only in fossil rhipidistians. In 1952 its habitat was discovered to be the deep waters around the Comoro Islands. A new population of *Latimeria* was discovered in 1998 north of Sulawesi in the Indonesian archipelago.

The Coelacanthiformes (or Actinistia) are the only fishes with a special rostral organ, a deep postcoronoid in the lower jaw, a tandem double articulation of the lower jaw, a postspiracular bone, and an additional bone, the extracleithrum, in the shoulder girdle. Like lungfish, coelacanths lack the marginal upper jaw bone, the maxilla, and possess a short dentary. Except for two Devonian (*Miguashaia* and *Gavinia* with heterocercal tail) and a Carboniferous (*Allenypterus* with diphycercal tail) genus, coelacanths have a caudal fin with equal-sized upper and lower



Overall shape and internal structures of *Latimeria chalumnae*.

lobe of unbranched fin rays separated by an axial notochordal lobe (triphycercal tail).

Latimeria shows sexual dimorphism; the female is longer than the male. Reproduction is by internal fertilization even though the male has no intermittent organ. *Latimeria* has the largest eggs of any bony fish. It is ovoviviparous; up to 30 developing juveniles have been found in one female.

Coelacanths are known since the Middle Devonian. They reach high diversity in the Early Triassic and Late Jurassic. Coelacanths acquired their common structure in the Carboniferous. The number of morphological changes is minor thereafter. There is no fossil record for the last 80 million years. Most fossil records refer to marine forms; nevertheless, some coelacanths were able to enter fresh water. *See* FOSSIL.

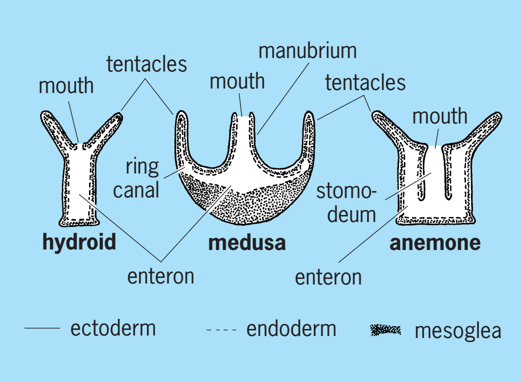
The phylogenetic position of the coelacanthiforms within sarcopterygian fishes is debated. Within extant fishes, they may be closer to tetrapods than to the lungfish, or vice versa. The living coelacanth is not, as often written, a survivor of human ancestry. *See* CROSSOPTERYGII; OSTEICHTHYES; SARCOPTERYGII. [H.P.S.]

Coelenterata That group of the Radiata whose members typically bear tentacles and possess intrinsic nematocysts. The name Cnidaria is also used for this phylum and is preferred by some because the name Coelenterata, as first used, included the sponges (Porifera) and the comb jellies (Ctenophora), as well as the animals called coelenterates. *See* CTENOPHORA; PORIFERA.

The coelenterates are mainly marine organisms and are best known as jellyfish or medusae, sea anemones, corals, the Portuguese man-of-war, small polypoid forms called hydroids, and the fresh-water hydras. Taken together, the phylum is divisible into three classes as follows: (1) Hydrozoa, the hydroids, hydras, and hydrozoan or craspedote jellyfish (hydromedusae); (2) Scyphozoa, the acraspedote jellyfish; and (3) Anthozoa, the sea anemones, corals, sea fans, sea pens, and sea pansies. *See* ANTHOZOA; HYDROZOA; SCYPHOZOA.

It is convenient to recognize two basic body forms in this phylum, the polyp and the medusa, into which all coelenterates can be classified. The polyp and the medusa, however, have many features in common (see illustration).

The polyp is a radially, biradially, or radiobilaterally symmetrical individual having a longitudinal oral-aboral axis and is usually sessile. The mouth is at the free end and is surrounded by one to many whorls or sets of tentacles which may be hollow or solid. The aboral end is commonly developed as an adhesive device for attachment and is conveniently referred to as a base. The central body cavity is the gastrovascular cavity, also called the enteron or coelenteron.



Comparison of hydroid polyp, medusa (inverted), and anthozoan polyp. (*After T. I. Storer and R. L. Usinger, General Zoology, 3d ed., McGraw-Hill, 1957*)

The medusa is a tetramerously or polymerously radial individual and is free-swimming. The body is usually bell- or bowl-shaped with the mouth suspended in the center of the underside of the bell on a stalk. Instead of directly surrounding the mouth as in the polyp, the tentacles are located at the margin of the bell. The outer or aboral part of the bell is recognized as the exumbrella and the under or oral part as the subumbrella. The mouth leads to the central stomach which in turn gives rise to four or more radial canals. These radial canals run through the umbrella, on the subumbrellar side, and commonly lead to a ring canal at the margin which is continuous around the margin.

The unique and most distinctive feature of coelenterates is the possession of intracellular, independent effector organelles called nematocysts, but also known as stinging cells or nettle cells. A coiled thread tube in each cell may be rapidly everted under proper stimulation and used for food gathering and for defense against predators, intruders, or enemies. Nematocysts are produced within cells called cnidoblasts. The morphologically simplest coelenterates, the Hydrozoa, have nematocysts limited to their outer epidermis whereas the more complex Scyphozoa and Anthozoa bear nematocysts in both the outer epidermis and inner gastrodermis.

The body systems of coelenterates may be divided into the following categories for the purpose of description: epithelial, nervous, muscular, mesogleal, skeletal, digestive, and reproductive. There is no analog of a circulatory system and the functions of respiration and excretion are carried out by each cell.

The epidermis is usually ciliated in polyps so that the net effect of the ciliary beat is to move material away from the mouth toward the margin of the oral disk and toward the tips of the tentacles. The gastrodermis, or inner epithelial layer, is also abundantly ciliated. These cilia move food materials about within the gastric cavity and circulate the contained water. One of the prime functions of the gastrodermis is digestion, and essentially every cell of the gastrodermis is capable of ingesting small food particles.

The coelenterate nervous system can be defined as consisting basically of an unpolarized network of bipolar and multipolar neurons. The nervous system is subepithelial in location, both subepidermal and subgastrodermal, and may in some forms consist of two networks in only limited contact with one another and with each specialized either for rapid through conduction or for slower, more general spread of conduction.

The muscular system varies considerably among coelenterates. In simple polyps there is an epidermal, longitudinal muscle sheath of epitheliomuscular cells and a gastrodermal, circular sheath. In medusae and in members of the classes Scyphozoa and Anthozoa, the musculature has become separated from the epithelial tissue as a subepithelial system. In many anthozoans a large sphincter muscle develops in the gastrodermal surface, at the top of the column. In medusae, where the primary swimming muscles are subumbrellar, large muscle bands, both circular and radial, develop.

The mesogleal system is represented by a layer between epidermis and gastrodermis which varies from the thin structureless cementing layer of hydrozoan polyps to the highly complex cellular, fibrous, gelatinous matrix of the scyphomedusans and anthozoans. Where the mesoglea is well developed, as in medusae and some anthozoans, it serves as a type of internal skeleton, against which muscles may act.

Two different types of skeleton occur in the phylum. The first is of an internal nature and is either the mesoglea against which the muscles operate or the contained hydroskeleton of most polyps. Of a quite different nature is the exoskeleton, seen in most hydrozoan polyps, some scyphozoan polyps, and corals, which supports and protects the organisms. Still another skeletal type known in the coelenterates is an axial skeleton composed of sclerified proteins. It is exceedingly tough and flexible and is characteristic of such anthozoans as gorgonians.

The digestive system in coelenterates is developed as a function of the gastrodermis. In hydrozoans, both polyps and medusae, glandular, enzyme-producing cells are abundant throughout the gastrodermis. These cells secrete proteolytic enzymes into the coelenteron which reduce food objects to a fine particulate state. In scyphozoans and anthozoans, although glandular cells are common throughout the gastrodermis, they tend to be most abundant along the free edges of the mesenteries of anthozoans and on the gastric tentacles of scyphozoans. These glandular cells are also the source of proteolytic enzymes which act in the extracellular environment of the coelenteron.

The phylum is characterized by its carnivorous diet, made possible first by the possession of nematocysts which make the predaceous habit successful. After food has been trapped, movements of the tentacles carry it to the mouth, where with the help of ciliary and muscular devices the food is moved to the coelenteron. Here extracellular proteases prepare the way for final intracellular digestion. No herbivorous coelenterates are known.

The reproductive system of coelenterates consists of specialized areas of epithelia, the gonads, which periodically appear and produce gametes. There are no ducts for the sex products or any accessory sexual structures. Fertilization usually occurs in the water surrounding the animal, although a few coelenterates have their eggs fertilized in place and may then brood their young.

The ability to regenerate lost parts is characteristic of coelenterates. Pieces cut from almost any part of polyps will in time grow into new polyps. The regenerative powers of medusae are much less well developed, and not only will the excised piece not develop but it may not even be replaced by the medusa. Gradients of regenerative ability in polyps exist with the ability for a piece to reconstitute a new whole organism decreasing from the mouth to the base. *See* REGENERATION (BIOLOGY). [C.H.]

The Coelenterata have a long and impressive fossil record stretching from the present into the Precambrian, about 700,000,000 years ago. Thus, the known duration of this phylum equals or exceeds that of other animal phyla. Forms with skeletons, primarily the Conulata, Tabulata, Rugosa, and Scleractinia, have left fairly complete fossil records, whereas soft-bodied forms, such as most of the Hydrozoa, Scyphomedusae, and Alcyonaria, are represented by very few fossils. [C.H.St.]

Coelom The mesodermally lined body cavity of most animals above the flatworms and nonsegmented roundworms. Its manner of origin provides one basis for classifying the major higher groups.

Annelids, arthropods, and mollusks have a coelom which develops from solid mesodermal bands. Within the trochophore larva of annelids, a single pole cell proliferates two strips of mesoblast lying on either side of the ventral midline. These bands subdivide transversely into bilateral solid blocks, the somites. Each somite then splits internally to form a hollow vesicle, the cavity of which is the coelom. The mollusks also form bands of mesoderm from a single pole cell, but these bands do not segment. They split internally to form single right and left coelomic sacs, but the cavities are soon reduced and the surrounding mesoblast disperses as separate cells, many of which become muscle. The only remnants of the coelom in the adult are the pericardial cavity and the cavities of the gonads and their ducts. In arthropods paired bands of mesoblast may proliferate from a posterior growth center or may separate inward from a blastoderm, a superficial layer of cells, on the ventral surface of the egg. These bands divide into linear series of somites which then hollow out. Their cavities represent the coelom.

Echinoderms and chordates constitute a second major group, characterized by the origin of the coelom from outpocketings of the primitive gut wall. In echinoderms one pair of bilateral pouches evaginates and separates from the archenteron or primitive digestive cavity. Each pouch constricts into three portions, not homologous to the metameres of other animals.

The protochordates of the groups Hemichordata and Cephalochordata have three coelomic pouches formed by separate evaginations of the archenteral roof. In hemichordates the head cavity remains single as the cavity of the proboscis and has a pore to the exterior on each side. The second pouches form cavities within the collar and also acquire external pores. The third pair is contained within the trunk and forms the major perivisceral cavity.

In cephalochordates the head cavity divides into lateral halves. The left side communicates, by a pore, to an ectodermal pit called the wheel organ. The second pair of pouches forms the pair of mesoblastic somites, and the third pouches subdivide transversely to give rise to the remainder of the linear series of somites. The upper or myotomic portion of each somite remains metameric and forms the segmental muscles. As it enlarges, the coelomic space is displaced ventrally and expands above and below the gut to form the perivisceral cavities and mesenteries, as described for annelids.

In vertebrates the mesoderm arises as a solid sheet from surface cells that have been involuted through the blastopore. Lateral to the notochord, beginning at about the level of the ear, the mesoderm subdivides into three parts: (1) the somites; (2) the nephrotomic cord, temporarily segmented in lower vertebrates, which will form excretory organs and ducts; and (3) the unsegmented lateral plate. The coelom arises as a split within the lateral plate. *See* ANIMAL KINGDOM; GASTRULATION. [H.L.H.]

Coelomycetes Mitosporic or anamorphic (asexual or imperfect) fungi (Deuteromycotina) with sporulation occurring inside fruit bodies (conidiomata) that arise from a thallus consisting of septate hyphae. About 1075 genera containing more than 10000 species are recognized.

The Coelomycetes, like other groups of deuteromycetes, is artificial, comprising almost entirely anamorphic fungi of ascomycete affinity. Some are known anamorphs of Ascomycotina, although there are a few (*Fibulocoela, Cenangiomyces*) with Basidiomycotina affinities because they have clamp connections or dolipore septa. Taxa are referred to as form genera and form species because the absence of a teleomorph (sexual or perfect) state means that they are classified and identified by artificial rather than phylogenetic means. The unifying feature of the group is the production of conidia inside cavities lined by fungal tissue, or by a combination of fungal and host tissue which constitutes the conidioma. *See* ASCOMYCOTA; BASIDIOMYCOTA.

Differences in conidiomatal structure traditionally have been used to separate three orders: the Melanconiales, the Sphaeropsidales, and the Pycnothyriales. However, differences in the ways that conidia are produced are now used in classification and identification.

Coelomycetes are known mainly from temperate and tropical regions. They grow, reproduce, and survive in a wide range of ecological situations and can be categorized as either stress-tolerant or combative species. They are commonly found in and recovered from soils, leaf litter and other organic debris from both natural and manufactured sources (as biodeteriogens and biodegradative organisms), and saline and fresh water; and on other fungi and lichens. Several are of medical importance, associated with acute conditions in humans and animals, often as opportunistic organisms causing infection in immunocompromised patients. Coelomycetes are consistently isolated from or associated with disease conditions in all types of vascular plants, often in association with other organisms. *See* PLANT PATHOLOGY. [B.C.S.]

Coenopteridales True ferns which span the Late Devonian through Permian time between the recognizable beginnings of fernlike morphology and the earliest-appearing extant filicalean families (Gleicheniaceae, Osmundaceae). A true fern is a relatively advanced type of vascular land plant with distinct stem, fronds, roots, and foliar-borne annulate sporangia.

Coenopterid ferns are mostly small and simple in contrast to late Paleozoic tree ferns of the Marattiales.

There are two major distinct groups. Zygopterid ferns are the most ancient and diverse, and apparently a dead-end evolutionary line; they differ the most from other ferns. Coenopterid ferns are usually placed in the Anachoropteridaceae and Botryopteridaceae, or in one of several extinct families assigned to the Filicales. Coenopterid ferns *sensu stricto* are probably ancestral to, and consequently form an imperceptible transition with, the Filicales.

The Zygopteridaceae appear in Late Devonian time, the Botryopteridaceae in Visean (Mississippian), the Anachoropteridaceae in the lower Westphalian A (Pennsylvanian), and all families extend into the Permian. *See* PALEOBOTANY. [T.L.P.]

Coenothecalia An order of the class Alcyonaria. The Coenothecalia have no spicules but form colonies with a massive skeleton composed of fibrocrystalline aragonite fused into lamellae. The skeleton is perforated by both numerous wide cylindrical cavities occupied by the polyps, and narrow ones containing the solenial systems. The order includes a few genera, of which *Heliopora*, or the blue coral, is often found on coral reefs. *See* ALCYONARIA. [K.At.]

Coenurosis The infection by the larval stage of several species of *Taenia* from canids, such as *T. multiceps, T. serialis*, and *T. brauni*. It is rare in humans. Symptoms are the result of toxic and allergenic metabolites and pressure effects. Surgery may be attempted; chemotherapy may be effective, but secondary effects still render a poor prognosis. Herbivores feeding on grass contaminated by the parasite's eggs also develop coenurosis. If the central nervous system is involved (as is frequent in sheep) neurological signs appear and the animal staggers and circles. Economic losses in sheep-raising regions due to coenurosis are considerable. The disease could be controlled by treatment of shepherd dogs. *See* CYCLOPHYLLIDEA. [J.F.M.]

Coenzyme An organic cofactor or prosthetic group (nonprotein portion of the enzyme) whose presence is required for the activity of many enzymes. The prosthetic groups attached to the protein of the enzyme (the apoenzyme) may be regarded as dissociable portions of conjugated proteins. Neither the apoenzyme nor the coenzyme moieties can function singly. In general, the coenzymes function as acceptors of electrons or functional groupings, such as the carboxyl groups in α-keto acids, which are removed from the substrate. *See* PROTEIN.

Well-known coenzymes include the pyridine nucleotides, nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP); thiamine pyrophosphate (TPP); flavin mononucleotide (FMN) and flavinadenine dinucleotide (FAD); iron protoporphyrin (hemin); uridine diphosphate (UDP) and UDP-glucose; and adenosine triphosphate (ATP), adenosine diphosphate (ADP), and adenosine monophosphate (AMP). Coenzyme A (CoA), a coenzyme in certain condensing enzymes, acts in acetyl or other acyl group transfer and in fatty acid synthesis and oxidation. Folic acid coenzymes are involved in the metabolism of one carbon unit. Biotin is the coenzyme in a number of carboxylation reactions, where it functions as the actual carrier of carbon dioxide. *See* ADENOSINE DIPHOSPHATE (ADP); ADENOSINE TRIPHOSPHATE (ATP); BIOTIN; ENZYME; HEMOGLOBIN; NICOTINAMIDE ADENINE DINUCLEOTIDE (NAD); NICOTINAMIDE ADENINE DINUCLEOTIDE PHOSPHATE (NADP); URIDINE DIPHOSPHOGLUCOSE (UDPG). [M.B.McC.]

Coesite Naturally occurring coesite, a mineral of wide interest and the high-pressure polymorph of SiO_2, was first discovered and identified from shocked Coconino sandstone of the Meteor Crater in Arizona in 1960. Since then coesite has been identified from the Wabar (meteorite) Crater in Saudi Arabia, from the Ries Crater in Bavaria in southern Germany, from the Lake Bosumtwi Crater in Ashanti, Ghana, Africa, and from Lake Mien in Sweden. Coesite has also been identified from some Thailand tektites which are considered to have been formed also by an impact cratering process. The finding of natural coesite elevates it as a true mineral species. Because it requires a unique physical condition, extremely high pressure, for its formation, its occurrence is diagnostic of a special natural phenomenon, in this case, the hypervelocity impact of a meteorite. *See* METEORITE.

Synthetic coesite was first produced in the laboratory by L. Coes, Jr., as a chemical compound at pressures of about 35 kilobars (3.5×10^9 pascals) in the temperature range of 500–800°F (246–404°C). Coesite has also been found in synthetic diamonds and has been formed by transformation from alpha quartz by the application of shearing stress. *See* DIAMOND.

Coesite occurs in grains that are usually less than 0.0002 in. (5 micrometers) in size and are generally present in small amounts. The properties of the mineral are known mainly from studies of synthesized crystals. It is colorless with vitreous luster and has no cleavage. It has a specific gravity of 2.915 ± 0.015 and a hardness of about 8 on Mohs scale.

Coesite has as yet no evident commercial use and therefore has no obvious economic value. As a stepping-stone in scientific research, it serves in at least two ways: where it occurs naturally, coesite is diagnostic of a past history of high pressure; the occurrence of coesite from Meteor Crater clearly suggests that shock as a process can transform a low-density ordinary substance to one of high density and unique properties. Coesite has been found in materials ejected from craters formed by the explosion of 500,000 tons (450,000 metric tons) of TNT. Research on the occurrence of coesite from rocks deformed by other energy sources, such as volcanic explosions and deep-seated tectonic movement, is continuing. The study of coesite and craters may be useful in understanding the impact craters on the Earth as well as those on the Moon. [E.C.T.C.]

Coffee A tropical evergreen shrub or small tree of the genus *Coffea* (Rubiaceae), a native of northeast Africa and adjacent southwest Asia. The beverage known as coffee is made by the hot-water extraction of solubles from the ground roasted beans (seeds) of the shrub. *Coffea* grows mainly between the Tropic of Cancer and Tropic of Capricorn at elevations of 2000–6000 ft (600–1800 m) above sea level, at temperatures near 70°F (21°C), and with annual rains near 60 in. (150 cm).

Annual international commerce is about 75 million bags (standard of 130 lb or 60 kg per bag) of green coffee beans, that is, coffee beans that have been cultivated, harvested, and are ready for commercial processing. The supply generally is a third each from Brazil, Africa, and all other countries. The United States and Europe consume 85% of all world exports. Coffee beverage has no nutritive value and is consumed for its flavor and stimulating effects. The stimulating ingredient in coffee is caffeine. The two main coffee varieties are Arabica with about 1.1% caffeine and Robusta with 2.2%. *See* CAFFEINE.

The coffee plant is a shrub or relatively small tree, often controlled to a height of 15–18 ft (4.5–5.5 m). *Coffea arabica* (milds) accounts for 69% of world production; *C. canephora* (robustas), 30%; and all others, 1%. Each species includes several varieties.

After the spring rains, the plant produces white flowers. About 6 months later the flowers are replaced by fruit the size of a small cherry. The cherries can be selectively picked to harvest only ripe ones, or strip-picked to yield mostly ripe but also some over- or underripe fruit. The green coffee beans are the two halves of the seed derived from the processed cherries.

Coffee cherries are processed by either dry or wet methods. In the dry method, the cherries from strip picking are spread on open drying ground and turned frequently to permit thorough drying by the sun and wind. Some producing areas use hot air, indirect steam, and other machine-drying devices. When the coffee cherries are thoroughly dry, they are transferred to hulling machines that remove the skin, pulp, parchment shell, and silver skin in a single operation. In the wet method, freshly picked ripe coffee cherries are fed to a tank for initial washing and removal of stones and other foreign material. The cherries are then transferred to depulping machines that remove the outer skin and most of the pulp, although some pulp mucilage clings to the parchment shells that encase the coffee beans. This is removed in fermentation tanks, usually containing water. The beans are then dried, either in the sun or in mechanical dryers. After drying, the coffee is further processed in machines that remove silver skins, producing green coffee beans. The coffee beans are then machine graded. After processing, the green beans have 10–12% moisture and maintain acceptable quality for about a year.

A series of basic bean processing steps is required to produce the major types of commercial coffee products. First, the green beans are weighed and cleaned, and then they are stored in silos, each containing a single bean type. Green coffee beans to be used for decaffeinated coffee products are processed separately to remove the required amount of caffeine (usually 97% in the United States) and then stored in special silos before further processing.

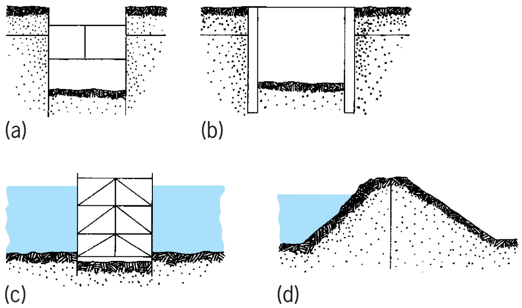
Roasting and grinding are key steps in producing all coffee products. The roasting step is the most important operation in defining the final product characteristics. Roasting is usually conducted by use of hot combustion gases in rotating cylinders or fluidized-bed systems. When the bean temperature reaches 375–475°F (190–246°C), roasting is terminated by rapidly adding a water quench. The final roast temperature is the critical control point that fixes the flavor and color of the product, and it must be consistent for good quality control. The quenched beans are air cooled and conveyed to storage bins for moisture and temperature equilibration prior to grinding. Residual foreign material (mostly stones) that has passed through the initial cleaning step is removed in transit to the storage bins by means of a high-velocity air lift, which leaves the heavier debris behind. Grinding of the roasted coffee beans is tailored to the requirements of the intended beverage preparation. For example, only coarse cracking of the beans is needed for instant coffee, whereas finer grinds are required for packaged roast and ground coffee. The most commonly used grinder is a multistep steel roll mill. Particle size is controlled by regulation of roll separation.

Instant coffee comprises the dried solids made from water extraction of the soluble solids in roasted and partially ground (cracked) coffee. The extraction process follows the same principle as home brewing using a filter-drip percolator, except that it is much more efficient and results in very high solid-extraction yields. The coffee extract is concentrated from about 20–35% to 50% by using multiple-effect vacuum evaporators or freeze concentration, or a combination of both. The flavor of the final dry product can be enhanced by recovering the aroma and flavor compounds prior to, or as part of, the concentration process and then introducing these to the concentrated extract just before drying. The method of drying defines the instant coffee as either spray dried or freeze dried. Spray drying involves spraying the concentrated aroma-enhanced extract into a concurrently flowing stream of hot combustion gases. Freeze drying uses special high-vacuum equipment to remove water from the frozen extract by sublimation. Freeze-dried coffee is more expensive to produce and requires a much higher investment than the spray-dried product. *See* DRYING; EXTRACTION.

Decaffeinated coffees represent about 18% of the total coffee consumption in the United States. Decaffeinated coffee was commercially developed in Europe about 1900. The early process involved direct contact of water-moistened beans with a solvent. The principle of moisturizing green coffee before decaffeination remains a key process step for all decaffeination processes, because it facilitates transport of caffeine through the cell walls. A water extraction process was developed in the United States in 1943 which provided a decaffeinated coffee with improved flavor and with very low solvent residues. Natural decaffeination processes were invented and commercialized from the mid-1970s through the 1980. Three processes for natural decaffeinated products are commercially available. The water process is in many ways the same as the earlier water extraction process. However, instead of using a solvent to remove caffeine from a green coffee extract, the extract is decaffeinated by adsorption using activated carbon. The supercritical CO_2 processes use carbon dioxide (CO_2) above its critical temperature (supercritical CO_2) to remove caffeine from green coffee beans. Other so-called natural processes are similar to older solvent processes but use solvents (such as ethyl acetate) considered to be natural, based on the designation "generally regarded as safe" (GRAS) by the U.S. Food and Drug Administration. *See* ACTIVATED CARBON; ADSORPTION. [F.Kr.]

Cofferdam A temporary, wall-like structure to permit dewatering an area and constructing foundations, bridge piers, dams, dry docks, and like structures in the open air. A dewatered area can be completely surrounded by a cofferdam structure or by a combination of natural earth slopes and cofferdam structure. The type of construction is dependent upon the depth, soil conditions, fluctuations in the water level, availability of materials, working conditions desired inside the cofferdam, and whether the structure is located on land or in water (see illustration). An important consideration in the design of cofferdams is the hydraulic analysis of seepage conditions, and erosion of the bottom when in streams or rivers.

Where the cofferdam structure can be built on a layer of impervious soil (which prevents the passage of water), the area within the cofferdam can be completely sealed off. Where the soils are pervious, the flow of water into the cofferdam cannot be completely stopped economically, and the water must be pumped out periodically and sometimes continuously.



Types of cofferdams for use on land: (*a*) cross-braced sheet piles, (*b*) cast-in-place concrete cylinder; and in water: (*c*) cross-braced sheet piles, (*d*) earth dam.

A nautical application of the term cofferdam is a watertight structure used for making repairs below the waterline of a vessel. The name also is applied to void tanks which protect the buoyancy of a vessel. [E.J.Q.]

Cogeneration The sequential production of electricity and thermal energy in the form of heat or steam, or useful mechanical work, such as shaft power, from the same fuel source. Cogeneration projects are typically represented by two basic types of power cycles, topping or bottoming. The topping cycle has the widest industrial application.

The topping cycle utilizes the primary energy source to generate electrical or mechanical power. Then the rejected heat, in the form of useful thermal energy, is supplied to the process. The cycle consists of a combustion turbine-generator, with the turbine exhaust gases directed into a waste-heat-recovery boiler that converts the exhaust gas heat into steam which drives a steam turbine, extracting steam to the process while driving an electric generator. This cycle is commonly referred to as a combined cycle arrangement. Combustion turbine-generators, steam turbine-generator sets, and reciprocating internal-combustion-engine generators are representative of the major equipment components utilized in a topping cycle. *See* GENERATOR; STEAM TURBINE; TURBINE.

A bottoming cycle has the primary energy source applied to a useful heating process. The reject heat from the process is then used to generate electrical power. The typical bottoming cycle directs waste heat from a process to a waste-heat-recovery boiler that converts this thermal energy to steam which is supplied to a steam turbine, extracting steam to the process and also generating electrical power. *See* ELECTRIC POWER GENERATION.

Cogeneration for building and district space heating and cooling purposes consists of producing electricity and sequentially utilizing useful energy in the form of steam, hot water, or direct exhaust gases. The two most common heating, ventilating, and air-conditioning cycles are the vapor compression cycle and the absorption cycle. *See* AIR CONDITIONING; CENTRAL HEATING AND COOLING; COMFORT HEATING; DISTRICT HEATING. [C.Bu.]

Cognition The internal structures and processes that are involved in the acquisition and use of knowledge, including sensation, perception, attention, learning, memory, language, thinking, and reasoning. Cognitive scientists propose and test theories about the functional components of cognition based on observations of an organism's external behavior in specific situations.

Cognition throughout life can be broadly described as an interaction between knowledge-driven processes and sensory processes; and between controlled processes and automatic processes. Over time, there is a trade-off between the amount of surface information that is retained in the internal representation of objects or events (bottom-up processing) and the amount of meaning that is incorporated (top-down processing). Following exposure to a stimulus, a sensory representation (sometimes called an image, icon, or echo) is constructed that encodes nearly all the surface characteristics of the stimulus (for example, color, shape, location, pitch, and loudness). The information is short lived, lasting less than a second. Much evidence suggests that extraction of information from this representation takes place in two stages, a feature analysis stage and an object recognition stage. It is during the latter stage that attention (controlled processing) and previous knowledge come into play. *See* MEMORY; PERCEPTION.

Conceptual knowledge is needed to classify objects and events in the world. Some aspects of conceptual knowledge are innate or emerge very early in development, while others are acquired through learning and inference.

A primary cognitive function of all social species is communication, which can be accomplished by a combination of vocal, gestural, and even hormonal signals. Of all species on Earth, only humans have developed a communication system based on abstract signs. This evolutionary development is closely tied to the greater reasoning capacity of humans as well. All reasoning can be broadly described as pattern recognition and search. Conceptual knowledge base are searched for relevant information in order to draw a conclusion, solve a problem, or guide behavior. Thinking often takes the form of a chain of associations among concepts in long-term memory, with one thought retrieving others to which it is related. The most common reasoning strategies include direct retrieval, imaging, means-ends analysis, analogy, classification, deduction, and formal procedures.

Reasoning by direct retrieval involves retrieving a known fact from memory to solve a problem. Reasoning imagistically involves constructing or retrieving images from conceptual memory and examining or manipulating them to solve a problem. For example, individuals reason imagistically when they determine how many windows there are in their living rooms by retrieving an image of the room and counting the windows in the image.

Means-ends analysis is typically employed when solving problems in unfamiliar domains. When a solution is not immediately apparent, reasoners typically compare the goal to the current situation and select means with which to reduce the differences between the two situations.

The restructuring of a problem representation that allows an available means to be used in a novel way or a seemingly unrelated bit of knowledge to be accessed to solve the probem is called insight.

Reasoning by analogy is used when a current situation allows an individual to recall another, similar situation that has a known solution or other information relevant to the task at hand. It is a technique that is powerful but error prone.

Reasoning by classification involves making inferences about an object or event based on its category membership.

Deductive reasoning involves drawing a conclusion based on its logical relation to one or more premises. A second common use for deduction is testing hypotheses.

Formal procedures for reasoning and for solving problems include logic, mathematics, probability theory and statistics, and scientific investigation. Understanding of the behavior and properties of physical, biological, and cognitive systems has been greatly enhanced through the use of these techniques. *See* PSYCHOLINGUISTICS.

By using noninvasive techniques such as positron emission tomography (PET scan), magnetic resonance imaging, electrical skin conductance, invasive surgical and chemical investigations of animal brains, and data from clinically observed syndromes associated with brain injury, cognitive neuroscientists have pieced together information concerning the role that specific brain regions play in the processing of emotional and cognitive events. High-level visual processing, such as object recognition, takes place in the occipital lobes of the cortex, although recognition of certain highly complex visual stimuli, such as faces, is handled by the right cerebral hemisphere. Auditory stimuli in general are processed by the temporal lobes of the cortex, and written and spoken word recognition and syntactical components of language processing are handled by certain regions of the left hemisphere of the cerebral cortex, notably Broca's and Wernicke's areas; while emotional, idiomatic, and prosodic aspects of language are handled by corresponding regions in the right hemisphere. Higher cognition, such as reasoning and problem solving, involves the frontal lobes of the cortex. Memory and the processing of emotional stimuli are handled by the combined effort of the cortex (notably the anterior and frontal regions) and subcortical structures (notably the limbic system).

One particular subcortical structure—the hippocampus—plays a major role in the formation of new explicit memories. It is believed that an intact hippocampus is needed to temporarily bind together distributed sites of activation in the cortex that together make up a whole, explicit memory for an event. *See* BRAIN; COMPUTERIZED TOMOGRAPHY.

Theories of cognition are often tested by building computer models that embody the theories and then comparing the model's performance with human performance on selected tasks. These models tend to be of two types. Rule-based models consist of a long-term memory containing rules which specify actions to take in the presence of particular input patterns, a short-term memory that encodes input patterns and temporarily stores data structures constructed by the rules, and a control structure that guides the process and resolves conflicts when more than one rule applies to the current input. Neural network models simulate cognition as a strengthening and weakening of associations among cognitive events. They consist of a network of interconnected nodes, a mathematical formula for modifying the connections, and a mathematical formula for propagating activation through the network. *See* EXPERT SYSTEMS; INFORMATION PROCESSING (PSYCHOLOGY); INTELLIGENCE; PROBLEM SOLVING (PSYCHOLOGY). [D.D.C.]

Coherence The attribute of two or more waves, or parts of a wave, whose relative phase is constant during the resolving time of the observer. The concept has been developed most extensively in optics, but is applicable to all wave phenomena.

Consider two waves, with the same mean angular frequency ω, given by Eqs. (1) and (2). It is convenient, and no restriction, to choose both A and B real. These expressions as they stand could describe de Broglie waves in quantum mechanics.

$$\Psi_A(x,t) = A \exp\{i[k(\omega)x - \omega t - \delta_A(t)]\} \quad (1)$$

$$\Psi_B(x,t) = B \exp\{i[k(\omega)x - \omega t - \delta_B(t)]\} \quad (2)$$

For real waves, such as components of the electric field in light or radio beams, or the pressure oscillations in sound, it is necessary to retain only the real parts of these and subsequent expressions. The frequency spectrum is assumed to be narrow, in the sense that a Fourier analysis of expressions (1) and (2) gives appreciable contributions only for angular frequencies close to ω. This assumption means that, on the average, $\delta_A(t)$ and $\delta_B(t)$ do not change much per period. *See* ELECTROMAGNETIC RADIATION; QUANTUM MECHANICS; SOUND.

Suppose that the waves are detected by an apparatus with resolving time T, that is, T is the shortest interval between two events for which the events do not seem to be simultaneous. For the human eye and ear, T is about 0.1 s, while a fast electronic device might have a T of 10^{-10} s. If the relative phase $\delta(t)$, given by Eq. (3), does not, on the average, change noticeably during T, then the waves are coherent.

$$\delta(t) = \delta_B(t) - \delta_A(t) \quad (3)$$

If during T there are sufficient random fluctuations for all values of $\delta(t)$, modulus 2π, to be equally probable, then the waves are incoherent. If during T there are noticeable random fluctuations in $\delta(t)$, but not enough to make the waves completely incoherent, then the waves are partially coherent. These distinctions are not useful unless T is specified. On the one hand, only waves that have existed forever and that fill all of space can have absolutely fixed frequency and phase. On the other hand, two independent sound waves in the phases change appreciably in 0.01 s would seem incoherent to the human ear, but would seem highly coherent to a fast electronic device.

The degree of coherence is related to the interference patterns that can be observed when the two beams are combined. *See* INTERFERENCE OF WAVES.

Coherence is also used to describe relations between phases within the same beam. Suppose that a wave represented by Eq. (1) is passing a fixed observer characterized by a resolving time T. The phase δ_A may fluctuate, perhaps because the source of the wave contains many independent radiators. The coherence time Δt_W of the wave is defined to be the average time required for $\delta_A(t)$ to fluctuate appreciably at the position of the observer. If Δt_W is much greater than T, the wave is coherent; if Δt_W is of the order of T, the wave is partially coherent; and if Δt_W is much less than T, the wave is incoherent. These concepts are very close to those developed above.

Extended sources give partial coherence and produce interference fringes with visibility V less than unity. A. A. Michelson exploited this fact with his stellar interferometer, a modified double-slit arrangement with movable mirrors that permit adjustment of the effective separation D' of the slits. It can be shown that if the source is a uniform disk of angular diameter θ, then the smallest value of D' that gives zero V is $1.22\lambda/\theta$. The same approach has also been applied in radio astronomy. A different technique, developed by R. Hanbury Brown and R. Q. Twiss, measures the correlation between the intensifies received by separated detectors with fast electronics. *See* INTERFEROMETRY.

Because they are highly coherent sources, lasers and masers provide very large intensities per unit frequency. *See* LASER.
[R.G.Wi.]

Photon statistics is concerned with the probability distribution describing the number of photons incident on a detector, or present in a cavity. By extension, it deals with the correlation properties of beams of light.

According to the quantum theory of electromagnetism, quantum electrodynamics, light is made up of particles called photons, each of which possesses an energy E of $\hbar\omega$, where $\hbar$ is Planck's constant divided by 2π and ω is the angular frequency of the light (the frequency multiplied by 2π). In general, however, the photon number is an intrinsically uncertain quantity. It is impossible to precisely specify both the phase $\phi = \omega t$ of a wave and the number of photons $n \approx E/(\hbar\omega)$ that it contains; the uncertainties of these two conjugate variables must satisfy $\Delta n \Delta\phi \geq \frac{1}{2}$. For a beam to be coherent in the sense of having a well-defined phase, it must not be describable in terms of a fixed number of particles. (Lacking a fixed phase, a single photon may interfere only with itself, not with other photons.) *See* PHOTON; QUANTUM ELECTRODYNAMICS.

The most familiar example of this uncertainty is shot noise, the randomness of the arrival times of individual photons. There is no correlation between photons in the coherent state emitted by a classical source such as an ideal laser or radio transmitter, so the number of photons detected obeys Poisson statistics, displaying an uncertainty equal to the square root of the mean. The shot noise constitutes the dominant source of noise at low light levels, and may become an important factor in optical communications as well as in high-precision optical devices (notably those that search for gravitational radiation). *See* DISTRIBUTION (PROBABILITY); ELECTRICAL NOISE.
[A.M.S.]

Cohesion (physics) The tendency of atoms or molecules to coalesce into extended condensed states. This tendency is practically universal. In all but exceptional cases, condensation occurs if the temperature is sufficiently low; at higher temperatures, the thermal motions of the constituents increase, and eventually the solid assumes gaseous form. The cohesive energy is the work required to separate the condensed phase into its constituents or, equivalently, the amount by which the energy of the condensed state is lower than that of the isolated constituents. The science of cohesion is the study of the physical origins and manifestations of the forces causing cohesion, as well as those opposing it. It is thus closely related to the science of chemical bonding in molecules, which treats small collections of atoms rather than extended systems. *See* CHEMICAL BONDING; INTERMOLECULAR FORCES.

The origin and magnitude of the attractive forces depend on the chemical nature of the constituent atoms or molecules. Strong attractive interactions are usually associated with constituents having valence electron shells which are partly filled or open; if the valence electron shells are completely filled or closed, the interactions are weaker. *See* VALENCE.

For open-shell constituents, as the atoms approach, the electron energy levels on different atoms begin to interact, forming a complex of energy levels in the solid. Some of these are below the atomic energy levels and some above. Since the atomic shells are partly filled, the lower energy levels in the solid are filled, but at least some of the higher levels are empty. Thus the average energy of the occupied levels in the solid is lower than that in the isolated atoms, resulting in an attractive force. Bonding in open-shell systems can be approximately divided into three categories, although most cases involve a combination. *See* BAND THEORY OF SOLIDS; FERMI-DIRAC STATISTICS; SOLID-STATE PHYSICS; VALENCE BAND.

1. *Covalent bonding*. This type of bonding is most similar to the molecular bond. The electron energy levels in the solid are split into a lower and a higher portion, with the states in the lower one filled and the higher one empty. Covalent bonds are strongly directional, with electron charge accumulating around the bond centers. Materials bonded in this fashion typically form structures with low coordination numbers, prototypical materials elements in group IV of the periodic table, the insulator carbon,

and the semiconductors silicon and germanium. *See* PERIODIC TABLE; SEMICONDUCTOR.

2. *Metallic bonding*. In this case, there is no split between the lower and higher states of the electrons in the solid; rather, they occupy levels from the bottom up to a cutoff point known as the Fermi level. For example, in transition metals, the electron states in the solid derived from the atomic *d* orbitals form a complex which is gradually filled with increasing atomic number. The bulk of the cohesive energy is due to this complex. The metallic bond is less directional than the covalent bond, with a more uniform distribution of electronic charge. Metals usually form closely packed structures. *See* FERMI SURFACE; FREE-ELECTRON THEORY OF METALS.

3. *Ionic bonding*. This occurs in compounds having at least two distinct types of atoms. One or more of the species of atoms (the cations) have only a small number of electrons in their valence shells, whereas at least one species (the anions) has a nearly filled valence shell. As the atoms approach each other, electrons drop from the cation valence states into holes in the anion valence shell, forming a closed-shell configuration in the solid. The different types of atoms in the solid have net charges; a strong attractive force results from the interaction between unlike charges. For example, in sodium chloride (NaCl), the sodium atoms acquire positive charges, and the chlorine atoms acquire negative charges. The closest interatomic separations in the solid are between sodium and chlorine, so that the attractive electrostatic interactions outweigh the repulsive ones. *See* IONIC CRYSTALS; SOLID-STATE CHEMISTRY.

In closed-shell constituents, the above effects are greatly reduced because the atomic or molecular shells are basically inert. The constituents retain their separate identities in the solid environment. If the constituents are atomic, as in rare-gas solids, the cohesion is due to the van der Waals forces. The positions of the electrons in an atom fluctuate over time, and at any given time their distribution is far from spherical. This gives rise to fluctuating long-ranged electric fields, which average zero over time, but can still have appreciable effects on neighboring atoms. The electrons on these atoms move in the direction of the force exerted by the electric field. The net result is that the interactions between unlike charges (electrons and nuclei) are increased in the solid, whereas the interactions between like charges are reduced. Thus the solid has a lower energy than the isolated atoms.

In solids made up of molecules, there are additional electrostatic interactions due to the nonspherical components of the molecular charge density. These interactions are strongest if the molecules are polar. This means that the center of the positive charge on the molecule is at a different point in space from that of the negative charge. Polar molecules, such as water (H_2O), form structures in which the positive charge on a molecule is close to the negative charges of its neighbors. For nonpolar molecules, the electrostatic interactions are usually weaker than the van der Waals forces. The nonspherical interactions in such cases are often so weak that the molecules can rotate freely at elevated temperatures, while the solid is still held together by the van der Waals forces.

The repulsive forces in the condensed phase are a dramatic illustration of the combined action of two quantum-mechanical principles, the exclusion principle and the uncertainty principle.

The exclusion principle states that the quantum-mechanical wave function for the electrons in the solid must be antisymmetric under the interchange of the coordinates of any two electrons. Consequently, two electrons of the same spin are forbidden from being very close to each other. *See* EXCLUSION PRINCIPLE.

The uncertainty principle states that if the motion of an electron is confined, its kinetic energy must rise, resulting in a repulsive force opposing the confinement. The kinetic energy due to the confinement is roughly inversely proportional to the square of the radius of the region of confinement. According to the exclusion principle, the motion of an electron in a solid is partially confined because it is forbidden from closely approaching other electrons of the same spin. Thus the uncertainty principle in turn implies a repulsive force. *See* UNCERTAINTY PRINCIPLE. [A.E.Ca.]

Coil One or more turns of wire used to introduce inductance into an electric circuit. At power line and audio frequencies a coil has a large number of turns of insulated wire wound close together on a form made of insulating material, with a closed iron core passing through the center of the coil. This is commonly called a choke and is used to pass direct current while offering high opposition to alternating current.

At higher frequencies a coil may have a powdered iron core or no core at all. The electrical size of a coil is called inductance and is expressed in henries or millihenries. In addition to the resistance of the wire, a coil offers an opposition to alternating current, called reactance, expressed in ohms. The reactance of a coil increases with frequency. *See* INDUCTOR; REACTOR (ELECTRICITY). [J.Mar.]

Coining A cold metalworking process in a press-type die. Coining is used to produce embossed parts, such as badges and medals, and for minting of coins. It is also used on portions of a blank or workpiece to form corners, indentations, or raised sections, frequently as part of a progressive die operation. The work is subjected to high pressure within the die cavity and thereby forced to flow plastically into the die details. The absence of overflow of excess metal from between the dies is characteristic of coining and is responsible for the fine detail achieved. *See* METAL FORMING. [R.L.Fr.]

Coir A natural fiber, also known as coco fiber, obtained from the husks of the coconut (*Cocos nucifera*). The outstanding characteristic of coir fiber is its resistance to rot. For example, a coir fiber doormat can stay out in the weather for years. Coir is only intermediate in strength among the vegetable fibers, but its elongation at break is greater than any of the bast or hard fibers. More than 95% of coir exports are from Sri Lanka and India; small amounts are exported from Thailand, Tanzania, Mexico, the Philippines, Malaysia, Kenya, and Trinidad and Tobago.

There are three main types of coir—yarn fiber, bristle fiber, and mattress fiber. Only the finest and longest fiber is suitable for spinning into yarn. It is obtained from the husks of unripe nuts and is the main cash crop rather than a by-product. The bristle fiber and most of the mattress fiber come from mature nuts and are by-products of copra production. Coir fiber ranges in color from light tan to dark brown. Bristles are sorted according to length and graded on the basis of length, stiffness, color, and cleanliness. Long, clean fibers and light color are desirable for any purpose, but stiffness is desirable in bristles and undesirable for yarn.

In developed countries, yarn fiber is used chiefly in mats and mattings; in the United States, for instance, its best-known use is in light-brown tufted doormats. In Asia it is used extensively for ropes and twines, and locally for hand-made bags. The principal outlet for bristle fiber has been in brush making, but the market has declined and most bristle fiber is now used in upholstery padding. Mattress fiber is used chiefly in innerspring mattresses, though it has found uses as an insulating material. *See* COCONUT; NATURAL FIBER. [E.G.N.]

Coke A coherent, cellular, carbonaceous residue remaining from the dry (destructive) distillation of a coking coal. It contains carbon as its principal constituent, together with mineral matter and residual volatile matter. The residue obtained from the carbonization of a noncoking coal, such as subbituminous coal, lignite, or anthracite, is normally called a char. Coke is produced chiefly in chemical-recovery coke ovens, but a small amount is also produced in beehive or other types of nonrecovery ovens.

Coke is used predominantly as a fuel reductant in the blast furnace, in which it also serves to support the burden. As the fuel, it supplies the heat as well as the gases required for the reduction of the iron ore. It also finds use in other reduction processes, the foundry cupola, and house heating.

Coke is formed when coal is heated in the absence of air. During the heating in the range of 660–930°F (350–500°C), the coal softens and then fuses into a solid mass. The degree of softening attained during heating determines to a large extent the character of the coke produced. In order to produce coke having desired properties, two or more coals are blended before charging into the coke oven. In addition to the types of coals blended, the carbonizing conditions in the coke oven influence the characteristics of the coke produced. Oven temperature is the most important of these and has a significant effect on the size and the strength of the coke. In general, for a given coal, the size and shatter strength of the coke increase with decrease in carbonization temperature.

The important properties of coke that are of concern in metallurgical operations are its chemical composition, such as moisture, volatile-matter, ash, and sulfur contents, and its physical character, such as size, strength, and density. The moisture and the volatile-matter contents are a function of manner of oven operation and quenching, whereas ash and sulfur contents depend upon the composition of the coal charged. *See* CHARCOAL; COAL; DESTRUCTIVE DISTILLATION. [M.P.]

Coking (petroleum) In the petroleum industry, a process for converting nondistillable fractions (residua) of crude oil to lower-boiling-point products and coke. Coking is often used in preference to catalytic cracking because of the presence of metals and nitrogen components that poison catalysts. *See* CRACKING.

The liquid products from the coker, after cleanup via commercially available hydrodesulfurization technology, can provide large quantities of low-sulfur liquid fuels (less than 0.2 wt% sulfur). Another major application for the processes is upgrading heavy low-value crude oils into lighter products.

Petroleum coke is used principally as a fuel or, after calcining, for carbon electrodes. The feedstock from which the coke is produced controls the coke properties, especially in terms of sulfur, nitrogen, and metals content. A concentration effect tends to deposit the majority of the sulfur, nitrogen, and metals in the coke. Cokes exceeding around 2.5% sulfur content and 200 parts per million vanadium are mainly used, environmental regulations permitting, for fuel or fuel additives. The properties of coke for nonfuel use include low sulfur, metals, and ash as well as a definable physical structure. *See* PETROLEUM PRODUCTS. [J.G.S.]

Cola A tree, *Cola acuminata*, of the sterculia family (Sterculiaceae) and a native of tropical Africa. Its fruit is a star-shaped follicle containing eight hard seeds, the cola nuts of commerce. These nuts are an important masticatory in many parts of tropical Africa. They have a caffeine content twice that of coffee. The nuts also contain an essential oil and a glucoside, kolanin, which is a heart stimulant. Cola nuts, in combination with an extract from coca, are used in the manufacture of the beverage Coca-Cola. Cola is now cultivated in Angola, Jamaica, Brazil, India, and other parts of tropical Asia. *See* COCA; MALVALES. [P.D.St./E.L.C.]

Colchicine The major alkaloid obtained from the seed capsules, corms, and bulbs of the meadow saffron (autumn crocus; *Colchicum autumnale*). The use of the colchicum plant to relieve the pain of gout has been known since medieval times, and colchicine is still the standard treatment for gout, although it is an extremely toxic substance. An important property of colchicine is its ability to interrupt the mitotic cycle before cell division occurs. This effect leads to cells with multiple chromosomes, which are of value in plant breeding. *See* ALKALOID; LILIALES; MITOSIS; POLYPLOIDY. [J.A.Mo.]

Cold hardiness (plant) The ability of temperate zone plants to survive subzero temperatures. This characteristic is a predominant factor that determines the geographical distribution of native plant species and the northern limits of cultivation of many important agronomic and horticultural crops. Further, freezing injury is a major cause of crop loss resulting from early fall frosts, low midwinter temperatures, or late spring frosts. Problems of cold hardiness are of concern to farmers in diverse areas of agriculture. As a result, the development of varieties of cultivated plants with improved cold hardiness is of long-standing concern.

Within the plant kingdom there is a wide range of diversity in low-temperature tolerance—from low levels of hardiness in herbaceous species such as potatoes, to intermediate levels of hardiness for winter annuals such as wheat and rye, to extremely hardy deciduous trees and shrubs such as black locust and red osier dogwood that can withstand temperatures of liquid nitrogen. Within a given species, the range in hardiness can be substantial. Within a given plant there is a wide range in the cold hardiness of different tissues and organs. For example, roots are much less tolerant of subzero temperatures than shoots; flower buds are more sensitive than vegetative buds.

The cold hardiness of a given species is an inherent genetic trait that requires certain environmental cues for its expression. With the shorter days and cooler nights of autumn, temperate zone plants become dormant and increase their cold hardiness. This process is referred to as cold acclimation. In the spring, increasing daylength and warmer temperatures result in the resumed growth and development of the plant and a corresponding decrease in cold hardiness. Cold hardiness may be influenced by radiation, temperature, photoperiod, precipitation, and stage of development of the plant, with different optimum conditions for different species or cultivars and ecotypes within a species. The various environmental cues serve to synchronize plant development with the environment. This synchronization has taken centuries to evolve, and freezing injury in cultivated species can result from any factor that disrupts this synchrony.

Temperature is the key environmental parameter for increasing a plant's capacity to withstand freezing temperatures. Low, above-freezing temperatures are conducive to an increase in hardiness in the fall, and warm temperatures are responsible for the decrease in the spring. Generally, it is considered that most plants will acclimate as temperatures are gradually lowered below 50°F (10°C). However, during acclimation, the progressive decline in temperatures is extremely important. The development of cold hardiness may take 4 to 6 weeks.

Photoperiod is the second major factor influencing cold acclimation, but only in those species that are photoperiodically responsive in relation to growth cessation or induction of dormancy (a true physiological rest period). In other species, light is important only in providing sufficient photosynthetic reserves required for the cold acclimation process. In some cases (for example, germinating seeds), sufficient energy reserves are already present and acclimation can occur in the dark. *See* PHOTOPERIODISM.

There are conflicting reports on the role of moisture in relation to cold hardiness. High soil moisture may reduce the degree of cold acclimation; however, severe winter injury of evergreens will occur if soil moisture levels are too low. Most often tissue moisture levels will influence the survival to a given freeze-thaw cycle rather than directly influencing the process of cold acclimation. Thus, whereas temperature and light effects on hardiness are probably mediated through the development of hardiness (cold acclimation), tissue moisture content directly affects the stresses that are incurred during a freeze-thaw cycle. In addition, various cultural practices can influence the cold hardiness of a given plant. For example, late fall applications of fertilizer or improper pruning practices may stimulate flushes of growth that do not have sufficient time to acclimate. Conversely, insufficient mineral nutrition can also impair the development of maximum cold hardiness.

The process of cold acclimation results in numerous biochemical changes within the plant. These include increases in growth inhibitors and decreases in growth promoters; changes in nucleic acid metabolism; alterations in cellular pigments such as carotenoids and anthocyanins; the accumulation of carbohydrates, amino acids, and water-soluble proteins; increases in fatty acid unsaturation; changes in lipid composition; and the proliferation of cellular membrane systems. Some of these are merely changes in response to slower growth rates and decreased photosynthate utilization; others are changes associated with growth at low, above-zero temperatures; and still others are associated with other developmental phenomena, such as vernalization or the induction of dormancy, that also occur during the period of cold acclimation.

Large increases in cellular solute concentrations are one of the most universal manifestations of cold acclimation. A doubling of the intracellular solute concentration, most notably sugars, is not uncommon. Such increases have several beneficial effects. First, they serve to depress the freezing point of the intracellular solution. More important, a doubling of the initial intracellular solute concentration will decrease the extent of cell dehydration at any subzero temperature by 50%. An increase in intracellular solutes will also decrease the concentration of toxic solutes at temperatures below 32°F (0°C), because less water will be removed. Following cold acclimation there are also substantial changes in the lipid composition of the plasma membrane. This includes an increase in free sterols with corresponding decreases in steryl glucosides and acylated steryl glucosides, a decrease in the glucocerebroside content, and an increase in the phospholipid content. The complexity of the plasma membrane lipid composition and the numerous changes that occur during cold acclimation preclude the possibility of any simple correlative analysis; however, studies have demonstrated that differential behavior of the plasma membrane observed in protoplasts isolated from nonacclimated and cold-acclimated leaves is a consequence of alterations in the lipid composition. *See* ALTITUDINAL VEGETATION ZONES; PLANT PHYSIOLOGY; PLANT-WATER RELATIONS. [P.L.S.]

Cold storage The storage of perishables at low temperatures, usually above freezing, by the use of refrigeration to increase the storage life. In general, the lower the temperature, the longer the storage life. If temperatures are maintained below the freezing point of the product stored, it is called freezer storage. Most fruits and many other products, however, are damaged by freezing and cannot be kept in freezer storage. A cold-storage plant is a large insulated building, with its attendant refrigeration equipment, for storage of commodities at low temperatures. Facilities are often included for quick-freezing fruits, vegetables, meats, and a variety of precooked foods and bakery products for the consumer convenience market. *See* REFRIGERATION. [C.F.K.]

Colemanite One of the more common minerals of the borate group (in which boron is chemically bonded to oxygen), colemanite is a hydroxy-hydrated calcium borate with the chemical formula $Ca[B_3O_4(OH)_3](H_2O)$ [Ca = calcium, B = boron, O = oxygen, OH = hydroxyl, H_2O = water].

Colemanite is white to gray with a white streak, is transparent to translucent, and has a vitreous luster. It occurs either as short highly modified prismatic crystals or as massive to granular aggregates. It has perfect cleavage in one direction, parallel to the sheet nature of its crystal structure. Colemanite has hardness of $4–4^1/_2$ on Mohs scale and a specific gravity of 2.42. *See* HARDNESS SCALES.

Colemanite typically occurs in lacustrine (lake) evaporite deposits of Tertiary age. It forms by thermal diagenesis of primary borate minerals, such as ulexite, $NaCa[B_5O_6(OH)_6](H_2O)_6$, and borax, $Na_2[B_4O_5(OH)_4](H_2O)_8$ (Na = sodium). *See* BORATE MINERALS; DIAGENESIS; SALINE EVAPORITES.

Colemanite is a principal source of boron, together with borax and ulexite, and is mined extensively in California and Nevada, Turkey, and Argentina. Boron is used in a wide variety of industrial commodities: soaps and washing powders, glasses and ceramics, specialty alloys, and fillers in many products. *See* BORON. [F.C.Ha.]

Coleoidea A subclass of the Cephalopoda that appeared in the middle Paleozoic (Early Devonian Period) and presumably evolved from the nautiloid stalk. Of the five orders of fossil coleoids, the belemnites are conspicuous with their fossilized shells termed lightning bolts. All these forms became extinct by the end of the Mesozoic, 65 million years ago. The surviving four orders that developed in the Late Triassic to Late Cretaceous represent all the living cephalopods today, except *Nautilus* (subclass Nautiloidea).

Coleoids are characterized by an internal chitinous or calcareous shell; 8–10 appendages around the mouth (8 arms and 2 tentacles when present) lined with suckers or hooks; one pair of gills; highly developed eyes; a fused, tubelike funnel; an ink sac (lost in some species); chromatophores; and fins on the body (lost in some octopuses).

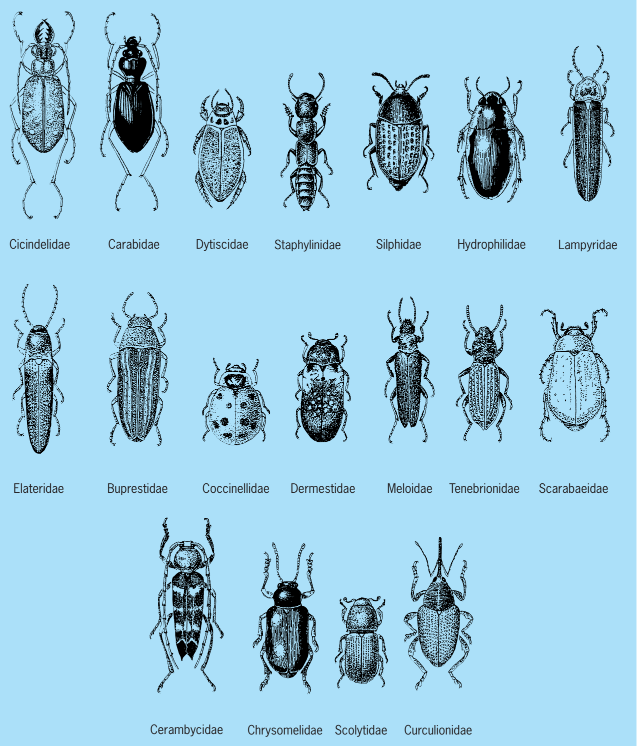
The living coleoids are the order Sepioidea (cuttlefishes, like *Sepia*; bobtail squids, *Spirula*); the order Teuthoidea (squids—nearshore myopsids, like *Loligo*; open-ocean oegopsids, like *Ommastrephes*); the order Vampyromorpha (the black, deep-sea vampire squid); and the order Octopoda (octopuses, argonauts, deep-sea finned or cirrate octopods). Living coleoids generally are fast, mobile predators with an advanced brain and central nervous system. *See* BELEMNOIDEA; CEPHALOPODA; MOLLUSCA; NAUTILOIDEA; SEPIOIDEA; TEUTHOIDEA; VAMPYROMORPHA. [C.F.E.R.]

Coleoptera An order of Insecta (generally known as beetles) with a complete metamorphosis (with larva and pupa stages), the forewings forming hard protective elytra under which the hindwings are normally folded in repose, and the indirect flight muscles of the mesothorax having been lost. The head capsule is characterized by a firm ventral (gular) closure, the antennae are basically 11-segmented, and mouthparts are of the biting type with 4-segmented maxillary palpi. The prothorax is large and free. The abdomen has sternite I normally absent, sternite II usually membranous and hidden, and segment X vestigial, with cerci absent. The female has one pair of gonapophyses, on segment IX. There are four or six malpighian tubules, which are often cryptonephric. True labial glands are nearly always absent.

General biological features. The order has well over 250,000 described species, more than any comparable group, showing very great diversity in size, form (see illustration), color, habits, and physiology. Beetles have been found almost everywhere on Earth (except as yet for the Antarctic mainland) where any insects are known, and species of the order exploit almost every habitat and type of food which is used by insects. Many species are economically important.

A common feature is for the exoskeleton to form an unusually hard and close-fitting suit of armor, correlated with a tendency for the adults to be less mobile but longer-lived than those of other orders of higher insects. It seems to be common in a number of groups for adults to survive and breed in 2 or more successive years, a rare occurrence in other Endopterygota. Adult beetles tend to be better runners than most other Endopterygota, and some (such as Cicindelidae) are among the fastest of running insects. The flight of most beetles is not very ready or frequent, often requiring prior climbing up onto some eminence, and in many beetles occurs only once or twice in an average life.

Apart from a tendency for the sclerotized layers to be thicker, the cuticle of beetles differs little from that of other insects in constitution or ultrastructure. The black coloring which is prevalent



Coleoptera. (***After T. I. Storer et al., General Zoology, 6th ed., McGraw-Hill, 1979***)

in many groups of beetles is produced by deposition of melanin in the process of cuticle hardening. In many groups with adults active by day, the black is masked by a metallic structural color produced by interference in the surface cuticle layers. Pigmentary colors, mainly ommochromes, giving reddish to yellowish colors, occur in the cuticle of many species.

Special defenses against predation are common in species with long-lived adults, particularly the ground-living species of Carabidae, Staphylinidae, and Tenebrionidae. These groups commonly possess defensive glands, with reservoirs opening on or near the tip of the abdomen, secreting quinones, unsaturated acids, and similar toxic substances. In some cases, the secretion merely oozes onto the body surface, but in others may be expelled in a jet, as in the bombardier beetles (Brachinini). Other common defensive adaptations include cryptic and mimetic appearances. The most frequent behavioral adaptations are the drop-off reflex and appendage retraction, in which adults will react to visual or tactile stimuli by dropping off the plant foliage on which they occur, falling to the ground with retracted appendages, and lying there for some time before resuming activity. In death feigning, the appendages are tightly retracted, often into grooves of the cuticle, and held in this position for some time. In such conditions, beetles often resemble seeds and are difficult for predators to perforate or grasp.

Sound production (stridulation) is widespread in beetles and may be produced by friction between almost any counterposed movable parts of the cuticle. Stridulatory organs may show sex dimorphism, and in some species may play an important role in the interrelations of the sexes.

Anatomy. The head of beetles rarely has a marked posterior neck, and the antennal insertions are usually lateral, rather than dorsal as in most other Endopterygota, a feature possibly related to an original habit of creeping under bark. Antennal forms are very various, with the number of segments often reduced, but rarely increased, from the basic 11. Mandible forms are very diverse and related to types of food.

The prothorax commonly has lateral edges which separate the dorsal part from the ventral part of the tergum. The mesothorax is the smallest thoracic segment. Dorsally, its tergum is usually exposed as a small triangular sclerite between the elytral bases, and ventrally, its sternite may have a median pit receiving the tip of the prosternum. The form of the metathorax is affected by far-forward insertions of the hind-wings and far-posterior ones of the hindlegs, so that the pleura are extremely oblique and the sternum usually long.

The tarsi of beetles show all gradations from the primitive five-segmented condition to total disappearance. The number of segments may differ between the legs of an individual or between the sexes of a species.

Most beetles have the entire abdomen covered dorsally by the elytra in repose, and ventrally only five or six sternites (of segments III to VII or VIII) exposed; segment IX is retracted inside VIII in repose. Tergites I-VI are usually soft and flexible, those of VII and VIII more or less sclerotized. A feature developed in several groups of Coleoptera, but particularly in Staphylinidae, is the abbreviation of the elytra to leave part of the abdomen uncovered in repose, but usually still covering the folded wings. One advantage of this may be to give greater overall flexibility to the body. Perhaps surprisingly, many beetles with short elytra fly readily.

Internally, the gut varies greatly in length and detailed structure. The foregut commonly ends in a distended crop whose posterior part usually has some internal setae and may be developed into a complex proventriculus; the midgut may be partly or wholly covered with small papillae (regenerative crypts) and sometimes has anterior ıceca. The four or six malpighian tubules open in various ways into the beginning of the hindgut and in many Polyphaga have their apices attached to it (cryptonephric). The central nervous system shows all degrees of concentration of the ventral chain, from having three thoracic and eight abdominal ganglia distinct to having all of these fused into a single mass.

The sense organs of beetles, adult or larval, are generally similar in type and function to those of other insects. For vision, some types are adapted for high visual acuity in bright light, others to high sensitivity in poor light, and many show light-dark adaptations of screening pigment. Color vision seems to be restricted to certain groups. In certain beetles, there is evidence of specialized infrared sensitivity. Antennae are mainly receptors for smell and touch, but detection of aerial vibrations (by Johnston's organ in the pedicel) may be important in some. The olfactory sensilla, which commonly are setae, are often concentrated on expanded apical segments, forming a club. Taste, or contact chemoreception, is usually mediated by sensilla with a single large apical opening. These sensilla are concentrated on the palpi and other mouthparts and are often found on tibiae or tarsi of the front legs.

Taste, or contact chemoreception, is usually mediated by sensilla with a single large apical opening. These sensilla are concentrated on the palpi and other mouthparts and are often found on tibiae or tarsi of the front legs.

Specialized sound receptors, other than Johnston's organ, have not been much studied in Coleoptera, though many species produce sounds and in some cases these play a significant part in courtship. A gravitational sense is evident in many burrowing beetles, which are able to sink accurately vertical burrows despite inclinations of the surface started from. A temperature sense is clearly present in some beetles and larvae, but little is known of the sensilla concerned. What might be called a time sense (otherwise known as a biological clock) clearly operates in many beetles that react specifically to changing daylight lengths marking the seasons in nontropical latitudes.

Food specialization. The biting mouthparts of many adult and larval beetles are adaptable to many types of food, and fairly widely polyphagous habits are not uncommon in the order, though most species can be assigned to one or another of a few main food categories: fungivores, carnivores, herbivores, or detritivores. Included in the last category are species feeding on decaying animal or vegetable matter and on dung. Most parasites could be included with carnivores, but those myrmecophiles and termitophiles which are fed by their hosts, and those Meloidae which develop on the food stores of bees, form special categories.

Water beetles. Beetles are unusual among the higher insects in that aquatic habits, where present, usually affect adults as well as larvae. The elytra may have been preadaptive to the invasion of water. Almost any type of fresh or brackish water body is liable to contain some types of water beetles, though very few species can live permanently in full marine salinities. Almost all aquatic beetles maintain an air reservoir, into which the second thoracic and abdominal spiracles open, under their elytra; and some, mainly small, species may have plastrons or physical gills. Aquatic larvae tend to have a last pair of abdominal spiracles that is large and effectively terminal, or tend to develop tracheal gills. Pupae are terrestrial in the large majority of water beetles, and eggs, when deposited underwater, are commonly laid in contact with airspaces in the stems of water plants, or in an air-filled egg cocoon. Most water beetles are confined to shallow waters, and many of them are ready colonists of temporary pools, through adult flight.

Special habitats and adaptations. More or less unusual adaptations and modes of life are manifest in dung and carrion beetles, ambrosia beetles, cave and subterranean beetles, desert beetles, and luminous beetles. Dung and carrion beetles exploit sporadic and very temporary food resources in which competition (particularly with Diptera larvae) tends to be fierce. Many dung beetles avoid the difficulties by burying dung stores in underground cells where their larvae can develop safely, and some beetles (Necrophorinae) adopt a similar strategy for carrion. They may also develop phoretic and symbiotic relations with specific mites preying on fly eggs.

In ambrosia beetles, the adults usually excavate burrows in wood, carrying with them spores of special fungi, which proceed to develop along the walls of the burrows and are fed on by larvae developing from eggs laid there. This type of relation between beetles, fungi, and trees exists in various forms in a number of families and may be of ecological importance if the fungi concerned are liable to kill trees.

More than one family of beetles contains highly adapted types living exclusively in deeper cave systems (cavernicolous) or the deeper layers of the soil (hypogeous). Such species are usually flightless and eyeless, poorly pigmented, and slow-moving, and of very restricted geographical distribution. Another marginal habitat in which beetles are the principal insect group represented is the desert. Here, too, wings are usually lost, but the cuticle tends to be unusually thick, firm, and black. Also beetles may be found in hot springs. A few water beetles are adapted to underground (phreatic) waters, showing parallel features with the cavernicolous and hypogeous terrestrial ones.

More or less parasitic relations to animals of other groups have developed in a number of lines of Coleoptera. The closest parallels to Hymenoptera-Parasitica are to be seen in the families Stylopidae (Strepsiptera of many authors) and Rhipiphoridae. Stylopid larvae are exclusively endoparasites of other insects, while the adult females are apterous, often legless, and remain in the host's body, while males have large fanlike hind-wings and the elytra reduced to halter-like structures. A considerable variety of Coleoptera develop normally in the nests of termites and social or solitary Hymenoptera-Aculeata, some being essentially detritivores or scavengers, but most feed either on the young or the food stores of their hosts. Ectoparasitism on birds or mammals is a rare development in beetles.

The beetles are notable in that some of them manifest the highest developments of bioluminescence known in nonmarine animals, the main groups concerned being Phengodidae, Lampyridae, and Elateridae-Pyrophorini, the glowworms and fireflies. In luminescent beetles, the phenomenon always seems to be manifest in the larvae and often in the pupae, but not always in the adults. In luminous adult beetles, there is often marked sex dimorphism, and a major function of the lights seems to be the mutual recognition of the sexes of a species.

Another possible function of adult luminosity, and the only seriously suggested for that of larvae, is as an aposematic signal. There is definite evidence that some adult fireflies are distasteful to some predators, and the luminous larvae of Phengodidae have dorsal glandular openings on the trunk segments that probably have a defensive function. *See* BIOLUMINESCENCE.

Phylogenetic history. Coleoptera are older than the other major endopterygote orders. The earliest fossils showing distinctively beetle features were found rather before the middle of the Permian Period. By the later Permian, fossils indicate that beetles had become numerous and diverse, and during the Mesozoic Era they appear as a dominant group among insect fossils. Fossils in Triassic deposits have shown features indicative of all four modem suborders, and the Jurassic probably saw the establishment of all modern superfamilies. By early Cretaceous times, it is likely that all "good" modern families had been established as separate lines. In the Baltic Amber fauna, of later Paleogene age (about 40,000,000 years ago), about half the fossil beetle genera appear to be extinct, and the other half have still-living representatives (often in remote parts of the world). Beetle fossils in Quaternary (Pleistocene) deposits are very largely of still-living species.

Geographical distribution. Almost every type of continuous or discontinuous distribution pattern which is known in any animal group could be matched in some taxon of Coleoptera, and every significant zoogeographical region or area could be characterized by endemic taxa of beetles. In flightless taxa, distributional areas are generally more limited than those of comparable winged taxa. Distinct distributional categories can be seen in those small, readily flying groups (in Staphylinidae and Nitidulidae, for example) which are liable to form part of "aerial plankton," and in those wood borers which may survive for extended periods in sea-drifted logs, both of which are liable to occur in oceanic islands beyond the ranges of most other beetle taxa. Climatic factors often seem to impose limits on the spread of beetle species (and sometimes of genera or families), and beetle remains in peats have been found to be sensitive indicators of climatic changes in glacial and postglacial times. *See* INSECTA.

[R.A.Cr.]

Coliiformes

A small order of birds containing only the family Coliidae with six species (the mousebirds) restricted to Africa. The mousebirds are small, grayish to brownish, with a long tail. The legs are short and the feet strong, with the four toes movable into many positions from all four pointing forward to two reversed backward. Mousebirds perch, climb, crawl, and scramble agilely in bushes and trees. They are largely vegetarian but eat some insects. They are nonmigratory and gregarious, and sleep in clusters, but they are monogamous as breeders. The nest is an open cup in a tree or bush, and the two to four young remain in the nest, cared for by both adults until they can fly. The relationships of the mousebirds to other birds are obscure. Mousebirds have a surprisingly good fossil record from the Miocene of France and Germany. *See* AVES. [W.J.B.]

Coliphage

Any bacteriophage able to infect the bacterium *Escherichia coli*; many are able to attack more than one strain of this organism. The T series of phage (T1–T7), propagated on a special culture of *E. coli*, strain B, have been used in extensive studies, from which most of the knowledge of phages is derived. *See* BACTERIOPHAGE; LYSOGENY. [P.B.C.]

Collagen

The major fibrous protein in animals, present in all types of multicellular animals and probably the most abundant animal protein in nature. It is estimated that collagen accounts for about 30% of the total human body protein. Collagen is located in the extracellular matrix of connective tissues. It is part of the interacting network of proteoglycans and proteins that provides a structural framework for both soft and calcified connective tissues. By self-associating into fibrils and by binding to proteoglycans and other matrix components, collagen contributes to tissue integrity and mechanical properties. Collagen interacts with cells through the integrin cell receptors and mediates cellular adhesion and migration. Important roles for collagen have been identified in development, wound healing, platelet aggregation, and aging. Its commercial importance in leather and the production of gelatin and glue have long been recognized. More recently, it is being used as a basis for biomaterials. Examples of its biomedical applications include injectable collagen to lessen facial wrinkles and defects; surgical collagen sponges to increase blood clotting; and artificial skin for the treatment of burns. *See* GELATIN; LEATHER AND FUR PROCESSING.

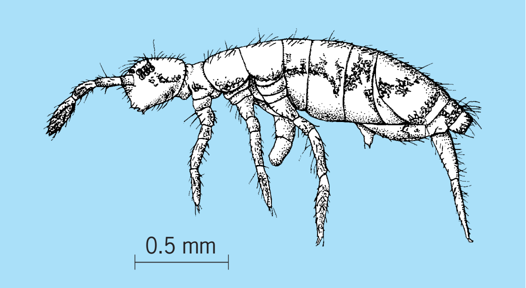
The classification of an extracellular matrix protein as a collagen is based on the presence of a domain with a distinctive triple-helical conformation. The collagen triple helix consists of three polypeptide chains supercoiled about a common axis and linked by hydrogen bonds. At least 19 distinct molecules have been classified as collagens, and specific types are associated with particular tissues. The most prevalent and well-studied collagens belong to the fibril-forming or interstitial collagen family. The molecules in a fibril are covalently cross-linked by an enzymatic mechanism to strengthen and stabilize them. Inhibition of the enzyme involved in cross-linking results in a dramatic decrease in the tensile strength of tissues, a condition known as lathyrism.

Type I is the most common fibril-forming collagen. Its fibrils make up the mineralized matrix in bone, the strong parallel bundles of fibers in tendon, and the plywoodlike alternating layers in the transparent cornea. Type II is the major fibril-forming collagen in cartilage, while type III is found in blood vessels and skin, together with type I. Basement membranes, which serve to separate cell layers and act as filtration barriers, contain a distinctive group of collagens, denoted as type IV collagens, which are organized into a network or meshlike sheet structure. In the kidney glomerulus, the network based on type IV collagen acts as a filter to determine which molecules will pass from the blood into the urine. *See* BONE; CONNECTIVE TISSUE; FIBROUS PROTEIN.

An orderly breakdown of collagen is necessary during development and tissue remodeling. For instance, following childbirth, the uterus reduces in size, which involves a massive degradation of collagen. An abnormal increase in the degradation of cartilage collagen is seen in osteoarthritis. Collagen breakdown also appears to be essential for tumor metastases. A number of hereditary diseases have been shown to be due to mutations in specific collagen genes. Osteogenesis imperfecta (brittle bone) disease is characterized by fragile bones and is due to mutations in type I collagen. Some cartilage disorders are caused by mutations in type II collagen. Ruptured arteries are found in Ehlers-Danlos syndrome type IV, which arises from mutations in type III collagen. [B.Bro.]

Collard A cool-season biennial crucifer, *Brassica oleracea* var. *acephala*, similar to nonheading cabbage. Collard is of Mediterranean origin and is grown for its rosette of leaves, which are cooked fresh as a vegetable. Important production centers are in the southern United States, where collards are an important nutritious green, especially during winter months. *See* CABBAGE; CAPPARALES; KALE. [H.J.C.]

Collembola An order of primitive insects, commonly called springtails, belonging to the subclass Apterygota. These tiny insects do not undergo a metamorphosis. They have six abdominal segments, some of which may be ankylosed to give an apparently smaller number (see illustration). Appended to the fourth abdominal segment in most of the species is a spring, or furcula. This consists of a basal piece and two apical parallel structures which end in hooks. Another pair of structures, united at the base, occur ventrally on the third abdominal segment. These bear teeth which engage with the furcula and hold it beneath the body. When released, the spring flies backward, catapulting the insect.



A collembolan, *Entomobrya cubensis*. (*After J. W. Folsom, Proc. U.S. Nat. Mus., 72(6), plate 6, 1927*)

Collembola live in humid places, often in leaf mold. Some species are active at cool temperatures, hence another common name, snowflea, is used. The earliest known insect fossil, *Rhyniella praecursor*, is thought to belong to this order. *See* INSECTA. [H.B.Mi.]

Collenchyma A primary, or early differentiated, supporting tissue of young shoot parts appearing while these parts are still elongating. It is located near the surface, usually just under the epidermis. When observed in transverse sections, it is characterized structurally by cell walls that are intermittently thickened, generally in the corners or places of juncture of three or more cells. Collenchyma is typically formed in the petioles and vein ribs of leaves, the elongating zone of young stems, and the pedicels of flowers. *See* CELL WALLS (PLANT).

As in parenchyma, the cells in collenchyma are living and may contain chloroplasts and starch grains. The cell wall of a collenchyma cell is its most striking feature structurally and functionally. It is composed of cellulose and pectic compounds plus a very high proportion of water. The cytoplasm is very rich in ribosomes and ribonucleic acids in the early stages of development. Another striking feature of collenchyma cell walls is their plasticity. They are capable of great elongation during the period of growth in length of the plant. The plasticity of collenchyma is associated with a tensile strength comparable to that shown by fibers of sclerenchyma. The combination of strength and plasticity makes the collenchyma effective as a strengthening tissue in developing stems and leaves having no other supporting tissue at that time. *See* CELLULOSE; EPIDERMIS (PLANT); PARENCHYMA; PECTIN. [R.L.Hu.]

Collision (physics) Any interaction between particles, aggregates of particles, or rigid bodies in which they come near enough to exert a mutual influence, generally with exchange of energy. The term collision, as used in physics, does not necessarily imply actual contact.

In classical mechanics, collision problems are concerned with the relation of the magnitudes and directions of the velocities of colliding bodies after collision to the velocity vectors of the bodies before collision. When the only forces on the colliding bodies are those exerted by the bodies themselves, the principle of conservation of momentum states that the total momentum of the system is unchanged in the collision process. This result is particularly useful when the forces between the colliding bodies act only during the instant of collision. The velocities can then change only during the collision process, which takes place in a short time interval. Under these conditions the forces can be treated as impulsive forces, the effects of which can be expressed in terms of an experimental parameter known as the coefficient of restitution. *See* Conservation of momentum; Impact.

The study of collisions of molecules, atoms, and nuclear particles is an important field of physics. Here the object is usually to obtain information about the forces acting between the particles. The velocities of the particles are measured before and after collision. Although quantum mechanics instead of classical mechanics should be used to describe the motion of the particles, many of the conclusions of classical collision theory are valid. *See* Scattering experiments (atoms and molecules); Scattering experiments (nuclei).

Collisions can be classed as elastic and inelastic. In an elastic collision, mechanical energy is conserved; that is, the total kinetic energy of the system of particles after collision equals the total kinetic energy before collision. For inelastic collisions, however, the total kinetic energy after collision is different from the initial total kinetic energy.

In classical mechanics the total mechanical energy after an inelastic collision is ordinarily less than the initial total mechanical energy, and the mechanical energy which is lost is converted into heat. However, an inelastic collision in which the total energy after collision is greater than the initial total energy sometimes can occur in classical mechanics. For example, a collision can cause an explosion which converts chemical energy into mechanical energy. In molecular, atomic, and nuclear systems, which are governed by quantum mechanics, the energy levels of the particles can be changed during collisions. Thus these inelastic collisions can involve either a gain or a loss in mechanical energy. [P.W.S.]

Colloid A state of matter characterized by large specific surface areas, that is, large surfaces per unit volume or unit mass. The term colloid refers to any matter, regardless of chemical composition, structure (crystalline or amorphous), geometric form, or degree of condensation (solid, liquid, or gas), as long as at least one of the dimensions is less than approximately 1 micrometer but larger than about 1 nanometer. Thus, it is possible to distinguish films (for example, oil slick), fibers (spider web), or colloidal particles (fog) if one, two, or three dimensions, respectively, are within the submicrometer range.

A colloid consists of dispersed matter in a given medium. In the case of finely subdivided particles, classification of a number of systems is possible, as given in the table. In addition to the colloids listed in the table, there are systems that do not fit into any of the listed categories. Among these are gels, which consist of a network-type internal structure loaded with larger or smaller amounts of fluid. Some gels may have the consistency of a solid, while others are truly elastic bodies that can reversibly deform. Another colloid system that may occur is termed coacervate, and is identified as a liquid phase separated on coagulation of hydrophilic colloids, such as proteins. *See* Gel.

It is customary to distinguish between hydrophobic and hydrophilic colloids. The former are assumed to be solvent-repellent, while the latter are solvent-attractant (dispersed matter is said to be solvated). In reality there are various degrees of hydrophilicity for which the degree of solvation cannot be determined quantitatively.

Types of colloid dispersions

Medium	Dispersed matter	Technical name	Examples
Gas	Liquid	Aerosol	Fog, sprays
	Solid	Aerosol	Smoke, atmospheric or interstellar dust
Liquid	Gas	Foam	Head on beer, lather
	Liquid	Emulsion	Milk, cosmetic lotions
	Solid	Sol	Paints, muddy water
Solid	Gas	Solid foam	Foam rubber
	Liquid	Solid emulsion	Opal
	Solid	Solid sol	Steel

Certain properties of matter are greatly enhanced in the colloidal state due to the large specific surface area. Thus, finely dispersed particles are excellent adsorbents; that is, they can bind various molecules or ions on their surfaces. This property may be used for removal of toxic gases from the atmosphere (in gas masks), for elimination of soluble contaminants in purification of water, or decolorization of sugar, to give just a few examples. *See* Adsorption.

Colloids are too small to be seen by the naked eye or in optical microscopes. However, they can be observed and photographed in transmission or scanning electron microscopes. Owing to their small size, they cannot be separated from the medium (liquid or gas) by simple filtration or normal centrifugation. Special membranes with exceedingly small pores, known as ultrafilters, can be used for collection of such finely dispersed particles. The ultracentrifuge, which spins at very high velocities, can also be employed to promote colloid settling. *See* Electron microscope; Scanning electron microscope; Ultracentrifuge; Ultrafiltration.

Colloids show characteristic optical properties. They strongly scatter light, causing turbidity such as in fog, milk, or muddy water. Scattering of light (recognized by the Tyndall beam) can be used for the observation of tiny particles in the ultramicroscope. Colloidal state of silica is also responsible for iridescence, the beautiful effect observed with opals. *See* Scattering of electromagnetic radiation; Tyndall effect.

Since the characteristic dimensions of colloids fall between those of simple ions or molecules and those of coarse systems, there are in principle two sets of techniques available for their preparation: dispersion and condensation. In dispersion methods the starting materials consist of coarse units which are broken down into finely dispersed particles, drawn into fibers, or flattened into films. For example, colloid mills grind solids to colloid sizes, nebulizers can produce finely dispersed droplets from bulk liquids, and blenders are used to prepare emulsions from two immiscible liquids (such as oil and water). *See* Emulsion.

In condensation methods, ions or molecules are aggregated to give colloidal particles, fibers, or films. Thus, insoluble monolayer films can be developed by spreading onto the surface of water a long-chain fatty acid (for example, stearic acid) from a solution in an organic liquid (such as benzene or ethyl ether). Colloidal aggregates of detergents (micelles) form by dissolving the surface-active material in an aqueous solution in amounts that exceed the critical micelle concentration. *See* Micelle; Monomolecular film.

The most common procedure to prepare sols is by homogeneous precipitation of electrolytes. Thus, if aqueous silver nitrate and potassium bromide solutions are mixed in proper concentrations, colloidal dispersions of silver bromide will form, which may remain stable for a long time. Major efforts have focused on preparation of monodispersed sols, which consist of colloidal particles that are uniform in size, shape, and composition. *See* Precipitation (chemistry). [E.Ma.]

Colloidal crystals Periodic arrays of suspended colloidal particles. Common colloidal suspensions (colloids) such as milk, blood, or latex are polydisperse; that is, the suspended particles have a distribution of sizes and shapes. However, suspensions of particles of identical size, shape, and interaction, the so-called monodisperse colloids, do occur. In such suspensions, a new phenomenon that is not found in polydisperse systems, colloidal crystallization, appears: under appropriate conditions, the particles can spontaneously arrange themselves into spatially periodic structures. This ordering is analogous to that of identical atoms or molecules into periodic arrays to form atomic or molecular crystals. However, colloidal crystals are distinguished from molecular crystals, such as those formed by very large protein molecules, in that the individual particles do not have precisely identical internal atomic or molecular arrangements. On the other hand, they are distinguished from periodic stackings of macroscopic objects like cannonballs in that the periodic ordering is spontaneously adopted by the system through the thermal agitation (brownian motion) of the particles. These conditions limit the sizes of particles which can form colloidal crystals to the range from about 0.01 to about 5 micrometers. *See* BROWNIAN MOVEMENT; KINETIC THEORY OF MATTER.

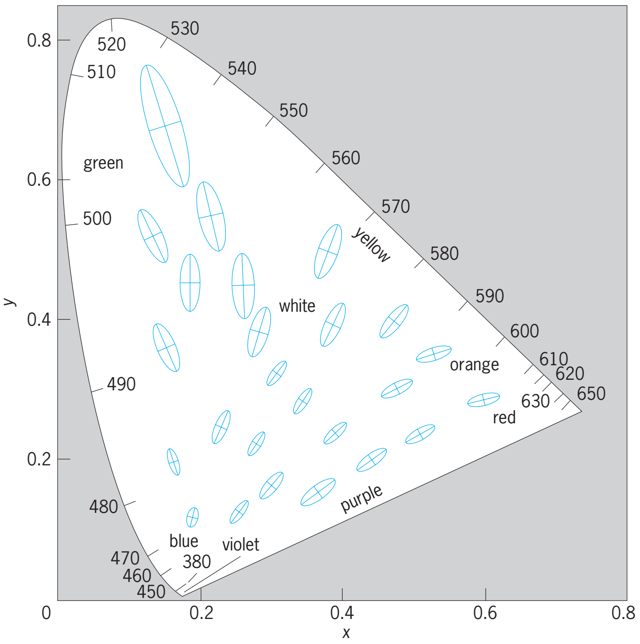
The most spectacular evidence for colloidal crystallization is the existence of naturally occurring opals. The ideal opal structure is a periodic close-packed three-dimensional array of silica microspheres with hydrated silica filling the spaces not occupied by particles. Opals are the fossilized remains of an earlier colloidal crystal suspension. Another important class of naturally occurring colloidal crystals are found in concentrated suspensions of nearly spherical virus particles, such as *Tipula* iridescent virus and tomato bushy stunt virus. Colloidal crystals can also be made from the synthetic monodisperse colloids, suspensions of plastic (organic polymer) microspheres. Such suspensions have become important systems for the study of colloidal crystals, by virtue of the controllability of the particle size and interaction. *See* COLLOID; CRYSTAL; OPAL; VIRUS. [N.A.C.]

Colon The portion of the intestine that runs from the cecum to the rectum; in some mammals, it may be separated from the small intestine by an ileocecal valve. It is also known as the large intestine. The colon is usually divided into ascending, transverse, and descending portions. In the human a fourth section, the sigmoid, is found. The colon is longer in herbivores and shorter in carnivores, and is about 4 to 6 ft (1.2 to 1.8 m) long in humans. No digestive enzymes are secreted in the colon. Much digestion (for example, all breakdown of cellulose) occurs by bacteria, of which *Escherichia coli* is the most common. Most of the fluid added to the food during digestion is reabsorbed into the body in the colon. All digestive action, water absorption, and so on, is completed before the food materials pass out of the colon into the rectum. *See* DIGESTIVE SYSTEM. [W.J.B.]

Color That aspect of visual sensation enabling a human observer to distinguish differences between two structure-free fields of light having the same size, shape, and duration. Although luminance differences alone permit such discriminations to be made, the term color is usually restricted to a class of differences still perceived at equal luminance. These depend upon physical differences in the spectral compositions of the two fields, usually revealed to the observer as differences of hue or saturation.

Color discriminations are possible because the human eye contains three classes of cone photoreceptors that differ in the photopigments they contain and in their neural connections. Two of these, the R and G cones, are sensitive to all wavelengths of the visible spectrum from 380 to 700 nanometers. (Even longer or shorter wavelengths may be effective if sufficient energy is available.) R cones are maximally sensitive at about 570 nm, G cones at about 540 nm. The ratio R/G of cone sensitivities is minimal at 465 nm and increases monotonically for wavelengths both shorter and longer than this. This ratio is independent of intensity, and the red-green dimension of color variation is encoded in terms of it. The B cones, whose sensitivity peaks at about 440 nm, are not appreciably excited by wavelengths longer than 540 nm. The perception of blueness and yellowness depends upon the level of excitation of B cones in relation to that of R and G cones. No two wavelengths of light can produce equal excitations in all three kinds of cones. It follows that, provided they are sufficiently different to be discriminable, no two wavelengths can give rise to identical sensations.

Different complex spectral distributions usually, but not always, look different. Suitable amounts of short-, middle-, and long-wavelength lights, if additively mixed, can for example excite the R, G, and B cones exactly as does a light containing equal energy at all wavelengths. As a result, both stimuli look the same. This is an extreme example of the subjective identity of physically different stimuli known as chromatic metamerism. Additive mixture is achievable by optical superposition, rapid alternation at frequencies too high for the visual system to follow, or (as in color television) by the juxtaposition of very small elements which make up a field structure so fine as to exceed the limits of visual acuity. *See* EYE (VERTEBRATE); LIGHT.



The 1931 CIE chromaticity diagram showing discrimination ellipses enlarged 10 times.

Although colors are often defined by appeal to standard samples, the trivariant nature of color vision permits their specification in terms of three values. Ideally these might be the relative excitations of the R, G, and B cones. Because too little was known about cone action spectra in 1931, the International Commission on Illumination (CIE) adopted at that time a different but related system for the prediction of metamers (the CIE system of colorimetry). This widely used system permits the specification of tristimulus values X, Y, and Z, which make almost the same predictions about color matches as do calculations based upon cone action spectra. If, for fields 1 and 2, $X_1 = X_2$, $Y_1 = Y_2$, and $Z_1 = Z_2$, then the two stimuli are said to match (and therefore have the same color) whether they are physically the same (isometric) or different (metameric).

Colors are often specified in a two-dimensional chart known as the CIE chromaticity diagram, which shows the relations among tristimulus values independently of luminance. In this plane, y is by convention plotted as a function of x, where $y = Y/(X + Y + Z)$ and $x = x/(x + Y + Z)$. [The value $z = Z/(X + Y + Z)$ also equals $1 - (x + y)$ and therefore carries no additional information.] Such a diagram is shown in the illustration, in which the continuous locus of spectrum colors is represented by the outermost contour. All nonspectral colors are contained within an area defined by this boundary and a straight line running from red to violet. The diagram also shows discrimination data for 25 regions, which plot as ellipses represented at 10 times their actual size. A discrimination unit is one-tenth the distance from the ellipse's center to its perimeter. Predictive schemes for interpolation to other regions of the CIE diagram have been worked out.

A chromaticity diagram has some very convenient properties. Chief among them is the fact that additive mixtures of colors plot along straight lines connecting the chromaticities of the colors being mixed. Although it is sometimes convenient to visualize colors in terms of the chromaticity chart, it is important to realize that this is not a psychological color diagram. Rather, the chromaticity diagram makes a statement about the results of metameric color matches, in the sense that a given point on the diagram represents the locus of all possible metamers plotting at chromaticity coordinates x, y. However, this does not specify the appearance of the color, which can be dramatically altered by preexposing the eye to colored lights (chromatic adaptation) or, in the complex scenes of real life, by other colors present in nearby or remote areas (color contrast and assimilation). Nevertheless, within limits, metamers whose color appearance is thereby changed continue to match.

For simple, directly fixated, and unstructured fields presented in an otherwise dark environment, there are consistent relations between the chromaticity coordinates of a color and the color sensations that are elicited. Therefore, regions of the chromaticity diagram are often denoted by color names, as shown in the illustration.

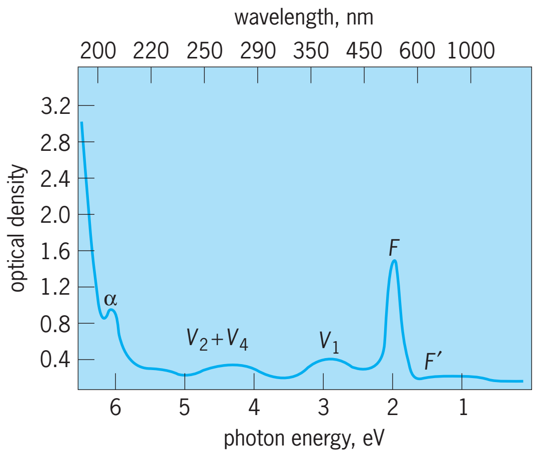
Although the CIE system works rather well in practice, there are important limitations. Normal human observers do not agree exactly about their color matches, chiefly because of the differential absorption of light by inert pigments in front of the photoreceptors. Much larger individual differences exist for differential colorimetry, and the system is overall inappropriate for the 4% of the population (mostly males) whose color vision is abnormal. The system works only for an intermediate range of luminances, below which rods (the receptors of night vision) intrude, and above which the bleaching of visual photopigments significantly alters the absorption spectra of the cones. *See* COLOR VISION. [R.M.Bo.]

Color (quantum mechanics) A term used to refer to a hypothetical quantum number carried by the quarks which are thought to make up the strongly interacting elementary particles. It has nothing to do with the ordinary, visual use of the word color.

The quarks which are thought to make up the strongly interacting particles have a spin angular momentum of one-half unit of h (Planck's constant). According to a fundamental theorem of relativity combined with quantum mechanics, they must therefore obey Fermi-Dirac statistics and be subject to the Pauli exclusion principle. No two quarks within a particular system can have exactly the same quantum numbers. *See* EXCLUSION PRINCIPLE; FERMI-DIRAC STATISTICS.

However, in making up a baryon, it often seemed necessary to violate this principle. The Ω^- particle, for example, is made of three strange quarks, and all three had to be in exactly the same state. O. W. Greenberg is responsible for the essential idea for the solution to this paradox. In 1964 he suggested that each quark type (u, d, and s) comes in three varieties identical in all measurable qualities but different in an additional property, which has come to be known as color. The exclusion principle could then be satisfied and quarks could remain fermions, because the quarks in the baryon would not all have the same quantum numbers. They would differ in color even if they were the same in all other respects. *See* BARYON; ELEMENTARY PARTICLE; MESON; QUARKS. [T.Ap.]

Color centers Atomic and electronic defects of various types which produce optical absorption bands in otherwise transparent crystals such as the alkali halides, alkaline earth fluorides, or metal oxides. They are general phenomena found in a wide range of materials. Color centers are produced by gamma radiation or x-radiation, by addition of impurities or excess constituents, and sometimes through electrolysis. A well-known example is that of the *F*-center in alkali halides such as sodium chloride, NaCl. The designation *F*-center comes from the German word *Farbe*, which means color. *F*-centers in NaCl produce a band of optical absorption toward the blue end of the visible spectrum; thus the colored crystal appears yellow under transmitted light. On the other hand, KCl with *F*-centers appears magenta, and KBr appears blue. *See* CRYSTAL.



Absorption bands produced in a KBr crystal by exposure to x-rays at 81 K. Bands are designated by letters. Optical density is equal to $\log_{10}(I_0/I)$, where I_0 is the intensity of incident light and I the intensity of transmitted light. Steep rise in optical density at far left is due to intrinsic absorption in crystals (modified slightly by existence of *F*-centers).

Color centers have been under investigation for many years. Theoretical studies guided by detailed experimental work have yielded a deep understanding of specific centers. The crystals in which color centers appear tend to be transparent to light and to microwaves. Consequently, experiments which can be carried out include optical spectroscopy, luminescence and Raman scattering, magnetic circular dichroism, magnetic resonance, and electromodulation. Color centers find practical application in radiation dosimeters; schemes have been proposed to use color centers in high-density memory devices; and tunable lasers have been made from crystals containing color centers.

The illustration shows the absorption bands due to color centers produced in potassium bromide by exposure of the crystal at the temperature of liquid nitrogen (81 K) to intense penetrating x-rays. Several prominent bands appear as a result of the irradiation. The *F*-band appears at 600 nanometers and the so-called *V*-bands appear in the ultraviolet.

Color bands such as the *F*-band and the *V*-band arise because of light absorption at defects dispersed throughout the lattice. This absorption is caused by electronic transitions at the centers. On the other hand, colloidal particles, each consisting of many atoms, dispersed through an optical medium also produce color bands. In this case, if the particles are large enough, the extinction of light is due to both light scattering and light absorption. Colloidal gold is responsible for the color of some types of ruby glass. Colloids may also form in alkali halide crystals—for example, during heat treatment of an additively colored crystal with an excess of alkali metal.

Atomically dispersed centers such as *F*-centers are part of the general phenomena of trapped electrons and holes in solids. The accepted model of the *F*-center is an electron trapped at a negative ion vacancy. Many other combinations of electrons, holes, and clusters of lattice vacancies have been used to explain the various absorption bands in ionic crystals.

Impurities can play an important role in color-center phenomena. Certain impurities in ionic crystals produce color bands characteristic of the foreign ion. For example, hydrogen can be incorporated into the alkali halides with resultant appearance of an absorption band (the *U*-band) in the ultraviolet. In this case, the *U*-centers interact with other defects. The rate at which *F*-centers are produced by x-irradiation is greatly increased by the incorporation of hydrogen, the *U*-centers being converted into *F*-centers with high efficiency. [F.C.Br.]

Color filter An optical element that partially absorbs incident radiation, often called an absorption filter. The absorption is selective with respect to wavelength, or color, limiting the colors that are transmitted by limiting those that are absorbed. Color filters absorb all the colors not transmitted. They are used in photography, optical instruments, and illuminating devices to control the amount and spectral composition of the light.

Color filters are made of glass for maximum permanence, of liquid solutions in cells with transparent faces for flexibility of control, and of dyed gelatin or plastic (usually cellulose acetate) for economy, convenience, and flexibility. The plastic filters are often of satisfactory permanence, but they are sometimes cemented between glass plates for greater toughness and scratch resistance. They do not have as good quality as gelatin filters.

Color filters are sometimes classified according to their type of spectral absorption: short-wavelength pass, long-wavelength pass or band-pass; diffuse or sharp-cutting; monochromatic or conversion. The short-wavelength pass transmits all wavelengths up to the specified one and then absorbs. The long-wavelength pass is the opposite. Every filter is a band-pass filter when considered generally. Even an ordinary piece of glass does not transmit in the ultraviolet or infrared parts of the spectrum. Color filters, however, are usually discussed in terms of the portion of the visible part of the spectrum. Sharp and diffuse denote the sharpness of the edges of the filter band pass. Monochromatic filters are very narrow band-pass filters. Conversion filters alter the spectral response or distribution of one selective detector or source to that of another, for example, from that of a light bulb to that of the Sun. *See* ABSORPTION OF ELECTROMAGNETIC RADIATION; COLOR; SUN. [W.L.Wo.]

Color index A quantitative measure of a star's color. Such color is closely related to temperature. Stars are reddish at around 3000 K (5000°F), orange about 4500 K (7500°F), yellowish about 6000 K (10,300°F), white about 10,000 K (17,500°F), and bluish above 10,000 K. With proper calibration, color provides a means by which the temperature and spectral class can be evaluated. *See* SPECTRAL TYPE; STAR.

Color is defined through the star's magnitude m, which indicates brightness. The original magnitudes were visual, being estimated with the unaided eye, and depended on the eye's response, which is maximized for yellow light. Early photographic emulsions, however, were sensitive primarily to blue light. As a result, blue stars look relatively brighter to the photographic plate than they do the eye, and red stars considerably fainter. It was then necessary to establish a separate magnitude system for photography, called m_{ptg}. The original visual magnitudes were distinguished by calling them m_{v}. The two magnitudes were set equal for white stars with temperatures of 9300 K (16,280°F). Color can then be quantified by taking the difference between the two magnitudes, the color index becoming $m_{\mathrm{ptg}} - m_{\mathrm{v}}$. Blue stars have slightly negative color indices, red stars positive ones. *See* ASTRONOMICAL PHOTOGRAPHY.

Photoelectric photometry allowed the establishment of the more precise UBV system, wherein V (yellow) and B (blue) filters respectively mimic the response of the human eye and the untreated photographic plate, and a U filter is added in the ultraviolet. The traditional color index is then replaced by B − V, and the addition of U allows a second color index, U − B. *See* HERTZSPRUNG-RUSSELL DIAGRAM; INTERSTELLAR EXTINCTION.

The standard system has been expanded into the red and the infrared with other filters. Numerous color indices are then available to examine stars that radiate primarily in the infrared. Other photometric schemes, such as the Strömgren four-color system (uvby, for ultraviolet, violet, blue, and yellow), allow more sophisticated color indices that are responsive not only to temperature but to a variety of other parameters. *See* INFRARED ASTRONOMY. [J.B.Ka.]

Color vision The ability to discriminate light on the basis of wavelength composition. It is found in humans, in other primates, and in certain species of birds, fishes, reptiles, and insects. These animals have visual receptors that respond differentially to the various wavelengths of visible light. Each type of receptor is especially sensitive to light of a particular wavelength composition. Evidence indicates that primates, including humans, possess three types of cone receptor, and that the cones of each type possess a pigment that selectively absorbs light from a particular region of the visible spectrum. The trichromatic system of colorimetry, using only three primary colors, is based on the concept of cone receptors with sensitivities having their peaks, respectively, in the long, middle, and short wavelengths of the spectrum. *See* COLOR; COLORIMETRY.

Color is usually presented to the individual by the surfaces of objects on which a more or less white light is falling. A red surface, for example, is one that absorbs most of the short-wave light and reflects the long-wave light to the eye. A set of primary colors can be chosen so that any other color can be produced from additive mixtures of the primaries in the proper proportions. Thus, red, green, and blue lights can be added together in various proportions to produce white, purple, yellow, or any of the various intermediate colors. Three-color printing, color photography, and color television are examples of the use of primaries to produce plausible imitations of colors of the original objects. *See* PHOTOGRAPHY; PRINTING.

Colors lying along a continuum from white to black are known as the gray, or achromatic, colors. They have no particular hue. Whiteness is a relative term; white paper, paint, and snow reflect some 80% or more of the light of all visible wavelengths, while black surfaces typically reflect less than 10% of the light. The term white is also applied to a luminous object, such as a gas or solid, at a temperature high enough to emit fairly uniformly light of all visible wavelengths.

Color blindness is a condition of faulty color vision. It appears to be the normal state of animals that are active only at night. It is also characteristic of human vision when the level of illumination is quite low or when objects are seen only at the periphery of the retina. Under these conditions, vision is mediated not by cone receptors but by rods, which respond to low intensities of light. In rare individuals, known as monochromats, there is total color blindness even at high light levels. Such persons are typically deficient or lacking in cone receptors, so that their form vision is also poor.

Dichromats are partially color-blind individuals whose vision appears to be based on two primaries rather than the normal three. Dichromatism occurs more often in men than in women because it is a sex-linked, recessive hereditary condition. One form of dichromatism is protanopia, in which there appears to be a lack of normal red-sensitive receptors. Red lights appear dim to protanopes and cannot be distinguished from dim yellow or green lights. A second form is deuteranopia, in which there is no marked reduction in the brightness of any color, but again there is a confusion of the colors normally described as red, yellow, and green. A third and much rarer form is tritanopia, which involves a confusion among the greens and blues. *See* HUMAN GENETICS.

Many so-called color-blind individuals might better be called color-weak. They are classified as anomalous trichromats because they have trichromatic vision of a sort, but fail to agree with normal subjects with respect to color matching or discrimination tests. Protanomaly is a case of this type, in which there is subnormal discrimination of red from green, with some darkening of the red end of the spectrum. Deuteranomaly is a mild form of red-green confusion with no marked brightness loss. Nearly 8% of human males have some degree of either anomalous trichromatism or dichromatism as a result of hereditary factors; less than 1% of females are color-defective.

Color blindness is most commonly tested by the use of color plates in which various dots of color define a figure against a background of other dots. The normal eye readily distinguishes the figure, but the colors are so chosen that even the milder forms of color anomaly cause the figure to be indistinguishable from its background.

Techniques of microspectrophotometry have been used to measure the absorption of light by single cone receptors from the eyes of primates, including humans. The results confirm that three types of cone receptors are specialized to absorb light over characteristic ranges of wavelength, with maximum absorption at about 420, 530, and 560 nanometers. In addition there are rod receptors sensitive to low intensities of light over a broad range of wavelengths peaking at about 500 nm. In each of the four types of receptor there is a photosensitive pigment that is distinguished by a particular protein molecule. This determines the range and spectral location of the light which it absorbs.

Central nervous system factors are also evident. Color vision, like other forms of perception, is highly dependent on the experience of the observer and on the context in which the object is perceived. *See* EYE (INVERTEBRATE); EYE (VERTEBRATE); NERVOUS SYSTEM (VERTEBRATE); PERCEPTION; PHOTORECEPTION; VISION. [L.A.R.]

Colorimetry Any technique by which an unknown color is evaluated in terms of known colors. Colorimetry may be visual, photoelectric, or indirect by means of spectrophotometry. These techniques are widely used in scientific studies involving the appearance of objects and lights, but are of greatest importance in the color specification of the raw materials and finished products of industry.

In visual colorimetry, the unknown color is presented beside a comparison field into which may be introduced any one of a range of known colors from which the operator chooses the one matching the unknown. To be generally applicable, the comparison field must not only cover a sufficient color range but must also be continuously adjustable in color.

In indirect colorimetry, the light leaving the unknown specimen is split into its component spectral parts by means of a prism or diffraction grating, and the amount of each component part is separately measured by a photometer. The quantity evaluated is spectral radiance of a light source, spectral transmittance of a filter (glass, plastic, gelatin, or liquid), or spectral reflectance of an opaque body. *See* SPECTROPHOTOMETRIC ANALYSIS.

In photoelectric colorimetry, the light leaving the specimen is measured separately by three photocells. The spectral sensitivity of these photocells is adjusted, usually by color filters, to conform as closely as possible to the three color-mixture functions for the average normal human eye (CIE standard observer). The responses of the photocells give directly the amounts of red, green, and blue primaries required to produce the color of the unknown specimen for the kind of vision represented by the three photocells.

If two objects have the same color because the light leaving one of them toward the eye is spectrally identical to that leaving the other, any type of colorimetry serves reliably to establish the fact of color match. If, however, the two lights are spectrally dissimilar, they may still color-match for any one observer; such pairs of lights are called metamers. Normal color vision differs sufficiently from person to person so that a metameric color match for one observer may be seriously mismatched for another. On this account, the question of color match of spectrally dissimilar lights can be reliably settled only by the indirect method which uses spectrophotometry combined with a precisely defined standard observer. *See* COLOR; COLOR FILTER; COLOR VISION. [D.B.J./J.L.L.]

Columbiformes An order of birds containing three families, the largest of which is the worldwide pigeons and doves (Columbidae). The members of this order are characterized by an ability to drink water by sucking instead of the sip-and-tilt method of most birds. However, some other groups of birds are able to suck water by various methods.

The order Columbiformes is divided into the suborder Pterocletes, with the single family Pteroclidae (sandgrouse; 16 species), and the suborder Columbae with the families Raphidae (dodos; 3 species) and Columbidae (pigeons and doves; 303 species). Relationships of Columbiformes appear to be to the Charadriiformes in one direction and to the Psittaciformes in another. Possibly the Columbiformes are a central stock in the evolution of birds. *See* CHARADRIIFORMES; PSITTACIFORMES.

Pigeons are found mainly in the tropics, but a number of species are common in temperate regions. They have a sleek plumage ranging from browns and grays to the brilliant greens, yellows, and reds of the tropical fruit pigeons. They feed on seeds, fruit, and other vegetarian food. Most pigeons live in flocks but breed solitarily. Almost all are nonmigratory.

The sandgrouse live in flocks in dry grasslands and deserts of the Old World, but depend on ponds of water to which flocks come in large numbers. The nest is generally a long distance from water, which is transported to the young by soaking specialized belly feathers. The young drink only from these moistened feathers, and will refuse water in pans placed before them.

The three species of dodos and solitares were found only in the several Macarene Islands and were completely exterminated by the seventeenth century by sailors and released pigs. *See* AVES. [W.J.B.]

Columbite A mineral with the composition $(Fe,Mn)Nb_2O_6$. Tantalum may substitute in all proportions for the niobium; and a complete series extends to the pure end-member tantalite $[(Fe,Mn)Ta_2O_6]$, a relatively rare mineral. With a complete solid solution of iron and manganese, four end-member compositions are possible: $FeNb_2O_6$ (ferrocolumbite), $MnNb_2O_6$ (mangancolumbite), $FeTa_2O_6$ (ferrotantalite), and $MnTa_2O_6$ (mangantantalite).

Physical properties vary with composition. The specific gravity may range from 5.0 for $MnNb_2O_6$ to 5.4 for $FeNb_2O_6$; $FeTa_2O_6$ has a specific gravity of 7.9. The hardness of columbite on the Mohs scale is 6, while that of tantalite is 6.5. When the mineral is studied as a hand specimen, the color is black; however, the streak may be dark red to black. Manganoan varieties, end-member compositions rich in manganese, are often reddish brown. The luster is submetallic to weakly vitreous.

Columbite is a common accessory mineral in granitic pegmatites, and it may occur as a heavy mineral in placer deposits in streams. Minerals of the columbite-tantalite series are the most abundant and widespread of the natural columbates and tantalates, and columbite is the chief ore mineral of niobium. Niobium is used chiefly as an alloying element in the manufacture of specialty steels and alloys with nuclear and aerospace applications. *See* MINERALOGY; NIOBIUM; PEGMATITE; TANTALITE; TANTALUM. [R.C.Ew.]

Column A structural member that carries its load in compression along its length. Most frequently, as in a building, the column is in a vertical position transmitting gravity loads from its top down to its base. Columns are present in other structures as well, such as in bridges, towers, cranes, airplanes, machinery, and furniture. Other terms used by both engineers and lay persons to identify a column are pillar, post, and strut. Columns of timber, stone, and masonry have been constructed since the dawn of civilization; modern materials also include steel, aluminum, concrete, plastic, and composite material. *See* COMPOSITE MATERIAL; LOADS, TRANSVERSE; STRUCTURAL MATERIALS; STRUCTURAL STEEL.

Modern steel columns are made by rolling, extruding, or forming hot steel into predetermined cross-sectional shapes in the manufacturing facility. Reinforced concrete columns are fabricated either in their final locations (cast-in-place concrete) or in a precast plant (precast concrete) with steel reinforcing rods embedded in the concrete. Masonry columns are usually built in their final locations; they are made of brick or concrete masonry blocks; sometimes steel reinforcing rods are embedded within the masonry. *See* BRICK; CONCRETE; MASONRY; PRECAST CONCRETE; REINFORCED CONCRETE.

According to their behavior under load, columns are classified as short, slender, or intermediate. A short column is one whose length is relatively short in comparison to its cross-sectional dimensions and, when loaded to its extreme, fails by reaching the compressive strength of its material. This is called failure in axial compression. A slender column is one whose length is large in comparison to its cross-sectional dimensions and, when loaded to its extreme, fails by buckling (abruptly bending) out of its straight-line shape and suddenly collapsing before reaching the compressive strength of its material. This is called a condition of instability. An intermediate column falls between the classifications of short and slender. When loaded to its extreme, the intermediate column falls by a combination of compression and instability. [R.T.R.]

Combinatorial chemistry A method in which very large numbers of chemical entities are synthesized by condensing a small number of reagents together in all combinations defined by a small set of reactions. The main objective of combinatorial chemistry is synthesis of arrays of chemical or biological compounds called libraries. These libraries are screened to identify useful components, such as drug candidates. Synthesis and screening are often treated as separate tasks because they require different conditions, instrumentation, and scientific expertise. Synthesis involves the development of new chemical reactions to produce the compounds, while screening aims to identify the biological effect of these compounds, such as strong binding to proteins and other biomolecular targets.

Combinatorial chemistry is sometimes referred to as matrix chemistry. If a chemical synthesis consists of three steps, each employing one class of reagent to accomplish the conversion, then employing one type of each reagent class will yield $1 \times 1 \times 1 = 1$ product as the result of $1 + 1 + 1 = 3$ total reactions. Combining 10 types of each reagent class will yield $10 \times 10 \times 10 = 1000$ products as the result of as few as $10 + 10 + 10 = 30$ total reactions; 100 types of each reagent will yield 1,000,000 products as the result of as few as 300 total reactions. While the concept is simple, considerable strategy is required to identify 1,000,000 products worth making and to carry out their synthesis in a manner that minimizes labor and maximizes the value of the resulting organized collection, called a chemical library. *See* MATRIX THEORY.

The earliest work was motivated by a desire to discover novel ligands (that is, compounds that associate without the formation of covalent bonds) for biological macromolecules, such as proteins. Such ligands can be useful tools in understanding the structure and function of proteins; and if the ligand meets certain physiochemical constraints, it may be useful as a drug. For this reason, pharmaceutical applications provided early and strong motivation for the development of combinatorial chemistry. *See* LIGAND. [A.W.Cz.]

In combinatorial chemistry, attention has been focused on the problem of how to identify the set of molecules that possess a desired combination of properties. In a drug-discovery effort, the library members that strongly bind to a particular biological receptor are of interest. In a search for new materials that behave as superconductors at relatively high temperatures, the special combination of elements yielding the best electrical properties is a goal. In each case, the library might consist of up to a million members, while the subset of target molecules might consist of several thousand contenders or just a single highly selective binder. This subset could then be studied in more detail by conventional means.

Several emerging strategies promise to address this problem. In the first case, a library is constructed in a spatial array such that the chemical composition of each location in the array is noted during the construction. The binding molecules, usually labeled with a fluorescent tag, are exposed to the entire assay. The locations that light up can then be immediately identified from their spatial location. This approach is being actively developed for libraries of proteins and nucleotides. A problem is that the chemistry required to attach various molecules to the solid surface, usually silicon, is quite tricky and difficult to generalize. The assaying strategy is intertwined with the available procedures for synthesizing the libraries themselves.

A conceptually straightforward approach is to first synthesize the library by using polystyrene beads as the solid support. The product molecules are then stripped from the support and pooled together into a master solution. This complex mixture consisting of a potentially large selection of ligand molecules could then be exposed to an excess of a target receptor. The next step is to devise a method for identifying the ligand-receptor pairs that point to molecularly specific binding. One approach is to examine a part of the mixture en masse by using affinity capillary electrophoresis. With this technique, the migration times of the ligand-receptor pair are significantly longer than the unreactive ligands, and can be interrogated by electrospray mass spectrometry.

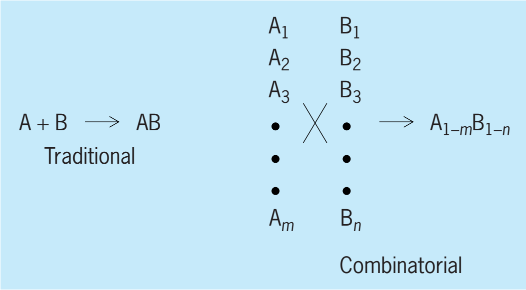
The mass spectrometric method often provides a direct structural identification of the ligand, either by determination of its molecular weight or by collision-induced dissociation experiments. In the latter case, the molecular ion is selected by a primary mass spectrometer and is driven into a region of high-pressure inert gas for fragmentation. The fragment ions are then used to reconstruct the original molecular structure. This direct approach to screening and assaying has the advantage that the screening is carried out in solution rather than on a solid support, and it avoids steric problems associated with resin-bound molecules. At present the approach seems limited to libraries of about 1000 compounds because of interference from unbound ligands, and limited by sensitivity issues. New strategies using mass spectrometry may eliminate this limit.

A different tack involves assaying the polystyrene beads one by one after the resin-bound molecules are exposed to a receptor. With this approach, active beads may be identified by color or by fluorescence associated with the receptor, and are subsequently indexed in standard 96-well titer plates. Identification is then possible by using a variety of spectroscopic techniques; at present, the most popular methods are electrospray mass spectrometry and matrix-assisted laser desorption ionization mass spectrometry. *See* MASS SPECTROMETRY. [N.W.]

Dynamic combinatorial chemistry integrates library synthesis and screening in one process, potentially accelerating the discovery of useful compounds. In the dynamic approach the libraries are not created as arrays of individual compounds, but are generated as mixtures of components, similar to natural pools of antibodies. One important requirement is that the mixture components exist in dynamic equilibrium with each other. According to basic laws of thermodynamics (Le Chatelier's principle), if one of the components (A_i) is removed from the equilibrated mixture, the system will respond by producing more of the removed component to maintain the equilibrium balance in the mixture. *See* CHEMICAL EQUILIBRIUM; LE CHATELIER'S PRINCIPLE.

The dynamic mixture, as any other combinatorial library, is so designed that some of the components have potentially high affinity to a biomolecular target. These high-affinity (effective) components can form strong complexes with the target. If the target is added to the equilibrated mixture, when the effective components form complexes with the target they are removed from the equilibrium. This forces the system to make more of these components at the expense of other ones that bind to the target with less strength. As a result of such an equilibrium shift, the combinatorial library reorganizes to increase the amount of strong binders and decrease the amount of the weaker ones. This reorganization leads to enrichment of the library with the effective components and simplifies their identification. [A.V.E.]

Combinatorial synthesis A method for preparing a large number of chemical compounds, commonly known as a combinatorial library, which are then screened to identify compounds having a desired function, such as a particular biological or catalytic activity. Combinatorial synthesis is an aspect of combinatorial chemistry, which allows for the simultaneous generation and rapid testing for a desired property of large numbers of chemically related compounds. One could regard combinatorial chemistry as the scientist's attempt to mimic the natural principles of random mutation and selection of the fittest. Combinatorial chemistry has already become an invaluable tool in the areas of molecular recognition, materials science, drug discovery and optimization, and catalyst development. *See* Combinatorial chemistry; Organic synthesis.



Traditional synthesis versus combinatorial synthesis.

Combinatorial synthesis was developed to prepare libraries of organic compounds containing from a few dozen to several million members simultaneously, in contrast to traditional organic synthesis where one target compound is prepared at a time in one reaction (see illustration). Thus, a target compound AB, for example, would be prepared by coupling of the substrates A and B in a traditional (orthodox) synthesis and would be isolated after reaction processing (workup) and purification (such as crystallization, chromatography, or distillation). Combinatorial synthesis offers the potential to prepare every combination of substrates, type A_{1-m} and type B_{1-n}, providing a set of compounds, $A_{(1-m)}B_{(1-n)}$. [Y.U.]

Combinatorial theory The branch of mathematics which studies arrangements of elements (usually a finite number) into sets under certain prescribed constraints. Problems combinatorialists attempt to solve include the enumeration problem (how many such arrangements are there?), the structure problem (what are the properties of these arrangements and how efficiently can associated calculations be made?), and, when the constraints become more subtle, the existence problem (is there such an arrangement?). [T.Br.]

Combining volumes, law of The principle that when gases take part in chemical reactions the volumes of the reacting gases and those of the products, if gaseous, are in the ratio of small whole numbers, provided that all measurements are made at the same temperature and pressure. The law is illustrated by the following reactions:

1. One volume of chlorine and one volume of hydrogen combine to give two volumes of hydrogen chloride.
2. Two volumes of hydrogen and one volume of oxygen combine to give two volumes of steam.
3. One volume of ammonia and one volume of hydrogen chloride combine to give solid ammonium chloride.
4. One volume of oxygen when heated with solid carbon gives one volume of carbon dioxide.

The law of combining volumes is similar to the other gas laws in that it is strictly true only for an ideal gas, though most gases obey it closely at room temperatures and atmospheric pressure. Under high pressures used in many large-scale industrial operations, such as the manufacture of ammonia from hydrogen and nitrogen, the law ceases to be even approximately true. *See* Gas. [T.C.W.]

Combustion The burning of any substance, in gaseous, liquid, or solid form. In its broad definition, combustion includes fast exothermic chemical reactions, generally in the gas phase but not excluding the reaction of solid carbon with a gaseous oxidant. Flames represent combustion reactions that can propagate through space at subsonic velocity and are accompanied by the emission of light. The flame is the result of complex interactions of chemical and physical processes whose quantitative description must draw on a wide range of disciplines, such as chemistry, thermodynamics, fluid dynamics, and molecular physics. In the course of the chemical reaction, energy is released in the form of heat, and atoms and free radicals, all highly reactive intermediates of the combustion reactions, are generated. *See* Flame; Free radical; Reactive intermediates.

The physical processes involved in combustion are primarily transport processes: transport of mass and energy and, in systems with flow of the reactants, transport of momentum. The reactants in the chemical reaction are normally a fuel and an oxidant. In practical combustion systems the chemical reactions of the major chemical species, carbon and hydrogen in the fuel and oxygen in the air, are fast at the prevailing high temperatures (greater than 1200 K or 1700°F) because the reaction rates increase exponentially with temperature. In contrast, the rates of the transport processes exhibit much smaller dependence on temperature are, therefore, lower than those of the chemical reactions. Thus in most practical flames the rate of evolution of the main combustion products, carbon dioxide and water, and the accompanying heat release depends on the rates at which the reactants are mixed and heat is being transferred from the flame to the fresh fuel-oxidant mixture injected into the flame. However, this generalization cannot be extended to the production and destruction of minor species in the flame, including those of trace concentrations of air pollutants such as nitrogen oxides, polycyclic aromatic hydrocarbons, soot, carbon monoxide, and submicrometer-size inorganic particulate matter. *See* Transport processes.

Combustion applications are wide ranging with respect to the fields in which they are used and to their thermal input, extending from a few watts for a candle to hundreds of megawatts for a utility boiler. Combustion is the major mode of fuel utilization in domestic and industrial heating, in production of steam for industrial processes and for electric power generation, in waste incineration, and in propulsion in internal combustion engines, gas turbines, or rocket engines. [J.M.Be.]

Combustion chamber The space at the head end of an internal combustion engine cylinder where most of the combustion takes place. *See* Combustion.

In the spark-ignition engine, combustion is initiated in the mixture of fuel and air by an electrical discharge. The resulting reaction moves radially across the combustion space as a zone of active burning, known as the flame front. The velocity of the flame increases nearly in proportion to engine speed so that the distance the engine shaft turns during the burning process is not seriously affected by changes in speed. *See* Internal combustion engine; Spark plug.

Occasionally a high burning rate, or too rapid change in burning rate, gives rise to unusual noise and vibration called engine roughness. Roughness may be reduced by using less squish or by shaping the combustion chamber to control the area of the flame front. A short burning time is helpful in eliminating knock because the last part of the charge is burned by the flame before it has time to ignite spontaneously. *See* Spark knock.

In compression-ignition (diesel) engines, the fuel is injected late in the compression stroke into highly compressed air. Mixing must take place quickly, especially in smaller high-speed engines, if the fuel is to find oxygen and burn while the piston remains near top center. After a short delay, the injected fuel ignites from contact with the hot air in the cylinder. There is no flame front travel to limit the combustion rate.

If mixing of fuel and air is too thorough by the end of the delay period, high rates of pressure rise result, and the operation of the engine is rough and noisy. To avoid this condition, the auxiliary chamber is most compression-ignition engines operates at high temperature so that the fuel ignites soon after injection begins. This reduces the amount of fuel present and the degree of mixing at the time that ignition takes place. High rates of pressure rise can also be reduced by keeping most of the fuel separated from the chamber air until the end of the delay period. Rapid mixing must then take place to ensure efficient burning of the fuel while the piston is near top center. *See* DIESEL ENGINE. [A.R.R.; D.L.An.]

Comet One of the major types of objects that move in closed orbits around the Sun. Compared to the orbits of planets and asteroids, comet orbits are more eccentric and have a much greater range of inclinations to the ecliptic (the plane of the Earth's orbit). Physically, a comet is a small, solid body which is roughly 2 mi (3 km) in diameter, contains a high fraction of icy substances, and shows a complex morphology, often including the production of an extensive atmosphere and tail, as it approaches the Sun. *See* ASTEROID; PLANET.

Astronomers consider comets to be worthy of detailed study for several reasons: (1) They are intrinsically interesting, involving a large range of physical and chemical processes. (2) They are valuable tools for probing the solar wind. (3) They are considered to be remnants of the solar system's original material and, hence, prime objects to be studied for clues about the nature of the solar system in the distant past. (4) Comets may be required to explain other solar system phenomena.

Present knowledge of comets is heavily influenced by the Halley's Comet campaign in 1986, which included images of the nucleus obtained by spacecraft sent to intercept the comet, and by the extensive studies of the very large Comet Hale-Bopp in 1997. While the data obtained from these comets are invaluable, comets are believed to be highly individualistic. *See* HALLEY'S COMET.

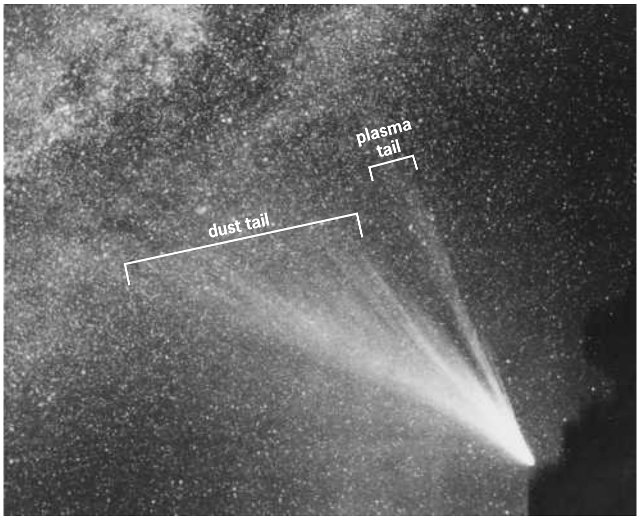
As seen from Earth, comets are nebulous in appearance, and the tail is usually the most visually striking feature. This tail can in some cases stretch along a substantial arc in the sky (see illustration). Some fainter comets, however, have little or no tail.

The coma or head of a comet is seen as the ball of light from which the tail or tails emanate. Within the coma is the nucleus, the origin of the material in the tail and coma.

The main components of a comet are the nucleus, coma, hydrogen cloud, and tails. Strong evidence points to the existence of a central nuclear body or nucleus for all comets from which all cometary material, both gas and dust, originates. In the early 1950s, F. L. Whipple proposed a model of the nucleus in which it is a single mass of ice with embedded dust particles, commonly called a dirty snowball. Such a nucleus could supply an adequate amount of gas to explain cometary phenomena and last through many apparitions because only a relatively thin surface layer would be eroded away (by sublimation) during each passage near the Sun.

The nucleus of Halley's Comet has been directly observed. Its shape was highly irregular, the surface exhibited features and structure, and the albedo (fraction of reflected light) was very low. While the confirmation of the existence of a single, nuclear body is important, Halley is just one comet and generalizations from it may not be valid. *See* ALBEDO.

The coma is observed as an essentially spherical cloud of gas and dust surrounding the nucleus. The principal gaseous constituents are neutral molecules. As the gas flows away from the nucleus, the dust particles are dragged along. In 1970, observations of Comet Tago-Sato-Kosaka and Comet Bennett from orbiting spacecraft showed that these comets were surrounded by a giant hydrogen cloud that extends to distances on the order of 10^7 km, or a size larger than the Sun.



Comet West as photographed on March 9, 1976, showing the general appearance of a bright comet. The fan-shaped structure emanating from the head or coma is the dust tail, while the single straight structure is the plasma tail. The tails are some 30° in length. (*S. M. Larson, Lunar and Planetary Laboratory, University of Arizona*)

Photographs of bright comets generally show two distinct types of tails (see illustration): the dust tails and the plasma tails. They can exist separately or together in the same comet. The plasma tails are generally straight and the plasma in these tails is composed of electrons and molecular ions. The dust tails are usually curved and the dust particles are probably silicate in composition.

The Oort Cloud, postulated by J. Oort in 1950, is the source of the long-period comets. The evidence from the statistics of cometary orbits indicates that it is an essentially spherical cloud of comets with dimensions in the range 10^4 to 10^5 AU. Gravitational perturbations from passing stars and gas clouds have several effects on the cloud. They limit its size and tend to make the orbits random (as observed). Most importantly, the perturbations continually send new comets from the cloud into the inner solar system, where they are observed. Thus, the Oort Cloud can be considered as a steady-state reservoir for new comets. Evidence is mounting for the view that the Oort Cloud is supplied by an inner cloud of comets.

The current consensus on the origin of comets holds that they condensed from the solar nebula at the same time as the formation of the Sun and planets, and their material may be little altered from the era of condensation to the present time. Generally accepted models of the solar nebula have temperature and density conditions suitable for the condensation of cometary materials at solar distances around the orbits of Uranus and Neptune. The condensate could coalesce to produce a ring of comets or cometesimals. Gravitational perturbations by the major planets would disperse the ring of comets, sending some into the inner cloud or Oort's Cloud and sending some inward to become short-period comets. *See* SOLAR SYSTEM. [J.C.B.]

Comfort heating The maintenance of the temperature in a closed volume, such as a home, office, or factory, at a comfortable level during periods of low outside temperature. Two principal factors determine the amount of heat required to maintain a comfortable inside temperature: the difference between inside and outside temperatures and the ease with which heat can flow out through the enclosure.

The first step in planning a heating system is to estimate the heating requirements. This involves calculating heat loss from the space, which in turn depends upon the difference between outside and inside space temperatures and upon the heat transfer coefficients of the surrounding structural members. Outside and inside design temperatures are first selected. Ideally, a heating system should maintain the desired inside temperature under the most severe weather conditions. The design temperature selected depends upon the heat capacity of the structure, amount of insulation, wind exposure, proportion of heat loss due to infiltration or ventilation, nature and time of occupancy or use of the space, difference between daily maximum and minimum temperatures, and other factors. Usually the outside design temperature used is the median of extreme temperatures. The selected inside design temperature depends upon the use and occupancy of the space. Generally it is between 66 and 75°F (19 and 24°C).

In localities where outdoor temperatures are often below 36°F (2°C), it is advisable to provide means for adding moisture in heated spaces to improve comfort. The colder the outside air is, the less moisture it can hold. When it is heated to room temperature, the relative humidity in the space becomes low enough to dry out nasal membranes, furniture, and other hygroscopic materials. This results in discomfort as well as deterioration of physical products. Various types of humidifiers are available. The most satisfactory type provides for the evaporation of the water to take place on a mold-resistant treated material which can be easily washed to get rid of the resultant deposits.

Good insulating material has air cells or several reflective surfaces. A good vapor barrier should be used with or in addition to insulation, or serious trouble may result. Air inside a space in which moisture has been added from cooking, washing, drying, or humidifying has a much higher vapor pressure than cold outdoor air. Therefore, moisture in vapor form passes from the high vapor pressure space to the lower pressure space and will readily pass through most building materials. When this moisture reaches a subfreezing temperature in the structure, it may condense and freeze. When the structure is later warmed, this moisture will thaw and soak the building material, which may be harmful. Good vapor barriers include asphalt-impregnated paper, metal foil, and some plastic-coated papers. Heat loss due to infiltration is the most difficult item to estimate accurately and depends upon how well the house is built. If a masonry or brick-veneer house is not well caulked or if the windows are not tightly fitted and weather-stripped, this loss can be quite large. *See* AIR REGISTER; CENTRAL HEATING AND COOLING; HOT-WATER HEATING SYSTEM; RADIATOR; STEAM HEATING; WARM-AIR HEATING SYSTEM. [G.B.P.]

Commelinales An order of flowering plants, division Magnoliophyta (Angiospermae), which is included in the subclass Commelinidae in the class Liliopsida (monocotyledons). It consists of 4 families and about 1000 species, the bulk of which is in the families Commelinaceae (about 700 species) and Xyridaceae (about 200 species). The order is marked by its flowers that ordinarily have the perianth well differentiated into sepals and petals but do not have nectaries or nectar. The ovary is consistently superior and the fruit capsular. The wandering Jew (species of *Tradescantia* and *Zebrina* in the Commelinaceae) belongs to this order. *See* COMMELINIDAE; LILIOPSIDA; MAGNOLIOPHYTA; PLANT KINGDOM. [A.Cr.; T.M.Ba.]

Commelinidae A subclass of the class Liliopsida (monocotyledons) of the division Magnoliophyta (Angiospermae), the flowering plants, consisting of 7 orders, 16 families, and nearly 15,000 species. The orders include Commelinales, Eriocaulales, Restionales, Juncales, Cyperales, Hydatellales, and Typhales. For further information see separate articles on each order.

These monocotyledons are syncarpous (the carpels are united in a compound ovary) or pseudomonomerous (reduced to a single carpel from a syncarpous ancestry). The endosperm is usually starchy, and the perianth is either well differentiated into sepals and petals or more or less reduced and not petallike. The stomates have two or more subsidiary cells, the pollen is either binucleate or more often trinucleate, and the endosperm may be nuclear. Many of the families have well-developed vessels in all vegetative organs. Several of the orders of Commelinidae have often been treated as a single order Farinosae or Farinales. *See* LILIOPSIDA; MAGNOLIOPHYTA; PLANT KINGDOM. [A.Cr.; T.M.Ba.]

Common cold An acute infectious disorder characterized by nasal obstruction and discharge that may be accompanied by sneezing, sore throat, headache, malaise, cough, and fever. The disorder involves all human populations, age groups, and geographic regions; it is more common in winter than in summer in temperate climates. Most people in the United States experience at least one disabling cold (causing loss of time from work or school or a physician visit) per year. Frequencies are highest in children and are reduced with increasing age.

Most, or possibly all, infectious colds are caused by viruses. More than 200 different viruses can induce the illness, but rhinoviruses, in the picornavirus family, are predominant. Rhinoviruses are small ribonucleic acid-containing viruses with properties similar to polioviruses. Other viruses commonly causing colds include corona, parainfluenza, influenza, respiratory syncytial, entero, and adeno. *See* ADENOVIRIDAE; ENTEROVIRUS; PARAINFLUENZA VIRUS; RHINOVIRUS.

Cold viruses are spread from one person to another in either of two ways: by inhalation of infectious aerosols produced by the sneezing or coughing of ill individuals, or by inoculation with virus-containing secretions through direct contact with a person or a contaminated surface. Controlled experiments have not shown that chilling produces or increases susceptibility to colds. Infection in the nasopharynx induces symptoms, with the severity of the illness relating directly to the extent of the infection. Recovery after a few days of symptoms is likely, but some individuals may develop a complicating secondary bacterial infection of the sinuses, ear, or lung (pneumonia).

Colds are treated with medications designed to suppress major symptoms until natural defense mechanisms terminate the infection. Immunity to reinfection follows recovery and is most effective in relation to antibody in respiratory secretions. There is no established method for prevention of colds; however, personal hygiene is recommended to reduce contamination of environmental air and surfaces with virus that may be in respiratory secretions. *See* PNEUMONIA. [R.B.C.]

Communications cable A cable that transmits information signals between geographically separated points. The heart of a communications cable is the transmission medium, which may be optical fibers, coaxial conductors, or twisted wire pairs. A mechanical structure protects the heart of the cable against handling forces and the external environment. The structure of a cable depends on the application.

Optical communications cables are used in both terrestrial and undersea systems. Optical communications cables for terrestrial use may be installed aerially, by direct burial, or in protective ducts. The terrestrial cable requires only enough longitudinal strength to support its own weight over relatively short pole-to-pole spans, or to allow installers to pull the cable into ducts or lay it in a trench. For the undersea cable, the high-strength steel strand allows it to be laid and recovered in ocean depths up to 4.5 mi (7315 m). *See* OPTICAL COMMUNICATIONS; SUBMARINE CABLE.

Optical communications cables are often used to carry input and output data to computers, or to carry such data from one computer to another. Then they are generally referred to as optical data links or local-area networks. The links are generally short enough that intermediate regeneration of the signals is not needed. *See* Fiber-optic circuit; Local-area networks.

Signals in these cables are carried by light pulses which are guided down the optical fiber. In most applications, two fibers make up a complete two-way signal channel. The guiding effect of the fiber confines light to the core of the glass fiber and prevents interference between signals being carried on different fibers. The guiding effect also delivers the strongest possible signal to the far end of the cable. Exceptionally pure silica glass in the fiber minimizes light loss for signals passing longitudinally through the glass fiber. *See* Optical fibers.

Optical cable systems are usually digital. Thus, information is coded into a train of off-or-on light pulses. These are detected by a photodetector at the far end of a cable span and converted into electronic pulses which are amplified, retimed, recognized in a decision circuit, and finally used to drive an optical transmitter. In the transmitter, a laser converts the electric signals back into a train of light pulses which are strong enough to traverse another cable span. By placing many spans in tandem, optical cable systems can carry signals faithfully for thousands of miles.

Rather than undersea regenerators, current optical-fiber cable systems use erbium-doped fiber amplifiers (EDFAs) to boost the optical signal on long spans. Conversion from optical to electronic modes and back again is then not needed in the undersea repeaters.

Coaxial communication systems evolved before optical systems. Most of these systems are analog in nature. Signals are represented by the amplitude of a wave representing the signal to be transmitted. In a multichannel system, each voice, data, or picture signal occupies its unique portion of a broadband signal which is carried on a shared coaxial conductor or "pipe." In the transmitting terminal, various signals are combined in the frequency-division transmitting multiplex equipment. At the receiving end of a link, signals are separated in the receiving demultiplex equipment. This combining and separation operates much as broadcast radio and television do, and the principles are identical. *See* Amplitude modulation; Coaxial cable; Electrical communications; Frequency modulation; Telephone service; Telephone systems construction. [S.T.B.]

Communications satellite A spacecraft in orbit around the Earth to receive and retransmit radio signals. Communications satellites amplify and sort or route these signals. In earlier days they functioned much like ground microwave repeaters but with greatly increased coverage. Whereas a ground repeater relays signals between two fixed locations, a communications satellite interconnects many locations, fixed and mobile, over a wide area. With the advent of on-board processing, switching and rerouting of signals has been added to the functionality of some communications satellites, making them "switchboards in the sky."

Choice of orbit. The height of a satellite in a circular orbit determines both the period and the great-circle-arc distance which can be covered.

At an altitude of 22,280 mi (35,860 km) the orbital period corresponds to a sidereal day (23 h 56 min 4 s), and if the plane of the orbit coincides with the equatorial plane the satellite appears geostationary. It hovers at a fixed point with respect to the rotating Earth. With coverage of about two-fifths of the entire Earth's surface from a single satellite, three geostationary spacecraft could, in principle, provide worldwide coverage. Satellites in geosynchronous equatorial (geostationary earth) orbit (GEO) currently provide most of the world's satellite communications, for both fixed and mobile services. *See* Orbital motion.

However, very high latitude regions cannot be covered from the geostationary orbit. To cover high latitudes, inclined orbits are used. For its domestic communications satellite system initiated in 1965, the Molniya system, the Soviet Union chose orbits inclined 63.5° with respect to the equatorial plane, with perigee at 300 mi (500 km), apogee at 25,000 mi (40,000 km), and orbital period of 12 h. For the above-mentioned orbit inclination, no rotation of the line of the apsides (otherwise induced by the Earth's oblateness) occurs, and the need for orbit maneuvers and corrections is reduced. It is necessary, however, to track the satellites, and several are required for continuous communications, together with tracking and handover equipment at earth stations. Tundra orbits are also highly inclined and elliptical, but with 24-h periods. The Molniya principle is not limited to high northern latitudes, and satellite communications systems that provide Molniya- and Tundra-type coverage to other regions, such as the contiguous United States, are being implemented.

As technology has progressed, low-altitude earth orbits (LEOs; less than 600 mi or 1000 km) and medium-altitude earth orbits (MEOs; less than 8000 mi or 14,400 km) have acquired some distinct advantages for mobile services. The lower-altitude satellites have much shorter paths from base stations (fixed earth stations) and mobile earth terminals as compared with satellites in geostationary orbit. Thus rf power requirements and path delay are much smaller. The consequence is that the mobile earth terminals can use low-gain antennas that need little or no tracking while still using low-power transmitters, and the system does not degrade from delay with multiple hops.

However, since the duration of an interconnection is limited to the interval of satellite visibility to the mobile earth terminals and base stations to be connected, constellations of satellites must be orbited to provide continuous communications. Typically, a system has several orbital planes, all inclined, with multiple satellites in each orbit. The satellites travel around the orbits in succession so that the next satellite rises over the horizon before the currently used satellite sets, and satellites hand over coverage (and users) in an orderly way. As the Earth rotates under the orbit planes, or, to the Earth-based observer, the orbit planes rotate around the Earth, a new orbit rotates into the field of view as the previously used orbit plane rotates out. Depending on altitude, 12–66 satellites are needed to maintain continuous worldwide communications. The orbits of choice for these constellations are below the lower Van Allen belt (that is, in LEOs) or between the Van Allen belts (that is, in MEOs). These regions are chosen to reduce the effects of radiation on solid-state components aboard, as compared to orbits inside the Van Allen belts. *See* Van Allen radiation.

Uses. Geostationary commercial communications satellites carry less than one-half of the long-distance international telephone traffic. Other services include television, satellite news gathering, private business networks, data, facsimile, electronic mail, and Internet interconnection. Worldwide television would be impossible without satellites, because no other pervasive wide-band transmission system exists. *See* Data communications; Facsimile; Internet; Telephone service; Television; Television networks.

In addition to these fixed-point satellite communications services (fixed satellite service; FSS), GEO satellites provide worldwide mobile communications services (mobile satellite service; MSS) of high quality and reliability. Mobile communications include ship-to-shore maritime communication (maritime mobile satellite service; MMSS), aircraft-to-ground (aeronautical mobile satellite service; AMSS), and land vehicle-to-base (land mobile satellite service; LMSS). Services provided include data, voice, paging, facsimile, and emergency services such as search and rescue for ships and aircraft and terrestrial emergency services (forest fire, flood, and earthquake). *See* Radio paging systems.

Broadcasting via satellites to individual homes and community antenna television (CATV) cable heads has been in use since 1983 employing medium-power satellites. The advent of high-power satellites in the late 1980s created the direct broadcast satellite (DBS) industry, which has experienced worldwide growth. Satellites are being built to provide direct radio services (in the same manner as broadcast radio stations) to vehicles;

this is called the digital audio radio service (DARS). *See* DIRECT BROADCASTING SATELLITE SYSTEMS.

Satellites are also widely used for military communications between fixed stations and mobile terminals on ships, airplanes, and land vehicles. *See* MILITARY SATELLITES.

Satellites in Molniya- and Tundra-type orbits provide much the same type of services, since the constellation appears quasi-geostationary for the region over which the very slow moving satellites hover near apogee.

In the latter half of the 1990s, satellite systems (constellations) were planned and some were launched to provide services from MEO and LEO. The planned and implemented services include paging, messaging, meter reading, and other low-data-rate services from the little LEO systems, to voice, data, private business networks, and Internet communication via the other LEO and MEO systems.

Basic configuration. Satellites represent a very significant step in the evolution of radio communications systems, whose progress can be largely attributed to the use of ever-higher carrier frequencies to obtain wider signaling bandwidths. Terrestrial ultrahigh-frequency (UHF) and superhigh-frequency (SHF) radio relay systems have high communications capacity, but are range-limited. Clearly, when terminals are separated by oceans, electronic equipment on an orbiting spacecraft provides a solution with which only fiber-optic cables can compete, and then only on trunk routes. *See* MICROWAVE; OPTICAL COMMUNICATIONS.

In a satellite communications system, the spacecraft carries the power subsystem, station-keeping and orientation devices, and the payload, the communications subsystem. Wideband linear receivers amplify the uplink signals. After a process of frequency conversion, the signals are further amplified in separate channels (to minimize intermodulation noise) and fed to the downlinks. Transmitter power output of individual channels falls in the range 5–40 W in satellites for fixed services. Travelling-wave tube amplifiers (TWTAs) are commonly used as power amplifiers, but solid-state power amplifiers (SSPAs) based upon field-effect transistors are competitive at 4 GHz and will become competitive at 12 GHz. Mobile satellites in geostationary orbit require higher effective radiated powers, and typically use solid-state matrix amplifiers and 20-ft (6-m) antennas to achieve them. Their Ku-band feeder links employ 100-W TWTAs on board. Broadcasting satellites, serving a multitude of users having small, inexpensive receivers and receive-only antennas (typically 1–3 ft or 0.3–1 m in diameter), require transmitter power up to a few hundred watts provided by TWTAs. The total power generated by solar-cell arrays has gradually climbed to over 10 KW. *See* AMPLIFIER; MICROWAVE SOLID-STATE DEVICES; TRANSISTOR.

Spacecraft antennas. Parabolic reflector spacecraft antennas provide spot beam coverage down to about 1°. The allocated frequency bands are reused many times by means of orthogonal polarizations (vertical–horizontal linear or clockwise–counterclockwise circular) and spatially separated beams. Beams have been synthesized to follow the contours of geographical areas such as continents and national or regional boundaries, using suitably arranged feed horns, excited with proper amplitude and phase, whose radiated energy impinges upon a reflector and illuminates desired areas on Earth.

In such frequency reuse systems, adequate isolation (up to 30 dB) must be maintained between dually polarized and spatially separated beams. Until the 1980s, parabolic reflectors with offset feed assemblies in the focal region were adequate. However, when more beams and higher frequency reuse factors are desired, dual-offset reflectors with gregorian or cassegrainian feeds provide better control of the illumination and permit the use of larger reflectors without the need for excessive focal lengths. These are usually fed by feed arrays backed by beam-forming networks to provide the multiplicity of beams or beam shaping required. Arrays of up to 160 feed horns have been employed, backed by three layers of beam-forming networks to provide reconfigurability while on station.

Antennas used on LEO and MEO satellite systems must radiate families of beams to provide coverage cells that resemble in some respects terrestrial coverage patterns. This has led to deployment of multibeam arrays in some configurations and constellations. As the satellites proceed along their orbital paths, these clusters of beams sweep out coverage swaths that move over the Earth. *See* ANTENNA (ELECTROMAGNETISM).

Transponders. Transponders are microwave repeaters carried by communications satellites. Transparent transponders can handle any signal whose format can fit in the transponder bandwidth. No signal processing occurs other than that of heterodyning (frequency changing) the uplink frequency bands to those of the downlinks. Such a satellite communications system is referred to as a bent-pipe system. Connectivity among earth stations, which is maximum with global-coverage antennas, is reduced when multiple narrow beams are used. Hence, the evolution proceeded from the transparent transponder to transponders that can perform signal switching and format processing.

On-board processing has increased in other areas as well, including (1) radio-frequency and intermediate-frequency signal switching, (2) baseband processing and switching, (3) phased-array antenna and feed-array control and beam forming, and (4) bus function support processing. The first two relate to the traffic through the transponder. The function of the antennas is growing ever more complex, especially on some LEO and MEO systems, and thus requires on-board processing and control. Similarly, control of the satellite bus functions (power systems, attitude, station-keeping, telemetry and the like) requires significant on-board processing. [G.Hy.; P.L.Ba.; C.E.Ma.]

Communications scrambling

The methods for ensuring the privacy of voice, data, and video transmissions. Various techniques are commonly utilized to perform such functions.

Analog voice-scrambling methods typically involve splitting the voice frequency spectrum into a number of sections by means of a filter bank and then shifting or reversing the sections for transmission in a manner determined by switch settings similar to those of a combination lock; the reverse process takes places at the receive end. Digital methods first convert the analog voice to digital form and then scramble or encrypt the digital voice data by one of the methods discussed below. *See* ANALOG-TO-DIGITAL CONVERTER; ELECTRIC FILTER.

A simple data-scrambling method involves the addition of a pseudorandom number sequence to the data at the transmit end. Devices using this method are known as stream ciphers. A second method partitions the data into blocks. Data within a block may be permutated bit by bit or substituted by some other data in a manner determined by the switch setting, which is often called a key. Devices using this method are known as block ciphers. *See* CRYPTOGRAPHY.

Typical video scrambling devices used for cable television applications involve modifying the amplitude or polarity of the synchronization signals, thereby preventing the normal receiver from detecting the synchronization signals. A more sophisticated technique, used in satellite transmission, introduces a random delay to the active video signal on a line-by-line basis. An even more advanced technique called cut-and-rotate has been proposed. Video signals can also be digitized by a number of coding techniques and then scrambled by any of the data-scrambling techniques discussed above to achieve high security. *See* CLOSED-CIRCUIT TELEVISION; TELEVISION. [L-N.L.]

Communications systems protection

The protection of wire and optical communications systems equipment and service from electrical disturbances. This includes the electrical protection of lines, terminal equipment, and switching centers, and inductive coordination, or the protection against interference from nearby electric power lines.

The principal sources of destructive electrical disturbances on wire communications systems are lightning and accidental energization by power lines. Lightning that directly strikes aerial or buried communication cable may cause localized thermal damage and crushing. Simultaneously, it energizes the communication line with a high-level voltage transient that is conducted to terminal equipment. Indirect strikes are more common than direct strikes and, although they normally do not cause mechanical damage, they propagate electrical transients along the line. *See* Lightning.

During fault conditions on commercial power lines, high voltages may occur in nearby communication lines by several mechanisms. The most common is magnetically induced voltage caused by the high unbalanced currents of a phase-to-ground power-line fault. During such an event, an aerial or buried communication line that is parallel to the faulted power line intercepts its time-varying magnetic field, incurring a high longitudinal voltage.

In city centers, the diversion of lightning strikes by steel-framed buildings, and the shielding effect of the many underground metallic utility systems, considerably reduce the probability of high-voltage transients from lightning or induction from power lines. Since communication and power facilities are routed in separate conduits, the possibility of a power contact is remote. *See* Electrical interference; Electrical noise.

Metallic communication lines often are made up of many closely spaced pairs of wires arranged as a cable. A grounded circumferential metallic shield on the cable reduces the magnitude of electrical transients from nearby lightning strikes, and also can intercept a low-current direct strike, minimizing damage to the internal conductors. The effectiveness of the shield is improved if its resistance per unit length is low and if the dielectric strength of the insulation between the shield and the internal conductors is high.

Damage to cable plant from a power-line contact is minimized by providing frequent bonds between the cable shield or aerial support strand and the neutral conductor of the power line. These bonds create low-resistance paths for fault currents returning to the neutral, and hasten deenergization by power-line fault-clearing devices. Closely spacing the bonds limits the length of communication cable that is damaged by the contact.

The outer metallic shields of belowground cables may be attacked by electrolytic action and require protective measures against corrosion. *See* Corrosion.

Optical-fiber communication lines are enclosed in cables that may contain metallic components to provide mechanical strength, water-proofing, local communications, or a rodent barrier. Though the cables otherwise would be immune to the effects of lightning or nearby power lines, such metallic components introduce a measure of susceptibility that is made all the more important by the high information rates carried by the fibers. A direct lightning strike to a metallic component of buried optical-fiber cable can cause localized thermal damage, arcing, and crushing that together may damage the fibers. Electrical protection is provided by cable designs that withstand these effects. As with metallic lines, the probability of this damage can be reduced by burying one or more shield wires at least 1 ft (0.3 m) above the cable.

Alternating currents may be conducted on the metallic sheath components of optical-fiber cables during an accidental contact with power-line conductors. Cable damage is minimized in extent by bonding the sheath to the neutral conductor of the power line, and by providing enough conductivity to carry the currents without damage to the fibers. *See* Optical communications; Optical fibers.

To protect the users, their premises, and terminal equipment, communication lines that are exposed to lightning or contacts with power lines are usually provided with surge protectors. Article 800 of the National Electrical Code requires that communication lines exposed to contact with power lines of voltages greater than 300 V be equipped with a protector at the entrance to the served premises. Interbuilding lines that are exposed to lightning also have protectors. Although not required, it is common practice to minimize equipment damage by so equipping communication lines in an area of significant lightning exposure even if there is no power-contact hazard. Article 830 extends similar requirements to coaxial circuits that provide network-powered broadband communications. *See* Electrical codes.

Switching centers contain electronic equipment that routes communications to their proper destinations. This equipment is protected from the effects of electrical transients appearing at interfaces with external communication lines in a similar way as for terminal equipment.

Inductive coordination refers to measures that reduce the magnitudes and effects of steady-state potentials and currents induced in metallic communication lines from paralleling power facilities. *See* Inductive coordination. [M.Pa.]

Commutation The process of transferring current from one connection to another within an electric circuit. Depending on the application, commutation is achieved either by mechanical switching or by electronic switching.

Commutation was conceived over a century ago through the invention of the direct-current (dc) motor. When direct current is supplied to a winding on a rotor that is subjected to a stationary magnetic field, it experiences a rotational force and resulting output torque. As the stator north and south poles are reversed relative to the rotating winding, the rotor current is reversed by a commutator in order to maintain the unidirectional torque required for continuous motor action. *See* Direct-current motor; Windings in electric machinery.

The principle is illustrated in Fig. 1. In its simplest form, a single rotor winding is connected between two segments of a cylindrical copper commutator which is mounted axially on the rotor. Connection to the external dc supply is through sliding carbon contacts (brushes). The segments have small insulated gaps at *A* and *B*. As *A* and *B* pass the brushes, the current in the rotor winding reverses. In the short interval where the brushes short-circuit the segments, the rotor current decays before building up in the reverse direction. The angular position of the brushes is selected to reverse the current at the appropriate rotor position. *See* Commutator.

The same principle of commutation applies to the ac commutator motor and universal ac/dc motor, which are common in variable-speed kitchen appliances and electric hand tools. *See* Alternating-current motor; Universal motor.

The equivalent of mechanical commutation occurs in solid-state converter circuits such as those used for rectifying ac to dc or inverting dc to ac. Figure 2 shows a three-phase converter widely used in industry. For simplicity, the ac supply network is represented by equivalent phase voltages in series with the effective supply inductance. (Often this inductance is mainly the inductance per phase of a converter transformer that interfaces

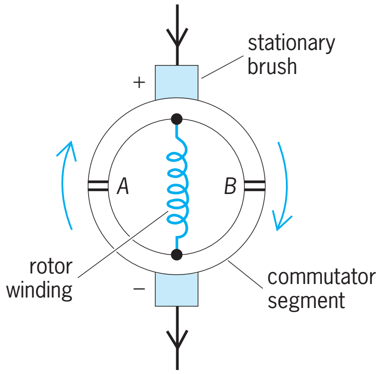


Fig. 1. Basic commutator for a dc motor.

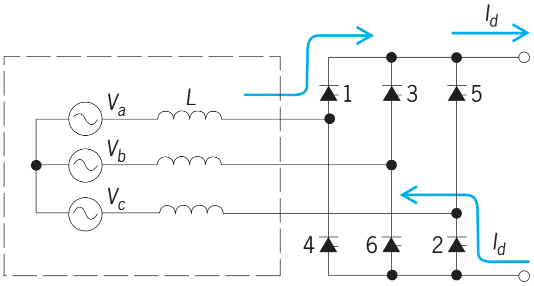

Fig. 2. Three-phase converter.

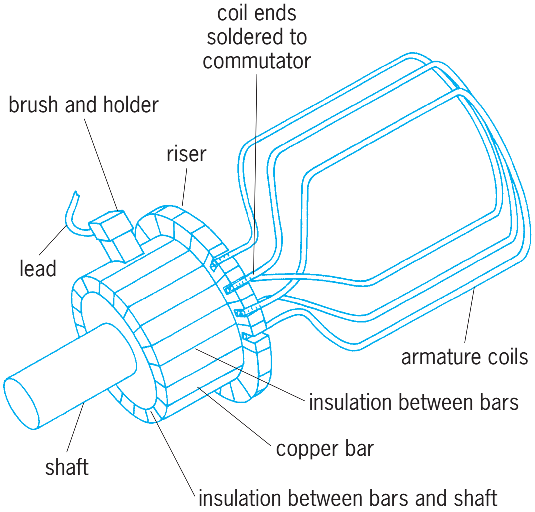
the converter and the three-phase supply.) Usually, supply resistance is relatively low and plays a negligible role in the converter action. As shown, thyristors 1 and 2 are conducting the dc current from phase *a* to phase *c*. A smooth dc current does not produce a voltage across the inductance *L* in each phase. In the cyclic conduction sequence, the dc current is commutated from phase *a* and thyristor 1 to phase *b* and thyristor 3. To achieve this, thyristor 3 is gated in a region of the ac waveform when its forward voltage is positive. Turning it on applies a reverse voltage to thyristor 1 (phase *b* being more positive than phase *a*), which ceases conduction to complete the commutation of the dc current. This is repeated in sequence for the other thyristors in each ac cycle. *See* Converter; Semiconductor rectifier. [J.Re.]

Commutator That part of a dc motor or generator which serves the dual function, in combination with brushes, of providing an electrical connection between the rotating armature winding and the stationary terminals, and of permitting the reversal of the current in the armature windings. For explanation of the necessity of this function *See* Commutation.



Commutator and brush assembly with coil connections for lap winding.

A commutator (see illustration) is composed of copper bars assembled to form a drumlike cylinder which is concentric with the axis of rotation. Insulation, commonly mica, to provide exceptional mechanical and electrical stability, is placed between commutator bars and between the bars and the shaft. Conducting brushes, commonly carbon, sufficient in size and number to carry the current, are spaced at intervals of 180 electrical degrees about the surface of the commutator and held in contact with the surface of the commutator by spring tension. *See* Direct-current generator; Direct-current motor; Electric rotating machinery. [A.R.E.]

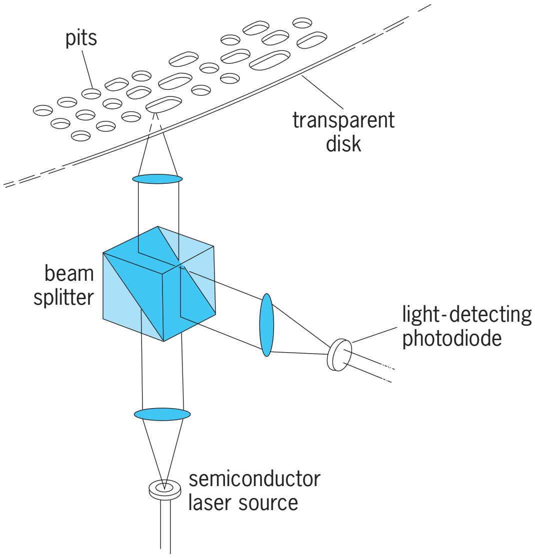
Compact disk A system for data storage in which digitally encoded information in the form of microscopic pits on a rotating disk is accessed by optical readout. The compact disk was originally developed as a music carrier providing high fidelity, random access, convenience, durability, and low cost. Its attributes made it suitable for storing diverse data such as video programs and computer software, and improvements allowed recordability and erasability. Greater storage capacity and more sophisticated integration of features is provided in the DVD (digital video disk or digital versatile disk) format.

An acoustic signal waveform is stored on the disk in the form of a binary code, as a series of 0's and 1's. This is done by forming pits along spiral tracks on a transparent plastic disk, overlaying this with a reflective coating, and covering this coating with a protective layer. The light from a semiconductor laser is focused onto the pits from below (see illustration). The presence or absence of pits within the laser spot changes the intensity of the reflected beam (pits diffract the light, reducing reflected intensity). The reflected light strikes a light-detecting photodiode that converts the varying-intensity light beam into a binary electrical signal. *See* Laser.

In the disk mastering and replication process, a glass disk is covered by a uniform coating of photoresist material. A laser exposes portions of the photoresist where pits are to be formed. The photoresist is then developed and washed, leaving the master recording. A nickel mother is derived from this master and is then used as a mold to produce multiple copies of the disk in transparent polycarbonate plastic. These substrates are coated with a thin metallic reflecting layer (usually aluminum), with a protective plastic coating on top of that.

Since the information that is read off the disk is in digital form, as a sequence of 0's and 1's, it can be processed in many ways that are not possible with analog systems. To enable this, information can be passed through a buffer memory, and then output at a rate that is controlled by the player's quartz-crystal (oscillator) clock, hence entirely eliminating the wow and flutter of conventional systems.

To recreate the original music signal, the binary data on the disk must be passed through a digital-to-analog (D/A) converter and a low-pass filter. The digital-to-analog converter accepts each 16-bit sample and outputs a voltage corresponding to its value. The series of samples forms a staircase waveform that is applied to a low-pass filter that removes all frequencies above the half-sampling frequency. In this way, the filter reconstructs the original waveform. A steep (high-order) analog filter can be



Optical readout system for an audio compact disk.

used, with a flat amplitude to the half-sampling frequency, at which point the amplitude falls to zero. *See* DIGITAL-TO-ANALOG CONVERTER; ELECTRIC FILTER.

Subsequent to its origin as a music carrier, the compact disk's format was extended to include the CD-ROM (read-only memory) format for computer applications. Newer formats that use the compact disk as their basis include the recordable CD-R and erasable CD-RW formats, and the multimedia DVD format. [K.C.Po.]

Comparator An electronic circuit that produces an output voltage or current whenever two input levels simultaneously satisfy predetermined amplitude requirements. A comparator circuit may be designed to respond to continuously varying (analog) or discrete (digital) signals, and its output may be in the form of signaling pulses which occur at the comparison point or in the form of discrete direct-current (dc) levels.

A linear comparator operates on continuous, or nondiscrete, waveforms. Most often one voltage, referred to as the reference voltage, is a variable dc or level-setting voltage and the other is a time-varying waveform. When the signal voltage becomes equal to the reference voltage, a discrete output level is obtained. If the time-varying (signal) voltage approaches the reference voltage from a more negative level the output voltage is of one polarity; if it approaches the reference from a more positive value the output is of the opposite polarity.

A very high-gain operational amplifier whose output is inverting with respect to one input terminal and noninverting with respect to the other and whose output voltage is limited at upper and lower levels (usually at voltages near the supply voltage levels) may be used as a voltage comparator. The high-gain operational-amplifier comparator used in the open-loop mode is designated as a nonregenerative comparator because there is no positive feedback path from the output back to the input.

An operational-amplifier comparator connected in a positive-feedback mode is referred to as a regenerative comparator. If the voltage gain is very high, then there is a difference between the input levels which will cause the output to switch.

This difference in input levels is referred to as the hysteresis of the circuit. Such regenerative comparators are generically referred to as Schmitt triggers. Historically, they were first implemented as discrete two-vacuum-tube devices, which were later replaced by transistors and then by the operational amplifier feedback circuit. *See* AMPLIFIER; FEEDBACK CIRCUIT; HYSTERESIS; OPERATIONAL AMPLIFIER.

The term digital comparator has historically been used when the comparator circuit is specifically designed to respond to a combination of discrete level (digital) signals, for example, when one or more such input signals simultaneously reach the reference level which causes the change of state of the output. Among other applications, such comparators perform the function of the logic gate such as the AND, OR, NOR, and NAND functions. More often, the term digital comparator describes an array of logic gates designed specifically to determine whether one binary number is less than or greater than another binary number. Such digital comparators are sometimes called magnitude or binary comparators. [G.M.G.]

Complement A group of proteins in the blood and body fluids that play an important role in humoral immunity and the generation of inflammation. When activated by antigen-antibody complexes, or by other agents such as proteolytic enzymes (for example, plasmin), complement kills bacteria and other microorganisms. In addition, complement activation results in the release of peptides that enhance vascular permeability, release histamine, and attract white blood cells (chemotaxis). The binding of complement to target cells also enhances their phagocytosis by white blood cells. The most important step in complement system function is the activation of the third component of complement (C3), which is the most abundant of these proteins in the blood.

Genetic deficiencies of certain complement subcomponents have been found in humans, rabbits, guinea pigs, and mice. Certain deficiencies lead to immune-complex diseases, such as systemic lupus erythematosus; other deficiencies result in increased susceptibility to bacterial infections, particularly those of the genus *Neisseria* (for example, gonorrhea and meningococcal meningitis), and hereditary angioneurotic edema. *See* COMPLEMENT-FIXATION TEST; IMMUNITY. [F.S.R.]

Complement-fixation test A sensitive reaction used in serology for the detection of either antigen or antibody, as in the diagnosis of many bacterial, viral, and other diseases, including syphilis. It involves two stages: Stage 1 is the binding or fixation of complement if certain antigen-antibody reactions occur, and stage II is detection of residual unbound complement, if any, by its hemolytic action on the sensitized erythrocytes subsequently added (see illustration).

In the first stage either the antigen or the antibody must be supplied as a reagent, with the other of the pair as the test unknown. Fresh guinea pig serum is normally used as a complement source. Sheep erythrocytes which are coated with their corresponding antibody (amboceptor or hemolysin) are used in the second stage. *See* COMPLEMENT.

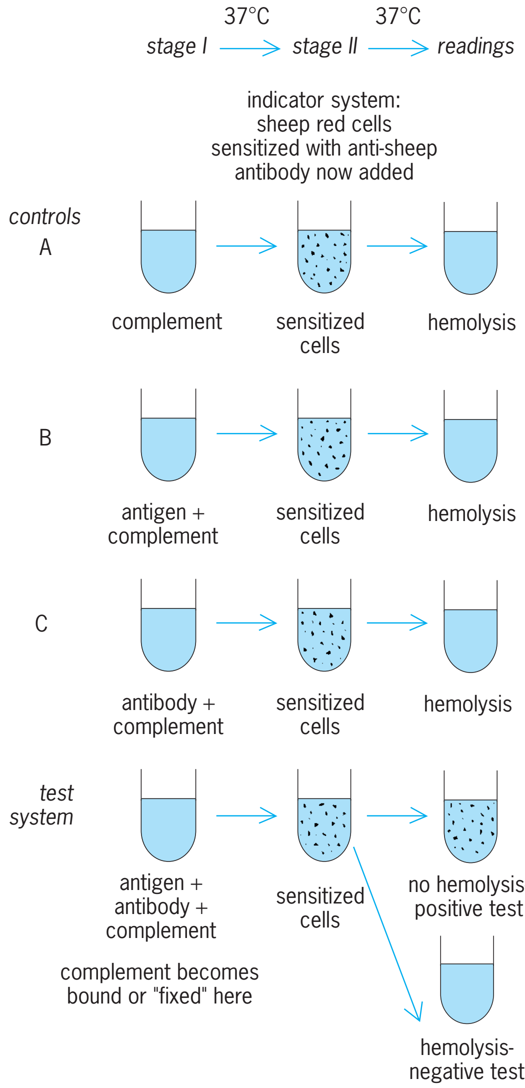


Diagram of the complement-fixation reaction.

The controls A, B, and C in the diagram demonstrate that sufficient complement is present to effect hemolysis of the sensitized indicator cells and that neither antigen or antibody added alone will interfere with this by binding complement. In the test system the combination of a suitable antigen and antibody in the presence of complement will bind the complement to the complex so that the complement becomes unavailable for the hemolysis of the indicator cells added in stage II. If either antigen or antibody is added as a reagent in stage I, then the presence of the other in the test unknown added can be detected through its ability to complete the antigen-antibody system. A lack of hemolysis denotes that the complement is bound. *See* IMMUNOLOGY; LYTIC REACTION. [H.P.T.]

Complementation (genetics) The complementary action of different genetic factors. The term usually implies two homologous chromosomes or chromosome sets, each defective because of mutation and unable by itself to promote the normal development or metabolism of the organism, but able to do so jointly when brought together in the same cell. *See* CHROMOSOME; MUTATION.

S. Benzer proposed the term cistron for the unit within which mutants do not complement each other. The word gene is often used in the same sense. The usual biochemical function of a cistron, or gene, is to determine the structure of a specific polypeptide component of a protein. Full complementation between different genes is the rule except when, as sometimes in bacteria, the genes form part of a functionally coordinated complex (operon). Allelic mutants (mutants within one gene) show limited complementation in some cases, for example, when certain pairs of mutant polypeptides correct each other's defects through coaggregation in a complex protein. *See* GENETICS; OPERON. [J.R.S.F.]

Complex numbers A natural and extremely useful extension of the familiar real numbers. They can be introduced formally as follows. Consider the two-dimensional real vector space consisting of all ordered pairs (a_1,a_2) of real numbers. Geometrically this space can be identified with the ordinary euclidean plane, viewing the real numbers a_1,a_2 as the coordinates of a point in the plane.

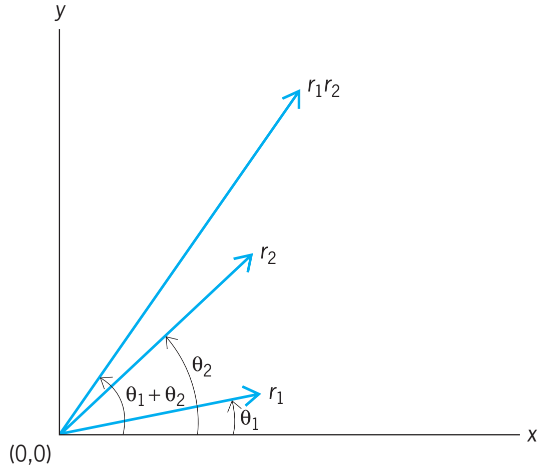
The addition of vectors is defined by $(a_1,a_2) + (b_1,b_2) = (a_1 + b_1,\ a_2 + b_2)$ and is just the usual addition of vectors by the parallelogram law. The multiplication of a vector (a_1,a_2) by a real number c is defined by $c(a_1,a_2) = (ca_1,ca_2)$, and is just the uniform dilation of the plane by the factor c. It may be asked whether it is possible to define a multiplication of one vector by another in such a manner that this multiplication is linear and satisfies the same formal rules as multiplication of real numbers. There does exist such a multiplication, given by the equation below, and it is

$$(a_1,a_2)\cdot(b_1,b_2) = (a_1b_1 - a_2b_2,\, a_1b_2 + a_2b_1)$$

essentially unique in the sense that any multiplication satisfying all the desired properties can be reduced to this equation by a suitable choice of coordinates in the plane. The plane with the ordinary addition and scalar multiplication of vectors and with the vector multiplication given above is the complex number system.

The above multiplication law can most easily be interpreted geometrically by introducing polar coordinates in the plane and writing $(a_1,a_2) = (r\cos\theta, r\sin\theta)$, where r is the length of the vector (a_1,a_2), or the modulus of the complex number (a_1,a_2), defined by $r^2 = a_1{}^2 + a_2{}^2$, and θ is the angle between the vector (a_1,a_2) and the first coordinate axis, or the argument of the complex number (a_1,a_2), defined by $\tan\theta = a_2/a_1$. Then multiplication of complex numbers amounts to multiplying their moduli and adding their arguments (see illustration).

Introducing the basis vectors $l = (1,0)$ and $i = (0,1)$, any vector (x,y) can be written uniquely as the sum $(x,y) = xl + yi$. It follows readily from the multiplication law that $l\cdot l = l$, $l\cdot i = i\cdot l = i$, and $i\cdot i = -l$, so that in particular the vector l is the identity element for the multiplication of complex numbers. The complex number l can be identified with the ordinary real number 1, and reflecting this identification the notation can be simplified by writing a complex number $z = (x,y) = xl + yi$ merely as $z = x + iy$. The component x is called the real part of the complex number z, and the component y is called the imaginary part. The modulus of the complex number z is denoted by $|z|$. [R.C.G.]

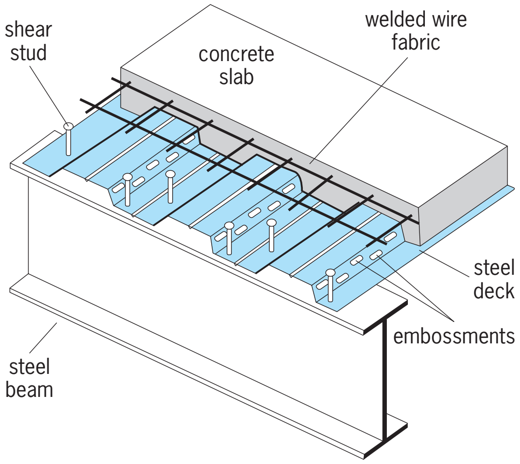


Multiplication of complex numbers.

Composite beam A structural member composed of two or more dissimilar materials joined together to act as a unit. An example in civil structures is the steel-concrete composite beam in which a steel wide-flange shape (I or W shape) is attached to a concrete floor slab (see illustration). The many other kinds of composite beam include steel-wood, wood-concrete, and plastic-concrete or advanced composite materials–concrete. Composite beams as defined here are different from beams made from fiber-reinforced polymeric materials. *See* COMPOSITE MATERIAL.

There are two main benefits of composite action in structural members. First, by rigidly joining the two parts together, the resulting system is stronger than the sum of its parts. Second, composite action can better utilize the properties of each constituent material. In steel-concrete composite beams, for example, the concrete is assumed to take most or all of the compression while the steel takes all the tension.

Steel-concrete composite beams have long been recognized as one the most economical structural systems for both multistory



Typical composite floor system.

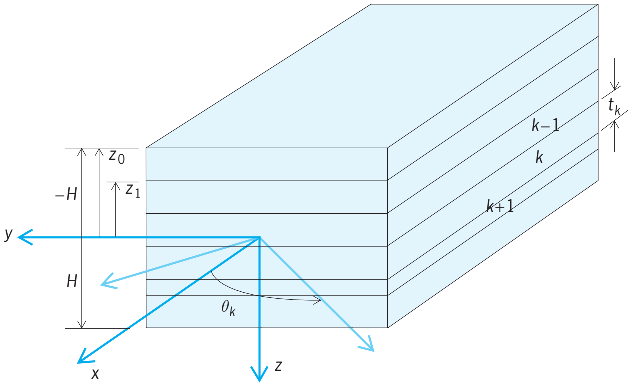
steel buildings and steel bridges. Buildings and bridges require a floor slab to provide a surface for occupants and vehicles, respectively. Concrete is the material of choice for the slab because its mass and stiffness can be used to reduce deflections and vibrations of the floor system and to provide the required fire protection. The supporting system underneath the slab, however, is often steel because it offers superior strength-weight and stiffness-weight ratio, ease of handling, and rapid construction cycles. Since both the steel and concrete are already present in the structures, it is logical to connect them together to better utilize their strength and stiffness. *See* CONCRETE; CONCRETE SLAB; STEEL. [R.Leo.]

Composite laminates Assemblages of layers of fibrous composite materials (see illustration) which can be tailored to provide a wide range of engineering properties, including inplane stiffness, bending stiffness, strength, and coefficients of thermal expansion.

The individual layers consist of high-modulus, high-strength fibers in a polymeric, metallic, or ceramic matrix material. Fibers currently in use include graphite, glass, boron, and silicon carbide. Typical matrix materials are epoxies, polyimides, aluminum, titanium, and alumina. Layers of different materials may be used, resulting in a hybrid laminate. The individual layers generally are orthotropic (that is, with principal properties in orthogonal directions) or transversely isotropic (with isotropic properties in the transverse plane) with the laminate then exhibiting anisotropic (with variable direction of principal properties), orthotropic, or quasi-isotropic properties. Quasi-isotropic laminates exhibit isotropic (that is, independent of direction) inplane response but are not restricted to isotropic out-of-plane (bending) response. Depending upon the stacking sequence of the individual layers, the laminate may exhibit coupling between inplane and out-of-plane response. An example of bending-stretching coupling is the presence of curvature developing as a result of inplane loading. *See* COMPOSITE MATERIAL; METAL MATRIX COMPOSITE; POLYMERIC COMPOSITE.

Classical lamination theory describes the mechanical response of any composite laminate subjected to a combination of inplane and bending loads. The laminate in Fig. 1 uses a global x-y-z coordinate system with z perpendicular to the plane of the laminate and positive downward. The origin of the coordinate system is located on the laminate midplane. The laminate has N layers numbered from top to bottom. Each layer has a distinct fiber orientation denoted θ_k. The z coordinate to the bottom of the kth layer is designated z_k with the top of the layer being z_{k-1}. The thickness, t_k, of any layer is then $t_k = z_k - z_{k-1}$. The top surface of the laminate is denoted z_0, and the total thickness is $2H$.

It is assumed that (1) there is perfect bonding between layers; (2) each layer can be represented as a homogeneous material with known effective properties which may be isotropic, orthotropic, or transversely isotropic; (3) each layer is in a state of plane stress; and (4) the laminate deforms according to the Kirchhoff (1850) assumptions for bending and stretching of thin plates: (a) normals to the midplane remain straight and normal to the deformed midplane after deformation, and (b) normals to the midplane do not change length.



Composite laminate consisting of layers with varying thickness.

The wide variety of coefficients of thermal expansion are possible through changes in the stacking arrangement of a given carbon/epoxy. The coefficient of thermal expansion is the strain associated with a change in temperature of 1°. Most materials have positive coefficients of expansion and thus expand when heated and contract when cooled. The effective axial coefficient of thermal expansion of the carbon/epoxy can be positive, negative, or zero, depending upon the laminate configuration. Laminates with zero coefficient of thermal expansion are particularly important because they do not expand or contract when exposed to a temperature change. Composites with zero (or near zero) coefficient of thermal expansion are therefore good candidates for application in space structures where the temperature change can be 500°F (from −250 to +250°F) [278°C (from −157 to +121°C)] during an orbit in and out of the Sun's proximity. There are many other applications where thermal expansion is a very important consideration. [C.T.H.]

Composite material A material system composed of a mixture or combination of two or more constituents that differ in form or material composition and are essentially insoluble in each other. In principle, composites can be constructed of any combination of two or more materials—metallic, organic, or inorganic; but the constituent forms are more restricted. The matrix is the body constituent, serving to enclose the composite and give it bulk form. Major structural constituents are fibers, particles, laminae or layers, flakes, fillers, and matrices. They determine the internal structure of the composite. Usually, they are the additive phase.

Because the different constituents are intermixed or combined, there is always a contiguous region. It may simply be an interface, that is, the surface forming the common boundary of the constituents. An interface is in some ways analogous to the grain boundaries in monolithic materials. In some cases, the contiguous region is a distinct added phase, called an interphase. Examples are the coating on the glass fibers in reinforced plastics and the adhesive that bonds the layers of a laminate together. When such an interphase is present, there are two interfaces, one between the matrix and the interphase and one between the fiber and the interface.

Interfaces are among the most important yet least understood components of a composite material. In particular, there is a lack of understanding of processes occurring at the atomic level of interfaces, and how these processes influence the global material behavior. There is a close relationship between processes that occur on the atomic, microscopic, and macroscopic levels. In fact, knowledge of the sequence of events occurring on these different levels is important in understanding the nature of interfacial phenomena. Interfaces in composites, often considered as surfaces, are in fact zones of compositional, structural, and property gradients, typically varying in width from a single atom layer to micrometers. Characterization of the mechanical properties of interfacial zones is necessary for understanding mechanical behavior.

Advanced composites comprise structural materials that have been developed for high-technology applications, such as airframe structures, for which other materials are not sufficiently stiff. In these materials, extremely stiff and strong continuous or discontinuous fibers, whiskers, or small particles are dispersed in the matrix. A number of matrix materials are available, including carbon, ceramics, glasses, metals, and polymers. Advanced composites possess enhanced stiffness and lower density compared to fiber-glass and conventional monolithic materials. While composite strength is primarily a function of the reinforcement, the ability of the matrix to support the fibers or particles and to transfer load to the reinforcement is equally important. Also, the matrix frequently dictates service conditions, for example, the upper temperature limit of the composite. [P.Sa.]

The use of fiber-reinforced materials in engineering applications has grown rapidly. Selection of composites rather than monolithic materials is dictated by the choice of properties. The high values of specific stiffness and specific strength may be the determining factor, but in some applications wear resistance or strength retention at elevated temperatures is more important. A composite must be selected by more than one criterion, although one may dominate.

Components fabricated from advanced organic-matrix–fiber-reinforced composites are used extensively on commercial aircraft as well as for military transports, fighters, and bombers. The propulsion system, which includes engines and fuel, makes up a significant fraction of aircraft weight (frequently 50%) and must provide a good thrust-to-weight ratio and efficient fuel consumption. The primary means of improving engine efficiency are to take advantage of the high specific stiffness and strength of composites for weight reduction, especially in rotating components, where material density directly affects both stress levels and critical dynamic characteristics, such as natural frequency and flutter speed.

Composites consisting of resin matrices reinforced with discontinuous glass fibers and continuous-glass-fiber mats are widely used in truck and automobile components bearing light loads, such as interior and exterior panels, pistons for diesel engines, drive shafts, rotors, brakes, leaf springs, wheels, and clutch plates.

The excellent electrical insulation, formability, and low cost of glass-fiber-reinforced plastics have led to their widespread use in electrical and electronic applications ranging from motors and generators to antennas and printed circuit boards.

Composites are also used for leisure and sporting products such as the frames of rackets, fishing rods, skis, golf club shafts, archery bows and arrows, sailboats, racing cars, and bicycles.

Advanced composites are used in a variety of other applications, including cutting tools for machining of superalloys and cast iron and laser mirrors for outer-space applications. They have made it possible to mimic the properties of human bone, leading to development of biocompatible prostheses for bone replacements and joint implants. In engineering, composites are used as replacements for fiber-reinforced cements and cables for suspension bridges. *See* MATERIALS SCIENCE AND ENGINEERING. [M.M.S.]

Composition board A wood product in which the grain structure of the original wood is drastically altered. Composition board may be divided into several types. When wood serves as the raw material for chemical processing, the resultant product may be insulation board, hardboard, or other pulp product. When the wood is broken down only by mechanical means, the resultant product is particle board. Because composition board can use waste products of established wood industries and because there is a need to find marketable uses for young trees, manufacture of composition board is one of the most rapidly developing portions of the wood industry. *See* PAPER.

Fiberboard is produced from wood chips. Synthetic resin may be added as a binder before the board is formed. After the board is formed, it may be impregnated with drying oils and heated in a kiln until the oils are completely polymerized to produce tempered board. If insulating board is required instead of hardboard, the material is less compacted, the degree of compaction being described by the specific gravity of the finished board.

When formed from wood particles that retain their woody structure, the product is termed particle board. Properties of such boards depend on the size and orientation of the particles, which may be dimensioned flakes, random-sized shavings, or splinters. After the particular type of particles are produced, they are screened to remove fines and to return oversizes for further reduction. Graded particles are dried, mixed with synthetic adhesive and other additives such as preservatives, and delivered to the board-forming machine.

Development of adhesives specifically for composition boards is extending their utilitarian value, and variety of textures is increasing their esthetic appeal. *See* WOOD PRODUCTS. [F.H.R.]

Compound (chemistry) Substances composed of two or more elements which do not vary in composition from sample to sample, and which have fixed and definite physical properties, such as density and refractive index. The elements in compounds cannot be separated by simple physical or mechanical means, but only by chemical treatment. When compounds are formed from their elements, heat is generated or absorbed. These properties distinguish them from mixtures. *See* ELEMENT (CHEMISTRY); MIXTURE.

Most chemical compounds are formed in fixed and definite proportions by weight from their elements, and they obey the laws of chemical combination. However, a number of solid compounds, known as nonstoichiometric compounds, exhibit departures from the law of definite proportions. *See* DEFINITE COMPOSITION, LAW OF; MULTIPLE PROPORTIONS, LAW OF; NONSTOICHIOMETRIC COMPOUNDS. [T.C.W.]

Compressible flow Flow in which density changes are significant. Pressure changes normally occur throughout a fluid flow, and these pressure changes, in general, induce a change in the fluid density. In a compressible flow, the density changes that result from these pressure changes have a significant influence on the flow. The changes in the flow that result from the density changes are often termed compressibility effects. All fluids are compressible. However, compressibility effects are more frequently encountered in gas flows than in liquid flows.

An important dimensionless parameter in compressible flows is the Mach number, M. This is defined by Eq. (1), where a is the

$$M = \frac{V}{a} \tag{1}$$

speed of sound and V is the velocity of the flow. For a gas, the speed of sound is given by Eq. (2), where R is the gas constant,

$$a = \sqrt{kRT} \tag{2}$$

$k = c_p/c_v$, c_p and c_v being the specific heats at constant pressure and constant volume respectively, and T is the temperature. If $M < 0.3$ in a flow, the density changes in the flow will usually be negligible; that is, the flow can be treated as incompressible. Compressible flows are, therefore, as a rough guide, associated with Mach numbers greater than 0.3.

When $M < 1$, the flow is said to be subsonic; when $M = 1$, the flow is said to be sonic; when M varies from slightly below 1 to slightly above 1, the flow is said to be transonic; and if $M > 1$, the flow is said to be supersonic. When the Mach number is very high, this usually being taken to mean $M > 5$, the flow is said to be hypersonic.

Compressible flows can have features that do not occur in low-speed flows. For example, shock waves and expansion waves can occur in supersonic flows. Another important phenomenon that can occur due to compressibility is choking, where the mass flow rate through a duct system may be limited as a result of the Mach number being equal to 1 at some point in the flow. *See* CHOKED FLOW; SHOCK WAVE; SONIC BOOM.

Another effect of compressibility is associated with the acceleration of a gas flow through a duct. In incompressible flow, an increase in velocity is associated with a decrease in the cross-sectional area of the duct, this in fact being true as long as $M < 1$. However, when $M > 1$, that is, when the flow is supersonic, the opposite is true; that is, an increase in the velocity is associated with an increase in the cross-sectional area. Therefore, in order to accelerate a gas flow from subsonic to supersonic velocities in a duct, it is necessary first to decrease the area and then, once the Mach number has reached 1, to increase the area, that is, to use a so-called convergent-divergent nozzle. An example is the nozzle fitted to a rocket engine. *See* FLUID FLOW; MACH NUMBER; NOZZLE; SUPERSONIC FLOW. [P.H.Oo.]

Compression ratio In a cylinder, the piston displacement plus clearance volume, divided by the clearance volume. This is the nominal compression ratio determined by cylinder geometry alone. In practice, the actual compression ratio is appreciably less than the nominal value because the volumetric efficiency of an unsupercharged engine is less than 100%, partly because of late intake valve closing. In spark ignition engines the allowable compression ratio is limited by incipient knock at wide-open throttle. *See* COMBUSTION CHAMBER; INTERNAL COMBUSTION ENGINE; VOLUMETRIC EFFICIENCY. [N.MacC.]

Compressor A machine that increases the pressure of a gas or vapor (typically air), or mixture of gases and vapors. The pressure of the fluid is increased by reducing the fluid specific volume during passage of the fluid through the compressor. When compared with centrifugal or axial-flow fans on the basis of discharge pressure, compressors are generally classed as high-pressure and fans as low-pressure machines.

Compressors are used to increase the pressure of a wide variety of gases and vapors for a multitude of purposes. A common application is the air compressor used to supply high-pressure air for conveying, paint spraying, tire inflating, cleaning, pneumatic tools, and rock drills. The refrigeration compressor is used to compress the gas formed in the evaporator. Other applications of compressors include chemical processing, gas transmission, gas turbines, and construction. *See* GAS TURBINE; REFRIGERATION.

Compressor displacement is the volume displaced by the compressing element per unit of time and is usually expressed in cubic feet per minute (cfm). Where the fluid being compressed flows in series through more than one separate compressing element (as a cylinder), the displacement of the compressor equals that of the first element. Compressor capacity is the actual quantity of fluid compressed and delivered, expressed in cubic feet per minute at the conditions of total temperature, total pressure, and composition prevailing at the compressor inlet. The capacity is always expressed in terms of air or gas at intake (ambient) conditions rather than in terms of arbitrarily selected standard conditions.

Air compressors often have their displacement and capacity expressed in terms of free air. Free air is air at atmospheric conditions at any specific location. Since the altitude, barometer, and temperature may vary from one location to another, this term does not mean air under uniform or standard conditions. Standard air is at 68°F (20°C), 14.7 lb/in.^{2} (101.3 kilopascals absolute pressure), and a relative humidity of 36%. Gas industries usually consider 60°F (15.6°C) air as standard.

Compressors can be classified as reciprocating, rotary, jet, centrifugal, or axial-flow, depending on the mechanical means used to produce compression of the fluid, or as positive-displacement or dynamic-type, depending on how the mechanical elements act on the fluid to be compressed. Positive-displacement compressors confine successive volumes of fluid within a closed space in which the pressure of the fluid is increased as the volume of the closed space is decreased. Dynamic-type compressors use rotating vanes or impellers to impart velocity and pressure to the fluid. [T.G.H.; D.L.An.]

Compton effect The increase in wavelength of electromagnetic radiation, observed mainly in the x-ray and gamma-ray region, on being scattered by material objects. This increase in wavelength is caused by the interaction of the radiation with the weakly bound electrons in the matter in which the scattering takes place. The Compton effect illustrates one of the most fundamental interactions between radiation and matter and displays in a very graphic way the true quantum nature of electromagnetic radiation. Together with the laws of atomic spectra, the photoelectric effect, and pair production, the Compton effect has provided the experimental basis for the quantum theory of electromagnetic radiation. *See* ANGULAR MOMENTUM; ATOMIC STRUCTURE AND SPECTRA; ELECTRON-POSITRON PAIR PRODUCTION; LIGHT; PHOTOEMISSION; QUANTUM MECHANICS; UNCERTAINTY PRINCIPLE.

Perhaps the greatest significance of the Compton effect is that it demonstrates directly and clearly that in addition to its wave nature with transverse oscillations, electromagnetic radiation has a particle nature and that these particles, the photons, behave quite like material particles in collisions with electrons. This discovery by A. H. Compton and P. Debye led to the formulation of quantum mechanics by W. Heisenberg and E. Schrödinger and provided the basis for the beginning of the theory of quantum electrodynamics, the theory of the interactions of electrons with the electromagnetic field.

The Compton effect has played a significant role in several diverse scientific areas. Compton scattering (often referred to as incoherent scattering, in contrast to Thomson scattering or also Rayleigh scattering, which are called coherent scattering) is important in nuclear engineering (radiation shielding), experimental and theoretical nuclear physics, atomic physics, plasma physics, x-ray crystalloghaphy, elementary particle physics, and astrophysics, to mention some of these areas. In addition the Compton effect provides an important research tool in some branches of medicine, in molecular chemistry and solid-state physics, and in the use of high-energy electron accelerators and charged-particle storage rings. [E.N.H.]

The development of high-resolution silicon and germanium semiconductor radiation detectors opened new areas for applications of Compton scattering. Semiconductor detectors make it possible to measure the separate probabilities for Rayleigh and Compton scattering. An effective atomic number has been assigned to compounds that appears to successfully correlate theory with Rayleigh-Compton ratios.

Average density can be measured by moving to higher energies where Compton scattering does not have to compete with Rayleigh scattering. At these energies, Compton scattering intensity has been successfully correlated with mass density. An appropriate application is the measurement of lung density in living organisms.

The ability to put large detectors in orbit above the Earth' atmosphere has created the field of gamma-ray astronomy. This field is now based largely on the data from the *Compton Gamma-Ray Observatory*, all of whose detectors made use of the Compton effect (although not exclusively). *See* GAMMA-RAY ASTRONOMY; GAMMA-RAY DETECTORS; GAMMA RAYS; X-RAYS. [I.K.M.]

Computational chemistry A branch of theoretical chemistry that uses a digital computer to model systems of chemical interest. In this discipline, the computer itself is the primary instrument of research. The use of computers for analysis of experimental data, and for the storage and display of results obtained with other tools, is distinct from computational chemistry. The latter permits calculation of quantities which can be measured experimentally, such as molecular geometries of ground and excited states, heats of formation, and ionization potentials. Alternatively, quantities not readily accessible by existing experimental techniques, such as geometries of transition states and detailed structure of liquids, may be evaluated. *See* DIGITAL COMPUTER.

Because of the increasing power and availability of computers, and the simultaneous development of well-tested and reliable theoretical methods, the use of computational chemistry as an adjunct to experimental research has increased rapidly. Calculations ranging from a few seconds to many hours of computer time can serve as a guide to exclude less favorable reactions or unstable products, or to select several more fruitful procedures from the many possible ones. In addition, modeling of chemical systems with a computer enables the researcher to examine them on a scale of space or time as yet unmeasurable by experimental techniques. This can give insight into a chemical system beyond that provided by experiment. Examples are examination of the dynamics of a chemical reaction or of detailed changes in conformation of a polymer in solution. Examination of the molecular orbitals occupied by the electrons of the molecule can provide insight into chemical bonding and the electronic interactions which determine specific geometric configurations. Thus computational chemistry can yield information which may not be experimentally available. *See* CHEMICAL DYNAMICS.

Computational chemistry may be the application of existing theory and numerical methods to new molecules, or it may be the development of new computational methods. The latter may include incorporating more physics into the mathematical model in order to provide a better theoretical description of the system being studied, for example, inclusion of interactions between individual electrons in molecular orbital calculations. These more complete studies, for “large” molecules, usually need to be performed on a supercomputer, or on a mid-size computer with an array processor. Another approach is to devise simpler methods which will approximate the accuracy of more complex calculations. These include semiempirical methods in which values of hard-to-calculate terms are derived from experiment. Such an approach allows fruitful work with a mid-size or even a desk-top computer, avoiding the need for expensive computer resources. *See* MICROCOMPUTER; SUPERCOMPUTER. [Z.R.W.]

Computational fluid dynamics The numerical approximation to the solution of mathematical models of fluid flow and heat transfer. Computational fluid dynamics is one of the tools (in addition to experimental and theoretical methods) available to solve fluid-dynamic problems. With the advent of modern computers, computational fluid dynamics evolved from potential-flow and boundary-layer methods and is now used in many diverse fields, including engineering, physics, chemistry, meteorology, and geology. The crucial elements of computational fluid dynamics are discretization, grid generation and coordinate transformation, solution of the coupled algebraic equations, turbulence modeling, and visualization.

Numerical solution of partial differential equations requires representing the continuous nature of the equations in a discrete form. Discretization of the equations consists of a process where the domain is subdivided into cells or elements (that is, grid generation) and the equations are expressed in discrete form at each point in the grid by using finite difference, finite volume, or finite element methods. The finite difference method requires a structured grid arrangement (that is, an organized set of points formed by the intersections of the lines of a boundary-conforming curvilinear coordinate system), while the finite element and finite volume methods are more flexible and can be formulated to use both structured and unstructured grids (that is, a collection of triangular elements or a random distribution of points). *See* FINITE ELEMENT METHOD.

There are a variety of approaches for resolving the phenomena of fluid turbulence. The Reynolds-averaged Navier-Stokes (RANS) equations are derived by decomposing the velocity into mean and fluctuating components. An alternative is large-eddy simulation, which solves the Navier-Stokes equations in conjunction with a subgrid turbulence model. The most direct approach to solving turbulent flows is direct numerical simulation, which solves the Navier-Stokes equations on a mesh that is fine enough to resolve all length scales in the turbulent flow. Unfortunately, direct numerical simulation is limited to simple geometries and low-Reynolds-number flows because of the limited capacity of even the most sophisticated supercomputers. *See* TURBULENT FLOW.

The final step is to visualize the results of the simulation. Powerful graphics workstations and visualization software permit generation of velocity vectors, pressure and velocity contours, streamline generation, calculation of secondary quantities (such as vorticity), and animation of unsteady calculations. Despite the sophisticated hardware, visualization of three-dimensional and unsteady flows is still particularly difficult. Moreover, many advanced visualization techniques tend to be qualitative, and the most valuable visualization often consists of simple x-y plots comparing the numerical solution to theory or experimental data. *See* COMPUTER GRAPHICS.

Computational fluid dynamics has wide applicability in such areas as aerodynamics, hydraulics, environmental fluid dynamics, and atmospheric and oceanic dynamics, with length and time scales of the physical processes ranging from millimeters and seconds to kilometers and years. Vehicle aerodynamics and hydrodynamics, which have provided much of the impetus in the development of computational fluid dynamics, are primarily concerned with the flow around aircraft, automobiles, and ships. *See* AERODYNAMIC FORCE; AERODYNAMICS; CLIMATE MODELING; DYNAMIC METEOROLOGY; FLUID FLOW; FLUID-FLOW PRINCIPLES; HYDRAULICS; HYDRODYNAMICS; OCEAN CIRCULATION; RIVER; SIMULATION; WATER POLLUTION. [E.Pa.; F.Ste.]

Computer A device that receives, processes, and presents information. The two basic types of computers are analog and digital. Although generally not regarded as such, the most prevalent computer is the simple mechanical analog computer, in which gears, levers, ratchets, and pawls perform mathematical operations—for example, the speedometer and the watt-hour meter (used to measure accumulated electrical usage). The general public has become much more aware of the digital computer with the rapid proliferation of the hand-held calculator and a large variety of intelligent devices and especially with exposure to the Internet and the World Wide Web. *See* CALCULATORS; INTERNET; WORLD WIDE WEB.

An analog computer uses inputs that are proportional to the instantaneous value of variable quantities, combines these inputs in a predetermined way, and produces outputs that are a continuously varying function of the inputs and the processing. These outputs are then displayed or connected to another device to cause action, as in the case of a speed governor or other control device. Small electronic analog computers are frequently used as components in control systems. If the analog computer is built solely for one purpose, it is termed a special-purpose electronic analog computer. In any analog computer the key concepts involve special versus general-purpose computer designs, and the technology utilized to construct the computer itself, mechanical or electronic. *See* ANALOG COMPUTER.

In contrast, a digital computer uses symbolic representations of its variables. The arithmetic unit is constructed to follow the rules of one (or more) number systems. Further, the digital computer uses individual discrete states to represent the digits of the number system chosen. A digital computer can easily store and manipulate numbers, letters, images, sounds, or graphical information represented by a symbolic code. Through the use of the stored program, the digital computer achieves a degree of flexibility unequaled by any other computing or data-processing device.

The advent of the relatively inexpensive and readily available personal computer, and the combination of the computer and communications, such as by the use of networks, have dramatically expanded computer applications. The most common application now is probably text and word processing, followed by electronic mail. *See* ELECTRONIC MAIL; LOCAL-AREA NETWORKS; MICROCOMPUTER; WORD PROCESSING.

Computers have begun to meet the barrier imposed by the speed of light in achieving higher speeds. This has led to research and development in the areas of parallel computers (in order to accomplish more in parallel rather than by serial computation) and distributed computers (taking advantage of network connections to spread the work around, thus achieving more parallelism). Continuing demand for more processing power has led to significant changes in computer hardware and software architectures, both to increase the speed of basic operations and to reduce the overall processing time. *See* COMPUTER SYSTEMS ARCHITECTURE; CONCURRENT PROCESSING; DISTRIBUTED SYSTEMS (COMPUTERS); MULTIPROCESSING; SUPERCOMPUTER. [B.A.G.; J.H.Sa.]

Computer-aided design and manufacturing

The application of digital computers in engineering design and production. Computer-aided design (CAD) refers to the use of computers in converting the initial idea for a product into a detailed engineering design. The evolution of a design typically involves the creation of geometric models of the product, which can be manipulated, analyzed, and refined. In CAD, computer graphics replace the sketches and engineering drawings traditionally used to visualize products and communicate design information. *See* COMPUTER GRAPHICS.

Engineers also use computer programs to estimate the performance and cost of design prototypes and to calculate the optimal values for design parameters. These programs supplement and extend traditional hand calculations and physical tests. When combined with CAD, these automated analysis and optimization capabilities are called computer-aided engineering (CAE). *See* COMPUTER-AIDED ENGINEERING; OPTIMIZATION.

Computer-aided manufacturing (CAM) refers to the use of computers in converting engineering designs into finished products. Production requires the creation of process plans and production schedules, which explain how the product will be made, what resources will be required, and when and where these resources will be deployed. Production also requires the control and coordination of the necessary physical processes, equipment, materials, and labor. In CAM, computers assist managers, manufacturing engineers, and production workers by automating many production tasks. Computers help to develop process plans, order and track materials, and monitor production schedules. They also help to control the machines, industrial robots, test equipment, and systems which move and store materials in the factory.

CAD/CAM can improve productivity, product quality, and profitability. Computers can eliminate redundant design and production tasks, improve the efficiency of workers, increase the utilization of equipment, reduce inventories, waste, and scrap, decrease the time required to design and make a product, and improve the ability of the factory to produce different products. Today most manufacturers employ CAD/CAM to varying degrees. *See* PRODUCTIVITY.

The fact that CAD, CAE, and CAM work best together has led to the breakdown of many of the traditional barriers between functional and manufacturing units. The goal of computer-integrated manufacturing (CIM) is a database, created and maintained on a factory-wide computer network, that will be used for design, analysis, optimization, process planning, production scheduling, robot programming, materials handling, inventory control, maintenance, and marketing. Although many technical and managerial obstacles must be overcome, computer-integrated manufacturing appears to be the future of CAD/CAM. *See* COMPUTER-INTEGRATED MANUFACTURING; DATABASE MANAGEMENT SYSTEM; FLEXIBLE MANUFACTURING SYSTEM; MATERIALS HANDLING; ROBOTICS. [K.P.W.]

Computer-aided engineering

Any use of computer software to solve engineering problems. With the improvement of graphics displays, engineering workstations, and graphics standards, computer-aided engineering (CAE) has come to mean the computer solution of engineering problems with the assistance of interactive computer graphics. *See* COMPUTER GRAPHICS.

CAE software is used on various types of computers, such as mainframes and superminis, engineering workstations, and even personal computers. The choice of a computer system is frequently dictated by the computing power required for the CAE application or the level (and speed) of graphics interaction desired. The trend is toward more use of engineering workstations, especially a new type known as supergraphics workstations. *See* DIGITAL COMPUTER; MICROCOMPUTER.

Design engineers use a variety of CAE tools, including large, general-purpose commercial programs and many specialized programs written in-house or elsewhere in the industry. Solution of a single engineering problem frequently requires the application of several CAE tools. Communication of data between these software tools presents a challenge for most applications. Data are usually passed through proprietary neutral file formats, data interchange standards, or a system database.

A typical CAE program is made up of a number of mathematical models encoded by algorithms written in a programming language. The natural phenomena being analyzed are represented by an engineering model. The physical configuration is described by a geometric model. The results, together with the geometry, are made visible via a user interface on the display device and a rendering model (graphics image). *See* ALGORITHM; COMPUTER PROGRAMMING; PROGRAMMING LANGUAGES.

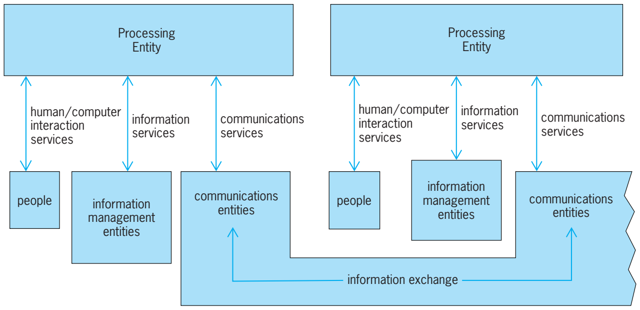
Computer-aided design and manufacturing (CAD/CAM) systems were created by the aerospace industry in the early 1960s to assist with the massive design and documentation tasks associated with producing airplanes. CAD/CAM systems have been used primarily for detail design and drafting along with the generation of numerical control instructions for manufacturing. Gradually, more CAE functions are being added to CAD/CAM systems. Modeling with CAD/CAM systems has become fairly sophisticated. Most popular commercial systems support 2D and 3D wireframe, surface models and solid models. Rendered surface models differ from solid models in that the latter have full information about the interior of the object. For solid models a combination of three types of representation is commonly used: constructive solid geometry, boundary representation, and sweep representation. *See* COMPUTER-AIDED DESIGN AND MANUFACTURING.

The CAE methods for electrical and electronics engineering are well developed. The geometry is generally two-dimensional, and the problems are primarily linear or can be linearized with sufficient accuracy. Chemical engineering makes extensive use of CAE with process simulation and control software. The fields of civil, architectural, and construction engineering have CAE interests similar to mechanical CAE with emphasis on structures. Aerospace, mechanical, industrial, and manufacturing engineering all make use of mechanical CAE software together with specialized software. [A.My.]

Computer-based systems

Complex systems in which computers play a major role. While complex physical systems and sophisticated software systems can help people to lead healthier and more enjoyable lives, reliance on these systems can also result in loss of money, time, and life when these systems fail. Much of the complexity of these systems is due to integration of information technology into physical and human activities. Such integration dramatically increases the interdependencies among components, people, and processes, and generates complex dynamics not taken into account in systems of previous generations. Engineers with detailed understanding both of the application domain and computer electronics, software, human factors, and communication are needed to provide a holistic approach to system development so that disasters do not occur.

Engineering activities. The computer-based systems engineer develops a system within a system; the properties of the former have pervasive effects throughout the larger system. The computer-based system consists of all components necessary to capture, process, transfer, store, display, and manage



Model of a distributed computer-based system.

information. Components include software, processors, networks, buses, firmware, application-specific integrated circuits, storage devices, and humans (who also process information). Embedded computer-based systems interact with the physical environment through sensors and actuators, and also interact with external computer-based systems (see illustration). The computer-based systems engineer must have a thorough understanding of the system in which the computer-based system is embedded, for example an automobile, medical diagnostic system, or stock exchange.

Model-based development. Models are necessary in systems engineering as they support interdisciplinary communication, formalize system definition, improve analysis of trade-offs and decision making, and support optimization and integration. The use of models can reduce the number of errors in the design and thus the system, reduce engineering effort, and preserve knowledge for future efforts. Maintaining models with up-to-date knowledge is a major problem as most systems are not generated from models, although this should be an industry goal. During the later stages of system development and testing, significant schedule pressure makes it difficult to keep the models and manually developed software consistent. [S.M.W.]

Computer graphics

A branch of computer science that deals with the theory and techniques of computer image synthesis. Computers produce images by analyzing a collection of dots, or pixels (picture elements). Computer graphics is used to enhance the transfer and understanding of information in science, engineering, medicine, education, and business by facilitating the generation, production, and display of synthetic images of natural objects with realism almost indistinguishable from photographs. Computer graphics facilitates the production of images that range in complexity from simple line drawings to three-dimensional reconstructions of data obtained from computerized axial tomography (CAT) scans in medical applications. User interaction can be increased through animation, which conveys large amounts of information by seemingly bringing to life multiple related images. Animation is widely used in entertainment, education, industry, flight simulators, scientific research, and heads-up displays (devices which allow users to interact with a virtual world). Virtual-reality applications permit users to interact with a three-dimensional world, for example, by “grabbing” objects and manipulating objects in the world. Digital image processing is a companion field to computer graphics. However, image processing, unlike computer graphics, generally begins with some image in image space, and performs operations on the components (pixels) to produce new images. *See* IMAGE PROCESSING.

Computers are equipped with special hardware to display images. Several types of image presentation or output devices convert digitally represented images into visually perceptible pictures. They include pen-and-ink plotters, dot-matrix plotters, electrostatic or laser-printer plotters, storage tubes, liquid-crystal displays (LCDs), active matrix panels, plasma panels, and cathode-ray-tube (CRT) displays. Images can be displayed by a computer on a cathode-ray tube in two different ways: raster scan and random (vector) scan. *See* CATHODE-RAY TUBE; COMPUTER PERIPHERAL DEVICES.

Interaction with the object takes place via devices attached to the computer, starting with the keyboard and the mouse. Each type of device can be programmed to deliver various types of functionality. The quality and ease of use of the user interface often determines whether users enjoy a system and whether the system is successful. Interactive graphics aids the user in the creation and modification of graphical objects and the response to these objects in real-time. The most commonly used input device is the mouse. Other kinds of interaction devices include the joystick, trackball, light pen, and data tablet. Some of these two-dimensional (2D) devices can be modified to extend to three dimensions (3D). The data glove is a device capable of recording hand movements. The data glove is capable of a simple gesture recognition and general tracking of hand orientation.

In the production of a computer-generated image, the designer has to specify the objects in the image and their shapes, positions, orientations, and surface colors or textures. Further, the viewer’s position and direction of view (camera orientation) must be specified. The software should calculate the parts of all objects that can be seen by the viewer (camera). Only the visible portions of the objects should be displayed (captured on the film). (This requirement is referred to as the hidden-surface problem.) The rendering software is then applied to compute the amount and color of light reaching the viewer eye (film) at any point in the image, and then to display that point. Some modern graphics work stations have special hardware to implement projections, hidden-surface elimination, and direct illumination. Everything else in image generation is done in software.

Solid modeling is a technique used to represent three-dimensional shapes in a computer. The importance of solid modeling in computer-aided design and manufacturing (CAD/CAM) systems has been increasing. Engineering applications ranging from drafting to the numerical control of machine tools increasingly rely on solid modeling techniques. Solid modeling uses three-dimensional solid primitives (the cube, sphere, cone, cylinder, and ellipsoid) to represent three-dimensional objects. Complex objects can be constructed by combining the primitives. *See* COMPUTER-AIDED DESIGN AND MANUFACTURING; COMPUTER-AIDED ENGINEERING.

The creation of images by simulating a model of light propagation is often called image synthesis. The goal of image synthesis is often stated as photorealism, that is, the criterion that the image look as good as a photograph. Rendering is a term used for methods or techniques that are used to display realistic-looking three-dimensional images on a two-dimensional medium such as the cathode-ray-tube screen (see illustration). The display of a wire-frame image is one way of rendering the object. The most common method of rendering is shading. Generally, rendering includes addition of texture, shadows, and the color of light that reaches the observer’s eye from any point in the image.

Computer-generated images are used extensively in the entertainment world and other areas. Realistic images have become essential tools in research and education. Conveying realism in

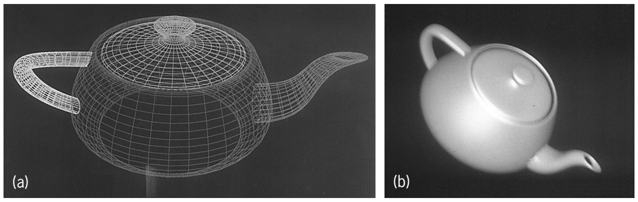


Image renderings of a teapot. (*a*) Wire-frame model with 512 polygons. (*b*) Smooth shading (non-shiny). (*A. Tokuta, Technical Report, Department of Computer Science and Engineering, University of South Florida*)

these images may depend on the convincing generation of natural phenomena. A fundamental difficulty is the complexity of the real world. Existing models are based on physical or biological concepts. The behavior of objects can be determined by physical properties or chemical and microphysical properties. [A.O.T.]

Computer-integrated manufacturing A system in which individual engineering, production, and marketing and support functions of a manufacturing enterprise are organized into a computer-integrated system. Functional areas such as design, analysis, planning, purchasing, cost accounting, inventory control, and distribution are linked through the computer with factory floor functions such as materials handling and management, providing direct control and monitoring of all process operations.

Computer-integrated manufacturing (CIM) may be viewed as the successor technology which links computer-aided design (CAD), computer-aided manufacturing (CAM), robotics, numerically controlled machine tools (NCMT), automatic storage and retrieval systems (AS/RS), flexible manufacturing systems (FMS), and other computer-based manufacturing technology. Computer-integrated manufacturing is also known as integrated computer-aided manufacturing (ICAM). Autofacturing includes computer-integrated manufacturing, but also includes conventional machinery, human operators, and their relationships within a total system. *See* COMPUTER-AIDED DESIGN AND MANUFACTURING; FLEXIBLE MANUFACTURING SYSTEM; ROBOTICS.

Agile manufacturing and lean manufacturing. The CIM factory concept includes both soft and hard technology. Soft technology can be thought of as the intellect or brains of the factory, and hard technology as the muscles of the factory. The type of hard technology employed depends upon the products or family of products made by the factory. For metalworking, typical processes would include milling, turning, forming, casting, grinding, forging, drilling, routing, inspecting, coating, moving, positioning, assembling, and packaging. For semiconductor device fabrication, typical processes would include layout, etching, lithography, striping, lapping, polishing, and cleaning, as well as moving, positioning, assembling, and packaging. More important than the list of processes is their organization.

Whatever the products, the CIM factory is made up of a part fabrication center, a component assembly center, and a product assembly center. Centers are subdivided into work cells, cells into stations, and stations into processes. Processes comprise the basic transformations of raw materials into parts which will be assembled into products. In order for the factory to achieve maximum efficiency, raw material must come into the factory at the left end and move smoothly and continuously through the factory to emerge as a product at the right end. No part must ever be standing; each part is either being worked on or is on its way to the next workstation.

In the part fabrication center, raw material is transformed into piece parts. Some piece parts move by robot carrier or automatic guided vehicle to the component fabrication center. Other piece parts (excess capacity) move out of the factory to sister factories for assembly. There is no storage of work in process and no warehousing in the CIM factory. To accomplish this objective, part movement is handled by robots or conveyors of various types. These materials handlers serve as the focus or controlling element of work cells and workstations. Each work cell contains a number of workstations. The station is where the piece part transformation occurs from a raw material to a part, after being worked on by a particular process.

Components, also known as subassemblies, are created in the component assembly center. Here materials handlers of various types, and other reprogrammable automation, put piece parts together. Components may then be transferred to the product assembly center, or out of the factory (excess capacity) to sister factories for final assembly operations there. Parts from other factories may come into the component assembly center of this factory, and components from other factories may come into the product assembly center of this factory. The final product moves out of the product assembly center to the product distribution center or in some cases directly to the end user. *See* AUTOMATION.

The premise of CIM is that a network is created in which every part of the enterprise works for the maximum benefit of the whole enterprise. Independent of the degree of automation employed, for example, whether it is robotic or not, the optimal organization of computer hardware and software is essential. The particular processes employed by the factory are specific to the product being made, but the functions performed can be virtually unchanged in the CIM factory no matter what the product. These typical functions include forecasting, designing, predicting, controlling, inventorying, grouping, monitoring, releasing, planning, scheduling, ordering, changing, communicating, and analyzing. [D.E.Wi.]

Computer numerical control The method of controlling machines by the application of digital electronic computers and circuitry. Machine movements that are controlled by cams, gears, levers, or screws in conventional machines are directed by computers and digital circuitry in computer numerical control (CNC) machines.

Computer numerical control provides very flexible and versatile control over machine tools. Most machining operations require that a cutting tool be fed at some speed against a workpiece. In a conventional machine such as a turret lathe, the turning tool is mounted on a slide with hand-operated infeed and crossfeed slides. The operator manually turns a crank that feeds the cutting tool into the workpiece (infeed) to the desired diameter. Another crank then moves the turning tool along the longitudinal axis of the machine and produces a cylindrical cut along the workpiece. The feed rate of the turning tool is sometimes controlled by selecting feed gears. These gears move the axis slide at the desired feed. A CNC machine replaces the hand cranks and feed gears with servomotor systems. *See* SERVOMECHANISM.

Computer numerical controls allow the desired cut depths and feed rates to be “dialed in” rather than controlled by cranks, cams, and gears. This provides precise, repeatable machine movements that can be programmed for optimal speeds, feeds, and machine cycles. All cutting-tool applications, whether on a lathe, drill press, or machining center, have optimum speeds and feeds, which are determined by carefully weighing the economics of tool life, required production rates, and operator attentiveness. With computer numerical control these parameters are set once, and then they are repeated precisely for each subsequent machine cycle.

In computer-aided manufacturing (CAM), computers are used to assist in programming CNC machines. In sophisticated CNC manufacturing operations, machined parts are first designed on computer-aided-design (CAD) equipment. The same electronic drawing is then used to create the CNC part program automatically. A less advanced version of CAM is the use of high-level part programming languages to write part programs. *See* COMPUTER-AIDED DESIGN AND MANUFACTURING.

Computer numerical control machines are used mainly when flexibility is required or variable and complex part geometries must be created. They are used to produce parts in lot sizes of a few pieces to several thousand. Extremely large manufacturing lot sizes frequently call for more product-specific machines, which can be optimized for large production runs. [J.R.C.B.]

Computer peripheral devices Any device connected internally or externally to a computer and used in the transfer of data. A personal computer or workstation processes information and, strictly speaking, that is all the computer does. Data (unprocessed information) must get into the computer, and the processed information must get out. Entering and displaying information is carried out on a wide variety of accessory devices called peripherals, also known as input/output (I/O) devices. Some peripherals, such as keyboards, are only input devices; other peripherals, such as printers, are only output devices; and some are both. *See* Digital computer; Microcomputer.

The monitor is the device on which images produced by the computer operator or generated by the program are displayed on a cathode-ray tube (CRT). Electron guns—one in a monochrome monitor, three in a color monitor—irradiate phosphors on the inside of the vacuum tube, causing them to glow. The flat-panel displays on most portable computers, known as liquid-crystal displays (LCDs), use two polarizing filters with liquid crystals between them to produce the image. *See* Electronic display; Liquid crystals.

The computer keyboard, based on the typewriter keyboard, contains keys for entering letters, numbers, and punctuation marks, as well as keys to change the meaning of other keys. The function keys perform tasks that vary from program to program. *See* Typewriter.

The mouse is a device that is rolled on the desktop to move the cursor on the screen. A ball on the bottom of the mouse translates the device's movements to sensors within the mouse and then through the connecting port to the computer. There are also mice that substitute optical devices for mechanical balls, and mice that use infrared rather than physical connections.

The trackball is essentially an upside-down mouse, with the ball that is used to move the cursor located on the top rather than on the bottom.

The joystick is a pointing device used principally for games.

The light pen performs the same functions as a mouse or trackball, but it is held up to the screen, where its sensors detect the presence of pixels and send a signal through a cable to the computer.

The graphics, or digitizing, tablet is a pad with electronics beneath the surface which is drawn upon with a pointed device, called a stylus. The shapes drawn appear on the monitor's screen.

The most common input, or storage, device in personal computers or workstations is a hard disk drive, a stack of magnetized platters on which information is stored by heads generating an electrical current to represent either 1 or 0 in the binary number system. The device is called hard because the platters are inflexible, and is called a drive because it spins at 3600 revolutions or more a minute, within a sealed case. Diskettes, made of flexible film like that used in recording tape, are usually stored within a hard shell and are spun by their drives at about 360 revolutions per minute. *See* Computer storage technology.

Data can also be stored and retrieved with light, the light of a laser beam reading a pattern of pits on an optical disk. The most familiar type of optical disk is the CD-ROM (compact disk-read only memory). Another kind of optical disk is the WORM (write once read many times). *See* Compact disk; Multimedia technology; Optical recording.

As a consequence of their greater efficiency and speed, disk drives have quickly replaced tape drives as the primary means of data and program storage. Tape drives are still in use for backup storage, copying the contents of a hard disk as insurance against mechanical failure or human error. *See* Magnetic recording.

The scanner converts an image of something outside the computer, such as text, a drawing, or a photograph, into a digital image that it sends into the computer for display or further processing. The image is viewed as a graphics image, not a text image, so it can be altered with a graphics program but cannot be edited with a word-processing program, unless the scanner is part of a character-recognition system. To digitize photographs, a scanner may dither the image (put the dots a varying amount of space apart), or use the tagged image file format (TIFF), storing the image in 16 gray values. Some scanners can use standard video cameras to capture images for the computer. *See* Character recognition.

The printer puts text or other images produced with a computer onto paper or other surfaces. Printers are either impact or nonimpact devices.

Daisy-wheel or thimble printers are so called from the shape of the elements bearing raised images of the characters. Their speed, perhaps 30 characters per second, is now considered unacceptably slow. Dot-matrix printers produce their images by striking a series of wire pins, typically, 9, 18, or 24, through the ribbon in the pattern necessary to form the letter, number, line, or other character.

Ink-jet printers carry their ink in a well, where it is turned into a mist by heat or vibration and sprayed through tiny holes to form the pattern of the character on paper. Laser printers are similar to photocopying machines. The quality of laser-printer output is the highest generally available. *See* Photocopying processes; Printing.

The modem connects one computer to another, ordinarily through the telephone lines, to exchange information. *See* Modem. [L.R.S.]

Computer programming Designing and writing computer programs, or sequences of instructions to be executed by a computer. A computer is able to perform useful tasks only by executing computer programs. A programming language or a computer language is a specialized language for expressing the instructions in a computer program.

Problem solving. In this stage, the programmer gains a full understanding of the problem that the computer program under development is supposed to solve, and devises a step-by step procedure (an algorithm) that, when followed, will solve the problem. Such a procedure is then expressed in a fairly precise yet readily understandable notation such as pseudo code, which outlines the essentials of a computer program using English statements and programming language-like key words and structures. *See* Algorithm.

A useful example concerns the problem of finding the greatest common divisor (gcd) of two given positive integers. After an analysis of the problem, a programmer may choose to solve the problem by the procedure described by the following pseudo code. (In the pseudo code, the modulus operator produces the remainder that results from the division of one integer by another; for example, 15 modulus 6 yields 3.)

```
1. Let x and y be the two given integers
2. As long an x and y are greater than 0, repeat lines 3–5
3.    if x is greater than y
4.        then replace x by the value of x modulus y
5.        else replace y by the value of y modulus x
6. If x is 0
7.        then y is the gcd
8.        else x is the gcd
```

See Number theory.

Lines 3–5 and 6–8 are examples of the selection control structure, which specifies alternative instructions and enables a computer to choose one alternative for execution and ignore the other. Lines 2–5 form a repetitive control structure (commonly called a loop), which causes the computer to execute certain instructions (lines 3–5) repeatedly.

Programmers indent to show the structural relationship among the statements and to enhance the readability of the program. In the example, indentation makes it clear that lines 4 and 5 are part of the selection structure beginning at line 3, that lines 3–5 are part of the loop that begins at line 2, and that lines 7 and 8 are part of the selection structure that begins at line 6.

An algorithm developed to solve a given problem should be verified to ensure that it will function correctly. The following list shows how the above procedure derives the gcd of 48 and 18 by successively modifying the values of x and y.

x	y	
48	18	(Let x be equal to 48 and y equal to 18)
48	18	(48 modulus 18 is 12, which replaces 48)
12	18	(18 modulus 12 is 6, which replaces 18)
12	6	(12 modulus 6 is 0, which replaces 12)
0	6	(since x is 0, the loop ends and 6 is the gcd)

Implementation. In this stage the pseudocode procedure developed in the problem-solving stage will be expressed in a programming language. There are numerous programming languages, in two broad classes: low-level languages, which are difficult for human programmers to understand and use but can be readily recognized by a physical computer; and high-level languages, which are easier for human programmers to use but cannot be directly recognized by a physical computer. Currently most computer programs are first written in a high-level language and then translated into an equivalent program in a low-level language so that a physical computer can recognize and obey the instructions in the program. The translator itself is usually a sophisticated computer program called a compiler. *See* PROGRAMMING LANGUAGES.

Shown below is the gcd-finding procedure written in a widely used high-level language called C++.

```
/**********************************************
 *The function findgcd computers the greatest*
 *common divisor of two int parameters, and  *
 *returns the result as an int value\hspace  *
 **********************************************/
 int findgcd (int x, int y)
 {      while (x > 0 && y < 0)
              if (x > y)
                    x = x % y;
              else   y = y % x;
              if (x = 0)
                    return y;
              else   return x;
 }
```

The text beginning with /* and ending with */ (the first five lines above) is a program comment. Program comments are not executable instructions and do not affect the functioning of a computer program in any way, but are intended as a way to document a computer program. Appropriate program comments enhance program readability and are considered an important part of a computer program. A more readable program is usually easier to enhance or modify when such needs arise later. The rest of the above text is C++ code (instructions in the language C++) to compute the gcd of two given integers. Indentation in C++ code serves the same purpose as in pseudo code. It is obvious that the above C++ code closely parallels the pseudo code developed previously, as they both express the same abstract procedure.

Object-oriented programming. Object-oriented programming is a way to structure a computer program. The object-oriented paradigm has gained widespread acceptance and is supported by such widely used languages as C++ and Java. An object includes relevant data and operations on the data as a self-contained entity. Interaction with an object can be made by invoking the object's operations. Each object is an instance of an object class. Object classes may be related by inheritance; one class may be a subclass (specialization) of another class. At the center of an object-oriented program design is a collection of objects that represent entities in the application domain. Identifying the objects and object classes, the relationship among the object classes, and the interactions among the objects is a major issue in designing an object-oriented program. *See* OBJECT-ORIENTED PROGRAMMING.

Language processors. Although many widely used programming languages are processed by compilation into machine-executable instructions, some programming languages (for example, LISP and Prolog) are usually interpreted instead of being compiled. When a computer program is interpreted, it is directly executed by another program called an interpreter without being translated into low-level, machine-executable instructions. Some other languages are processed by a hybrid approach. For example, a program in the language Java is first compiled into an equivalent program in an intermediate-level language, which is executed by an interpreter. *See* COMPUTER; DIGITAL COMPUTER.

[S.C.Hs.]

Computer security

Computer security The process of ensuring confidentiality, integrity, and availability of computers, their programs, hardware devices, and data. Lack of security results from a failure of one of these three properties. The lack of confidentiality is unauthorized disclosure of data or unauthorized access to a computing system or a program. A failure of integrity results from unauthorized modification of data or damage to a computing system or program. A lack of availability of computing resources results in what is called denial of service.

An act or event that has the potential to cause a failure of computer security is called a threat. Some threats are effectively deflected by countermeasures called controls. Kinds of controls are physical, administrative, logical, cryptographic, legal, and ethical. Threats that are not countered by controls are called vulnerabilities.

Encryption. Encryption is a very effective technique for preserving the secrecy of computer data, and in some cases it can also be employed to ensure integrity and availability. An encrypted message is converted to a form presumed unrecognizable to unauthorized individuals. The principal advantage of encryption is that it renders interception useless. *See* CRYPTOGRAPHY.

Access control. Computer security implies that access be limited to authorized users. Therefore, techniques are required to control access and to securely identify users. Access controls are typically logical controls designed into the hardware and software of a computing system. Identification is accomplished both under program control and by using physical controls.

Typically, access within a computing system is limited by an access control matrix administered by the operating system or a processing program. All users are represented as subjects by programs executing on behalf of the users; the resources, called the objects of a computing system, consist of files, programs, devices, and other items to which users' accesses are to be controlled. The matrix specifies for each subject the objects that can be accessed and the kinds of access that are allowed.

Access control as described above relates to individual permissions. Typically, such access is called discretionary access control because the control is applied at the discretion of the object's owner or someone else with permission. With a second type of access control, called mandatory access control, each object in the system is assigned a sensitivity level, which is a rating of how serious would be the consequences if the object were lost, modified, or disclosed, and each subject is assigned a level of trust.

Access control is not necessarily as direct as just described. Unauthorized access can occur through a covert channel. One process can signal something to another by opening and closing files, creating records, causing a device to be busy, or changing the size of an object. All of these are acceptable actions, and so their use for covert communication is essentially impossible to detect, let alone prevent.

Security of programs. Computer programs are the first line of defense in computer security, since programs provide logical controls. Programs, however, are subject to error, which can affect computer security.

A computer program is correct if it meets the requirements for which it was designed. A program is complete if it meets all requirements. Finally, a program is exact if it performs only those operations specified by requirements.

Simple programmer errors are the cause of most program failures. Fortunately, the quality of software produced under rigorous design and production standards is likely to be quite high. However, a programmer who intends to create a faulty program can do so, in spite of development controls. *See* SOFTWARE ENGINEERING.

A salami attack is a method in which an accounting program reduces some accounts by a small amount, while increasing one other account by the sum of the amounts subtracted. The amount reduced is expected to be insignificant; yet, the net amount summed over all accounts is much larger.

Some programs have intentional trapdoors, additional undocumented entry points. If these trapdoors remain in operational systems, they can be used illicitly by the programmer or discovered accidentally by others.

A Trojan horse is an intentional program error by which a program performs some function in addition to its advertised use. For example, a program that ostensibly produces a formatted listing of stored files may write copies of those files on a second device to which a malicious programmer has access.

A program virus is a particular type of Trojan horse that is self-replicating. In addition to performing some illicit act, the program creates a copy of itself which it then embeds in other, innocent programs. Each time the innocent program is run, the attached virus code is activated as well; the virus can then replicate and spread itself to other, uninfected programs. Trojan horses and viruses can cause serious harm to computing resources, and there is no known feasible countermeasure to halt or even detect their presence.

Security of operating systems. Operating systems are the heart of computer security enforcement. They perform most access control mediation, most identification and authentication, and most assurance of data and program integrity and continuity of service.

Operating systems structured specifically for security are built in a kernelized manner, embodying the reference monitor concept. A kernelized operating system is designed in layers. The innermost layer provides direct access to the hardware facilities of the computing system and exports very primitive abstract objects to the next layer. Each successive layer builds more complex objects and exports them to the next layer. The reference monitor is effectively a gate between subjects and objects. *See* OPERATING SYSTEM.

Security of databases. Integrity is a much more encompassing issue for databases than for general applications programs, because of the shared nature of the data. Integrity has many interpretations, such as assurance that data are not inadvertently overwritten, lost, or scrambled; that data are changed only by authorized individuals; that when authorized individuals change data, they do so correctly; that if several people access data at a time, their uses will not conflict; and that if data are somehow damaged, they can be recovered.

Database systems are especially prone to inference and aggregation. Through inference, a user may be able to derive a sensitive or prohibited piece of information by deduction from nonsensitive results without accessing the sensitive information itself. Aggregation is the ability of two or more separate data items to be more (or less) sensitive together than separately. Various statistical methods make it very difficult to prevent inference, and aggregation is also extremely difficult to prevent, since users can access great volumes of data from a database over long periods of time and then correlate the data independently. *See* DATABASE MANAGEMENT SYSTEMS.

Security of networks. As computing needs expand, users interconnect computers. Network connectivity, however, increases the security risks in computing. Whereas users of one machine are protected by some physical controls, with network access, a user can easily be thousands of miles from the actual computer. Furthermore, message routing may involve many intermediate machines, called hosts, each of which is a possible point where the message can be modified or deleted, or a new message fabricated. A serious threat is the possibility of one machine's impersonating another on a network in order to be able to intercept communications passing through the impersonated machine.

The principal method for improving security of communications within a network is encryption. Messages can be encrypted link or end-to-end. With link encryption, the message is decrypted at each intermediate host and reencrypted before being transmitted to the next host. End-to-end encryption is applied by the originator of a message and removed only by the ultimate recipient. *See* LOCAL-AREA NETWORK; WIDE-AREA NETWORK. [C.P.P.]

To benefit from sharing access to computing systems that are not all located together, organizations have established virtual private networks (VPNs). These networks approach the security of a private network at costs closer to those of shared public resources. The primary security technique used is encryption.

The Internet, or any similar public network, is subject to threats to its availability, integrity, and confidentiality. A complicating feature is that there is effectively no control on transmissions over the Internet. Consequently, a system connected to the Internet is exposed to any malicious attack that any other Internet user wants to launch.

Security perimeter. A security perimeter is a logical boundary surrounding all resources that are controlled and protected. The protected resources are called a domain (or enclave or protected subnetwork). There may be overlapping domains of varying protection, so that the most sensitive resources are in the innermost domain, which is the best protected. Protecting the security perimeter may be physical controls, identification and authentication, encryption, and other forms of access control. Two controls that relate especially to the security perimeter are network vulnerability scanning and firewalls.

A network vulnerability scan is the process of determining the connectivity of the subnetwork within a security perimeter, and then testing the strength of protection at all the access points to the subnetwork. With a network domain, if a forgotten access point is not secured, its weakness can undermine the protection of the rest of the domain. A network scanner maps the connectivity of a domain, typically by probing from outside the domain, to determine what resources are visible from the outside. Once all outside connections are identified, each is tested with a range of attacks to determine the vulnerabilities to which it is susceptible and from which it needs to be better protected.

A firewall is a host that fuctions as a secured gateway between a protected enclave and the outside. The firewall controls all traffic according to a predefined access policy. For example, many firewalls are configured to allow unhindered communication outbound (from the protected domain to a destination outside the domain) but to allow only certain kinds of inbound communication. A firewall can be a separate computer, or firewall functionality can be built into the communications switch connecting the enclave to the external network.

Intrusion detection. It is most effective to eliminate vulnerabilities, but if that is not possible, it is then desirable to recognize that an attack is occuring or has occured, and take action to prevent future attacks or limit the damage from the current one. Intrusion detection can be either anomaly detection, which seeks to identify an attack by behavior that is out of the norm, or misuse detection, to identify an attack by its attempted effect on sensitive resources. Intrusion detection systems monitor a computing system in order to warn of an attack that is imminent, is under way, or has occurred. [C.P.P.]

Computer storage technology The techniques, equipment, and organization for providing the memory capability required by computers in order to store instructions and data for processing at high electronic speeds.

Memory hierarchy. Memory hierarchy refers to the different types of memory devices and equipment configured into an operational computer system to provide the necessary attributes of storage capacity, speed, access time, and cost to make a cost-effective practical system. The fastest-access memory in any hierarchy is the main memory in the computer. In most computers, random-access memory (RAM) chips are used because of their high speed and low cost. The secondary storage in the hierarchy usually consists of disks. The last, or bottom, level (sometimes called the tertiary level) of storage hierarchy is made up of magnetic tape transports and mass-storage tape systems. Performance is usually measured by two parameters: capacity and access time. (Speed or data rate is a third parameter, but it is not so much a function of the device itself as of the overall memory design.) Capacity refers to the maximum on-line user capacity of a single connectable memory unit. Access time is the time required to obtain the first byte of a randomly located set of data. *See* BIT.

Memory organization. The efficient combination of memory devices from the various hierarchy levels must be integrated with the central processor and input/output equipment, making this the real challenge to successful computer design. The resulting system should operate at the speed of the fastest element, provide the bulk of its capacity at the cost of its least expensive element, and provide sufficiently short access time to retain these attributes in its application environment. Another key ingredient of a successful computer system is an operating system (that is, software) that allows the user to execute jobs on the hardware efficiently. Operating systems are available which achieve this objective reasonably well. *See* COMPUTER SYSTEMS ARCHITECTURE.

The computer system hardware and the operating system software must work integrally as one resource. In many computer systems, the manufacturer provides a virtual memory system. It gives each programmer automatic access to the total capacity of the memory hierarchy without specifically moving data up and down the hierarchy and to and from the central processing unit (CPU). *See* COMPUTER PROGRAMMING; DATABASE MANAGEMENT SYSTEM; OPERATING SYSTEM; PROGRAMMING LANGUAGES.

A cache memory is a small, fast buffer located between the processor and the main system memory. Cache memory is used to speed up the flow of instructions and data into the central processing unit from main memory. This cache function is important because the main memory cycle time is typically slower than the central processing unit clocking rates.

Main memory. Random access memory (RAM) chips come in a wide variety of organizations and types. Computer main memories are organized into random addressable words in which the word length is fixed to some power-of-2 bits (for example, 4, 8, 16, 32, or 64 bits). But there are exceptions, such as 12-, 18-, 24-, 48-, and 60-bit word-length machines. Usually RAMs contain NK · 1 (for example, 64 · 1) bits, so the main memory design consists of a stack of chips in parallel with the number of chips corresponding to that machine's word length. There are two basic types of RAMs, static and dynamic. The differences are significant. Dynamic RAMs are those which require their contents to be refreshed periodically. They require supplementary circuits on-chip to do the refreshing and to assure that conflicts do not occur between refreshing and normal read-write operations. Even with those extra circuits, dynamic RAMs still require fewer on-chip components per bit than do static RAMs (which do not require refreshing).

Static RAMs are easier to design, and compete well in applications in which less memory is to be provided, since their higher cost then becomes less important. They are often chosen for minicomputer memory, or especially for microcomputers. Because they require more components per chip, making higher bit densities more difficult to achieve, the introduction of static RAMs of any given density occurs behind that of dynamic versions.

There is another trade-off to be made with semiconductor RAMs in addition to the choice between static and dynamic types, namely that between MOS and bipolar chips. Biopolar devices are faster, but have not yet achieved the higher densities (and hence the lower costs) of MOS. Within each basic technology, MOS and bipolar, there are several methods of constructing devices, and these variations achieve a variety of memory speeds and access times, as well as power consumption and price differences. Within the basic MOS technologies there are several types, such as the *n*-channel MOS referred to as NMOS and the complementary MOS solid-state structure referred to as CMOS. For bipolar there are several types such as transistor-to-transistor logic (TTL) and the emitter-coupled logic (ECL). *See* LOGIC CIRCUITS.

Secondary memory. High-capacity, slower-speed memory consists of two major functional types: random-access, which has been provided primarily by disk drives, and sequential-access, which has been provided primarily by tape drives. Since tape drives provide removability of the medium from the computer, tape is used for the majority of off-line, archival storage, although some disks are removable also. The on-line random-access disk devices are classed as secondary, and tape-based systems are classed as tertiary.

Conventional magnetic-disk memories consist of units which vary in capacity from the small floppy disks to gigabyte and higher capacity disk drives. The major area of development in disks has been the progressive and even spectacular increases in capacity per drive, particularly in terms of price per byte.

Optical recording is a nonmagnetic disk technology that uses a laser beam to burn pits in the recording medium to represent the bits of information, and a lower-power laser to sense the presence or absence of pits for reading.

CD-ROM (compact disk-read-only memory) and WORM (write once, read many) are special types of optical disks. CD-ROM resembles the related audio compact disk technology in that users of CD-ROM can read only prerecorded data on the disk. A 5-in. (125-mm) CD-ROM can hold 500 to 600 megabytes, which is equivalent to 1400 to 1700 (360-kilobyte) diskettes. *See* COMPACT DISK.

Bubble memories are chips rather than disks, but are different from semiconductor memories in that they are magnetic devices, in which the absence or presence of a magnetic domain is the basis for a binary 1 to 0. The performance characteristics of these devices makes them competitive as small-capacity secondary storage. For portable and other special applications, bubbles have definite advantages such as nonvolatility, low power, and high compactness. Performance capabilities relative to floppy disks are 100 kilobits per second for bubbles versus 200–250 kilobits per second for floppies, and 40 milliseconds average access time for bubbles versus 200–250 milliseconds for floppies.

Magnetic tape units. In magnetic tape units, the tape maintains physical contact with the fixed head while in motion, allowing high-density recording. The long access times to find user data on the tape are strictly due to the fact that all intervening data have to be searched until the desired data are found. This is not true of rotating disk memories or RAM word-addressable main memories. The primary use of tape storage is for seldom-used data files and as back-up storage for disk data files. Half-inch (12.5-mm) tape has been the industry standard since it was first used commercially in 1953. Half-inch magnetic tape drive transports are reel-to-reel recorders with extremely high tape speeds (up to 200 in. or 5 m per second), and fast start, stop (on the order of 1 millisecond), reverse, and rewind times. Performance and data capacity of magnetic tape have improved by orders of magnitude.

Mass storage systems. With the gradual acceptance of virtual memory and sophisticated operating systems, a significant operational problem arose with computer systems, particularly the large-scale installations. The expense and attendant delays and errors of humans storing, mounting, and demounting tape reels at the command of the operating system began to become a problem. Cartridge storage facilities are designed to alleviate this problem.

Their common attributes are: capacity large enough to accommodate a very large database on-line; access times between those of movable-head disks and tapes; and operability, without human intervention, under the strict control of the operating system. The cartridge storage facility is included within the virtual address range. All such configurations mechanically extract from a bin, mount on some sort of tape transport, and replace in a bin, following reading or writing, a reel or cartridge of magnetic tape.

Cartridge storage systems are hardware devices that need operating system and database software in order to produce a truly integrated, practical hardware-software system. Users require fast access to their files, and thus there is a definite need to queue up (stage) files from the cartridge storage device onto the disks. The database software must function efficiently to make this happen. In general, users base their storage device selection on the file sizes involved and the number of accesses per month. Magnetic tape units are used for very large files accessed seldom or infrequently. Mass-storage devices are for intermediate file sizes and access frequencies. Disk units are used for small files or those which are accessed often. [P.P.C.; M.Ple.; D.Th.]

Computer-system evaluation The evaluation of performance, from the perspectives of both developers and users, of complex systems of hardware and software. Modern computer-based information systems have become increasingly complex because of networking, distributed computing, distributed and heterogeneous databases, and the need to store large quantities of data. People are relying increasingly on computer systems to support daily activities. When these systems fail, significant breakdowns may ensue. *See* DISTRIBUTED SYSTEMS (COMPUTERS); LOCAL-AREA NETWORKS.

A computer system can fail in two major ways. First, functional failure occurs when the system fails to generate the correct results for a set of inputs. For example, if an information system fails to retrieve records that match a set of keywords, or if an air-missile tracking system fails to distinguish between a friendly and enemy missile, a functional failure has occurred. Second, performance failure occurs when the system operates correctly but fails to deliver the results in a timely fashion. For example, if an information system takes a longer time than users are willing to wait for the records they requested, the system is said to fail performance-wise even though it may eventually retrieve the correct set of records. Also, if the air-missile tracking system fails to detect an enemy missile in sufficient time to launch a counterattack, the system manifests performance failure.

Therefore, in designing a computer system it is necessary to guarantee that the end product will display neither functional nor performance failure. It is then necessary to predict the performance of computer systems when they are under design and development, as well as to predict the impact of changes in configurations of existing systems. This requires the use of predictive performance models.

The input parameters of performance models include workload intensity parameters, hardware and system parameters, and resource demand parameters. The outputs generated by performance models include response times, throughputs, utilization of devices, and queue lengths. There are analytic, simulation, and hybrid performance models. Analytic models are composed of a set of equations, or computational algorithms, used to compute the outputs from the input parameters. Simulation models are based on computer programs that emulate the behavior of a system by generating arrivals of so-called customers through a probabilistic process and by simulating their flow through the system. As these simulated entities visit the various system elements, they accumulate individual and system statistics. Hybrid models combine both analytic and simulation approaches by, for example, replacing an entire subsystem in an analytic model by an equivalent device whose input–output behavior is obtained by simulating the subsystem. Analytic models can be exact or approximate. *See* SIMULATION.

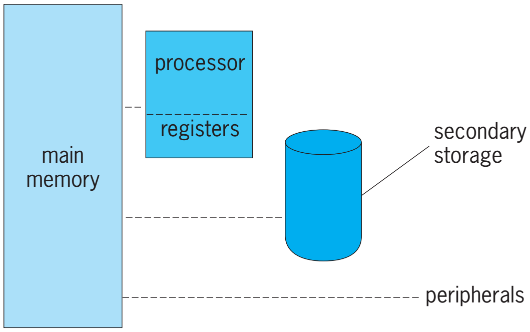
Approximations are needed either when there is no known mathematically tractable exact solution or when the computation of an exact solution is very complex. Modern computer systems are very complex because of ubiquitous networking, distributed processing using client–server architectures, multiprocessing, and sophisticated input–output subsystems using network-attached storage devices. For this reason, most computer system performance models are approximate models. *See* CLIENT-SERVER SYSTEM; MULTIPROCESSING.

The design and development of complex software systems is a time-consuming and expensive task. Performance modeling techniques must be integrated into the software development methodology. This integrated approach is called software performance engineering. One goal is to estimate the resource consumption of software under development so that performance models can be used to influence the architecture of the software under development. Better estimates on the resource consumption are obtained as the software development process evolves. *See* INFORMATION SYSTEMS ENGINEERING; SOFTWARE ENGINEERING. [D.A.Men.]

Computer systems architecture The discipline that defines the conceptual structure and functional behavior of a computer system. It is analogous to the architecture of a building, determining the overall organization, the attributes of the component parts, and how these parts are combined. It is related to, but different from, computer implementation. Architecture consists of those characteristics which affect the design and development of software programs, whereas implementation focuses on those characteristics which determine the relative cost and performance of the system. The architect's main goal has long been to produce a computer that is as fast as possible, within a given set of cost constraints. Over the years, other goals have been added, such as making it easier to run multiple programs concurrently or improving the performance of programs written in higher-level languages.

A computer system consists of four major components (see illustration): storage, processor, peripherals, and input/output (communication). The storage system is used to keep data and programs; the processor is the unit that controls the operation of the system and carries out various computations; the peripheral devices are used to communicate with the outside world; and the input/output system allows the previous components to communicate with one another.

Storage. The storage or memory of a computer system holds the data that the computer will process and the instructions that indicate what processing is to be done. In a digital computer, these are stored in a form known as binary, which means that each datum or instruction is represented by a series of bits. Bits are conceptually combined into larger units called bytes (usually 8 bits each) and words (usually 8 to 64 bits each). A computer will generally have several different kinds of storage devices, each organized to hold one or more words of data. These types include registers, main memory, and secondary or auxiliary storage. *See* BIT.



Overview of a computer system. Storage is made up of registers, main memory, and secondary storage. Broken lines indicate input/output.

Registers are the fastest and most costly storage units in a computer. Normally contained within the processing unit, registers hold data that are involved with the computation currently being performed.

Main memory holds the data to be processed and the instructions that specify what processing is to be done. A major goal of the computer architect is to increase the effective speed and size of a memory system without incurring a large cost penalty. Two prevalent techniques for increasing effective speed are interleaving and cacheing, while virtual memory is a popular way to increase the effective size. Interleaving involves the use of two or more independent memory systems, combined in a way that makes them appear to be a single, faster system. With cacheing, a small, fast memory system contains the most frequently used words from a slower, larger main memory.

Virtual memory is a technique whereby the programmer is given the illusion of a very large main memory, when in fact it has only a modest size. This is achieved by placing the contents of the large, "virtual" memory on a large but slow auxiliary storage device, and bringing portions of it into main memory, as required by the programs, in a way that is transparent to the programmer.

Auxiliary memory (sometimes called secondary storage) is the slowest, lowest-cost, and highest-capacity computer storage area. Programs and data are kept in auxiliary memory when not in immediate use, so that auxiliary memory is essentially a long-term storage medium. There are two basic types of secondary storage: sequential and direct-access. Sequential-access secondary storage devices, of which magnetic tape is the most common, permit data to be accessed in a linear sequence. A direct-access device is one whose data may be accessed in any order. Disks and drums are the most commonly encountered devices of this type.

Memory mapping is one of the most important aspects of modern computer memory designs. In order to understand its function, the concept of an address space must be considered. When a program resides in a computer's main memory, there is a set of memory cells assigned to the program and its data. This is known as the program's logical address space. The computer's physical address space is the set of memory cells actually contained in the main memory. Memory mapping is simply the method by which the computer translates between the computer's logical and physical address spaces. The most straightforward mapping scheme involves use of a bias register. Assignment of a different bias value to each program in memory enables the programs to coexist without interference.

Another strategy for mapping is known as paging. This technique involves dividing both logical and physical address spaces into equal-sized blocks called pages. Mapping is achieved by means of a page map, which can be thought of as a series of bias registers. *See* COMPUTER STORAGE TECHNOLOGY.

Processing. A computer's processor (processing unit) consists of a control unit, which directs the operation of the system, and an arithmetic and logic unit, which performs computational operations. The design of a processing unit involves selection of a register set, communication paths between these registers, and a means of directing and controlling how these operate. Normally, a processor is directed by a program, which consists of a series of instructions that are kept in main memory.

Although the process of decoding and executing instructions is often carried out by logic circuitry, the complexity of instruction sets can lead to very large and cumbersome circuits for this purpose. To alleviate this problem, a technique known as microprogramming was developed. With microprogramming, each instruction is actually a macrocommand that is carried out by a microprogram, written in a microinstruction language. The microinstructions are very simple, directing data to flow between registers, memories, and arithmetic units.

It should be noted that microprogramming has nothing to do with microprocessors. A microprocessor is a processor implemented through a single, highly integrated circuit. *See* MICROPROCESSOR.

Peripherals and communication. A typical computer system includes a variety of peripheral devices such as printers, keyboards, and displays. These devices translate electronic signals into mechanical motion or light (or vice versa) so as to communicate with people.

There are two common approaches for connecting peripherals and secondary storage devices to the rest of the computer: The channel and the bus. A channel is essentially a wire or group of wires between a peripheral device and a memory device. A multiplexed channel allows several devices to be connected to the same wire. A bus is a form of multiplexed channel that can be shared by a large number of devices. The overhead of sharing many devices means that the bus has lower peak performance than a channel; but for a system with many peripherals, the bus is more economical than a large number of channels.

A computer controls the flow of data across buses or channels by means of special instructions and other mechanisms. The simplest scheme is known as program-controlled input/output (I/O). Direct memory access I/O is a technique by which the computer signals the device to transmit a block of data, and the data are transmitted directly to memory, without the processor needing to wait.

Interrupts are a form of signal by which a peripheral device notifies a processor that it has completed transmitting data. This is very helpful in a direct memory access scheme, for the processor cannot always predict in advance how long it will take to transmit a block of data. Architects often design elaborate interrupt schemes to simplify the situation where several peripherals are active simultaneously. *See* COMPUTER; DIGITAL COMPUTER. [D.J.F.]

Computer vision

The technology concerned with computational understanding and use of the information present in visual images. In part, computer vision is analogous to the transformation of visual sensation into visual perception in biological vision. For this reason the motivation, objectives, formulation, and methodology of computer vision frequently intersect with knowledge about their counterparts in biological vision. However, the goal of computer vision is primarily to enable engineering systems to model and manipulate the environment by using visual sensing. *See* VISION.

Computer vision begins with the acquisition of images. A camera produces a grid of samples of the light received from different directions in the scene. The position within the grid where a scene point is imaged is determined by the perspective transformation. The amount of light recorded by the sensor from a certain scene point depends upon the type of lighting, the reflection characteristics and orientation of the surface being imaged, and the location and spectral sensitivity of the sensor.

One central objective of image interpretation is to infer the three-dimensional (3D) structure of the scene from images that are only two-dimensional (2D). The missing third dimension necessitates that assumptions be made about the scene so that the image information can be extrapolated into a three-dimensional description. The presence in the image of a variety of three-dimensional cues is exploited. The two-dimensional structure of an image or the three-dimensional structure of a scene must be represented so that the structural properties required for various tasks are easily accessible. For example, the hierarchical two-dimensional structure of an image may be represented through a pyramid data structure which records the recursive embedding of the image regions at different scales. Each region's shape and homogeneity characteristics may themselves be suitably coded. Alternatively, the image may be recursively split into parts in some fixed way (for example, into quadrants) until each part is homogeneous. This approach leads to a tree data structure. Analogous to two dimensions, the three-dimensional structures estimated from the imaged-based cues may be used to define three-dimensional representations. The shape of a three-dimensional volume or object may be represented by its three-dimensional axis and the manner in which the cross section about the axis changes along the axis. Analogous to the two-dimensional case, the three-dimensional space may also be recursively divided into octants to obtain a tree description of the occupancy of space by objects.

A second central objective of image interpretation is to recognize the scene contents. Recognition involves identifying an object based on a variety of criteria. It may involve identifying a certain object in the image as one seen before. A simple example is where the object appearance, such as its color and shape, is compared with that of the known, previously seen objects. A more complex example is where the identity of the object depends on whether it can serve a certain function, for example, drinking (to be recognized as a cup) or sitting (to be recognized as a chair). This requires reasoning from the various image attributes and the derivative three-dimensional characteristics to assess if a given object meets the criteria of being a cup or a chair. Recognition, therefore, may require extensive amounts of knowledge representation, reasoning, and information retrieval.

Visual learning is aimed at identifying relationships between the image characteristics and a result based thereupon, such as recognition or a motor action.

In manufacturing, vision-based sensing and interpretation systems help in automatic inspection, such as identification of cracks, holes, and surface roughness; counting of objects; and alignment of parts. Computer vision helps in proper manipulation of an object, for example, in automatic assembly, automatic painting of a car, and automatic welding. Autonomous navigation, used, for example, in delivering material on a cluttered factory floor, has much to gain from vision to improve on the fixed, rigid paths taken by vehicles which follow magnetic tracks prelaid on the floor. Recognition of symptoms, for example, in a chest x-ray, is important for medical diagnosis. Classification of satellite pictures of the Earth's surface to identify vegetation, water, and crop types, is an important function. Automatic visual detection of storm formations and movements of weather patterns is crucial for analyzing the huge amounts of global weather data that constantly pour in from sensors. *See* CHARACTER RECOGNITION; COMPUTER GRAPHICS; INTELLIGENT MACHINE; ROBOTICS. [N.Ah.]

Computerized tomography

An imaging technique which uses an array of detectors to collect information from a beam that has passed through an object (for example, a portion of the human body). The information collected is then used by a computer to reconstruct the internal structures, and the resulting image can be displayed—for example, on a television screen. The technique relies on the fact that wave phenomena can penetrate into regions where it is impossible or undesirable to introduce ordinary probes. Since wave attenuation and velocity are affected by material properties, such as temperature and density, information concerning these properties is accumulated by a wave packet as it travels along its path. The intensities and travel times of such pulses measured at a receiver represent such accumulations. Although a single such datum does not allow point-to-point variation to be inferred, when many rays crisscross a region the corresponding interrelated data contain constraints that allow an inversion to determine interior structures. Considerable computational power and mathematical sophistication are needed in dealing with indirect, incomplete, and imperfect measurements, notably the branch of mathematics called inverse theory. The term computerized tomography for this technology arose in medicine, where x-ray attenuation data along many straight paths confined to a plane were used to obtain a map of density structure in a body section. The term tomography refers to methods that display only thin slices or sections through an object or a human body. *See* INVERSE SCATTERING THEORY.

Examining a person or object in the laboratory requires the use of a gantry, composed of an x-ray tube, an array of detectors opposite the tube, and a central aperture in which the person or object is placed. The rigid gantry maintains the proper alignment between the x-ray tube and the detectors. An electron beam is used, which is focused on stationary anode rings located in the gantry surrounding the patient, making it possible to generate considerable x-ray output within a very short time and to acquire images while the patient is advancing through the gantry. Up to 34 scans or slices can be obtained within 1 s. The computer reconstructs the image from the information collected by the detectors. In order to obtain enough information to calculate one image, at least 90,000 readings (300 pulses and 300 detectors) are needed.

In medicine, computerized tomography represents a noninvasive way of seeing internal structures. In the brain, for example, computerized tomography can readily locate tumors and hemorrhages, thereby providing immediate information for evaluating neurological emergencies. Another advantage of computerized tomography is three-dimensional reconstruction. It is most useful in cases of fracture of the hip or facial bones, helping the surgeon to do reconstructive surgery. Other medical imaging techniques that make use of computerized tomographic methods include magnetic resonance imaging, positron emission tomography, and single-photon emission tomography. *See* MEDICAL IMAGING; RADIOGRAPHY. [N.F.B.]

After the success of computerized tomography in medicine, its possibilities in other fields were quickly realized. In the earth, atmospheric, and ocean sciences it has supplemented, but by no means replaced, older methods of remote sensing. Seismic tomography is now an important tool for investigating the deep structure of the Earth, testing theories such as plate tectonics, and exploring for oil. Ocean acoustic tomography is applied to physical oceanography, climatology, and antisubmarine warfare. Atmospheric tomography finds applications to weather, climate, and the environment. *See* OCEANOGRAPHY; PLATE TECTONICS; SEISMOLOGY. [T.J.E.; R.N.]

Concentration scales

Concentration is a very important property of mixtures, because it defines the quantitative relation of the components. In solutions the concentration is expressed as the mass, volume, or number of moles of solute present in proportion to the amount of solvent or of total solution.

The simplest scale to measure is percentage; hence it is often used for medicinal or household solutions. Weight percent is the number of parts of weight of solute per hundred parts of solution (total). For example, a 10% saline solution contains 10 g of salt in 90 g of water, that is, 100 g total weight. Gaseous mixtures, being difficult to weigh, are often expressed as volume percent. Thus, air is said to contain 78% nitrogen by volume. Solutions of liquids in liquids (say, alcohol in water) may also be expressed in volume percent.

To the chemist, the number of moles of solute is of more significance than the number of grams. The molarity (abbreviated *M*) is the number of moles of solute per liter of total solution. Thus, 12 *M* HCl means that the solution contains 12 formula weights (12 × 36.5), or 438 g, of HCl/liter. (As used here, the mole is an amount of substance whose weight in grams is numerically the same as the molecular weight.)

Molality (abbreviated *m*) relates the number of moles of solute to the weight of solvent rather than to the volume of solution. This scale indicates the number of moles of solute/1000 g of solvent. Thus 34.2 g of sucrose ($C_{12}H_{22}O_{11}$, mol wt 342), if dissolved in 200 g of water, has the concentration of 0.5 mole of sucrose/1000 g of water, and hence is 0.5 *m*.

When it is important to know the reactive capacities of reagents, as in volumetric analysis, the normality scale is used. Normality (abbreviated *N*) is found by multiplying molarity by the number of active units in the formula.

In recent years many chemists have sought to avoid the molarity scale lest it imply that electrolyte solutes exist as molecules rather than ions. The formality scale (abbreviated *F*) represents formula weights per liter. Its values are identical with the molarities of un-ionized solutes.

Many properties of solutions (for example, vapor pressure of one component) are dependent on the ratio of the number of moles of solute to the number of moles of solvent, rather than on the ratios of respective volumes or masses. The mole fraction (abbreviated N_A or X_A for component *A*) is the ratio of the number of moles of solute to the total number of moles of all components. Thus for 16 g of methanol (0.5 mole) dissolved in 18 g of water (1 mole), the mole fraction of methanol is 0.5/1.5, or 1/3; the mole percent is 33.3. For gases the mole percent is identical with the volume percent. *See* GRAM-MOLECULAR WEIGHT; SOLUTION; TITRATION. [A.L.H.]

Concrete Any of several manufactured, stonelike materials composed of particles, called aggregates, that are selected and graded into specified sizes for construction purposes and that are bonded together by one or more cementitious materials into a solid mass.

The term concrete, when used without a modifying adjective, ordinarily is intended to indicate the product formed from a mix of portland cement, sand, gravel or crushed stone, and water. There are, however, many different types of concrete. The names of some are distinguished by the types, sizes, and densities of aggregates—for example, wood-fiber, lightweight, normal-weight, or heavyweight concrete. The names of others may indicate the type of binder used—for example, blended-hydraulic cement, natural-cement, polymer, or bituminous (asphaltic) concrete.

Concretes are similar in composition to mortars, which are used to bond unit masonry. Mortars, however, are normally made with sand as the sole aggregate, whereas concretes contain much larger aggregates and thus usually have greater strength. As a result, concretes have a much wider range of structural applications, including pavements, footings, pipes, unit masonry, floor slabs, beams, columns, walls, dams, and tanks. *See* CONCRETE BEAM; CONCRETE COLUMN; CONCRETE SLAB; MASONRY; MORTAR.

Because ordinary concrete is much weaker in tension than in compression, it is usually reinforced or prestressed with a much stronger material, such as steel, to resist tension. Use of plain, or unreinforced, concrete is restricted to structures in which tensile stresses will be small, such as massive dams, heavy foundations, and unit-masonry walls. For reinforcement of other types of structures, steel bars or structural-steel shapes may be incorporated in the concrete. Prestress to offset tensile stresses may be applied at specific locations by permanently installed compressing jacks, high-strength steel bars, or steel strands. Alternatively, prestress may be distributed throughout a concrete component by embedded pretensioned steel elements. Another option is use of a cement that tends to expand concrete while enclosures prevent that action, thus imposing compression on the concrete. *See* PRESTRESSED CONCRETE; REINFORCED CONCRETE.

There are various methods employed for casting ordinary concrete. For very small projects, sacks of prepared mixes may be purchased and mixed on the site with water, usually in a drum-type, portable, mechanical mixer. For large projects, mix ingredients are weighed separately and deposited in a stationary batch mixer, a truck mixer, or a continuous mixer. Concrete mixed or agitated in a truck is called ready-mixed concrete. In general, concrete is placed and consolidated in forms by hand tamping or puddling around reinforcing steel or by spading at or near vertical surfaces. Another technique, vibration or mechanical puddling, is the most satisfactory one for achieving proper consolidation.

Finishes for exposed concrete surfaces are obtained in a number of ways. Surfaces cast against forms can be given textures by using patterned form liners or by treating the surface after forms are removed, for instance, by brushing, scrubbing, floating, rubbing, or plastering. After the surface is thoroughly hardened, other textures can be achieved by grinding, chipping, bush-hammering, or sandblasting. Unformed surfaces, such as the top of pavement slabs or floor slabs, may be either broomed or smoothed with a trowel. Brooming or dragging burlap over the surface produces scoring, which reduces skidding when the pavement is wet.

Adequate curing is essential to bring the concrete to required strength and quality. The aim of curing is to promote the hydration of the cementing material. This is accomplished by preventing moisture loss and, when necessary, by controlling temperature. Moisture is a necessary ingredient in the curing process, since hydration is a chemical reaction between the water and the cementing material. Unformed surfaces are protected against moisture loss immediately after final finishing by means of wet burlap, soaked cotton mats, wet earth or sand, sprayed-on sealing compounds, waterproof paper, or waterproof plastic sheets. Formed surfaces, particularly vertical surfaces, may be protected against moisture loss by leaving the forms on as long as possible, covering with wet canvas or burlap, spraying a small stream of water over the surface, or applying sprayed-on sealing compounds. The length of the curing period depends upon the properties desired and upon atmospheric conditions, such as temperature, humidity, and wind velocity, during this period. Short curing periods are used in fabricating concrete products such as block or precast structural elements. Curing time is shortened by the use of elevated temperatures. [F.S.M.]

Concrete beam A structural member of reinforced concrete placed horizontally to carry loads over openings. Because both bending and shear in such beams induce tensile stresses, steel reinforcing tremendously increases beam strength. Usually, beams are designed under the assumption that tensile stresses have cracked the concrete and the steel reinforcing is carrying all the tension. *See* STRESS AND STRAIN. [F.S.M.]

Concrete column A structural member subjected principally to compressive stresses. Concrete columns may be unreinforced, or they may be reinforced with longitudinal bars and ties (tied columns) or with longitudinal bars and spiral steel (spiral-reinforced columns). Sometimes the columns may be a composite of structural steel of cast iron and concrete.

Unreinforced concrete columns are seldom used because of transverse tensile stresses and the possibility of longitudinal tensile stresses being induced by buckling or unanticipated bending. Because concrete is weak in tension, such stresses are generally avoided. When plain concrete columns are used, they usually are limited in height to five or six times the least thickness. Under axial loading, the load divided by the cross-sectional area of the concrete should not exceed the allowable unit compressive stress for the concrete. *See* CONCRETE; REINFORCED CONCRETE; STEEL. [F.S.M.]

Concrete slab A shallow, reinforced-concrete structural member that is very wide compared with depth. Spanning between beams, girders, or columns, slabs are used for floors, roofs, and bridge decks. If they are cast integrally with beams or girders, they may be considered the top flange of those members and act with them as a T beam. *See* CONCRETE; CONCRETE BEAM.

A one-way slab is supported on four sides and has a much larger span in one direction than in the other may be assumed to be supported only along its long sides. It may be designed as a beam spanning in the short direction. For this purpose a 1-ft width can be chosen and the depth of slab and reinforcing determined for this unit. Some steel is also placed in the long direction to resist temperature stresses and distribute concentrated loads. The area of the steel generally is at least 0.20% of the concrete area.

A slab supported on four sides and with reinforcing steel perpendicular to all sides is called a two-way slab. Such slabs generally are designed by empirical methods. A two-way slab is divided into strips for design purposes.

When a slab is supported directly on columns, without beams and girders, it is called a flat plate or flat slab. Although thicker and more heavily reinforced than slabs in beam-and-girder construction, flat slabs are advantageous because they offer no obstruction to passage of light (as beam construction does); savings in story height and in the simpler formwork involved; less danger of collapse due to overload; and better fire protection with a sprinkler system because the spray is not obstructed by beams. *See* CONCRETE COLUMN; REINFORCED CONCRETE. [F.S.M.]

Concretion A loosely defined term used for a sedimentary mineral segregation that may range in size from inches to many feet. Concretions are usually distinguished from the sedimentary matrix enclosing them by a difference in mineralogy, color, hardness, and weathering characteristics. Some concretions show definite sharp boundaries with the matrix, while others have gradational boundaries. Most concretions are composed dominantly of calcium carbonate, with or without an admixture of various amounts of silt, clay, or organic material. Coal balls are calcareous concretions found in or immediately above coal beds. Concretions are normally spherical or ellipsoidal; some are flattened to disklike shapes. Frequently a concretion is dumbbell-shaped, indicating that two separate concretionary centers have grown together. *See* COAL BALLS; SEDIMENTARY ROCKS. [R.Si.]

Concurrent processing The simultaneous execution of several interrelated computer programs. A sequential computer program consists of a series of instructions to be executed one after another. A concurrent program consists of several sequential programs to be executed in parallel. Each of the concurrently executing sequential programs is called a process. Process execution, although concurrent, is usually not independent. Processes may affect each other's behavior through shared data, shared resources, communication, and synchronization.

Concurrent programs can be executed in several ways. Multiprogramming systems have one processing unit and one memory bank. Concurrent process execution is simulated by randomly interleaving instructions of the sequential programs. All processes have access to a common pool of data. In contrast, multiprocessing systems have several processing units and one memory bank. Processes are executed in parallel on the separate processing units while sharing common data. In distributed systems, or computer networks, each process is executed on its own processor with its own memory bank. Interaction between processes occurs by transmission of data from one process to another along a communication channel. *See* DISTRIBUTED SYSTEMS (COMPUTERS); MULTIPROCESSING.

One of the first uses of concurrent processing was in operating systems. If the computer is to support a multiuser environment, the operating system must employ concurrent programming techniques to allow several users to access the computer simultaneously. The operating system should also permit several input/output devices to be used simultaneously, again utilizing concurrent processing. *See* MULTIACCESS COMPUTER; OPERATING SYSTEM.

Concurrent programming is also used when several computers are joined in a network. An airline reservation system is one example of concurrent processing on a distributed network of computers. *See* LOCAL-AREA NETWORKS; WIDE-AREA NETWORK.

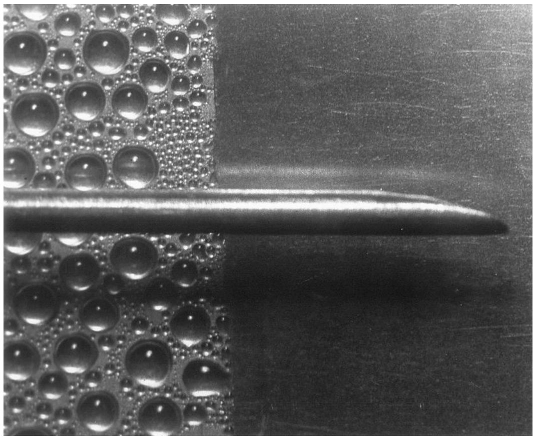
A simple example of a task that can be performed more efficiently by concurrent processing is a program to calculate the sum of a large list of numbers. Several processes can simultaneously compute the sum of a subset of the list, after which these sums are added to produce the final total.

Concurrent programs can be created explicitly or implicitly. Explicit concurrent programs are written in a programming language designed for specifying processes to be executed concurrently. Implicit concurrent programs are created by a compiler that automatically translates programs written in a sequential programming language into programs with several components to be executed in parallel. *See* DATA-FLOW SYSTEMS; PROGRAMMING LANGUAGES. [J.Wi.]

Concussion A state following injury in which there is temporary functional impairment without physical evidence of damage to the impaired tissues. The term usually refers to cerebral concussion produced by any type of trauma.

From a clinical point of view cerebral concussion is produced by a head injury which causes temporary unconsciousness but with complete recovery within 24 h. This temporary alteration is believed to result from one of several mechanisms. In all of these a sudden acceleration or deceleration appears to be a prerequisite. The sudden movement is thought to cause an unequal shifting of tissues of different specific gravities within the skull, between skull and brain, or between different brain tissues. *See* BRAIN. [E.G.St./N.K.M.]

Condensation A phase-change process in which vapor converts into liquid when the temperature of the vapor is reduced below the saturation temperature corresponding to the pressure in the vapor. For a pure vapor this pressure is the total pressure, whereas in a mixture of a vapor and a noncondensable gas it is the partial pressure of the vapor. Sustaining the process of condensation on a cold surface in a steady state requires cooling of the surface by external means. Condensation is an efficient heat transfer process and is utilized in various



Steam at atmospheric pressure condensing on a vertical copper surface. Film condensation is visible on the right side, and dropwise condensation in the presence of a promoter is visible on the left side. The horizontal tube is a thermocouple. (*J. F. Welch and J. W. Westwater, Department of Chemical Engineering, University of Illinois, Urbana*)

industrial applications. Condensation of vapor on a cold surface can be classified as filmwise or dropwise. Direct-contact condensation refers to condensation of vapor (bubbles or a vapor stream) in a liquid or condensation on liquid droplets entrained in the vapor. If vapor temperature falls below its saturation temperature, condensation can occur in the bulk vapor. This phenomenon is called homogeneous condensation (formation of fog) and is facilitated by foreign particles such as dust. *See* GAS; HEAT TRANSFER.

In film condensation, a thin film of liquid forms upon condensation of vapor on a cold surface that is well wetted by the condensate. The liquid film flows downward as a result of gravity.

In dropwise condensation, on surfaces that are not well wetted, vapor may condense in the form of droplets (see illustration). The droplets form on imperfections such as cavities, dents, and cracks on the surface. The droplets of 10–100 μm diameter contribute most to the heat transfer rate. As a droplet grows to a size that can roll down the surface because of gravity, it wipes the surface of the droplets in its path. In the wake behind the large droplet, numerous smaller droplets form and the process repeats. The heat transfer coefficients with dropwise condensation can be one to two orders of magnitude greater then that for film condensation.

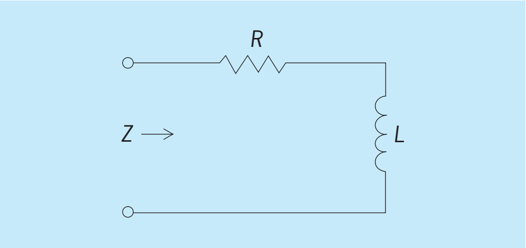
Direct-condensation involves condensation of vapor bubbles in a host liquid and condensation on droplets entrained in vapor. Both are also very efficient heat transfer processes, especially when the vapor-liquid interface oscillates. [V.K.D.]

Conditioned reflex A learned response performed by a trained animal to a signal that was previously associated with an event of consequence for that animal. Conditioned reflex (CR) was first used by the Russian physiologist I. P. Pavlov to denote the criterion measure of a behavioral element of learning, that is, a new association between the signal and the consequential event, referred to as the conditioned stimulus (CS) and unconditioned stimulus (US), respectively. In Pavlov's classic experiment, the conditioned stimulus was a bell and the unconditioned stimulus was sour fluid delivered into the mouth of a dog restrained by harness; the conditioned stimulus was followed by the unconditioned stimulus regardless of the dog's response. After training, the conditioned reflex is manifested when the dog salivates to the sound of the bell.

Ideally, certain conditions must be met to demonstrate the establishment of a conditioned reflex according to Pavlov's classical conditioning method. Before conditioning, the bell conditioned stimulus should attract the dog's attention or elicit the orienting reflex (OR), but it should not elicit salivation, the response to be conditioned. That response should be specifically and reflexively elicited by the sour unconditioned stimulus, thus establishing its unlearned or unconditioned status. After conditioned pairings of the conditioned stimulus and the unconditioned stimulus, salivation is manifested prior to the delivery of the sour unconditioned stimulus. Salivation in response to the auditory conditional stimulus is now a "psychic secretion" or the conditioned reflex.

To this day, Pavlov's methods provide important guidelines for basic research upon brain mechanisms in learning and memory. Scientists all over the world have paired a vast array of stimuli with an enormous repertoire of reflexes to test conditioned reflexes in representative species of almost all phyla, classes, and orders of animals. As a result, classical conditioning is now considered a general biological or psychobiological phenomenon which promotes adaptive functioning in a wide variety of physiological systems in various phylogenetic settings. *See* COGNITION; MEMORY. [J.G.]

Conductance The real part of the admittance of an alternating-current circuit. The admittance Y of an alternating-current circuit is a complex number given by Eq. (1).



Circuit with a resistor and inductor in series.

$$Y = G + jB \qquad (1)$$

The real part G is the conductance. The units of conductance, like those of admittance, are called siemens or mhos. Conductance is a positive quantity. The conductance of a resistor R is given by Eq. (2).

$$G = \frac{1}{R} \qquad (2)$$

In general the conductance of a circuit may depend on the capacitors and inductors in the circuit as well as on the resistors. For example, the circuit in the illustration has impedance at frequency ω given by Eq. (3) and admittance given by Eq. (4), so that the conductance, given by Eq. (5), depends on

$$Z = R + jL\omega \qquad (3)$$

$$Y = \frac{1}{R + jL\omega} \qquad (4)$$

$$G = \frac{R}{R^2 + L^2\omega^2} \qquad (5)$$

the inductance L as well as the resistance R. *See* ADMITTANCE; ALTERNATING-CURRENT CIRCUIT THEORY; ELECTRICAL IMPEDANCE. [J.O.S.]

Conduction (electricity) The passage of electric charges due to a force exerted on them by an electric field. Conductivity is the measure of the ability of a conductor to carry electric current; it is defined as the ratio of the amount of charge passing through unit area of the conductor (perpendicular to the current direction) per second divided by the electric field intensity (the force on a unit charge). Conductivity is the reciprocal of resistivity and is therefore commonly expressed in units of siemens per meter, abbreviated S/m. *See* ELECTRICAL RESISTIVITY.

In metals and semiconductors (such as silicon, of which transistors are made) the charges that are responsible for current are free electrons and holes (which, as missing electrons, act like positive charges). These are electrons or holes not bound to any particular atom and therefore able to move freely in the field. Conductivity due to electrons is known as *n*-type conductivity; that due to holes is known as *p*-type. *See* HOLE STATES IN SOLIDS; SEMICONDUCTOR.

The conductivity of metals is much higher than that of semiconductors because they have many more free electrons or holes. The free electrons or holes come from the metal atoms. Semiconductors differ from metals in two important respects. First, the semiconductor atoms do not contribute free electrons or holes unless thermally excited, and second, free electrons or holes can also arise from impurities or defects.

An exception to some of the rules stated above has been found in conjugated polymers. Polyacetylene, for example, although a semiconductor with extremely high resistance when undoped, can be doped so heavily with certain nonmetallic impurities (iodine, for example) that it attains a conductivity comparable to that of copper. *See* ORGANIC CONDUCTOR.

In metals, although the number of free carriers does not vary with temperature, an increase in temperature decreases conductivity. The reason is that increasing temperature causes the lattice atoms to vibrate more strongly, impeding the motion of the free carriers in the field. This effect also occurs in semiconductors, but the increase in number of free carriers with temperature is usually a stronger effect. At low temperatures the thermal vibrations are weak, and the impediment to the motion of free carriers in the field comes from imperfections and impurities, which in metals usually does not vary with temperature. At the lowest temperatures, close to absolute zero, certain metals become superconductors, possessing infinite conductivity. *See* ELECTRICAL CONDUCTIVITY OF METALS; SUPERCONDUCTIVITY.

Electrolytes conduct electricity by means of the positive and negative ions in solution. In ionic crystals, conduction may also take place by the motion of ions. This motion is much affected by the presence of lattice defects such as interstitial ions, vacancies, and foreign ions. *See* ELECTROLYTIC CONDUCTANCE; IONIC CRYSTALS.

Electric current can flow through an evacuated region if electrons or ions are supplied. In a vacuum tube the current carriers are electrons emitted by a heated filament. The conductivity is low because only a small number of electrons can be "boiled off" at the normal temperatures of electron-emitting filaments. *See* ELECTRON EMISSION; ELECTRON MOTION IN VACUUM; VACUUM TUBE. [E.M.Co.]

Conduction (heat) The flow of thermal energy through a substance from a higher- to a lower-temperature region. Heat conduction occurs by atomic or molecular interactions. Conduction is one of the three basic methods of heat transfer, the other two being convection and radiation. *See* CONVECTION (HEAT); HEAT RADIATION; HEAT TRANSFER.

Steady-state conduction is said to exist when the temperature at all locations in a substance is constant with time, as in the case of heat flow through a uniform wall. Examples of essentially pure transient or periodic heat conduction and simple or complex combinations of the two are encountered in the heat-treating of metals, air conditioning, food processing, and the pouring and curing of large concrete structures. Also, the daily and yearly temperature variations near the surface of the Earth can be predicted reasonably well by assuming a simple sinusoidal temperature variation at the surface and treating the Earth as a semi-infinite solid. The widespread importance of transient heat flow in particular has stimulated the development of a large variety of analytical solutions to many problems. The use of many of these has been facilitated by presentation in graphical form.

For an example of the conduction process, consider a gas such as nitrogen which normally consists of diatomic molecules. The temperature at any location can be interpreted as a quantitative specification of the mean kinetic and potential energy stored in the molecules or atoms at this location. This stored energy will be partly kinetic because of the random translational and rotational velocities of the molecules, partly potential because of internal vibrations, and partly ionic if the temperature (energy) level is high enough to cause dissociation. The flow of energy results from the random travel of high-temperature molecules into low-temperature regions and vice versa. In colliding with molecules in the low-temperature region, the high temperature molecules give up some of their energy. The reverse occurs in the high-temperature region. These processes take place almost instantaneously in infinitesimal distances, the result being a quasi-equilibrium state with energy transfer. The mechanism for energy flow in liquids and solids is similar to that in gases in principle, but different in detail. [W.H.Gi.]

Conduction band The electronic energy band of a crystalline solid which is partially occupied by electrons. The electrons in this energy band can increase their energies by going to higher energy levels within the band when an electric field is applied to accelerate them or when the temperature of the crystal is raised. These electrons are called conduction electrons, as distinct from the electrons in filled energy bands, which, as a whole, do not contribute to electrical and thermal conduction. In metallic conductors the conduction electrons correspond to the valence electrons (or a portion of the valence electrons) of the constituent atoms. In semiconductors and insulators at sufficiently low temperatures, the conduction band is empty of electrons. Conduction electrons come from thermal excitation of electrons from a lower energy band or from impurity atoms in the crystal. *See* BAND THEORY OF SOLIDS; ELECTRIC INSULATOR; SEMICONDUCTOR; VALENCE BAND. [H.Y.F.]

Conductor (electricity) Metal wires, cables, rods, tubes, and bus-bars used for the purpose of carrying electric current. (The most common forms are wires, cables, and bus-bars.) Although any metal assembly or structure can conduct electricity, the term conductor usually refers to the component parts of the current-carrying circuit or system.

Wires employed as electrical conductors are slender rods or filaments of metal, usually soft and flexible. They may be bare or covered by some form of flexible insulating material. They are usually circular in cross section; for special purposes they may be drawn in square, rectangular, ribbon, or other shapes. Conductors may be solid or stranded, that is, built up by a helical lay or assembly of smaller solid conductors.

Insulated stranded conductors in the larger sizes are called cables. Small, flexible, insulated cables are called cords. Assemblies of two or more insulated wires or cables within a common jacket or sheath are called multiconductor cables.

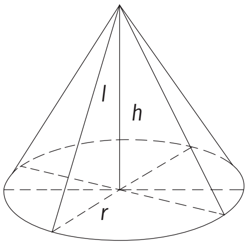
Bus-bars are rigid, solid conductors and are made in various shapes, including rectangular, rods, tubes, and hollow squares. Bus-bars may be applied as single conductors, one bus-bar per phase, or as multiple conductors, two or more bus-bars per phase. The individual conductors of a multiple-conductor installation are identical.

Most wires, cables, and bus-bars are made from either copper or aluminum. Copper, of all the metals except silver, offers the least resistance to the flow of electric current. Both copper and aluminum may be bent and formed readily and have good flexibility in small sizes and in stranded constructions. Aluminum, because of its higher resistance, has less current-carrying capacity than copper for a given cross-sectional area. However, its low cost and light weight (only 30% that of the same volume of copper) permit wide use of aluminum for bus-bars, transmission lines, and large insulated-cable installations.

For overhead transmission lines where superior strength is required, special conductor constructions are used. Typical of these are aluminum conductors, steel reinforced, a composite construction of electrical-grade aluminum strands surrounding a stranded steel core. Other constructions include stranded, high-strength aluminum alloy and a composite construction of aluminum strands around a stranded high-strength aluminum alloy core.

For extra-high-voltage transmission lines, conductor size is often established by corona performance rather than current-carrying capacity. Thus special "expanded" constructions are used to provide a large circumference without excessive weight. Typical constructions use helical lays of widely spaced aluminum strands around a stranded steel core. The space between the expanding strands is filled with paper twine, and outer layers of conventional aluminum strands are applied. [H.W.Be.]

Cone The solid of revolution obtained by revolving a right triangle about one of its shorter sides is called a cone, or more precisely a right circular cone (see illustration). More generally, the term cone is used in solid geometry to describe a solid bounded by a plane and a portion of one nappe of a conical surface. In analytic geometry, however, the term cone refers not to a solid but to a conical surface. This is a surface generated by a straight



Right circular cone.

line which moves so that it always intersects a given plane curve, called the directrix, and passes through a point, called the vertex, not in the plane of the directrix. The generating line in each of its positions is called an element of the cone. The vertex divides the surface into two parts, called nappes.

If the elements of a cone make equal angles with a line through the vertex, the cone is called a cone of revolution. Plane sections of a cone of revolution are called conic sections.

The volume of a solid cone is $V = Bh/3$, where B is the base area included within the directrix, and h is the altitude (or height) measured from the vertex to the plane of the base. The volume V and surface area S of a right circular cone are $V = \pi r^2 h/3$ and $S = 2\pi rl + 2\pi r^2$, where r denotes the radius of the base and $I = \sqrt{r^2 + h^2}$ denotes the slant height, measured from vertex to base along an element of the cone. *See* CONIC SECTION; EUCLIDEAN GEOMETRY; SURFACE AND SOLID OF REVOLUTION. [J.S.F.]

Confocal microscopy A technique that creates high-resolution images of very small objects but differs from conventional optical microscopy in that it uses a condenser lens to focus the illuminating light from a point source into a very small, diffraction-limited spot within the specimen, and an objective lens to focus the light emitted from that spot onto a small pinhole in an opaque screen. Located behind the screen is a detector capable of quantifying how much light passes through the hole at any instant. Because only light from within the illuminated spot is properly focused to pass through the pinhole and reach the detector, any stray light from structures above, below, or to the side of the spot is filtered out. The image quality is therefore greatly enhanced.

Only the smallest possible spot is illuminated at any one time, and so a coherent image must be built up by scanning point by point over the desired field of view and recording the intensity of the light emitted from each spot. The size of the spot is equal to the ultimate resolution of the instrument and is typically about 0.25 micrometer in diameter and about 0.5 μm deep, although the dimensions vary with the wavelength of the light and the lens system used. [R.J.Ta.]

Conformal mapping A special operation in mathematics in which a set of points in one coordinate system is mapped or transformed into a corresponding set in another coordinate system, preserving the angle of intersection between pairs of curves.

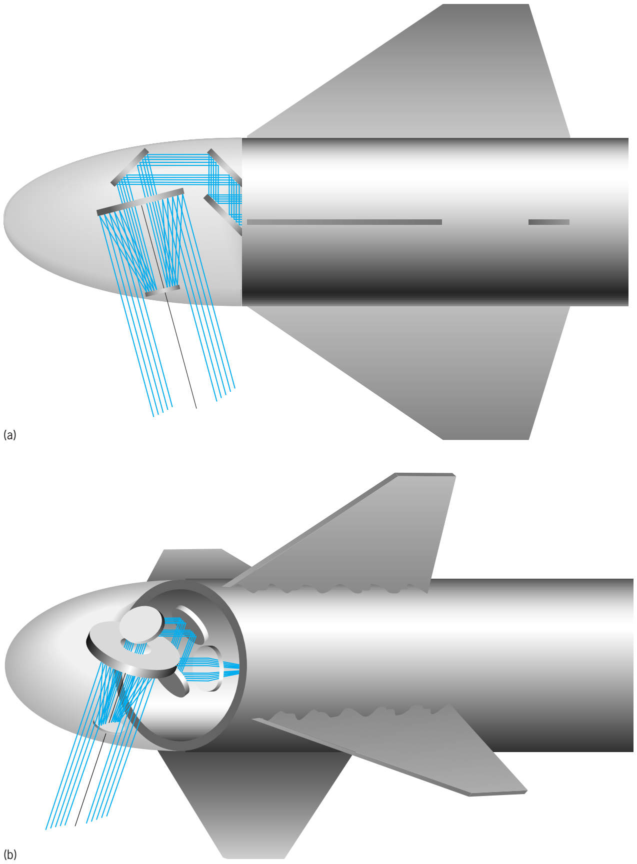
A mapping or transformation of a set E of points in the xy plane onto a set F in the uv plane is a correspondence that is defined for each point (x, y) in E and sends it to a point (u, v) in F, so that each point in F is the image of some point in E. A mapping is one to one if distinct points in E are transformed to distinct points in F. A mapping is conformal if it is one to one and it preserves the magnitudes and orientations of the angles between curves. Conformal mappings preserve the shape but not the size of small figures.

If the points (x, y) and (u, v) are viewed as the complex numbers $z = x + iy$ and $w = u + iv$, the mapping becomes a function of a complex variable: $w = f(z)$. It is an important fact that a one-to-one mapping is conformal if and only if the function f is analytic and its derivative $f'(z)$ is never equal to zero.

Conformal mappings are important in two-dimensional problems of fluid flow, heat conduction, and potential theory. They provide suitable changes of coordinates for the analysis of difficult problems. For example, the problem of finding the steady-state distribution of temperature in a conducting plate requires the calculation of a harmonic function with prescribed boundary values. If the region can be mapped conformally onto the unit disk, the transformed problem is readily solved by the Poisson integral formula, and the required solution is the composition of the resulting harmonic function with the conformal mapping. The method works because a harmonic function of an analytic function is always harmonic. *See* CONDUCTION (HEAT); FLUID-FLOW PRINCIPLES; POTENTIALS.

The term conformal applies in a more general context to the mapping of any surface onto another. A problem of great importance for navigation is to produce conformal mappings of a portion of the Earth's surface onto a portion of the plane. The Mercator and stereographic projections are conformal in this sense. *See* MAP PROJECTIONS. [P.L.D.]

Conformal optics Conformal optical systems have outer surfaces whose shape is chosen to optimize the interaction with the environment in which the optical system is being used. The imaging through such conformal optical windows is likely to suffer from extreme aberration, requiring special techniques for correction. Computer-intensive methods of design, fabrication, and testing of optics have reached a level where the development of cost-effective methods for insertion of these conformal



Geometric optics of an optical tracker behind a conformal window that is shaped to provide an improved drag profile for a missile. Paths of rays through the optical system are shown. (*a*) Side view. (*b*) Oblique view. (*Optical Research Associates*)

optics concepts into operational systems appears to be practical. *See* ABERRATION (OPTICS).

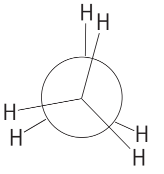
Important applications of conformal optics are found in missile and aircraft systems. Missiles and aircraft carry optical sensors for imaging, detection, and ranging that must look at the world through the outer skin of the vehicle. Traditionally, the windows for viewing through the skin of missiles and aircraft have had simple optical forms, such as flats or spheres, that enable the optical tracking systems to operate by using well-known technology. But these optically advantageous windows degrade the performance of the vehicle through increased drag, aerodynamic heating, or other undesirable effects. One example is the use of an optical tracker or seeker on the front end of a missile. The use of a conformal window, whose shape conforms more closely to the optimal, pointed ogival shape, reduces the drag of the missile and provides significant gains in the missile's performance. Such ogival shapes produce considerable optical aberration, however (see illustration).

The approach to design with conformal optics does not call for complete abandonment of current understanding of the image-formation process. Optical design methods are based on the description of the wavefront passing through surfaces by use of numerical ray tracing. The understanding of the aberrations arising at surfaces is obtained from an analytic method for describing the surface and the wavefront to stated levels of accuracy. The aberrations produced by general aspheric surfaces defy simple analytic descriptions but can be obtained by fitting of the numerical ray-tracing results. *See* GEOMETRICAL OPTICS. [R.R.S.]

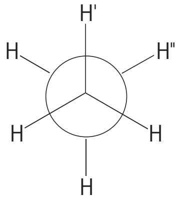
Conformational analysis

The study of the energies and structures of conformations of organic molecules and their chemical and physical properties. Organic molecules are not static entities. The constituent atoms vibrate and groups rotate about the bond axes. *See* STEREOCHEMISTRY.

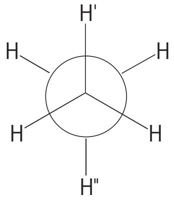
Linear structures. Rotation about the C-C bond in ethane, for example, results in an infinite number of slightly different structures called conformations; one of these is indicated below. In conformation (**1**) of ethane, the pairs of C-H bonds on the two carbon atoms reside in a plane, and are termed eclipsed. (The circle represents the front-most carbon atom, and the long bonds those from that carbon atom to the hydrogen atoms. The bonds from the circle represent those bonds from the rearward carbon to its hydrogen atoms.) Conformation (**1**) is called the eclipsed conformation. In conformation (**2**), the C-H bonds on one carbon reside between the C-H bonds on the other carbon. Conformation (**2**) is called the staggered conformation. An infinite number of conformations between (**1**) and (**2**) are possible; however, conformations (**1**) and (**2**) are of greatest interest because they are the maximum and minimum energy structures. In conformation (**1**), the electrons in the C-H bonds and the nuclear charges of the hydrogen atoms repel each other, resulting in a higher energy state. In conformation (**2**), the electrons and hydrogen atoms are at their greatest possible separation and the repulsion is at a minimum. The conversion of (**2**) to (**3**) by rotation of one of the methyl groups by 120° requires the input of energy, approximately 3.0 kcal (13 kilojoules) per mole, in order to pass through the eclipsed conformation. This amount is small compared to the thermal energy at room temperature, and the rotation about the C-C bond in ethane occurs at about 10^9–10^{10} times per second.



(**1**)

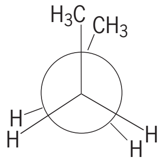


(**2**)

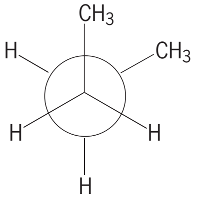


(**3**)

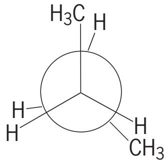
Butane provides a more complicated case. There are two different eclipsed (**4** and **6**) and two staggered (**5** and **7**) conformations which are designated by the names below the structures. As the methyl group is larger than a hydrogen atom, (**4**) is higher in energy than (**6**), and (**5**) is higher in energy than (**7**). As the molecular weight of an alkane increases, the number of molecular conformations (combinations of all possible individual bond conformations) increases dramatically, although the antiperiplanar conformations are always favored.



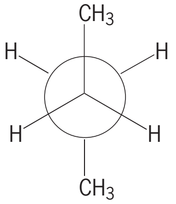
(**4**)
synperiplanar



(**5**)
synclinal



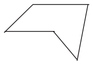
(**6**)
anticlinal



(**7**)
antiperiplanar

Cyclic structures. These also exist in various conformations. Cyclopropane, a planar structure, can exist in only one conformation. In cyclobutane, slight twisting about the C-C bonds can occur which relieves some of the C-H eclipsing strain energy. Cyclobutane exists in rapidly interconverting so-called butterfly conformations (**8**). Cyclopentane exists in two types of nonplanar conformations: the envelope conformation (**9**) and the half-chair (or twist) conformation (**10**). The flap atom of (**9**), the atom out of the plane of the other four, can migrate around the ring, as can also the twist in (**10**). These motions, called pseudorotation, require very little energy, and cyclopentane presents a very complex conformational system.

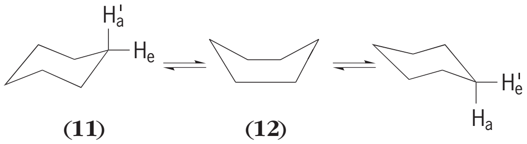
(**8**)



(**9**)

(**10**)

Cyclohexane exists predominantly in the chair conformation (**11**), in which all C-C bond conformations are of the staggered type. Interconversion between chair conformations occurs rapidly at room temperature, passing through the high-energy, boat conformation (**12**). In the chair conformation, there are two



(11) (12)

distinctly different types of hydrogen atoms; one set oriented perpendicular to the general plane of the ring, called axial (a) hydrogens, and one set oriented parallel to the plane of the ring, called equatorial (e) hydrogens. These hydrogens interchange orientation on chair interconversion. Axial and equatorial hydrogens possess different chemical and physical properties, although at room temperature the interconversion occurs very rapidly ($\sim 10^5$ per second), and it is in general not possible to detect the differences. It is easy to design molecules in which the interconversion is not possible and the differences in properties become readily apparent. [D.J.Pa.]

Congenital anomalies Structural abnormalities of the body that develop during embryogenesis and the fetal period; also called birth defects. Children with significant birth defects need more medical care than other children do, require more frequent hospitalizations, need community support services, and often require special education programs. Among children, over half of all visits to subspecialty medical clinics and admissions to hospitals are for treatment of disorders resulting from errors in embryonic development, chromosomal abnormalities, and genetic and familial disorders. Two-thirds of the deaths of infants and children in pediatric hospitals in developed countries are caused by underlying congenital anomalies.

Screening programs are available to identify fetuses and newborns likely to have disorders such as congenital malformations and genetic diseases. Examples of screening include amniocentesis to detect fetal chromosomal abnormalities in mothers over 35 years of age; measurement of maternal serum alpha-fetoprotein levels at 15–16 weeks' gestation to help identify fetuses with certain malformations; and screening of newborns for phenylketonuria, sickle cell disease, thalassemia, galactosemia, and congenital hypothyroidism. *See* ALPHA FETOPROTEIN; PHENYLKETONURIA; SICKLE CELL DISEASE.
