Birth defects can be caused by genetic factors, exposure to malformation-causing agents (teratogens), or a combination of both. Dysmorphology is the area of medicine and science concerned with the cause of congenital anomalies resulting from errors in embryonic development (dysmorphogenesis). The study of normal and abnormal embryonic development allows identification of the latest time in embryogenesis when a malformation could occur. Examples of such times include 28 days of gestation for neural tube defects, 36 days for cleft lip, and 10 weeks for cleft palate.

To facilitate study, birth defects are divided into malformations, disruptions, deformations, and dysplasias. Malformations are structural defects that are caused by primary errors in morphogenesis. They are classified as major and minor. Major malformations require medical or surgical intervention or are of substantial cosmetic importance. Minor malformations do not require such treatment or do not greatly affect appearance. Disruptions are structural defects resulting from interruption of normal morphogenesis, with consequent destruction of previously existing structures and incomplete development of tissues. Deformations are congenital anomalies resulting from external compression of a normally formed part of the fetus. Dysplasias are disorders that result from an abnormal organization of cells into tissues; the morphological result is called dyshistogenesis.

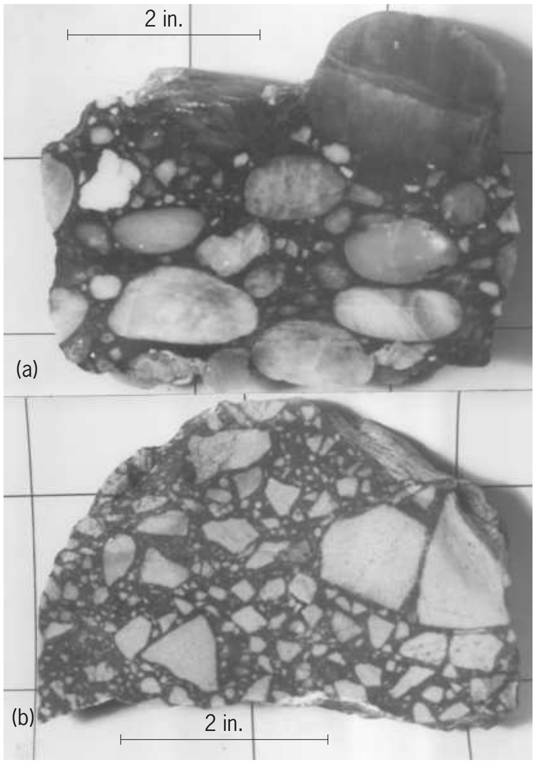
Some individuals have various major and minor congenital anomalies that together form a recognizable pattern, called a syndrome. Syndromes can have both genetic and environmental causes.

Tetratology is the study of the effect of environmental agents on the developing embryo and fetus. Teratogens are agents that interfere with normal embryonic development. They can cause miscarriages, retard prenatal growth, and produce congenital anomalies or mental retardation. There are five general groups of teratogens: (1) infectious diseases and agents; (2) physical agents, such as radiation; (3) drugs and chemical agents; (4) maternal metabolic and genetic factors, such as diabetes; and (5) paternal factors, although rare.

Treatment of congenital anomalies is specific for each individual. Individuals with severe or numerous abnormalities usually require multidisciplinary treatment, including such measures as medical management, surgical correction, nursing care, special diets, rehabilitation, prosthetic devices, special education, and community support. Measures that help reduce the risk of having a child with congenital anomalies include avoidance of teratogenic exposures, medical treatment of maternal illnesses, good nutrition, and routine obstetrical care. *See* PREGNANCY. [M.I.V.A.]

Conglomerate The consolidated equivalent of gravel. Conglomerates are aggregates of more or less rounded particles greater than 0.08 in. (2 mm) in diameter. Frequently they are subdivided on the basis of size of particles into pebble (fine), cobble (medium), and boulder (coarse) conglomerates. The common admixture of sand-sized and gravel-sized particles in the same deposit leads to further subdivisions, into conglomerates (50% or more pebbles), sandy conglomerates (25–50% pebbles), and pebbly or conglomeratic sandstones (less than 25% pebbles). The pebbles of conglomerates are always somewhat rounded, giving evidence of abrasion during transportation; this distinguishes them from some tillites and from breccias, whose particles are sharp and angular (see illustration).

Conglomerates fall into two general classes: the well-sorted, matrix-poor conglomerates with homogeneous pebble lithology, and the poorly sorted, matrix-rich conglomerates with heterogeneous pebble lithology. The well-sorted class includes



Lithified gravels. (*a*) Conglomerate, composed of rounded pebbles. (*b*) Brecica, containing many angular fragments. 2 in. = 5.2 cm. (*Specimens from Princeton University Museum of Natural History; photo by Willard Starks*)

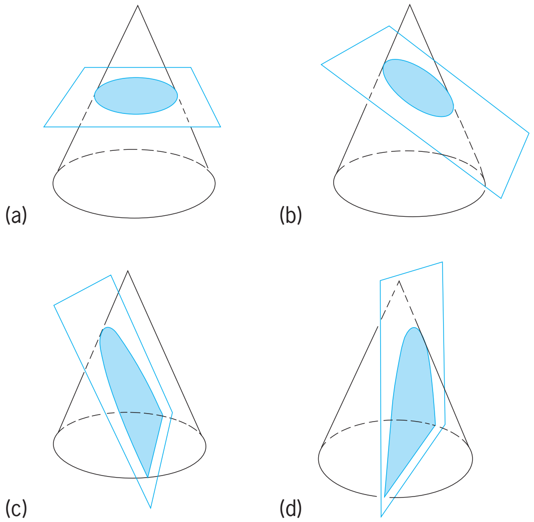
quartz-pebble, chert-pebble, and limestone-pebble conglomerates which tend to be distributed in thin, widespread sheets, normally interbedded with well-sorted, quartzose sandstones. The poorly sorted conglomerates include many different types, all related in having very large amounts of sandy or clayey matrix and pebbles of many different rock classes. The graywacke conglomerates are the outstanding representatives. All poorly sorted conglomerates tend to occur in fairly thick sequences, and some of them, typically the fanglomerates (conglomerates formed on alluvial fans) are wedge-shaped accumulations. *See* SEDIMENTARY ROCKS.

Special types of conglomerates, such as volcanic conglomerates and agglomerates and some intraformational conglomerates composed of shale pebbles or deformed limestone pebbles, do not seem to fall easily into either class. *See* BRECCIA; GRAVEL; GRAYWACKE; TILL. [R.Si.]

Conglutination A term used in serology to describe the completion or enhancement of an incomplete agglutinating system by the addition of certain substances. Some bacteria or ery-throcyte suspensions do not exhibit the visible agglutination ordinarily expected after they have been coated with their specific antibodies and complement. Further addition of a conglutinating agent—normal bovine serum—however, initiates visible agglutination. Complement is an essential component of the system. The conglutination reagent is itself without effect in the absence of antibody and complement. Similar overall actions, such as agglutination of Rh^+ cells, occur when human serum, gelatin, or bovine serum albumin are added to the incomplete Rh antibodies found in some sera, but since this enhancing effect occurs also in the absence of complement, these reactions probably are to be distinguished in mechanism from that of the traditional conglutination. The conglutination reaction can be used for a variety of serological diagnostic reactions in bacterial and viral infections. *See* AGGLUTINATION REACTION; BLOOD GROUPS; COMPLEMENT; COMPLEMENT-FIXATION TEST. [H.P.T.]

Conic section One of the class of curves in which a plane may cut a cone (surface) of revolution. The section is a parabola if the plane is parallel to an element of the cone, an ellipse or circle if the plane cuts all elements of one nappe (but does not go through the apex), and a hyperbola if the plane cuts elements of both nappes (for example, the plane parallel to the cone's axis of revolution) and does not go through the apex (see illustration).

After the advent of analytic geometry, the synthetic method used by the Greeks to develop the properties of conics gave way to algebraic procedures which, using other definitions, divorced these curves from their original relationship to cones and regarded them as graphs of second-degree equations in cartesian coordinates *x*,*y*. The third phase in the study of conic sections began with the development of projective geometry. *See* ANALYTIC GEOMETRY; CONE; ELLIPSE; HYPERBOLA; PARABOLA; PROJECTIVE GEOMETRY. [L.M.BI.]



Four conic sections illustrated. (*a*) Circle. (*b*) Ellipse. (*c*) Parabola. (*d*) Hyperbola.

Conjugation and hyperconjugation A higher-order bonding interaction between electron orbitals on three or more contiguous atoms in a molecule, which leads to characteristic changes in physical properties and chemical reactivity. One participant in this interaction can be the electron pair in the π-orbital of a multiple (that is, double or triple) bond between two atoms, or a single electron or electron pair or electron vacancy on a single atom. The second component will be the pair of π-electrons in an adjacent multiple bond in the case of conjugation, and in the case of hyperconjugation it will be the pair of electrons in an adjacent polarized σ-bond (that is, a bond where the electrons are held closer to one atom than the other due to electronegativity differences between the two atoms). *See* CHEMICAL BONDING.

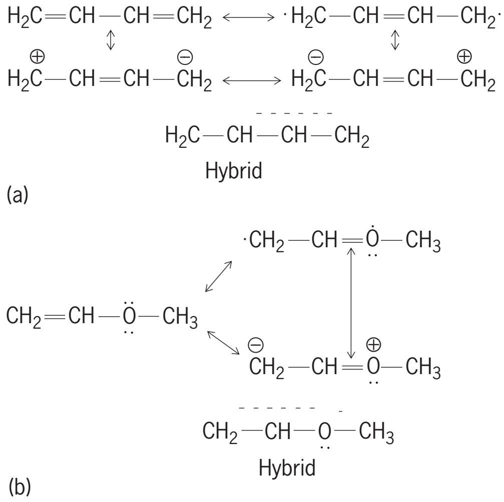


Fig. 1. Conjugated molecules. Broken overbars indicate the effects of conjugation. (*a*) 1,3-Butadiene. (*b*) Methyl vinyl ether.

The conjugated orbitals reside on atoms that are separated by a single bond in the classical valence-bond molecular model, and the conjugation effect is at a maximum when the axes of the component orbitals are aligned in a parallel fashion because this allows maximum orbital overlap. Conjugation thus has a stereoelectronic requirement, or a restriction on how the participating orbitals must be oriented with respect to each other. Two simple examples are shown in Fig. 1; in 1,3-butadiene ($H_2C{=}H\underline{C{-}C}H{=}CH_2$) conjugation occurs between the *p* orbitals (π-bonds) of the two double bonds, and in methyl vinyl ether ($H_2C{=}H\underline{C{-}O}{-}CH_3$) the nonbonding sp^3 orbital on oxygen is conjugated with the *p* orbitals of the double bond. This interaction is manifest in an effective bond order between single and double for the underlined single bond.

Hyperconjugation, the conjugation of polarized σ-bonds with adjacent π-orbitals, was introduced in the late 1930s by R. S. Mulliken. This rationale was used to explain successfully a wide variety of chemical phenomena; however, the confusing adaptation of the valence-bond model necessary to depict it and its inappropriate extension to some phenomena led to difficulties. The advent of the molecular orbital treatment has eliminated many of these difficulties.

Early on, hyperconjugation was used to explain the stabilization by alkyl groups of carbocations, or positively charged

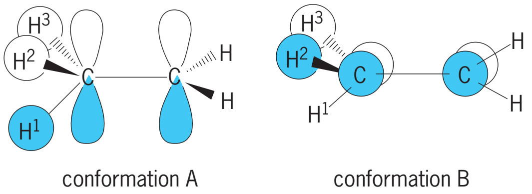

Fig. 2. Diagram showing hyperconjugative effect of orbitals of the σ-bonds of a methyl group (H_3C) on a neighboring *p* orbital of a methylene group (CH_2). Algebraic phase is indicated by the presence or absence of tint.

trivalent carbon. Figure 2 shows how the orbitals of the σ-bonds of a methyl group (H_3C) exert a hyperconjugative stabilizing effect upon a neighboring *p* orbital on a methylene group (CH_2). The bonding molecular orbitals of the methyl group utilize aspects of its carbon *p* orbitals; in both of the conformations or rotations the methyl group has such an orbital which overlaps in phase with the neighboring *p* orbital on CH_2. As hydrogen is an electropositive atom, the methyl group acts as an electron donor to stabilize an empty *p* orbital and to destabilize a filled *p* orbital on the right-hand carbon. This is in accord with empirical observations. If H^1 is replaced with some other atom X, the hyperconjugative effect of X will be at a maximum in conformation A, where there is orbital density on X, and it will be at a minimum in conformation B, where X is in the nodal or null plane. If X is a more electropositive atom such as silicon, the C-X bond is a donor bond and will stabilize an adjacent empty *p* orbital, such as in a cation. If X is a more electronegative element such as fluorine, the C-X bond is an acceptor bond and will stabilize an adjacent filled *p* orbital such as in an anion; this result accords with experiment as well. The donor and acceptor effects are also important where the single *p* orbital is replaced by a multiple bond. *See* MOLECULAR ORBITAL THEORY; REACTIVE INTERMEDIATES.

A number of scientific phenomena depend on the properties of conjugated systems; these include vision (the highly tuned photoreceptors are triggered by molecules with extended conjugation), electrical conduction (organic semiconductors such as polyacetylenes are extended conjugated systems), color (most dyes are conjugated molecules designed to absorb particular wavelengths of light), and medicine (a number of antibiotics and cancer chemotherapy agents contain conjugated systems which trap enzyme sulfhydryl groups by conjugate addition). *See* VALENCE. [M.F.S.]

Connecting rod

A link in several kinds of mechanisms. Usually one end of a connecting rod is intended to follow a circular path, while the other end follows a path along a straight line or curve of large radius. The term is sometimes applied, however, to any straight link that transmits motion or power from one linkage to another within a mechanism. The illustration shows some conventional arrangements.

The connecting rod of the four-bar linkage, often called the coupler, has special significance. The motion of its plane can now be synthesized to furnish desired paths for points, or desired positions of the entire connecting-rod plane. The connecting rod is then not primarily used for transmission of force or motion from input to output crank, but the entire mechanism is employed to impart to the connecting-rod plane certain displacements, and sometimes velocities and accelerations. *See* FOUR-BAR LINKAGE; MECHANISM. [D.P.Ad.]

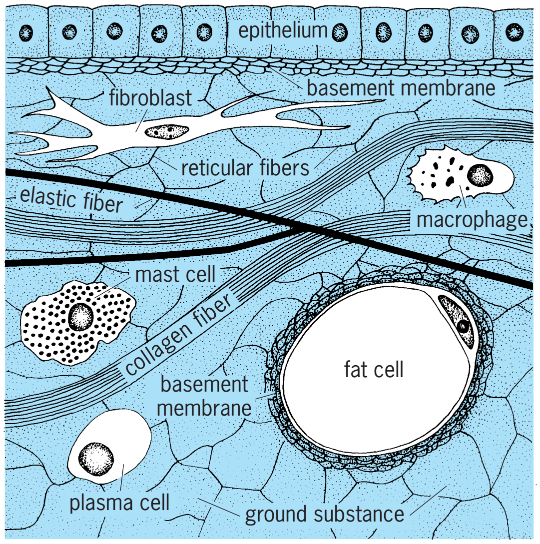
Connective tissue

One of the four primary tissues of the body. It differs from the other three tissues in that the extracellular components (fibers and intercellular substances) are abundant. It cannot be sharply delimited from the blood, whose cells may give rise to connective tissue cells, and whose plasma components continually interchange with and augment the ground substance of connective tissue. Bone and cartilage are special kinds of connective tissue.

The functions of connective tissues are varied. They are largely responsible for the cohesion of the body as an organism, of organs as functioning units, and of tissues as structural systems. The connective tissues are essential for the protection of the body both in the elaborate defense mechanisms against infection and in repair from chemical or physical injuries. Nutrition of nearly all cells of the body and the removal of their waste products are both mediated through the connective tissues. Connective tissues are important in the development and growth of many structures. Constituting the major environment of most cells, they are probably the major contributor to the homeostatic mechanisms of the body so far as salts and water are concerned. They act as the great storehouse for the body of salts and minerals, as well as of fat. The connective tissues determine in most cases the pigmentation of the body. Finally, the skeletal system (cartilage and bones) plus other kinds of connective tissue (tendons, ligaments, fasciae, and others) make motion possible.

The connective tissues consist of cells and extracellular or intercellular substance (see illustration). The cells include many varieties, of which the following are the most important: fibroblasts, macrophages (histiocytes), mast cells, plasma cells, melanocytes, and fat cells. Most of the cells of the connective tissue are developmentally related even in the adult; for example, fibroblasts may be developed from histiocytes or from undifferentiated mesenchymal cells.

The extracellular components of connective tissues may be fibrillar or nonfibrillar. The fibrillar components are reticular fibers, collagenous fibers, and elastic fibers. The nonfibrillar component of connective tissues appears amorphous with the light microscope and is the matrix in which cells and fibers are embedded. It consists of two groups of substances: (1) those probably derived from secretory activity of connective tissue cells including mucoproteins, protein-polysaccharide complexes, tropocollagen, and antibodies; and (2) those probably derived from the



Components of connective tissue.

blood plasma, including albumin, globulins, inorganic and organic anions and cations, and water. In addition, the ground substance contains metabolites derived from, or destined for, the blood.

All the manifold varieties of connective tissue may contain all the cells and fibers discussed above in addition to ground substance. They differ from each other in the relative occurrence of one or another cell type, in the relative proportions of cells and fibers, in the preponderance and arrangement of one or another fiber, and in the relative amount and chemical composition of ground substance. They are classified as:

1. Irregularly arranged connective tissue—which may be loose (subcutaneous connective tissue) or dense (dermis). The dominant fiber type is collagen.
2. Regularly arranged connective tissue—primarily collagenous—with the fibers arranged in certain patterns depending on whether they occur in tendons or as membranes (dura mater, capsules, fasciae, aponeuroses, or ligaments).
3. Mucous connective tissue—ground substance especially prominent (umbilical cord).
4. Elastic connective tissue—predominance of elastic fibers or bands (ligamentum nuchae) or lamellae (aorta).
5. Reticular connective tissue—fibers mostly reticular, moderately rich in ground substance, frequently numerous undifferentiated mesenchymal cells.
6. Adipose connective tissue—yellow or brown fat cells constituting chief cell type, reticular fibers most numerous.
7. Pigment tissue—melanocytes numerous.
8. Cartilage—cells exclusively of one type, derived from mesenchymal cells.
9. Bone—cells are predominantly osteocytes, but also include fibroblasts, mesenchymal cells, endothelial cells, and osteoclasts.

See ADIPOSE TISSUE; BLOOD; BONE; CARTILAGE; COLLAGEN; HISTOLOGY; LIGAMENT; TENDON. [I.G.]

Connective tissue disease Any of a group of diseases involving connective tissue; formerly termed collagen vascular disease. These diseases are clinically and pathologically discrete from each other but have overlapping features. The group includes lupus erythematosus, systemic vasculitis, polymyolitis, scleroderma (and systemic sclerosis), and Sjögren's syndrome. Each of the diseases can involve multiple organ systems and is often coupled with various immunologic abnormalities. *See* CONNECTIVE TISSUE.

The set of diseases known as lupus erythematosus includes limited, primarily cutaneous disorders (discoid lupus and subacute cutaneous lupus) and a diffuse systemic illness (systemic lupus erythematosus), all of which are of unknown cause. Also, a lupuslike reaction known as drug-induced lupus can be caused by certain therapeutic agents.

Systemic vasculitis comprises a series of different clinical illnesses that are all characterized by intense inflammation in the walls of blood vessels, especially arteries (that is, arteritis). These illnesses differ clinically, pathologically, and with respect to therapeutic responsiveness and outcome. Even the age and sex of the typical affected person varies from one to another. The clinical pattern of illness varies with the sites of blood vessel involvement and the character of vascular injury. Tissue death in the vessel wall can lead to narrowing, or even blockage, of the vessel or weakening of the wall with formation of an aneurysm. Impaired circulation and altered blood flow result. Symptoms, therefore, can arise not only from the tissue inflammation itself but also from the lack of adequate blood supply. *See* ANEURYSM; CIRCULATION DISORDERS.

Polymyositis involves intense inflammation in skeletal muscle that, if untreated, can lead to destruction of muscle fibers. When typical skin lesions are present, the term dermatomyositis is applied. The cause of polymyositis, or dermatomyositis, is not known in most cases. These conditions can occur alone or in association with other connective tissue disorders (that is, systemic lupus, scleroderma, and Sjögren's syndrome). In older persons, they sometimes accompany malignant tumors. If diagnosed early, before loss of muscle fibers and replacement by fibrous scarring is extensive, myositis is reversible; recovery with minimal residual loss of strength is to be expected in almost all patients.

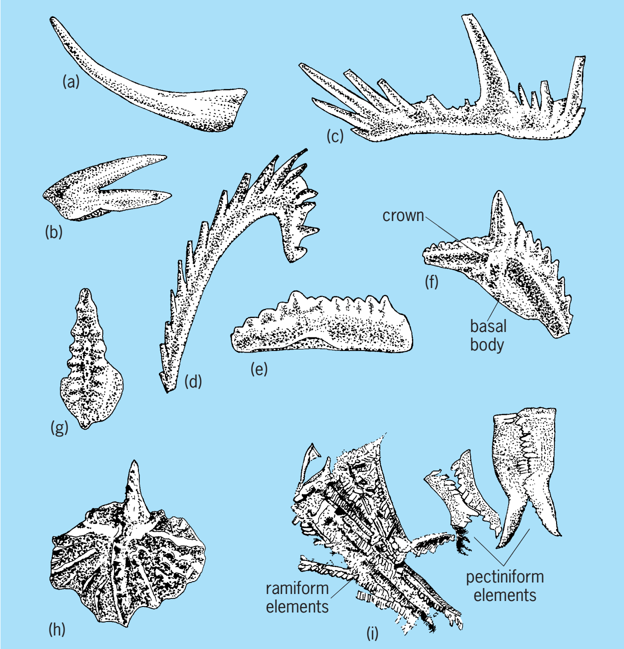
The term scleroderma means "hard skin," designating a disorder in which increased deposition of collagen fibers in the deeper dermis leads to thickened, leathery, bound-down skin. When organ involvement is associated with such skin changes, the term systemic sclerosis is used. Raynaud's phenomenon, a hyperreactivity to cold exposure with blanching and discoloration of the fingers and toes, is the common initial manifestation and may precede sclerodermatous skin changes by decades. Systemically, the gastrointestinal tract is most commonly involved. Difficulty in swallowing and mid-chest discomfort result from loss of peristalsis in the esophagus. Diarrhea, inability to absorb nutrients, abdominal pain, and distention can occur with bowel involvement and lead to weight loss and wasting. Scarring of the lungs and decreased pulmonary function occur frequently. The most serious lesions are those of the heart and kidney, which may result from vascular abnormalities related to Raynaud's phenomenon. Joint inflammation is mild and uncommon; but advanced skin changes, especially in the hands, may restrict joint mobility.

Sjögren's syndrome is characterized primarily by dryness of the membranes due to excretory gland failure, especially dryness of the eyes (xerophthalmia) and mouth (xerostomia) from loss of tears and saliva, respectively. This sicca (dryness) syndrome reflects the infiltration of lacrimal and salivary glands by immunologically competent cells (lymphocytes). Sjögren's syndrome may be primary or secondary; that is, superimposed on another disorder like rheumatoid arthritis or systemic lupus. *See* IMMUNOLOGY; INFLAMMATION. [M.B.S.]

Conodont A group of extinct marine animals that are often abundant in strata of Late Cambrian to Late Triassic age, a time span of about 300 million years. Only the mineralized elements, which are usually 0.2 to 2 mm (0.008 to 0.08 in.) in dimension (the largest known reach 14 mm or 0.6 in.), are normally preserved. They are routinely extracted as isolated discrete specimens by chemical degradation of the rock in which they occur. In the earliest euconodonts ("true" conodonts, as opposed to the more primitive, and possibly unrelated, protoconodonts and paraconodonts), the elements comprise an upper crown and a basal body. The basal body occupies a cavity in the base of the crown, but is not present in the majority of post-Devonian species. In advanced conodonts the crown incorporates regular patches of opaque, finely crystalline, white matter.

For many years, conodont taxonomists treated individual element types as separate species. There are three major shape categories, coniform, ramiform, and pectiniform (see illustration). Coniform elements were dominant in the Cambrian to Early Ordovician and common until the Devonian. Ramiform (comblike) elements extend into elongate processes with various arrangements of denticles. Pentiniform elements include straight and arched blades, and may be expanded laterally to form a platform.

In the absence of preserved soft parts, the nature of the affinities of conodonts was the subject of considerable speculation and debate. Since the first discovery of isolated elements in 1856, conodonts have been variously aligned with algae, higher plants, several wormlike phyla, mollusks, arthropods, lophophorates, chaetognaths, and chordates, or have been assigned to a separate phylum, Conodonta. It was not until 1983 that evidence of the soft parts was described by D. E. G. Briggs, E. N. K. Clarkson, and R. J. Aldridge, on the basis of the first of several specimens discovered in lower Carboniferous rocks near Edinburgh, Scotland. The evidence of the soft-part morphology indicates that the conodonts belong within the chordates; it is no longer



Conodont elements: (*a*, *b*) coniform elements, (*c*, *d*) ramiform elements, (*e*, *f*) pectiniform blade elements, (*g*, *h*) pectiniform platform elements, (*i*) bedding-plane assemblage.

possible to justify their separation as a phylum, Conodonta. *See* CHORDATA.

Although the biological affinities of conodonts and the function of the elements were essentially unknown until recently, they have nonetheless been extensively studied because of their important geological applications. Most significant of these is the use of conodont elements in biostratigraphy. *See* STRATIGRAPHY.

[R.J.Al.; D.E.G.B.]

Conservation laws (physics)

Principles which state that the total values of specified quantities remain constant in time for an isolated system. Conservation laws occupy enormously important positions both at the foundations of physics and in its applications.

Realization in classical mechanics. There are three great conservation laws of mechanics: the conservation of linear momentum, often referred to simply as the conservation of momentum; the conservation of angular momentum; and the conservation of energy.

The linear momentum, or simply momentum, of a particle is equal to the product of its mass and velocity. It is a vector quantity. The total momentum of a system of particles is simply the sum of the momenta of each particle considered separately. The law of conservation of momentum states that this total momentum does not change in time. *See* CONSERVATION OF MOMENTUM; MOMENTUM.

The angular momentum of a particle is more complicated. It is defined by the vector product of the position and momentum vectors. The law of conservation of angular momentum states that the total angular momentum of an isolated system is constant in time. *See* ANGULAR MOMENTUM.

The conservation of energy is perhaps the most important law of all. Energy is a scalar quantity, and takes two forms: kinetic and potential. The kinetic energy of a particle is defined to be one-half the product of its mass and the square of its velocity. The potential energy is loosely defined as the ability to do work. The total energy is the sum of the kinetic and potential energies, and according to the conservation law it remains constant in time for an isolated system.

The essential difficulty in applying the conservation of energy law can be appreciated by considering the problem of two colliding bodies. In general, the bodies emerge from the collision moving more slowly than when they entered. This phenomenon seems to violate the conservation of energy, until it is recognized that the bodies involved may consist of smaller particles. Their random small-scale motions will require kinetic energy, which robs kinetic energy from the overall coherent large-scale motion of the bodies that are observed directly. One of the greatest achievements of nineteenth-century physics was the recognition that small-scale motion within macroscopic bodies could be identified with the perceived property of heat. *See* CONSERVATION OF ENERGY; ENERGY; KINETIC THEORY OF MATTER.

Position in modern physics. As physics has evolved, the great conservation laws have likewise evolved in both form and content, but have never ceased to be important guiding principles.

In order to account for the phenomena of electromagnetism, it was necessary to go beyond the notion of point particles, to postulate the existence of continuous electric and magnetic fields filling all space. To obtain valid conservation laws, energy, momentum, and angular momentum must be ascribed to the electromagnetic fields. *See* ELECTROMAGNETIC RADIATION; MAXWELL'S EQUATIONS; POYNTING'S VECTOR.

In the special theory of relativity, energy and momentum are not independent concepts. Einstein discovered perhaps the most important consequence of special relativity, that is, the equivalence of mass and energy, as a consequence of the conservation laws. The "law" of conservation of mass is understood as an approximate consequence of the conservation of energy. *See* CONSERVATION OF MASS; RELATIVITY.

A remarkable, beautiful, and very fruitful connection has been established between symmetries and conservation laws. Thus the law of conservation of linear momentum is understood as a consequence of the homogeneity of space, the conservation of angular momentum as a consequence of the isotropy of space, and the conservation of energy as a consequence of the homogeneity of time. *See* SYMMETRY LAWS (PHYSICS).

The development of general relativity, the modern theory of gravitation, necessitates attention to a fundamental question for the conservation laws: The laws refer to an "isolated system," but it is not clear that any system is truly isolated. This is a particularly acute problem for gravitational forces, which are long range and add up over cosmological distances. It turns out that the symmetry of physical laws is actually a more fundamental property than the conservation laws themselves, for the symmetries remain valid while the conservation laws, strictly speaking, fail.

In quantum theory, the great conservation laws remain valid in a very strong sense. Generally, the formalism of quantum mechanics does not allow prediction of the outcome of individual experiments, but only the relative probability of different possible outcomes. One might therefore entertain the possibility that the conservation laws were valid only on the average. However, momentum, angular momentum, and energy are conserved in every experiment. *See* QUANTUM MECHANICS; QUANTUM THEORY OF MEASUREMENT.

Conservation laws of particle type. There is another important class of conservation laws, associated not with the motion of particles but with their type. Perhaps the most practically important of these laws is the conservation of chemical elements. From a modern viewpoint, this principle results from the fact that the small amount of energy involved in chemical transformations is inadequate to disrupt the nuclei deep within atoms. It is not an absolute law, because some nuclei decay spontaneously, and at sufficiently high energies it is grossly violated. *See* RADIOACTIVITY.

Several conservation laws in particle physics are of the same character: They are useful even though they are not exact because, while known processes violate them, such processes are either unusually slow or require extremely high energy. *See* ELEMENTARY PARTICLE. [F.Wil.]

Conservation of energy

The principle of conservation of energy states that energy cannot be created or destroyed, although it can be changed from one form to another. Thus in any isolated or closed system, the sum of all forms of energy remains constant. The energy of the system may be interconverted among many different forms—mechanical, electrical, magnetic, thermal, chemical, nuclear, and so on—and as time progresses, it tends to become less and less available; but within the limits of small experimental uncertainty, no change in total amount of energy has been observed in any situation in which it has been possible to ensure that energy has not entered or left the system in the form of work or heat. For a system that is both gaining and losing energy in the form of work and heat, as is true of any machine in operation, the energy principle asserts that the net gain of energy is equal to the total change of the system's internal energy. *See* THERMODYNAMIC PRINCIPLES.

There are many ways in which the principle of conservation of energy may be stated, depending on the intended application. Of particular interest is the special form of the principle known as the principle of conservation of mechanical energy which states that the mechanical energy of any system of bodies connected together in any way is conserved, provided that the system is free of all frictional forces, including internal friction that could arise during collisions of the bodies of the system.

J. P. Joule and others demonstrated the equivalence of heat and work by showing experimentally that for every definite amount of work done against friction there always appears a definite quantity of heat. The experiments usually were so arranged that the heat generated was absorbed by a given quantity of water, and it was observed that a given expenditure of mechanical energy always produced the same rise of temperature in the water. The resulting numerical relation between quantities of mechanical energy and heat is called the Joule equivalent, or is also known as mechanical equivalent of heat.

In view of the principle of equivalence of mass and energy in the restricted theory of relativity, the classical principle of conservation of energy must be regarded as a special case of the principle of conservation of mass-energy. However, this more general principle need be invoked only when dealing with certain nuclear phenomena or when speeds comparable with the speed of light (1.86×10^5 mi/s or 3×10^8 m/s) are involved. [D.E.R./L.N.]

Conservation of mass

The notion that mass, or matter, can be neither created nor destroyed. According to conservation of mass, reactions and interactions which change the properties of substances leave unchanged their total mass; for instance, when charcoal burns, the mass of all of the products of combustion, such as ashes, soot, and gases, equals the original mass of charcoal and the oxygen with which it reacted.

The special theory of relativity of Albert Einstein, which has been verified by experiment, has shown, however, that the mass of a body changes as the energy possessed by the body changes. Such changes in mass are too small to be detected except in subatomic phenomena. Furthermore, matter may be created, for instance, by the materialization of a photon (quantum of electromagnetic energy) into an electron-positron pair; or it may be destroyed, by the annihilation of this pair of elementary particles to produce a pair of photons. *See* ELECTRON-POSITRON PAIR PRODUCTION; RELATIVITY. [L.N.]

Conservation of momentum

The principle that, when a system of masses is subject only to forces that masses of the system exert on one another, the total vector momentum of the system is constant. Since vector momentum is conserved, in problems involving more than one dimension the component of momentum in any direction will remain constant. The principle of conservation of momentum holds generally and is applicable in all fields of physics. In particular, momentum is conserved even if the particles of a system exert forces on one another or if the total mechanical energy is not conserved. Use of the principle of conservation of momentum is fundamental in the solution of collision problems. *See* COLLISION (PHYSICS); MOMENTUM. [P.W.S.]

Conservation of resources

Management of the human use of natural resources to provide the maximum benefit to current generations while maintaining capacity to meet the needs of future generations. Conservation includes both the protection and rational use of natural resources.

Earth's natural resources are either nonrenewable, such as minerals, oil, gas, and coal, or renewable, such as water, timber, fisheries, and agricultural crops. The combination of growing populations and increasing levels of resource consumption is degrading and depleting the natural resource base. The world's population stood at 850 million at the onset of the industrial age. The global population has grown to nearly seven times as large (6 billion), and the level of consumption of resources is far greater. This human pressure now exceeds the carrying capacity of many natural resources.

Nonrenewable resources, such as fossil fuels, are replaced over geologic time scales of tens of millions of years. Human societies will eventually use up all of the economically available stock of many nonrenewable resources, such as oil. Conservation entails actions to use these resources most efficiently and thereby extend their life as long as possible. By recycling aluminum, for example, the same piece of material is reused in a series of products, reducing the amount of aluminum ore that must be mined. Similarly, energy-efficient products help to conserve fossil fuels since the same energy services, such as lighting or transportation, can be attained with smaller amounts of fuel. *See* HUMAN ECOLOGY.

It may be expected that the biggest challenge of resource conservation would involve nonrenewable resources, since renewable resources can replenish themselves after harvesting. In fact, the opposite is the case. Historically, when nonrenewable resources have been depleted, new technologies have been developed that effectively substitute for the depleted resources. Indeed, new technologies have often reduced pressure on these resources even before they are fully depleted. Fiber optics, for example, has substituted for copper in many electrical applications, and it is anticipated that renewable sources of energy, such as photovoltaic cells, wind power, and hydropower, will ultimately take the place of fossil fuels when stocks are depleted. Renewable resources, in contrast, can be seriously depleted if they are subjected to excessive harvest or otherwise degraded, and no substitutes are available for, say, clean water or food products such as fish or agricultural crops. Moreover, when the misuse of biological resources causes the complete extinction of a species or the loss of a particular habitat, there can be no substitute for that diversity of life.

"Conservation" is sometimes used synonymously with "protection." More appropriately, however, it refers to the protection and sustainable use of resources. Critical elements of the effective conservation of natural resources include sustainable resource management, establishment of protected areas, and ex situ (off-site) conservation.

Resource management. Some of the most pressing resource conservation problems stem directly from the mismanagement of important biological resources. Many marine fisheries are being depleted, for example, because of significant overcapacity of fishing vessels and a failure of resource managers to closely regulate the harvest. In theory, a renewable resource stock could be harvested at its maximum sustainable yield and maintain constant average annual productivity in perpetuity. In practice, however, fishery harvest levels are often set too high and, in many regions, enforcement is weak, with the result that fish stocks are driven to low levels. A similar problem occurs in relation to the management of timber resources. Short-term economic incentives encourage cutting as many trees as quickly as possible. *See* FISHERIES ECOLOGY; FOREST MANAGEMENT.

A number of steps are being taken to improve resource conservation in managed ecosystems. (1) Considerable scientific research has been undertaken to better understand the natural variability and productivity of economically important resources. (2) Many national and local governments have enacted regulations for resource management practices on public and private lands. (3) In some of regions, programs recently have been established either to involve local communities who have a greater incentive to manage for long-term production more directly in resource management decisions or to return to them resource ownership rights. (4) Efforts are under way to manage resources on a regional or ecosystem scale using methods that have come to be known as ecosystem management or bioregional management. Since the actions taken in one location often influence species and processes in other locations, traditional resource conservation strategies were often focused too narrowly to succeed.

Protected areas. One of the most effective strategies to protect species from extinction is the establishment of protected areas designed to maintain populations of a significant fraction of the native species in a region. Worldwide, 9832 protected areas, totaling more than 9.25 million square kilometers (24 million square miles), cover about 8% of land on Earth. Although these sites are not all managed exclusively for the conservation of species, they play an essential role in protecting species from extinction.

Many problems remain, however, in ensuring effective protected-area conservation networks. For example, several regions with important biodiversity still lack effective protected-area networks. In addition, where protected areas have been designated, human and financial resources are not always available to effectively manage the areas. Particularly in developing countries, the establishment of protected areas has resulted in conflicts with local communities that had been dependent upon the areas for their livelihood. These challenges are now being addressed through international efforts, such as the International Convention on Biological Diversity, which aims to increase the financing available for protected areas and to integrate conservation and development needs.

Ex situ conservation. The most effective and efficient means for conserving biological resources is to prevent the loss of important habitats and to manage resources for their long-term productivity of goods and services. In many cases, effective conservation in the field is no longer possible. For example, some species have been so depleted that only a few individuals remain in their natural habitat. In these cases, there is no alternative to the ex situ conservation of species and genetic resources in zoos, botanical gardens, and seed banks. Ex situ collections play important conservation roles as well as serving in public education and research. Worldwide, zoos contain more than 3000 species of birds, 1000 species of mammals, and 1200 species of reptiles, and botanic gardens are believed to hold nearly 80,000 species of plants. These collections hold many endangered species, some of which have breeding populations and thus could potentially be returned to the wild. Genebanks hold an important collection of the genetic diversity of crops and livestock. *See* LAND-USE PLANNING; MINERAL RESOURCES; SOIL CONSERVATION; WATER CONSERVATION. [W.Re.]

Constellation

One of the 88 areas into which the sky is divided. Each constellation has a name that reflects its earliest recognition. Though pictures are associated with the constellations, they have no official status, and constellations have been depicted differently by different artists.

The catalog of Ptolemy, in Hellenic Alexandria in the second century of the Christian Era, included over 1000 stars grouped into 48 constellations. Johann Bayer's *Uranometria* (1603) included the constellations listed by Ptolemy and also named 12 new ones containing stars observed on expeditions to the Southern Hemisphere. Bayer originated the scheme of labeling individual stars in constellations with Greek and other letters, roughly in order of brightness, and the genitive form of the constellation name. In some cases, Bayer labeled stars in order around figures in the sky, as for the Big Dipper.

Johannes Hevelius added nine more southern constellations in his 1690 star atlas, *Firmamentum Sobiescianum sive Uranographia*. Nicolas Louis de Lacaille added 14 constellations in 1763 from his expedition to the Cape of Good Hope.

In 1928, the International Astronomical Union formally accepted the division of the sky into 88 constellations, with the final list provided 2 years later; each star now falls in only one constellation. The boundaries follow north-south or east-west celestial coordinates (right ascension and declination lines) from the year 1875; because of precession, the current boundaries do not match rounded values of celestial coordinates. *See* ASTRONOMICAL COORDINATE SYSTEMS; PRECESSION OF EQUINOXES.

Some of the most familiar patterns in the sky are asterisms rather than constellations. For example, the asterism known as the Big Dipper is part of the constellation Ursa Major. The asterism known as the Great Square of Pegasus has three of its corners in Pegasus but the fourth in Andromeda. The Northern Cross is made of stars in Cygnus. [J.M.P.]

Constraint

A restriction on the natural degrees of freedom of a system. If n and m are the numbers of the natural and actual degrees of freedom, the difference $n - m$ is the number of constraints. In principle $n = 3N$, where N is the number of particles, for example, atoms. In practice n is determined by the number of effectively rigid components.

A holonomic system is one in which the n original coordinates can be expressed in terms of m independent coordinates and possibly also the time. It is characterized by frictionless contacts and inextensible linkages. The new coordinates are called generalized coordinates. *See* LAGRANGE'S EQUATIONS.

Nonholonomic systems cannot be reduced to independent coordinates because the constraints are not on the n coordinate values themselves but on their possible changes. For example, an ice skate may point in all directions but at each position it must point along its path. *See* DEGREE OF FREEDOM (MECHANICS). [B.G.]

Construction engineering

A specialized branch of civil engineering concerned with the planning, execution, and control of construction operations for such projects as highways, buildings, dams, airports, and utility lines. Planning consists of scheduling the work to be done and selecting the most suitable construction methods and equipment for the project. Execution requires the timely mobilization of all drawings, layouts, and materials on the job to prevent delays. Control consists of analyzing progress and cost to ensure that the project will be done on schedule and within the estimated cost. *See* CONSTRUCTION EQUIPMENT; CONSTRUCTION METHODS. [W.Her.]

Construction equipment

A wide variety of relatively heavy machines which perform specific construction (or demolition) functions under power. The power plant is commonly an integral part of an individual machine, although in some cases it is contained in a separate prime mover, for example, a towed wagon or roller. It is customary to classify construction machines in accordance with their functions such as hoisting, excavating, hauling, grading, paving, drilling, or pile driving. There have been few changes for many years in the basic types of machines available for specific jobs, and few in the basic configurations of those that have long been available. Design emphasis for new machines is on modifications that increase speed, efficiency, and accuracy (particularly through more sophisticated controls); that improve operator comfort and safety; and that protect the public through sound attenuation and emission control. The selection of a machine for a specific job is mainly a question of economics and depends primarily on the ability of the machine to complete the job efficiently, and secondarily on its availability.

Hoisting equipment is used to raise or lower materials from one elevation to another or to move them from one point to another over an obstruction. The main types of hoisting equipment are derricks, cableways, cranes, elevators, and conveyors. *See* BULK-HANDLING MACHINES; HOISTING MACHINES.

Excavating equipment is divided into two main classes: standard land excavators and marine dredges; each has many variations. The standard land excavator comprises machines that merely dig earth and rock and place it in separate hauling units, as well as those that pick up and transport the materials. Among the former are power shovels, draglines, backhoes, cranes with a variety of buckets, front-end loaders, excavating belt loaders, trenchers, and the continuous bucket excavator. The second group includes such machines as bulldozers, scrapers of various types, and sometimes the front-end loader.

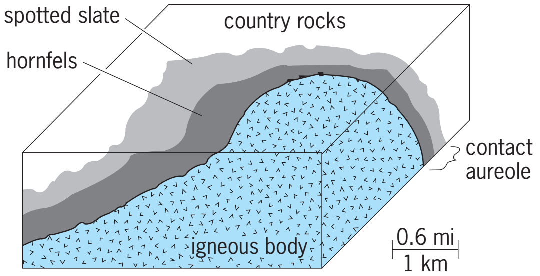
Usually called a dredge, the marine excavator is an excavating machine mounted on a barge or boat. Two common types are similar to land excavators, the clamshell and the bucket excavator. The suction dredge is different; it comprises a movable suction pipe which can be lowered to the bottom, usually with a fast-moving cutter head at the bottom end.

Excavated materials are moved great distances by a wide variety of conveyances. The most common of these are the self-propelled rubber-tired rear-dump trucks, which are classed as over-the-road or off-the-road trucks. Wagons towed by a rubber-tired prime mover are also used for hauling dirt. These commonly have bottom dumps which permit spreading dirt as the vehicle moves. In special cases side-dump trucks are also used. Conveyors, while not commonly used on construction jobs for hauling earth and rock great distances, have been used to good advantage on large jobs where obstructions make impractical the passage of trucks.

Graders are high-bodied, wheeled vehicles that mount a leveling blade between the front and rear wheels. The principal use is for fine-grading relatively loose and level earth. Pavers place, smooth, and compact paving materials. Asphalt pavers embody tamping pads that consolidate the material; concrete pavers use vibrators for the same purpose. Drilling equipment is used to drill holes in rock for wells and for blasting, grouting, and exploring. Drills are classified according to the way in which they penetrate rock, namely, percussion, rotary percussion, and rotary. Specialized construction equipment includes augers, compactors, pile hammers, road planars, and bore tunneling machines. *See* CONSTRUCTION ENGINEERING. [E.M.Y.]

Construction methods The procedures and techniques utilized during construction. Construction operations are generally classified according to specialized fields. These include preparation of the project site, earth-moving, foundation treatment, steel erection, concrete placement, asphalt paving, and electrical and mechanical installations. Procedures for each of these fields are generally the same, even when applied to different projects, such as buildings, dams, or airports. However, the relative importance of each field is not the same in all cases. For a description of tunnel construction, which involves different procedures, *see* TUNNEL. [W.Her.]

Contact aureole The zone of alteration surrounding a body of igneous rock caused by heat and volatiles given off as the magma crystallized. Changes can be in mineralogy, texture, or elemental and isotopic composition of the original enclosing (country or wall) rocks, and progressively increase closer to the igneous contact. The contact aureole is the shell of metamorphosed or metasomatized rock enveloping the igneous body (see illustration). The ideal contact aureole forms locally around a single magma after it is emplaced. Metamorphism over a much larger area can result from coalescing of several contact aureoles. This is termed a contact-regional metamorphic aureole and is thought responsible for the regional metamorphism of several mountain areas. Other contact aureoles develop at greater depths and may be physically emplaced to shallower levels along with the igneous body. These are termed dynamothermal aureoles. *See* IGNEOUS ROCKS; MAGMA; METAMORPHIC ROCKS; METAMORPHISM; METASOMATISM; PLUTON.



Zoned contact aureole developed around an igneous body.

The aureole extends from the igneous contact, where the metamorphic effects are the greatest, out into the country rocks to where the temperature or heat energy is insufficient to effect any changes. This temperature lies between 400 and 750°F (200 and 400°C), and actual widths of contact aureoles range from several inches to miles.

Contact metamorphism can occur over a wide range of temperatures, pressures, or chemical gradients in rocks of any composition. Thus any mineral assemblage or facies of metamorphic rocks an be found. However, the nature of contact aureoles results in minerals characteristic of low to moderate pressures and moderate to high temperatures usually in common rock types: shales, basalt, limestone, and sandstone. Characteristic minerals developed in shales are andalusite, sillimanite, cordierite, biotite, orthopyroxene, and garnet. At the highest temperatures, tridymite, sanidine, mullite, and pigeonite form; whereas in limestone unusual calcium silicates form, including tilleyite, spurrite, rankinite, larnite, merwinite, akermanite, monticellite, and melilite. *See* FACIES (GEOLOGY).

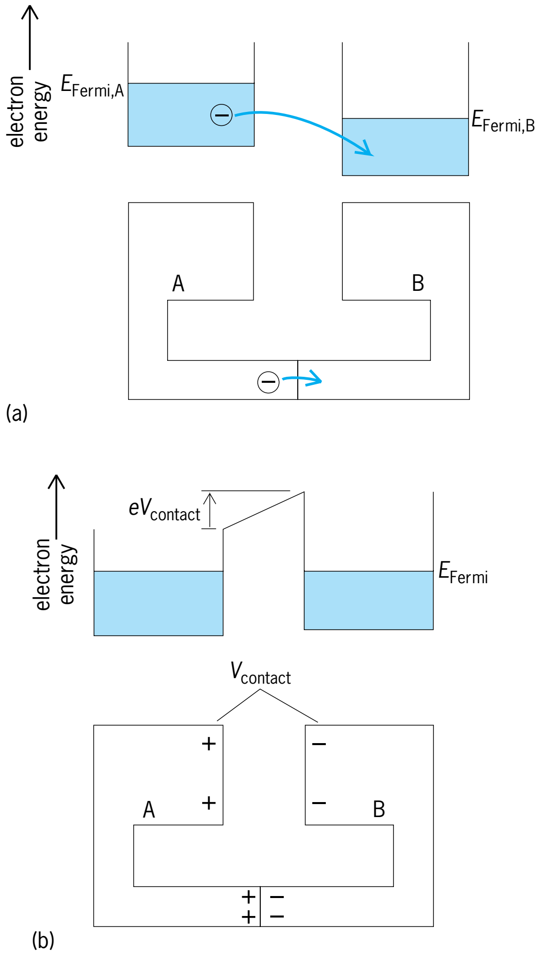
Compositional changes in a contact aureole range from none to great, but as a rule, contact metamorphism entails relatively little change in bulk rock composition. Because metamorphic changes are largely brought about by heat, contact aureoles are often termed thermal aureoles. However, there is a tendency for volatiles (water, carbon dioxide, oxygen) and alkalies (sodium, potassium) to be lost from rocks in the aureole. Stable isotope compositions (oxygen, sulfur) change in response to the thermal gradient and flow of fluids through the rocks. In some cases, volatiles (boron, fluorine, and chlorine) and other elements from the crystallizing magma are gained.

Some wall rock compositions, such as limestone, can be greatly changed and form rocks termed skarn. These contact aureoles are economically important because they often contain ore deposits of iron, copper, tungsten, graphite, zinc, lead, molybdenum, and tin. Conversely, the magma can incorporate material from the wall rocks by assimilation or mixing with any partial melts formed. Mixing results in elemental and isotopic contamination of the magma, crystallization of different minerals from the melt, and hybrid rock types at the margin of the igneous body. *See* ORE AND MINERAL DEPOSITS; PNEUMATOLYSIS; SKARN. [J.A.Sp.]

Contact condenser A device in which a vapor is brought into direct contact with a cooling liquid and condensed by giving up its latent heat to the liquid. In almost all cases the cooling liquid is water, and the condensing vapor is steam. Contact condensers are classified as jet, barometric, and ejector condensers. In all three types the steam and cooling water are mixed in a condensing chamber and withdrawn together. Noncondensable gases are removed separately from the jet condenser, entrained in the cooling water of the ejector condenser, and removed either separately or entrained in the barometric condenser. The jet condenser requires a pump to remove the mixture of condensate and cooling water and a vacuum breaker to avoid accidental flooding. The barometric condenser is self-draining. The ejector condenser converts the energy of high-velocity injection water to pressure in order to discharge the water, condensate, and noncondensables at atmospheric pressure. *See* VAPOR CONDENSER. [J.F.Se.]

Contact potential difference An electrostatic potential that exists between samples of two dissimilar electrically conductive materials (metals or semiconductors with different electron work functions) that have been brought into thermal equilibrium with each other, usually through a physical contact. Although normally measured between two surfaces which are not in contact, this potential is called the contact potential difference. Initially it is expected that mobile charge carriers (electrons or holes) will migrate from one sample to the other. If there is a net flow of electrons from material A to material B (see illustration), material B will become negatively charged and material A will become positively charged, assuming that they were originally neutral. This process is self limiting because a potential difference between the two samples will develop due to the charge separation and will grow to a value sufficient to stop further motion of the electrons from A to B.

In a metal or a semiconductor, the electrons are distributed in energy such that virtually all of them exist at or below a level called the Fermi level. When any combination of metals and semiconductors are put into equilibrium with one another, the Fermi levels in all will coincide. The contact potential difference between materials is that value necessary to raise or lower the potential energies of the electrons to produce a common Fermi level. Since they are then at the same energy, electrons in either material will have no net force on them, that is, no reason to travel to the other material. Because it causes no net force on the equilibrium distribution of electrons, contact potential difference cannot be directly measured with an ordinary voltmeter. Nevertheless, it profoundly affects the behavior of a number of electronic devices. *See* FREE-ELECTRON THEORY OF METALS; SCHOTTKY BARRIER DIODE; SEMICONDUCTOR; WORK FUNCTION (ELECTRONICS). [J.E.No.]



Development of a contact potential as two conductive materials are brought into thermal equilibrium. (*a*) Initial charge transfer. (*b*) Thermal equilibrium. Diagrams show corresponding electron energy distributions. E_{Fermi} = Fermi level; V_{contact} = contact potential difference; *e* = electron charge.

Continent A protuberance of the Earth's crustal shell with an area of several million square miles and with sufficient elevation above neighboring depressions (the ocean basins) so that much of it is above sea level.

The great majority of maps now in use imply that the boundaries of continents are their shorelines. From the geological point of view, however, the line of demarcation between a continent and an adjacent ocean basin lies offshore, at distances ranging from a few to several hundred miles, where the gentle slope of the continental shelf changes somewhat abruptly to a steeper declivity. This change occurs at depths ranging from a few to several hundred fathoms (1 fathom = 6 feet) at different places around the periphery of various continents. *See* CONTINENTAL MARGIN.

On such a basis, numerous offshore islands, including the British Isles, Greenland, Borneo, Sumatra, Java, New Guinea, Tasmania, Taiwan, Japan, and Sri Lanka, are parts of the nearby continent. Thus, there are six continents: Eurasia (Europe, China, and India are parts of this largest continent), Africa, North America, South America, Australasia (including Australia, Tasmania, and New Guinea), and Antarctica.

All continents have similar structural features but display great variety in detail. Each includes a basement complex (shield) of metamorphosed sedimentary and volcanic rocks of Precambrian age, with associated igneous rocks, mainly granite. Originally formed at considerable depths below the surface, this shield was later exposed by extensive erosion, then largely covered by sediments of Paleozoic, Mesozoic, and Cenozoic age, chiefly marine limestones, shales, and sandstones. In at least one area on each continent, these basement rocks are now at the surface (an example is the Canadian Shield of North America). In some places they have disappeared beneath a sedimentary platform occupying a large fraction of the area of each continent, such as the area in the broad lowland drained by the Mississippi River in the United States. In each continent there are long belts of mountains in which thick masses of sedimentary rocks have been compressed into folds and broken by faults. *See* CONTINENTS, EVOLUTION OF.

Continents are the less dense, subaerially exposed portion of the plates that make up the Earth's lithosphere, or outer shell of rigid rock material. As such, continents together with part of the ocean's floor are intimately joined portions of the lithospheric plates. As plates rip apart and migrate horizontally over the Earth's surface, so too do continents rip apart and migrate, sometimes colliding with other continental segments scores of millions of years later. Mountain systems, such as the Appalachian-Ouachita, the Arbuckle-Wichita, and the Urals systems, are now believed to represent the sutures of former continents attached to their respective plates which collided long ago.

The Red Sea and the linear rift-volcano-lakes district of Africa are also believed by many to manifest continental ripping and early continental drifting. Such continental collision and accretion are believed to have occurred throughout most of the Earth's history. *See* Africa; Antarctica; Asia; Europe; Isostasy; Lithosphere; North America; Plate tectonics; Seismology; South America.

[D.L.J.]

Continental drift The concept that the world's continents once formed part of a single mass and have since drifted into their present positions. Although it was outlined by Alfred Wegener in 1912, the idea was not particularly new. Paleontological studies had already demonstrated such strong similarities between the flora and fauna of the southern continents between 300,000,000 and 150,000,000 years ago that a huge supercontinent, Gondwana, containing South America, Africa, India, Australia, and Antarctica, had been proposed. However, Gondwana was thought to be the southern continents linked by land bridges, rather than contiguous units.

Wegener's ideas were almost universely rejected in 1928; the fundamental objection was the lack of a suitable mechanism. Almost simultaneously with the temporary eclipse of Wegener's theory, Arthur Holmes was considering a mechanism that is still widely accepted. Holmes conceived the idea of convective currents within the Earth's mantle which were driven by the radiogenic heat produced by radioactive minerals within the mantle. At that time, Holmes's ideas, like those of Wegener, were largely ignored. Nonetheless, several geologists, particularly those living in the Southern Hemisphere, continued to believe the theory and accumulate more data in its support.

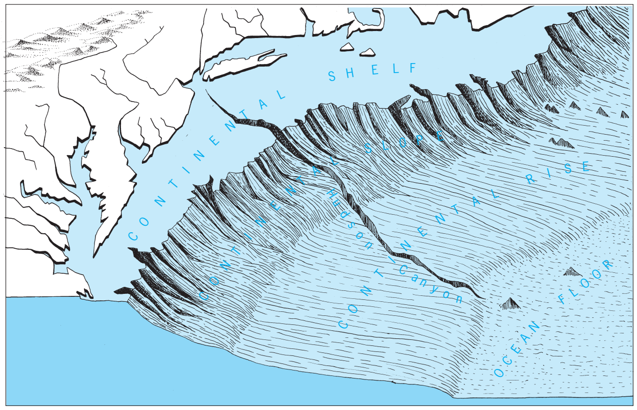
By the 1950s, convincing evidence had accumulated, with studies of the magnetization of rocks, paleomagnetism, beginning to provide numerical parameters on the past latitude and orientation of the continental blocks. Early work in North America and Europe clearly indicated how these continents had once been contiguous and had since separated. The discovery of the midoceanic ridge system also provided further evidence for the geometric matching of continental edges, but the discovery of magnetic anomalies parallel to these ridges and their interpretation in terms of sea-floor spreading finally led to almost universal acceptance of continental drift as a reality.

In the 1970s and 1980s, the interest changed from proving the reality of the concept to applying it to the geologic record, leading to a greater understanding of how the Earth has evolved through time. The fundamental change in concept was that not only have the continents drifted, but the continents are merely parts of thicker tectonic plates comprising both oceanic and continental crust, with 50–300 km (31–186 mi) of the Earth's mantle moving along with them. *See* Continents, evolution of; Earth, convection in; Paleomagnetism; Plate tectonics; Geodynamics.

[D.H.T.]

Continental margin The submerged portions of the continental masses on crustal plates, including the continental shelf, the continental slope, and the continental rise. All continental masses have some continental margin, but there is great variety in the size, shape, and geology depending upon the tectonic setting.

The most common settings are the trailing-edge margin and the leading-edge margin. The former is associated with tectonic stability, as exemplified by the Atlantic side of the North American landmass (see illustration). Here the margin is wide and geologically relatively uncomplicated, with thick sequences of coastal plain to shallow marine strata dipping slightly toward the ocean basin. By contrast, the leading-edge margin (for example, the Pacific side of the United States) is narrow, rugged, and geologically complicated. The global distribution of these widespread continental margin types is controlled by the plate tectonic setting in which the landmass resides. Some major landmasses, such as Australia, are surrounded by wide margins, but most, such as North and South America, have some of both types. *See* Plate tectonics.



Continental margin off the northeastern United States.

Any consideration of the continental margin must include a general understanding of global seal-level history over the past few million years. As glaciers expanded greatly just over 2 million years ago, sea level was lowered more than 300 ft (100 m). The cyclic growth and decay of glaciers during this period caused the shoreline to move from near its present position to near the edge of the present continental shelf on multiple occasions. These sea-level changes had a profound effect on the entire continental margin, particularly the shelf and the rise. During times of glacial advance, the coast was near the shelf edge, causing large volumes of river-borne sediment to flow down the continental slope and pile up on the rise; deltas were poorly developed for lack of place for sediment to accumulate. During times of high sea-level stand similar to the present time, little sediment crossed the shelf and large volumes of riverine sediment accumulated in large fluvial deltas. *See* Delta.

The continental shelf is simply an extension of the adjacent landmass. It is characterized by a gentle slope and little relief except for shelf valleys (see illustration), which are old rivers that were active during times of low sea level. The outer limit of the shelf shows a distinct change in gradient to the much steeper slope.

The continental slope and rise of the outer continental margin includes the relatively steep slope and the rise that accumulates at the base of the slope. This continental material has the same general composition as the landmass.

The leading-edge continental margin that is commonly associated with a crustal plate boundary displays a very different geology, geomorphology, and bathymetry than the outer continental margin. In this type there is no distinct shelf, slope, and rise. Like the trailing-edge margin, the leading-edge margin exhibits the same characteristics as the adjacent landmass, in this case a structurally complex geology with numerous fault basins and high relief. The borderland is narrow and overall steep. Its geomorphology consists of numerous local basins that receive sediment through numerous submarine canyons. The canyons commonly extend nearly to the beach; there is no shelf as such. *See* Submarine canyon.

The continental margin contains a vast amount and array of natural resources, most of which are being harvested. The primary fishing grounds around the globe are in shelf waters. The Grand Banks off northeastern North America and the North Sea adjacent to Europe are among the most heavily fished. There are also many mineral resources that are taken from shelf sediments, including heavy minerals that are sources of titanium, phosphate, and even placer gold. Important commodities such as sand, gravel, and shell are also taken in large quantities from the inner shelf. Salt domes that underlie the shelf, especially in the northern Gulf of Mexico, provide salt and sulfur.

Probably the most important resource obtained from the continental margin is petroleum, in the form of both oil and gas. Production is extremely high is some places, ranging from the deltas at the coast across the entire shelf and onto the outer margin, and reserves are high. *See* MARINE GEOLOGY; OIL AND GAS, OFFSHORE. [R.A.D.]

Shelf circulation is the pattern of flow over continental shelves. An important part of this pattern is any exchange of water with the deep ocean across the shelf-break and with estuaries or marginal seas at the coast. The circulation transports and distributes materials dissolved or suspended in the water, such as nutrients for marine life, fresh-water and fine sediments originating in rivers, and domestic and industrial waste. Water movements over continental shelves include tidal motions, wind-driven currents, and long-term mean circulation. The inflow of fresh water from land also contributes to shelf circulation, because such water would tend to spread out on the surface on account of its low density. Rapid nearshore mixing reduces the density contrast, and the Earth's rotation deflects the offshore flow into a shore-parallel direction, leaving the coast to the right. A compensating shoreward flow at depth is deflected in the opposite direction, adding to the complexity of shelf circulation. *See* NEARSHORE PROCESSES; OCEAN CIRCULATION. [G.T.C.]

Continents, evolution of The process that led to the formation of the continents. The Earth's crust is distinctively bimodal in thickness. Oceanic crust is normally about 4 mi (7 km) thick, varying mainly with the temperature of the mantle beneath the sea-floor spreading ridges when the crust was formed. In contrast, the typical 22–25-mi (35–40-km) thickness of continental crust is controlled ultimately—through the agents of erosion, sedimentation, and isostatic adjustment—by sea level. Oceanic crust is formed at spreading ridges, continental crust at subduction zones. Both are recycled to the mantle, but oceanic crust, being less buoyant, is recycled about 30 times faster than continental crust. Consequently, continents, having a mean age of almost 2 billion years and a maximum age of 4 billion years, provide the only directly accessible record spanning most of Earth history. They are, however, structurally more complex than ocean basins because of their great antiquity and weak rheology. *See* EARTH CRUST; MID-OCEANIC RIDGE.

Constructive processes. Subduction zones are the main factories for making continental crust (see illustration). The primary constructive processes are trench accretion, arc magmatism, and arc-continent collision. Mantle plumes and lithospheric stretching cause secondary magmatic additions to continental crust. *See* LITHOSPHERE; MAGMA; SUBDUCTION ZONES.

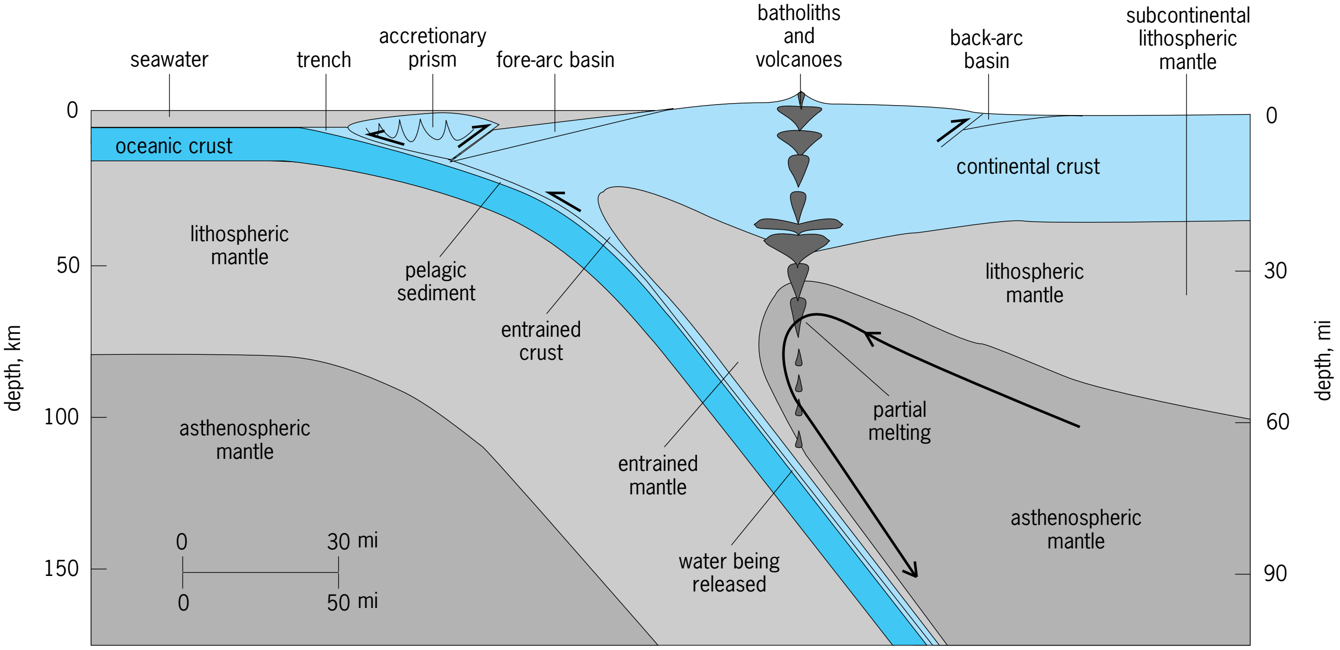
Trench accretion occurs where an oceanic plate sinks beneath a continental plate or another oceanic plate; sediment scraped off the top of the descending plate accumulates as an accretionary prism at the leading edge of the overriding plate; Trench accretion is dominantly a process of crustal reworking, not crustal growth, because the bulk of the sediment is derived from the erosion of preexisting crust.

A volcanic arc is a surface manifestation of partial melting near the tip of the mantle wedge above the subducting slab. Melting in the wedge is induced by the infiltration of aqueous fluids, which lower the temperature required for melting to begin (hydration melting). Although the main source of arc magmas is the mantle wedge, sediment and ablated crust entrained in the slab make subordinate contributions to arc magmas. The mantle-derived fraction represents new crustal addition.

Where subduction occurs beneath continental lithosphere, trench accretion and arc magmatism add crust to the continent directly. Continental-type protocrust is also formed at subduction zones (often having complex developmental histories) situated entirely within oceanic lithosphere. Incorporation of such protocrust in a continent is accomplished by arc-continent collision.

Plumes are jets of anomalously hot mantle that partially melts as it reaches the lithosphere, causing the volcanism of Hawaiian-type islands and related seamount chains. Plumes also cause volcanism on continents, for example, Yellowstone in North America. In addition to surface volcanism, the melts may pond at or near the base of the crust, causing magmatic underplating. Seamounts and oceanic plateaus are fragmentarily accreted to continents at trenches. *See* BASALT; OCEANIC ISLANDS; SEAMOUNT AND GUYOT; VOLCANOLOGY.

Destructive processes. Subduction zones may also cause destruction of continental crust (see illustration). The destructive processes are sediment subduction and subduction ablation. Constructive and destructive processes may be at work simultaneously, and the net balance may swing one way or the



Recycling of continental crust at a subduction zone. Arrows show direction of movement.

other with time. Selective destruction of lower crust may occur in continent-continent collision zones as a result of convective dripping of tectonically thickened lithosphere.

Even at subduction zones with well-developed accretionary prisms, some of the sediments disappear beneath the deformation front of the prism. Some is accreted structurally to the base of the prism, and some is transferred to the magmatic arc by melting. Some escapes melting and sinks deeply into the mantle, where it constitutes an isotopically recognizable component in the source of plume basalts. Sediment subduction, being fed by surface erosion, preferentially destroys the upper crust.

It is postulated that crust and lithospheric mantle from the overriding plate may become entrained in the subducting slab, causing tectonic ablation. Like subducted sediment, ablated crust is potentially capable of melting as it passes beneath the convecting mantle wedge. Unlike subducted sediment, ablated material may include lower crust and lithospheric mantle as well as upper crust.

Where continental lithosphere is tectonically thickened, cold lithospheric mantle is forced downward into hotter convecting mantle. Lithospheric thickening generates lateral thermal gradients, which drive mantle convection. The thickened lithospheric mantle is therefore unstable and may drip away. Unlike sediment subduction, upper crust is not lost by dripping; and unlike subduction ablation, continental drips are not susceptible to hydration melting.

Continents and Earth history. The mean age of extant continental crust is about 2 billion years. The conventional interpretation is that there was little continental crust following a period of high impact flux and that continental growth was slow at first, then rose to a peak 2–3 billion years ago, after which it slowly tapered off. An alternative interpretation, however, holds that the volume of continental crust has been in a near steady state since the impact flux waned. The present age distribution is explained by assuming a secular decline in the rate of crustal recycling, presumably modulated by the decreasing vigor of mantle convection as the Earth cooled. The difference in interpretation hinges on the importance assigned to recycling of continental crust. In crustal growth models, there is little crust older than 3 billion years, because little was formed. In steady-state models, much crust was formed early on but little of it survives. The steady-state interpretation is consistent with isotopic data showing that the oldest crustal relics contain highly evolved as well as juvenile components, and that the contemporaneous mantle was also heterogeneous and included strongly depleted regions. Furthermore, the near steady-state alternative is supported by comparative planetology, which indicates that for the hot young mantle not to be thoroughly differentiated by near-surface melting is physically implausible. *See* CONTINENTAL DRIFT; EARTH; EARTH, AGE OF; EARTH, CONVECTION IN; FAULT AND FAULT STRUCTURES; MARINE GEOLOGY; GEOPHYSICS; PLATE TECTONICS; SEISMOLOGY. [P.Ho.]

Continuous-wave radar

A radar in which the transmitter output is uninterrupted, in contrast to pulse radar, where the output consists of short pulses. Among the advantages of continuous-wave (CW) radar is its ability to measure velocity with extreme accuracy by means of the Doppler shift in the frequency of the echo. The detected, reflected wave is shifted in frequency by an amount which is a function of the relative velocity between the target and the transmitter-receiver. Range data are extracted from the change in Doppler frequency with time. *See* DOPPLER RADAR.

In order to measure the range of targets, some form of frequency modulation (FM) of the continuous-wave output must be used. In one very effective form of modulation, the carrier frequency of the transmitted signal is varied at a uniform rate. Range is determined by comparing the frequency of the echo with that of the transmitter, the difference being proportional to the range of the target that produced the echo. Systems in which this is done are known as FM-CW radars. *See* FREQUENCY MODULATION.

A modified form of FM-CW radar employs long, but not continuous, transmission. This might be regarded as the same as transmitting extremely long pulses on an FM carrier. Systems of this type are referred to as pulse compression radars.

Design objectives for continuous-wave radar include: protecting the receiver from the transmitter output and close-by return echoes when a single antenna is used; resolving side-lobe ambiguity; resolving range ambiguity; distinguishing between approaching and receding targets; eliminating noise and clutter; simultaneously measuring both target range and velocity; determining the shapes of targets; handling multiple targets; measuring target acceleration; communicating with targets; and increasing the received signal-to-noise ratio.

One disadvantage of continuous-wave radar is that when a single antenna is used for both reception and transmission it is difficult to protect the receiver against the transmitter because, in contrast to pulse radar, both are on all the time. Use of isolation circuitry gives the receiver protection from a transmitter output up to 200 W. Use of magnetically biased yttrium-iron-garnet (YIG) provides three tuned, tandem-connected power-limiter stages in one X-band FM-CW radar. *See* FERRIMAGNETIC GARNETS.

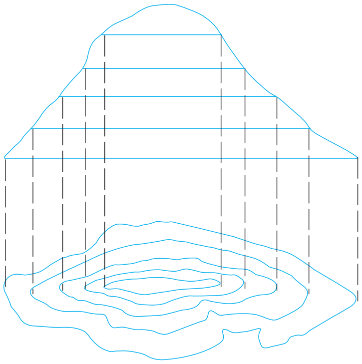
Applications of continuous-wave radar include missile guidance; detection of hostile targets; terrain clearance indication and ground surveillance; laser radar systems; atmospheric studies; automobile safety; surveillance of personnel; ice studies; remote sensing; and reproduction of the shape of a patient's pulse.

The principal use of continuous-wave radar is in short-range missile guidance. Typically the missile's course is tracked from the ground while the missile is simultaneously illuminated. Continuous-wave radar, in some cases the same radar, can be used for both tracking and illumination, although it is more common for pulse Doppler radar to be used for tracking.

A variant of continuous-wave radar is used to illuminate persons under surveillance by techniques employing semiconductor tracer diodes. These devices are secreted on or implanted in the subject's body without his or her knowledge, or else concealed in objects that are to be protected against theft. Despite the fact that pulsed X-band sources could provide the needed power levels more conveniently, the requirement to reduce clutter makes it desirable to use continuous-wave power. [J.M.C.]

Contour

The locus of points of equal elevation used in topographic mapping. Contour lines represent a uniform series of elevations, the difference in elevation between adjacent lines being the contour interval of the given map. Thus, contours represent the shape of terrain on the flat map surface (*see* illustration). Closely spaced contours indicate steep ground; sparseness or absence of contours indicates gentle slope or flat ground.



Contour representation.

Contours do not cross each other unless there is an overhang. *See* Topographic surveying and mapping. [R.H.Do.]

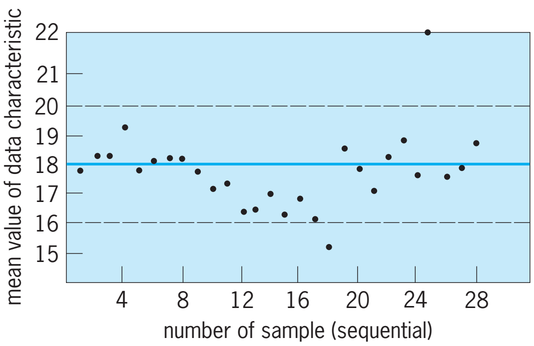
Control chart A graphical technique for determining whether a process is or is not in a state of statistical control. Being in statistical control means that the extent of variation of the output of the process does not exceed that which is expected on the basis of the natural statistical variability of the process. Several main types of control charts are used, based on the nature of the process and on the intended use of the data.

Every process has some inherent variability due to random factors over which there is no control and which cannot be eliminated economically. For instance, in a metal fabrication process random factors may include the distribution of impurities and structural faults among the metal molecules, vibrations of the fabrication equipment, fluctuations in the power supply that affect the speed and torque of the equipment, and variations in the operator performance from one cycle to the next. The inherent variability of the process is the aggregate result of many individual causes, each having a small impact.

The control chart technique is applicable to processes that produce a stream of discrete output units. Control charts are designed to detect excessive variability due to specific assignable causes that can be corrected. Assignable causes result in relatively large variations, and they usually can be identified and economically removed. Examples of assignable causes of variations that may occur in the example of metal fabrication include a substandard batch of raw material, a machine malfunction, and an untrained or poorly motivated operator.

A control chart is a two-dimensional plot of the evolution of the process over time. The horizontal dimension represents time, with samples displayed in chronological order, such that the earliest sample taken appears on the left and each newly acquired sample is plotted to the right. The vertical dimension represents the value of the sample statistic, which might be the sample mean, range, or standard deviation in the case of measurement by variables, or in the case of measurement by attributes, the number of nonconforming units, the fraction nonconforming, the number of nonconformities, or the average number of nonconformities per unit.

Typically a control chart includes three parallel horizontal lines (see illustration): a center line and two control limits. The center line (CL) intersects the vertical dimension at a value that represents the level of the process under stable conditions (natural variability only). The process level might be based on a given standard or, if no standard is available, on the current level of the process calculated as the average of an initial set of samples. The two lines above and below the center-line are called the upper control limit (UCL) and lower control limit (LCL) respectively, and they both denote the normal range of variation for the sample statistic. The control limits intersect the vertical axis such that if only the natural variability of the process is present, then the probability of a sample point falling outside the control limits and causing a false alarm is very small. Typically, control limits are located at three standard deviations from the center line on both sides. This results in a probability of a false alarm being equal to 0.0027.



Control chart, showing changes in average of process.

The principle of operation of control charts is rather simple and consists of five general steps:

1. Samples are drawn from the process output at regular intervals.
2. A statistic is calculated from the observed values of the units in the sample; a statistic is a mathematical function computed on the basis of the values of the observations in the sample.
3. The value of the statistic is charted over time; any points falling outside the control limits or any other nonrandom pattern of points indicate that there has been a change in the process, either its setting or its variability.
4. If such change is detected, the process is stopped and an investigation is conducted to determine the causes for the change.
5. Once the causes of the change have been ascertained and any required corrective action has been taken, the process is resumed.

The main benefit of control charts is to provide a visual means to identify conditions where the process level or variation has changed due to an assignable cause and consequently is no longer in a state of statistical control. The visual patterns that indicate either the out-of-control state or some other condition that requires attention are known as outliers, runs of points, low variability, trends, cycles, and mixtures. *See* Control systems; Quality control. [T.Ra.]

Control systems Interconnections of components forming system configurations which will provide a desired system response as time progresses. The steering of an automobile is a familiar example. The driver observes the position of the car relative to the desired location and makes corrections by turning the steering wheel. The car responds by changing direction, and the driver attempts to decrease the error between the desired and actual course of travel. In this case, the controlled output is the automobile's direction of travel, and the control system includes the driver, the automobile, and the road surface. The control engineer attempts to design a steering control mechanism which will provide a desired response for the automobile's direction control. Different steering designs and automobile designs result in rapid responses, as in the case of sports cars, or relatively slow and comfortable responses, as in the case of large autos with power steering.

Open- and closed-loop control. The basis for analysis of a control system is the foundation provided by linear system theory, which assumes a cause-effect relationship for the components of a system. A component or process to be controlled can be represented by a block. Each block possesses an input (cause) and output (effect). The input-output relation represents the cause-and-effect relationship of the process, which in turn represents a processing of the input signal to provide an output signal variable, often with power amplification. An open-loop control system utilizes a controller or control actuator in order to obtain the desired response (Fig. 1).

In contrast to an open-loop control system, a closed-loop control system utilizes an additional measure of the actual output

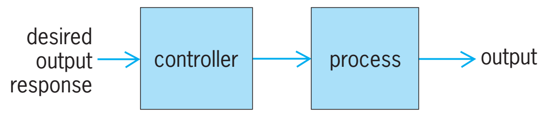


Fig. 1. Open-loop control system.

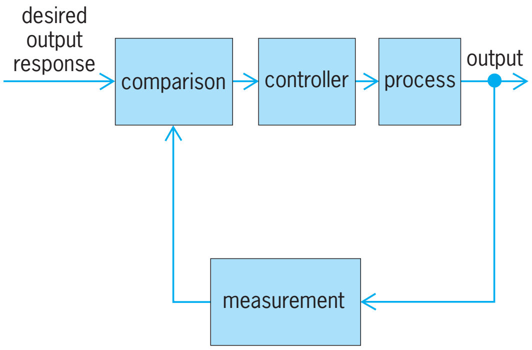

Fig. 2. Closed-loop control system.

in order to compare the actual output with the desired output response (Fig. 2). A standard definition of a feedback control system is a control system which tends to maintain a prescribed relationship of one system variable to another by comparing functions of these variables and using the difference as a means of control. In the case of the driver steering an automobile, the driver uses his or her sight to visually measure and compare the actual location of the car with the desired location. The driver then serves as the controller, turning the steering wheel. The process represents the dynamics of the steering mechanism and the automobile response.

A feedback control system often uses a function of a prescribed relationship between the output and reference input to control the process. Often, the difference between the output of the process under control and the reference input is amplified and used to control the process so that the difference is continually reduced. The feedback concept has been the foundation for control system analysis and design.

Applications for feedback systems. Familiar control systems have the basic closed-loop configuration. For example, a refrigerator has a temperature setting for desired temperature, a thermostat to measure the actual temperature and the error, and a compressor motor for power amplification. Other examples in the home are the oven, furnace, and water heater. In industry, there are controls for speed, process temperature and pressure, position, thickness, composition, and quality, among many others. Feedback control concepts have also been applied to mass transportation, electric power systems, automatic warehousing and inventory control, automatic control of agricultural systems, biomedical experimentation and biological control systems, and social, economic, and political systems. *See* BIOMEDICAL ENGINEERING; ELECTRIC POWER SYSTEMS; MATHEMATICAL BIOLOGY; SYSTEMS ANALYSIS; SYSTEMS ENGINEERING.

Advantages of feedback control. The addition of feedback to a control system results in several important advantages. A process, whatever its nature, is subject to a changing environment, aging, ignorance of the exact values of the process parameters, and other natural factors which affect a control process. In the open-loop system, all these errors and changes result in a changing and inaccurate output. However, a closed-loop system senses the change in the output due to the process changes and attempts to correct the output. The sensitivity of a control system to parameter variations is of prime importance. A primary advantage of a closed-loop feedback control system is its ability to reduce the system's sensitivity.

One of the most important characteristics of control systems is their transient response, which often must be adjusted until it is satisfactory. If an open-loop control system does not provide a satisfactory response, then the process must be replaced or modified. By contrast, a closed-loop system can often be adjusted to yield the desired response by adjusting the feedback loop parameters.

A second important effect of feedback in a control system is the control and partial elimination of the effect of disturbance signals. Many control systems are subject to extraneous disturbance signals which cause the system to provide an inaccurate output. Feedback systems have the beneficial aspect that the effect of distortion, noise, and unwanted disturbances can be effectively reduced.

Costs of feedback control. While the addition of feedback to a control system results in the advantages outlined above, it is natural that these advantages have an attendant cost. The cost of feedback is first manifested in the increased number of components and the complexity of the system. The second cost of feedback is the loss of gain. Usually, there is open-loop gain to spare, and one is more than willing to trade it for increased control of the system response. Finally, a cost of feedback is the introduction of the possibility of instability. While the open-loop system is stable, the closed-loop system may not be always stable.

Stability of closed-loop systems. The transient response of a feedback control system is of primary interest and must be investigated. A very important characteristic of the transient performance of a system is the stability of the system. A stable system is defined as a system with a bounded system response. That is, if the system is subjected to a bounded input or disturbance and the response is bounded in magnitude, the system is said to be stable.

The concept of stability can be illustrated by considering a right circular cone placed on a plane horizontal surface. If the cone is resting on its base and is tipped slightly, it returns to its original equilibrium position. This position and response is said to be stable. If the cone rests on its side and is displaced slightly, it rolls with no tendency to leave the position on its side. This position is designated as neutral stability. On the other hand, if the cone is placed on its tip and released, it falls onto its side. This position is said to be unstable.

The stability of a dynamic system is defined in a similar manner. The response to a displacement, or initial condition, will result in a decreasing, neutral, or increasing response.

Design. A feedback control system that provides an optimum performance without any necessary adjustments is rare indeed. Usually one finds it necessary to compromise among the many conflicting and demanding specifications and to adjust the system parameters to provide a suitable and acceptable performance when it is not possible to obtain all the desired optimum specifications.

It is often possible to adjust the system parameters in order to provide the desired system response. However, it is often not possible to simply adjust a system parameter and thus obtain the desired performance. Rather, the scheme or plan of the system must be reexamined, and a new design or plan must be obtained which results in a suitable system. Thus, the design of a control system is concerned with the arrangement, or the plan, of the system structure and the selection of suitable components and parameters. For example, if one desires a set of performance measures to be less than some specified values, one often encounters a conflicting set of requirements. If these two performance requirements cannot be relaxed, the system must be altered in some way. The alteration or adjustment of a control system, in order to make up for deficiencies and inadequacies and provide a suitable performance, is called compensation.

In redesigning a control system in order to alter the system response, an additional component or device is inserted within the structure of the feedback system to equalize or compensate for the performance deficiency. The compensating device may be an electric, mechanical, hydraulic, pneumatic, or other-type device or network, and is often called a compensator.

Digital computer systems. The use of a digital computer as a compensator device has grown since 1970 as the price and reliability of digital computers have improved.

Within a computer control system, the digital computer receives and operates on signals in digital (numerical) form, as contrasted to continuous signals. The measurement data are converted from analog form to digital form by means of a converter. After the digital computer has processed the inputs, it provides and output in digital form, which is then converted to analog form by a digital-to-analog converter. *See* Analog-to-digital converter; Digital-to-analog converter.

Automatic handling equipment for home, school, and industry is particularly useful for hazardous, repetitious, dull, or simple tasks. Machines that automatically load and unload, cut, weld, or cast are used by industry in order to obtain accuracy, safety, economy, and productivity. Robots are programmable computers integrated with machines. They often substitute for human labor in specific repeated tasks. Some devices even have anthropomorphic mechanisms, including what might be recognized as mechanical arms, wrists, and hands. Robots may be used extensively in space exploration and assembly. They can be flexible, accurate aids on assembly lines. *See* Robotics. [R.C.D.]

Controlled rectifier A three-terminal semiconductor junction device with four regions of alternating conductivity type (*p-n-p-n*), also called a thyristor. This switching device has a characteristic such that, once it conducts, the voltage in the circuit in which it conducts must drop below a threshold before the controlled rectifier regains control. Such devices are useful as high-current switches and may be used to drive electromagnets and relays.

The principle of operation can be understood by referring to the illustration. The central junction is reverse-biased (positive collector, grounded emitter). The wide *n* region between collector and base regions prevents holes injected at the collector junction from reaching the collector-to-base barrier by diffusion. The junction between emitter and base is the emitter. When operated as a normal transistor, this device shows a rapid increase of current gain with collector current. This effect may be due to a field-induced increase of transport efficiency across the floating n region, or to increased avalanching in the high-field barrier region, or to increased injection efficiency at the two forward-biased junctions, or to a combination of these phenomena.

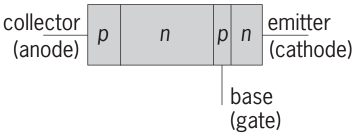

Diagram of a controlled rectifier.

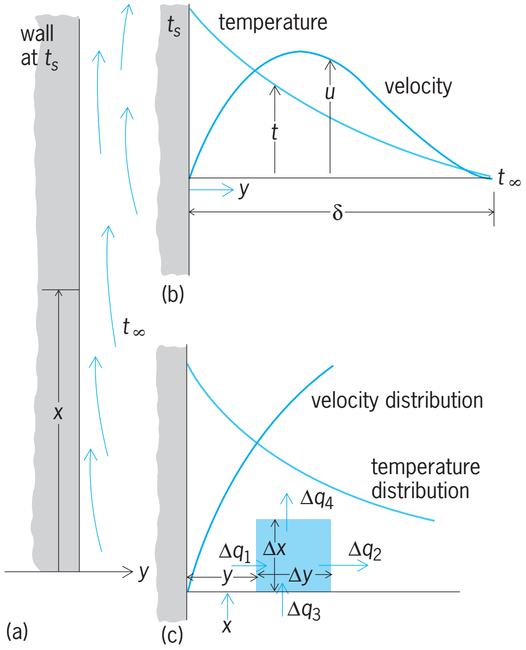
If this device is operated as a three-terminal device, the switching between the nonconducting and conducting states can be controlled by the base. *See* Semiconductor rectifier. [L.P.H.]

Conularida A small group of extinct invertebrates showing a fourfold symmetry and a narrow pyramidal shape; the cross section commonly is square. Specimens are chitinous and frequently impregnated with calcium phosphate. The four side walls are characteristically ornamented by numerous transverse lines. The posterior tip may bear an attachment disk or may be broken off and sealed with a septum. Internal structures are rare; the few known show fourfold symmetry. Conularida are regarded as a subclass of the Coelenterata because of the characteristic symmetry. *See* Coelenterata.

Specimens are worldwide in occurrence and are known from rocks of Cambrian through Triassic age. They have been found in sandstone, shales, and limestones. About 20 genera and 150 species are known. Except for a few local occurrences, Conularida are rare fossils. [E.L.Y.]

Convection (heat) The transfer of thermal energy by actual physical movement from one location to another of a substance in which thermal energy is stored. A familiar example is the free or forced movement of warm air throughout a room to provide heating. Technically, convection denotes the nonradiant heat exchange between a surface and a fluid flowing over it. Although heat flow by conduction also occurs in this process, the controlling feature is the energy transfer by flow of the fluid—hence the name convection. Convection is one of the three basic methods of heat transfer, the other two being conduction and radiation. *See* Conduction (heat); Heat radiation; Heat transfer.



Temperature and velocity distributions in air near a heated vertical surface at arbitary vertical location. The distance δ is that distance at which the velocity and the temperature reach ambient surrounding conditions.

Natural convection is exemplified by the cooling of a vertical surface in a large quiescent body of air of temperature t_∞. The lower-density air next to a hot vertical surface moves upward because of the buoyant force of the higher-density cool air farther away from the surface. At any arbitrary vertical location *x*, the actual variation of velocity *u* with distance *y* from the surface will be similar to that in the illustration *b*, increasing from zero at the surface to a maximum, and then decreasing to zero as ambient surrounding conditions are reached. In contrast, the temperature *t* of the air decreases from the heated wall value *t*'s to the surrounding air temperature. These temperature and velocity distributions are clearly interrelated, and the distances from the wall through which they exist are coincident because, when the temperature approaches that of the surrounding air, the density difference causing the upward flow approaches zero.

The region in which these velocity and temperature changes occur is called the boundary layer. Because velocity and temperature gradients both approach zero at the outer edge, there will be no heat flow out of the boundary layer by conduction or convection. *See* Boundary-layer flow.

When air is blown across a heated surface, forced convection results. Although the natural convection forces are still present in this latter case, they are clearly negligible compared with the imposed forces. The process of energy transfer from the heated surface to the air is not, however, different from that described for natural convection. The major distinguishing feature is that the maximum fluid velocity is at the outer edge of the boundary layer. This difference in velocity profile and the higher velocities provide more fluid near the surface to carry along the heat conducted normal to the surface. Consequently, boundary layers are very thin.

Heat convection in turbulent flow is interpreted similarly to that in laminar flow. Rates of heat transfer are higher for comparable velocities, however, because the fluctuating velocity components of the fluid in a turbulent flow stream provide a macroscopic exchange mechanism which greatly increases the transport of energy normal to the main flow direction. Because of the complexity of this type of flow, most of the information regarding heat transfer has been obtained experimentally. *See* LAMINAR FLOW; TURBULENT FLOW.

Convection heat transfer which occurs during high-speed flight or high-velocity flow over a surface is known as aerodynamic heating. This heating effect results from the conversion of the kinetic energy of the fluid as it approaches a body to internal energy as it is slowed down next to the surface. In the case of a gas, its temperature increases, first, because of compression as it passes through a shock and approaches the stagnation region, and second, because of frictional dissipation of kinetic energy in the boundary layer along the surface.

The phenomena of condensation and boiling are important phase-change processes involving heat release or absorption. Because vapor and liquid movement are present, the energy transfer is basically by convection. Local and average heat-transfer coefficients are determined and used in the Newton cooling-law equation for calculating heat rates which include the effects of the latent heat of vaporization. [W.H.Gi.]

Convective instability A state of fluid flow in which the distribution of body forces along the direction of the net body force is unstable and will thus break down. Fluid flows are subject to a variety of instabilities, which may be broadly viewed as the means by which relatively simple flows become more complex. Instabilities are an important step in the transition between smooth and turbulent flow, and in the atmosphere they are responsible for phenomena ranging from thunderstorms to low- and high-pressure systems. Meteorologists and oceanographers divide instabilities into two broad classes: convective and dynamic. *See* DYNAMIC INSTABILITY.

In the broadest terms, convective instabilities arise when the displacement of a small parcel of fluid causes a force on that parcel which is in the same direction as the displacement. The parcel of fluid will then continue to accelerate away from its initial position, and the fluid is said to be unstable. In most geophysical flows, the convective motions that result from convective instabilities operate very quickly compared with the processes acting to destabilize the fluid; the result is that such fluids *see*m to be nearly neutrally stable to convection.

The simplest type of convective instability arises when a fluid is heated from below or cooled from above. Warm air rises and cold air sinks; thus a fluid whose temperature decreases with altitude is convectively unstable, while one in which the temperature increases with height is convectively stable. A fluid at constant temperature is said to be convectively neutral.

The above description assumes that density depends on temperature alone and that density is conserved in parcels of fluid, so that when the parcels are displaced their density does not change. However, in the Earth's atmosphere, neither of these assumptions is true. In the first place, the density of air depends on pressure and on the amount of water vapor in the air, in addition to temperature. Second, the density will change when the parcel is displaced because both its pressure and its temperature will change. Because of these conditions it is convenient to define a quantity known as virtual potential temperature (θ_v) that both is conserved and reflects the actual density of air. This quantity is given by the equation below, where T is the temperature

$$\theta_v \equiv T\left(\frac{1+(r/0.622)}{1+r}\right)\left(\frac{1000}{p}\right)^{0.287}$$

in kelvins, p is the pressure in millibars, and r is the number of grams of water vapor in each gram of dry air. When θ_v decreases with height in the atmosphere, it is convectively unstable, while θ_v increasing with height denotes stability.

In the oceans, density is a function of pressure, temperature, and salinity; convection there is driven by cooling of the ocean surface by evaporation of water into the atmosphere and by direct loss of heat when the air is colder than the water. It is also driven by salinity changes resulting from precipitation and evaporation. In many regions of the ocean, a convectively driven layer exists near the surface in analogy with the atmospheric convective layer. This oceanic mixed layer is also nearly neutral to convection.

Convective instabilities are also responsible for convection in the Earth's mantle, which among other things drives the motion of the plates, and for many of the motions of gases within other planets and in stars. [K.A.Em.]

Converter A device for processing alternating-current (ac) or direct-current (dc) power to provide a different electrical waveform. The term converter denotes a mechanism for either processing ac power into dc power (rectifier) or deriving power with an ac waveform from dc (inverter). Some converters serve both functions, others only one. *See* ALTERNATING CURRENT; DIRECT CURRENT; RECTIFIER.

Converters are used for such applications as (1) rectification from ac to supply electrochemical processes with large controlled levels of direct current; (2) rectification of ac to dc followed by inversion to a controlled frequency of ac to supply variable-speed ac motors; (3) interfacing dc power sources (such as fuel cells and photoelectric devices) to ac distribution systems; (4) production of dc from ac power for subway and streetcar systems, and for controlled dc voltage for speed-control of dc motors in numerous industrial applications; and (5) transmission of dc electric power between rectifier stations and inverter stations within ac generation and transmission networks. *See* ALTERNATING-CURRENT MOTOR; DIRECT-CURRENT TRANSMISSION.

The introduction of the thyristor (silicon-controlled rectifier) in the 1960s had an immediate effect on converter applications because of its ruggedness, reliability, and compactness. Power semiconductor devices for converter circuits include (1) thyristors, controlled unidirectional switches that, once conducting, have no capability to suppress current; (2) triacs, thyristor devices with bidirectional control of conduction; (3) gate turn-off devices with the properties of thyristors and the further capability of suppressing current; and (4) power transistors, high-power transistors operating in the switching mode, somewhat similar in properties to gate turn-off devices. Thyristors are available with ratings from a few watts up to the capability of withstanding several kilovolts and conducting several kiloamperes. *See* SEMICONDUCTOR RECTIFIER. [J.Re.]

Convertiplane An aircraft combining vertical takeoff and landing capabilities as in the helicopter with forward-flight effectiveness and high-speed potentials of the airplane. In forward flight a convertiplane relies, at least partially, on the fixed wing, while for vertical takeoffs, landings, and hovering, a separate vertical thrust generator is provided. Between vertical and forward-flight regimes, the aircraft goes through a conversion. *See* AIRPLANE; HELICOPTER; VERTICAL TAKEOFF AND LANDING (VTOL).

Of many systems suitable as vertical-thrust generators, those applied to practical convertiplanes will probably be either of the direct type, in which combustion products are used directly for thrust generation (turbojets and rockets), or of the indirect type, in which all or a part of the available combustion energy is used to drive a mechanical system, functioning as an actuator disk to accelerate the ambient air. The actuator disks may be either free (helicopter rotors and propellers) or shrouded (shrouded propellers and ducted fans).

The principle of the convertiplane can be applied to many types of aircraft. The first practical attempts were directed toward rotary-wing aircraft. In the so-called compounds as much lift as

Fig. 1. NASA-Army-Bell XV-15 in airplane configuration after conversion from helicopter mode. (*Bell Helicopter Textron*)

possible is transferred in forward flight from the rotor (which is either put into autorotation or slowed down) to more efficient fixed wings, while a propeller (or propellers) provides the forward thrust.

To achieve high speeds the helicopter-type rotor must be eliminated from the forward-flight configuration, which should be as close as possible to that of conventional aircraft. Configurations have been studied wherein rotors are stopped, folded, and retracted into the fuselage or into nacelles.

In the nonhelicopter-type convertiplane, the same device can be used both as a vertical-thrust generator and as a means of forward propulsion. Two basic solutions are technically feasible: (1) the wing remains fixed, while either the entire thrust generator or only the thrust vector tilts from the vertical to the horizontal position, and (2) both the wing and the thrust generator tilt as a unit.

Fig. 2. Bell-Boeing V-22 Osprey tilt-rotor aircraft. (*Bell Helicopter Textron*)

Fig. 3. Harrier fighter aircraft, manufactured by Hawker Siddeley, now British Aerospace, and McDonnell Douglas. Close ground support and reconnaissance are provided through use of vectored-thrust turbofans.

In the fixed-wing, free-airscrew group, the NASA-Army-Bell XV-15, a flight research aircraft with 375 mi/h (167 m/s) speed capabilities, went through complete conversion in 1979 (Fig. 1). In the ensuing years of extensive flight testing, the XV-15 proved the feasibility of the tilt-rotor concept, thus paving the way for the development of an operational aircraft, the Bell-Boeing V-22 Osprey (Fig. 2), for the U.S. military forces, especially the Marine corps.

The Harrier (manufactured by Hawker Siddeley, now British Aerospace, and McDonnell Douglas), with Pegasus vectored-thrust turbofan engines (manufactured by British Siddeley, now Rolls Royce), is a fighter that is produced for the military forces (including the U.S. Marines) of several Western countries and was an important factor for the British in the 1982 Falkland Islands conflict (Fig. 3). The Yakovlev, a Russian single-seat, carrier-based combat aircraft, is similar in concept. [W.Z.S.]

Conveyor A horizontal, inclined, declined, or vertical machine for moving or transporting bulk materials, packages, or objects in a path predetermined by the design of the device and having points of loading and discharge fixed or selective. Included in this category are skip hoist and vertical reciprocating and inclined reciprocating conveyors; but in the strictest sense this category does not include those devices known as industrial trucks, tractors and trailers, cranes, hoists, monorail cranes, power and hand shovels or scoops, bucket drag lines, platform elevators, or highway or rail vehicles. *See* BULK-HANDLING MACHINES.

Gravity conveyors provide the most economical means for lowering articles and materials. Chutes depend upon sliding friction to control the rate of descent; wheel and roller conveyors use rolling friction for this purpose.

Gravity chutes may be made straight or curved and are fabricated from sheet metal or wood, the latter being sometimes covered with canvas to prevent slivering. The bed of the chute can be shaped to accommodate the products to be handled. In spiral chutes centrifugal force is the second controlling factor. Spirals with roller beds or wheels provide smooth descent of an article and tend to maintain the position of the article in its original starting position. Rollers may be constructed of metals, wood, or plastic and can be arranged in an optimum position, depending upon the articles to be carried.

To move loads on level or inclined paths, or declining paths that exceed the angle of sliding or rolling friction of the particular material to be conveyed, powered conveyors must be employed. There are various types of powered conveyors. Belt conveyors move loads on a level or inclined path by means of power-driven belts. Belt conveyors with rough-top belts make possible inclines up to 28°; cleated belts are limited on degree of incline only by the position of the center of gravity of the conveyed item.

Live-roller conveyors move objects over series of rollers by the application of power to all or some of the rollers. The power-transmitting medium is usually belting or chain. [A.M.P.]

Vibrating conveyors are designed to move bulk materials along a horizontal, or almost horizontal, path in a controlled system. They can be used to simply transport material from one point to another or to perform various functions en route, such as cooling, drying, blending, metering, spreading, and, by installing a screen, or dedusting. [R.F.M.]

Cooling tower A tower- or building-like device in which atmospheric air (the heat receiver) circulates in direct or indirect contact with warmer water (the heat source) and the water is thereby cooled (*see* illustration). A cooling tower may serve as the heat sink in a conventional thermodynamic process, such as refrigeration or steam power generation, or it may be used in any process in which water is used as the vehicle for heat removal, and when it is convenient or desirable to make final heat rejection to atmospheric air. Water, acting as the heat-transfer fluid, gives up heat to atmospheric air, and thus cooled, is recir-

Counterflow natural-draft cooling tower at Trojan Power Plant in Spokane, Washington. (*Research-Cottrell*)

culated through the system, affording economical operation of the process.

Two basic types of cooling towers are commonly used. One transfers the heat from warmer water to cooler air mainly by an evaporation heat-transfer process and is known as the evaporative or wet cooling tower. Evaporative cooling towers are classified according to the means employed for producing air circulation through them: atmospheric, natural draft, and mechanical draft. The other transfers the heat from warmer water to cooler air by a sensible heat-transfer process and is known as the nonevaporative or dry cooling tower. Nonevaporative cooling towers are classified as air-cooled condensers and as air-cooled heat exchangers, and are further classified by the means used for producing air circulation through them. These two basic types are sometimes combined, with the two cooling processes generally used in parallel or separately, and are then known as wet-dry cooling towers.

Evaluation of cooling tower performance is based on cooling of a specified quantity of water through a given range and to a specified temperature approach to the wet-bulb or dry-bulb temperature for which the tower is designed. Because exact design conditions are rarely experienced in operation, estimated performance curves are frequently prepared for a specific installation, and provide a means for comparing the measured performance with design conditions. [J.F.Se.]

Coordinate systems Schemes for locating points in a given space by means of numerical quantities specified with respect to some frame of reference. These quantities are the coordinates of a point. To each set of coordinates there corresponds just one point in any coordinate system, but there are useful coordinate systems in which to a given point there may correspond more than one set of coordinates.

A coordinate system is a mathematical language that is used to describe geometrical objects analytically; that is, if the coordinates of a set of points are known, their relationships and the properties of figures determined by them can be obtained by numerical calculations instead of by other descriptions. It is the province of analytic geometry, aided chiefly by calculus, to investigate the means for these calculations.

The most familiar spaces are the plane and the three-dimensional euclidean space. in the latter a point P is determined by three coordinates (x,y,z). The totality of points for which x has a fixed value constitutes a surface. The same is true for y and z so that through P there are three coordinate surfaces. The totality of points for which x and y are fixed is a curve and through each point there are three coordinate lines. If these lines are all straight, the system of coordinates is said to be rectilinear. If some or all of the coordinate lines are not straight, the system is curvilinear. If the angles between the coordinate lines at each point are light angles, the system is rectangular.

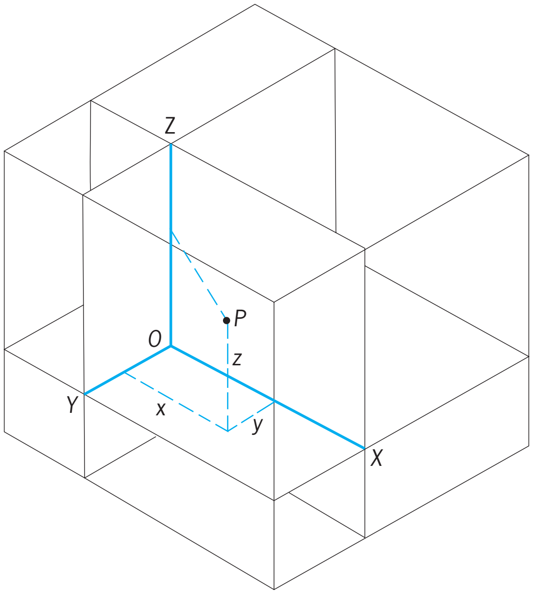


Fig. 1. Cartesian coordinate system.

A cartesian coordinate system is one of the simplest and most useful systems of coordinates. It is constructed by choosing a point O designated as the origin. Through it three intersecting directed lines OX, OY, OZ, the coordinate axes, are constructed. The coordinates of a point P are x, the distance of P from the plane YOZ measured parallel to OX, and y and z, which are determined similarly (Fig. 1). Usually the three axes are taken to be mutually perpendicular, in which case the system is a rectangular cartesian one. Obviously a similar construction can be made in the plane, in which case a point has two coordinates (x,y).

A polar coordinate system is constructed in the plane by choosing a point O called the pole and through it a directed straight

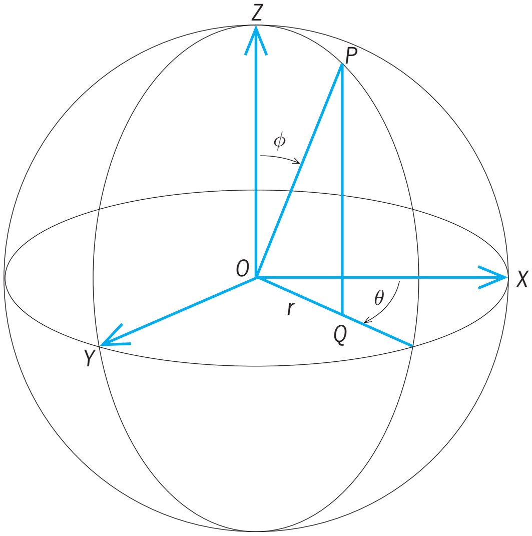

Fig. 2. Spherical coordinate system.

line, the initial line. A point *P* is located by specifying the directed distance *OP* and the angle through which the initial line must be turned to coincide with *OP* in position and direction. The coordinates of P are (r, θ). The radius vector *r* is the directed line *OP*, and the vectorial angle θ is the angle through which the initial line was turned, + if turned counterclockwise, – if clockwise.

Spherical coordinates are constructed in three-dimensional euclidean space by choosing a plane and in it constructing a polar coordinate system. At the pole *O* a polar axis *OZ* is constructed at right angles to the chosen plane. A point *P*, not on *OZ*, and *OZ* determine a plane. The spherical coordinates of *P* are then the directed distance *OP* denoted by *p*, the angle θ through which the initial line is turned to lie in *ZOP* and the angle $\phi = ZOP$ (Fig. 2).

Cylindrical coordinates are constructed by choosing a plane with a pole *O*, an initial line in it, and a polar axis *OZ*, as in spherical coordinates. A point *P* is projected onto the chosen plane. The cylindrical coordinates of *P* are (r,θ,z) where *r* and θ are the polar coordinates of *Q* and $z = QP$ (Fig. 2).

By means of a system of equations the description of a geometrical object in one coordinate system may be translated into an equivalent description in another coordinate system. *See* ANALYTIC GEOMETRY; CALCULUS; CONFORMAL MAPPING; CURVE FITTING; SPHERICAL HARMONICS. [M.S.Kn.]

Coordination chemistry A field which, in its broadest usage, is acid-base chemistry as defined by G. N. Lewis. However, the term coordination chemistry is generally used to describe the chemistry of metals and metal ions in their interactions with other molecules or ions. For example, reactions (1)–(3)

$$\mathrm{Mg^{2} + 6H_2O \rightarrow Mg(H_2O)_6{}^{2+}} \qquad (1)$$

$$\mathrm{Ni + 4CO \rightarrow Ni(CO)_4} \qquad (2)$$

$$\mathrm{Fe^{2+} + 6CN^{-} \rightarrow Fe(CN)_6{}^{4-}} \qquad (3)$$

show acid-base-type reactions; the products formed are coordination ions or compounds, and this area of chemistry is known as coordination chemistry.

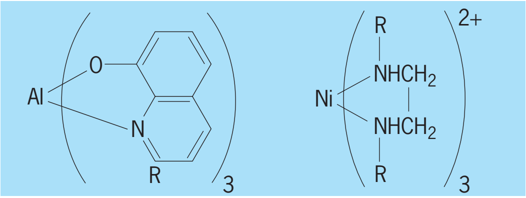
Thus, it follows that coordination compounds are compounds that contain a central atom or ion and a group of ions or molecules surrounding it. Such a compound tends to retain its identity, even in solution, although partial dissociation may occur. The charge on the coordinated species may be positive, zero, or negative, depending on the charges carried by the central atom and the coordinated groups. These groups are called ligands, and the total number of attachments to the central atom is called the coordination number. Other names commonly used for these compounds include complex compounds, complex ions, Werner complexes, coordinated complexes, chelate compounds, or simply complexes. *See* ACID AND BASE; CHELATION.

Experimental observations as early as the middle of the 18th century reported the isolation of coordination compounds, but valence theory could not adequately account for such materials. The correct interpretation of these compounds was given by Alfred Werner in 1893. He introduced the concept of residual or secondary valence, and suggested that elements have this type of valence in addition to their normal or primary valence. Thus, platinum(IV) has a normal valence of 4 but a secondary valence or coordination number of 6. This then led to the formulaton of $\mathrm{PtCl_4 \cdot 6NH_3}$ as $\mathrm{[Pt(NH_3)_6]^{4+}, 4Cl^{-}}$ and of $\mathrm{PtCl_4 \cdot 5NH_3}$ as $\mathrm{[Pt(NH_3)_5Cl]^{3+}, 3Cl^{-}}$. The compound with five ammonias has only three ionic chlorides, the fourth is inside the coordination sphere, and therefore is not readily precipitated upon the addition of silver ion. Although the exact nature of the coordinate bond between metal and ligand remains the subject of considerable discussion, it is agreed that the formulations of Werner are essentially correct.

Three theories have been used to explain the nature of the coordinate bond. These are the valence bond theory, the electrostatic theory, including crystal field corrections, and the molecular orbital theory. Currently, the theory used almost exclusively is the molecular orbital theory. The valence bond theory for metal complexes considers that the pair of electrons on the ligand enter the hybridized atomic orbitals of the metal and that the bond is either essentially covalent or essentially ionic. Several of the properties of these substances can be explained on the basis of this theory. The electrostatic theory, plus the crystal field theory for the transition metals, assumes that the metal-ligand bond is caused by electrostatic interactions between point charges and dipoles and that there is no sharing of electrons. In addition to explaining the structure and magnetic properties, the crystal field theory affords an adequate interpretation of the visible spectra of metal complexes. The molecular orbital theory assumes that the electrons move in molecular orbitals which extend over all the nuclei of the metalligand system. In this manner, it serves to make use of both the valence bond theory and crystal field theory. The molecular orbital theory is therefore the best approximation to the nature of the coordinate bond because it is sufficiently flexible to permit both covalent and ionic bonding as well as the splitting of d orbitals into various energy levels. *See* MOLECULAR ORBITAL THEORY.

The stability of metal complexes depends both on the metal ion and the ligand. In general the stability of metal complexes increases if the central ion increases in charge, decreases in size, and increases in electron affinity. Several characteristics of the ligand are known to influence the stability of complexes: (1) basicity of the ligand, (2) the number of metal-chelate rings per ligand, (3) the size of the chelate ring, (4) steric effects, (5) resonance effects, and (6) the ligand atom. Since coordination compounds are formed as a result of acid-base reactions where the metal ion is the acid and the ligand is the base, it follows that generally the more basic ligand will tend to form the more stable complex. The size of the chelate ring is likewise an important factor. For saturated ligands such as ethylenediamine, five-membered rings are the most stable for chelates containing one or more double bonds.

Steric factors often have a very large effect on the stability of metal complexes. This is most frequently observed with ligands having a large group attached to the ligand atom or near it. Thus complexes, of the type shown in the illustration, with alkyl groups R in the position designated are much less stable than the parent complex where R = H. This results from the steric strain introduced by the size of the alkyl group on or adjacent to the ligand atom. In contrast to this, alkyl substitution at any other position results in the formation of more stable complexes because the ligand becomes more basic, and the bulky group is now removed from a position near the coordination site.



Structural formulas of metal complexes which are affected by steric factors.

Finally, the ligand atom itself plays a significant role in controlling the stability of metal complexes. For most of the metal ions, the smallest ligand atom with the largest electron density will form the most stable complex.

Often the most stable complex is also the least reactive or most inert. Several factors, such as the electronic configuration of the central metal ion, its coordination number, and the extent of chelation, all have a marked effect on the rate of reaction of a given compound. *See* CHEMICAL BONDING; MAGNETOCHEMISTRY; SOLID-STATE CHEMISTRY; STEREOCHEMISTRY. [F.Ba.]

Coordination complexes A group of chemical compounds in which a part of the molecular bonding is of the coordinate covalent type. For a discussion of the nature of the coordinate bond, and the stability and reactivity of complex compounds. *See* CHELATION; COORDINATION CHEMISTRY.

Coordination complexes contain a central atom or ion and a group of ions or molecules surrounding it. Many simple hydrates, such as $MgCl_2 \cdot 6H_2O$, are best formulated as $[Mg(H_2O)_6]C_2$ because it is known that the 6 molecules of water surround the central magnesium ion. Therefore, $[Mg(H_2O)_6]^{2+}$ is a complex ion, and $[Mg(H_2O)_6]Cl_2$ is a complex compound. The charge on this complex ion is $+2$, because this is the charge on the magnesium ion and the coordinated water molecules are neutral. However, if the coordinated groups are charged, then the charge on the complex is represented by the sum of the charge on the metal and that of the coordinated ions. *See*, for example, the progression of charges on the platinum(IV) complexes listed below.

$[Pt(NH_3)_6]Cl_4$	Hexaammineplatinum(IV) chloride
$[Pt(NH_3)_5Cl]Cl_3$	Chloropentaammineplatinum(IV) chloride
$[Pt(NH_3)_4Cl_2]Cl_2$	Dichlorotetraammineplatinum(IV) chloride
$[Pt(NH_3)_3Cl_3]Cl$	Trichlorotriammineplatinum(IV) chloride
$[Pt(NH_3)_2Cl_4]$	Tetrachlorodiammineplatinum(IV)
$K[Pt(NH_3)Cl_5)]$	Potassium pentachloroammineplatinate(IV)
$K_2[PtCl_6]$	Potassium hexachloroplatinate(IV)

Thus the charge is $+4$ for $[Pt(NH_3)_6]^{4+}$ because Pt is $+4$ and NH_3 is neutral. But the charge is -2 for $[PtCl_6]^{2-}$ because of the 6 for Cl^-, that is, $+4 - 6 = -2$.

Metal complexes exhibit various types of isomerism. In many ways, inorganic stereochemistry is similar to that observed with organic compounds. Geometrical isomers are common among the inert complexes of coordination numbers 4 and 6. *See* STEREOCHEMISTRY.

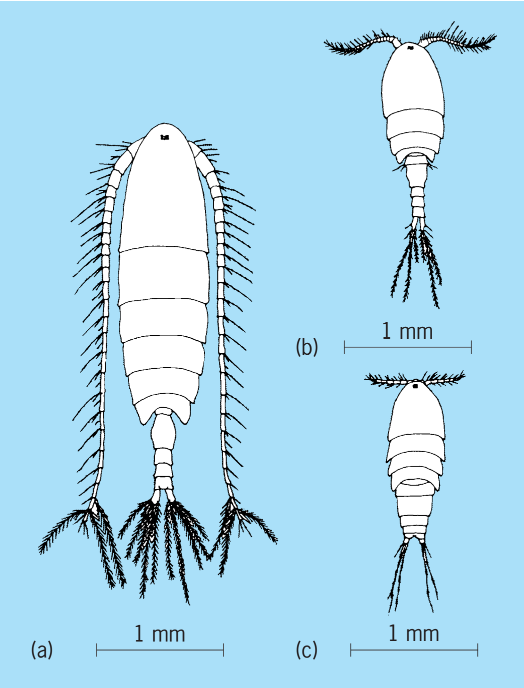
The synthesis of metal complexes containing only one kind of ligand generally involves just the reaction of the metal salt in aqueous solution with an excess of the ligand reagent, as shown below.

$$[Ni(H_2O)_6](NO_3)_2 + 6NH_3 \rightarrow [Ni(NH_3)_6](NO_3)_2 + 6H_2O$$

The desired complex salt can then be isolated by removal of water until it crystallizes, or by addition of a water-miscible organic solvent to cause it to separate. For the inert complexes (those slow to react), prolonged treatment at more drastic conditions is often necessary. The preparation of geometrical isomers is much more difficult, and in most cases, the approach used is rather empirical. Generally, reactions yield a mixture of cis-trans products, and these are separated on the basis of their differences in solubility. *See* AMMINE; HYDRATE. [F.Ba.]

Copepoda A subclass of Crustacea with eight orders. There are over 6000 species, most of which are free-living in aqueous environments, though many are parasitic or symbiotic with other aquatic animals. The free-living forms are the most abundant of all animals in the sea and directly constitute the main food for vast numbers of fishes, many invertebrates, and also at times for baleen whales.

The structure of copepods, although similar in basic pattern, varies greatly (see illustration). In free-living forms the body is composed externally of a series of small chitinous cylinders, or segments, some of which may be more or less fused. The head bears two pairs of antennae. The feeding appendages are one pair of mandibles, two pairs of maxillae, and one pair of maxillipeds. The thorax, consisting of six segments, bears the swimming feet. The abdomen consists of one to five segments and bears no appendages except a pair of terminal processes known as caudal rami. The sexes are separate and sexual dimorphism is frequently evidenced. Free-living species usually range in size from less than 0.02 in. (0.5 mm) to about 0.4 in. (10 mm) in length.



Free-living copepods. (*a*) *Calanus finmarchicus*, a calanoid. (*b*) *Cyclops*, a cyclopoid. (*c*) *Harpacticus*, a harpacticoid.

Three orders, Calanoida, Cyclopoida, and Harpacticoida, are wholly or primarily free-living and because of overwhelming numbers are of greatest general interest.

In the adult state the remaining orders (Poecilostomatoida, Siphonostomatoida, Monstrilloida, Misophrioida, and Mormonilloida) are parasitic at least part of their lives. Their numbers are relatively small, but they may be conspicuous and important as "fish lice," burrowing deep into the flesh or feeding externally upon the skin and gills. *See* CALANOIDA; CYCLOPOIDA; MISOPHRIOIDA; MONSTRILLOIDA; MORMONILLOIDA; POECILOSTOMATOIDA; SIPHONOSTOMATOIDA.

Copepod habitats are extremely varied, but the vast majority of species live in the sea. They are mostly planktonic throughout their lives, some occurring only in coastal waters while others live in the open sea. Many frequent only the upper layers to about 650–1000 ft (200–300 m) depth. Others are bathypelagic at great depths. The harpacticoids, however, are primarily a benthic, or bottom-dwelling, group, though many are truly planktonic.

The role of copepods in the economy of the sea consists mainly of converting plant into animal substance. Many species are adapted to graze directly upon the chief synthesizers of organic material, the microscopic diatoms and dinoflagellates that constitute the great pasturage of the sea. Some species are predatory on other copepods, fish larvae, and other small animals, such as protozoa. Commonly copepods constitute about 70% of the zooplankton, and at times their numbers are so great as to impart a pinkish color to the sea. *See* MARINE ECOLOGY. [H.C.Y.]

Copolymer A macromolecule in which two or more different species of monomer are incorporated into a polymer chain. The properties of copolymers depend on both the nature of the monomers and their distribution in the polymer. Thus, monomers A and B can polymerize randomly to form ABBAABA; they can alternate to give ABAB; they can form blocks AAABBB; or one monomer can be grafted onto a polymer of the other:

AAAA
B
B

Copolymers can be prepared by all the known methods of polymerization: addition polymerization of vinyl monomers (by free-radical, anionic, cationic, or coordination catalysis), ring-opening polymerization, or condensation polymerization. *See* Polymerization.

In the polymerization of two monomers, M_1 and M_2, the monomers can add to a growing chain ending in either monomer, designated as M_1^* and M_2^*. To a first approximation, only the terminal group of the growing chain is important, so two reactivity ratios can be defined: r_1 is the relative reactivity of chain end M_1^* to monomers M_1 and M_2, and r_2 is the relative reactivity of chain end M_2^* to monomers M_2, and M_1. The reactivity ratios can be determined experimentally by analyzing polymer compositions at different monomer feeds. *See* Acrylonitrile; Polyacrylonitrile resins; Polymer. [D.S.Br.]

Copper A chemical element, Cu, atomic number 29, atomic weight 63.546. Copper, a nonferrous metal, is the twentieth most abundant element present in the Earth's crust, at an average level of 68 parts per million (0.22 lb/ton or 0.11 kg/metric ton). Copper metal and copper alloys have considerable technological importance due to their combined electrical, mechanical, and physical properties. The discoveries that mixed-valence Cu(II)/Cu(III) oxides exhibit superconductivity (zero electrical resistance) at temperatures as high as 125 K (−234°F; liquid nitrogen, a cheap coolant, boils at 90 K or −297°F) have generated intense international competition to understand these new materials and to develop technological applications. Although some pure copper metal is present in nature, commercial copper is obtained by reduction of the copper compounds in ores followed by electrolytic refining. The rich chemistry of copper is restricted mostly to the valence states Cu(I) and Cu(II); compounds containing Cu(0), Cu(III), and Cu(IV) are uncommon. Soluble copper salts are potent bacteriocides and algicides at low levels and toxic to humans in large doses. Yet copper is an essential trace element that is present in various metalloproteins required for the survival of plants and animals. *See* Copper alloys.

Copper is located in the periodic table between nickel and zinc in the first row of transition elements and in the same subgroup as the other so-called coinage metals, silver and gold. The electronic configuration of elemental copper is $[1s^2 2s^2 2p^6 3s^2]\ 3d^{10}4s^1$ or $[\mathrm{argon}]3d^{10}4s^1$. At first glance, the sole $4s$ electron might suggest chemical similarity to potassium, which has the $[\mathrm{argon}]4s^1$ configuration. However, metallic copper, in sharp contrast to metallic potassium, is relatively unreactive. The higher nuclear charge of copper relative to that of potassium is not fully shielded by the 10 additional *d* electrons, with the result that the copper 4*s* electron has a higher ionization potential than that of potassium (745.5 versus 418.9 kilojoules/mole, respectively). Moreover, the second and third ionization potentials of copper (1958.1 and 3554 J/mole, respectively) are considerably lower than those of potassium, and account for the higher valence-state accessibility associated with transition-metal chemistry as opposed to alkali-metal chemistry. *See* Periodic table; Transition elements; Valence.

Copper is a comparatively heavy metal. The density of the pure solid is 8.96 g/cm^3 (5.18 oz/in.^{3}) at 20°C (68°F). The density of commercial copper varies with method of manufacture, averaging 8.90–8.92 g/cm^3 (5.14–5.16 oz/in.^{3}) in cast refinery shapes, 8.93 g/cm^3 (5.16 oz/in.^{3}) for annealed tough-pitch copper, and 8.94 g/cm^3 (517 oz/in.^{3}) for oxygen-free copper. The density of liquid copper is 8.22 g/cm^3 (4.75 oz/in.^{3}) near the freezing point.

The melting point of copper is 1083.0 ∓ 0.1°C (1981.4 ∓ 0.2°F). Its normal boiling point is 2595°C (4703°F).

The coefficient of linear expansion of copper is 1.65×10^{-5}/°C at 20°C.

The specific heat of the solid is 0.092 cal/g at 20°C (68°F). The specific heat of liquid copper is 0.112 cal/ g, and of copper in the vapor state about 0.08 cal/g.

The electrical resistivity of copper in the usual volumetric unit, that of a cube measuring 1 cm in each direction, is 1.6730×10^{-6} ohm · cm at 20°C (68°F). Only silver has a greater volumetric conductivity than copper. On a relative basis in which silver is rated 100, copper is 94, aluminum 57, and iron 16.

The mass resistivity of pure copper for a length of 1 m weighing 1 g at 20°C (68°F) is 0.14983 ohm. The conductivity of copper on the mass basis is surpassed by several light metals, notably aluminum. The relative values are 100 for aluminum, 50 for copper, and 44 for silver.

By far the largest use of copper is in the electrical industry, and therefore high electrical conductivity is its most important single property, although for industrial use this property must be accompanied by suitable characteristics in other respects. *See* Conductor (electricity); Electrical conductivity of metals.

Copper-containing proteins provide diverse biochemical functions, including copper uptake and transport (ceruloplasmin), copper storage (metallothionen), protective roles (superoxide dismutase), catalysis of substrate oxygenation (dopamine β-monooxygenase), biosynthesis of connective tissue (lysyl oxidase), terminal oxidases for oxygen metabolism (cytochrome *c* oxidase), oxygen transport (hemocyanin), and electron transfer in photosynthetic pathways (plastocyanin). *See* Biorganic chemistry; Enzyme. [H.Sc.]

Copper alloys Solid solutions of one or more metals in copper. Many metals, although not all, alloy with copper to form solid solutions. Some insoluble metals and nonmetals are intentionally added to copper alloy to enhance certain characteristics. *See* Solid solution.

Copper alloys form a group of materials of major commercial importance because they are characterized by such useful mechanical properties as high ductility and formability and excellent corrosion resistance. Copper alloys are easily joined by soldering and brazing. Like gold alloys, copper alloys have decorative red, pink, yellow, and white colors. Copper has the second highest electrical and thermal conductivity of any metal. All these factors make copper alloys suitable for a wide variety of products.

Copper and zinc melted together in various proportions produce one of the most useful groups of copper alloys, known as the brasses. Brasses containing 5–40% zinc constitute the largest volume of copper alloys. One important alloy, cartridge brass (70% copper, 30% zinc), has innumerable uses, including cartridge cases, automotive radiator cores and tanks, lighting fixtures, eyelets, rivets, screws, springs, and plumbing products.

Lead is added to both copper and the brasses, forming an insoluble phase which improves machinability of the material. Free cutting brass (61% copper, 3% lead, 36% zinc) is the most important alloy in the group. It is machined into parts on high-speed (10,000 rpm) automatic screw machines for a multiplicity of uses. Increased strength and corrosion resistance are obtained by adding up to 2% tin or aluminum to various brasses.

Alloys of copper, nickel, and zinc are called nickel silvers. Nickel is added to the copper-zinc alloys primarily because of its influence upon the color of the resulting alloys; color ranges from yellowish-white, to white with a yellowish tinge, to white. Because of their tarnish resistance, these alloys are used for table flatware, zippers, camera parts, costume jewelry, nameplates, and some electrical switch gear.

Three copper-base alloys containing 10%, 20%, and 30% nickel, with small amounts of manganese and iron added to enhance casting qualities and corrosion resistance, have gained commercial importance. These alloys are known as cupronic-kels and are well suited for application in industrial and marine installations as condenser and heat-exchanger tubing because of their high corrosion resistance and particular resistance to impingement attack.

Copper-tin alloys (3–10% tin), deoxidized with phosphorus, form an important group known as phosphorus bronzes. Tin increases strength, hardness, and corrosion resistance. These alloys are widely used for springs and screens in papermaking machines. *See* ALLOY; COPPER. [R.E.R.]

Copper loss The power loss due to the flow of current through copper conductors. When an electric current flows through a copper conductor (or any conductor), some energy is converted to heat. The heat, in turn, causes the operating temperature of the device to rise. This happens in transformers, generators, motors, relays, and transmission lines, and is a principal limitation on the conditions of operation of these devices. Excessive temperature rises lead to equipment failure.

Much research has been undertaken to reduce the loss in machines and thus to increase the output capability and efficiency for a given amount of conductor. For large machines and for transmission lines, the concept of superconductivity appears to hold much promise for substantial improvements in operating efficiencies. *See* SUPERCONDUCTING DEVICES. [E.C.Jo.]

Copper metallurgy The economic production of pure copper metal, suitable for fabrication and use, from copper ores containing as little as 0.5% Cu. Over 90% of the consumption of primary copper in the Western world is produced from ores containing sulfide minerals (chalcopyrite, $CuFeS_2$; chalcocite, Cu_2S; and bornite, Cu_5FeS_4) that can be economically treated only by pyrometallurgical processes. *See* PYROMETALLURGY, NONFERROUS.

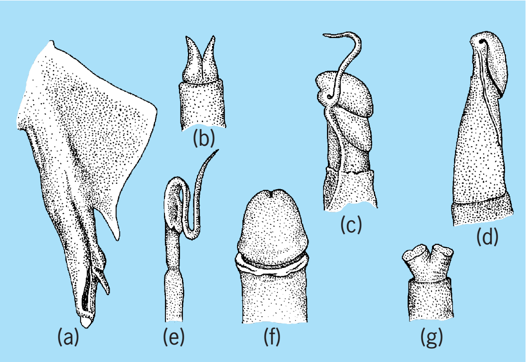
In the main processes used in the production of copper from sulfide ores, the mined ore (0.5–2.0% Cu) is finely ground, and then concentrated by flotation to form copper concentrates containing 20–30% Cu. The concentrates are then smelted at high temperatures (about 2280°F or 1250°C) to form a molten mixture of copper and iron sulfides called matte. The molten matte is converted to blister copper (about 99% Cu) by oxidizing the remaining iron and sulfur. After removing the residual sulfur and oxygen in an anode furnace, copper anodes are cast and then refined electrolytically to produce high-purity cathode copper (99.99% Cu), which is suitable for most uses. *See* ORE DRESSING.

Smelting and converting a typical copper concentrate generates over 0.50 ton SO_2 per ton concentrate (0.50 metric ton SO_2 per metric ton concentrate), and the resulting SO_2 emissions must be controlled to meet local environmental standards. This is generally achieved by converting the SO_2 to sulfuric acid in a contact acid plant, as long as the SO_2 concentration exceeds 4% and a viable market for acid exists. *See* SULFUR.

Electrorefining is used to remove the remaining impurities in the anode copper (principally As, Bi, Ni, Pb, Sb, and Se) and produce a pure cathode copper (99.99+% Cu). Also, many copper ores contain appreciable amounts of precious metals (Ag, Au, Pt, and so on), which are concentrated into the anode copper during smelting and are recovered as valuable by-products in electrorefining. The impure anodes are suspended alternately with pure copper cathodes in tanks through which an electrolyte of copper sulfate and free sulfuric acid is continuously circulated. When direct current is applied, the copper in the anodes is electrochemically dissolved and then plated as pure copper on the cathodes. Some of the anode impurities, such as arsenic and nickel, are less noble than copper and dissolve in the electrolyte, but they do not plate out at the cathode as long as their concentrations are controlled. The other impurities, such as silver, lead, and selenium, are virtually insoluble in the electrolyte and fall as slimes to the bottom of the tank. These slimes are recovered and processed for eventual recovery of selenium and the precious-metal values. *See* ELECTROCHEMICAL PROCESS; ELECTROMETALLURGY.

Oxidized copper ores are more effectively treated by hydrometallurgical processes. The ore is crushed, ground if necessary, and leached with dilute sulfuric acid, either by percolation through heaps of ore or by agitation in tanks. Copper is recovered from the resulting solution by either cementation or solvent extraction-electrowinning. In cementation, copper is precipitated by contact with scrap iron to form an impure cement copper, which is smelted, then refined. Solvent extraction-electrowinning has become the preferred process. In solvent extraction special organic reagents are used to selectively extract copper from solution. The resulting copper-containing organic phase is then stripped to give a pure and more concentrated aqueous copper solution for electrowinning. Electrowinning is similar to electrorefining except that an inert anode is used and more energy is required. Although electrowon cathode copper is generally not as pure as electrorefined copper, it is still suitable for many applications. *See* COPPER; HYDROMETALLURGY; SOLVENT EXTRACTION. [J.G.Pe.]

Copulatory organ An organ utilized by certain male vertebrates for insemination, that is, to deposit spermatozoa directly into the female reproductive tract. In fish, internal fertilization is restricted to certain groups. The pelvic fin of male elasmobranchs and holocephalians is modified for the transmission of sperm and is known as the clasper or clasping organ. A pair of anterior claspers (illus. *a*) and a frontal clasper which protrudes from the head occur among holocephalians in addition to the modified pelvic clasper of elasmobranchs. The anal fin of teleosts, in which copulation occurs, may be elongated to form a gonopodium.



Vertebrate copulatory organs. (*a*) Clasper of dogfish (*Squalus*). Glans penis of (*b*) opossum, (*c*) ram, (*d*) bull, (*e*) short-tailed shrew, (*f*) man, (*g*) Echidna.

Hemipenes which can be everted during copulation are common to both snakes and lizards; however, these structures lack erectile tissue. Turtles and crocodiles possess a single penis with associated erectile tissue, the corpora cavernosa, which becomes distended with blood. A few species of birds have a penis; among these are the ostriches and anseriforms. The penis is present in all mammals.

The copulatory organ (illus. *b*–*g*) is variously modified morphologically. Among certain mammals such as rodents, bats, whales, some carnivores, and lower primates, a penis bone, the os priapi or baculum, occurs, increasing the rigidity of the penis. *See* PENIS. [C.B.C.]

Coquina A calcarenite or clastic limestone whose detrital particles are chiefly fossils, whole or fragmented. The term is most frequently used for an aggregate of large shells more or less cemented by calcite. If the rock consists of fine-sized shell debris, it is called a microcoquina. Some coquinas show little evidence of any transportation by currents. *See* LIMESTONE. [R.S.]

Coraciiformes A diverse order of land birds that is found mainly in the tropics. The relationships of these families have been disputed, with no resolution; the closest affinities may be with other land birds, such as the Piciformes and Passeriformes. *See* PASSERIFORMES; PICIFORMES.

The Coraciiformes are divided into four suborders and families: Alcedines, including the families Alcedinidae (kingfishers; 91 species), Todidae (todies; 5 species), and Momotidae (motmots; 9 species); Meropes, with the single family Meropidae (bee-eaters; 24 species); Coracii, containing the families Coraciidae (rollers; 11 species), Brachypteraciidae (ground-rollers; 5 species), Leptosomatidae (cuckoo-rollers; 1 species), Upupidae (hoopoes; 1 species), and Phoeniculidae (wood hoopoes; 8 species); and Bucerotes, with the single family Bucerotidae (hornbills; 45 species). Several of these families, such as the different groups of rollers, are sometimes merged into a single family, and several families, such as the kingfishers and hornbills, are divided into subfamilies.

Coraciiform birds are characterized by a syndactyl foot in which the three anterior toes are joined together at the base, although the cuckoo rollers have a zygodactyl foot. Most groups are tropical or warm temperate and are brilliantly colored. Except for bee eaters and wood hoopoes, coraciiforms are generally solitary. Most temperate species are migratory; the tropical ones are permanent residents. Most coraciiforms feed on insects and other animal prey, including fish; hornbills are omnivorous and some feed mainly on fruit. All nest, either solitarily or in colonies in holes burrowed in earthern banks or in tree cavities. *See* AVES. [W.J.B.]

Corallimorpharia An order of the subclass Zoantharia or Hexacorallia. These sea anemones resemble corals in their weak musculature, capitate (spherically tipped) tentacles, and complex nematocysts. They do not possess a skeleton, however. The tentacles are arranged in radial rows, not cycles, on the disk, and the base has no musculature. The group occurs in shallow water from the temperate zone to the tropics. The species are solitary, although they may occur in large, asexually produced aggregations. Examples are *Corallimorphus* and *Corynactis*. *See* ANTHOZOA. [C.H.]

Corallinales An order of red algae (Rhodophyceae), commonly called coralline algae. Only one family is recognized, the Corallinaceae, which formerly was assigned to the order Cryptonemiales. These algae are distinguished by the impregnation of cell walls with calcite, a form of calcium carbonate, which causes the thallus to be stony or brittle. *See* RHODOPHYCEAE.

Coralline algae, comprising about 40 genera and 500 species, are widespread, abundant, and ecologically important. They are divisible into two groups on the basis of the presence or absence of uncalcified, moderately flexible joints (genicula) between calcified segments (intergenicula). The most simple nonarticulated coralline algae are individual crusts of varying extent and thickness (to 8 in. or 20 cm thick). These often become confluent and cover large expanses of substrate. Many crusts bear rounded or pointed, branched or unbranched protuberances that can break off and continue to grow as free nodules known collectively as maerl.

Coralline algae are exclusively marine, although some species can tolerate a reduction in salinity to 13 parts per thousand. Some species thrive only where light is intense, as at the crest of a coral reef, while others grow only in shaded habitats or in deep water. Most species require constant immersion.

The ecosystem in which coralline algae are most important is the coral reef, where they are primary producers, adding carbon to the ecosystem, adding new material to the reefs, and cementing together other calcareous organisms. They have been engaged in similar activities through the millennia, with modern genera recognizable in limestones at least as old as 150 million years (Jurassic). [P.C.Si.; R.L.Moe]

Corbino disk A conducting disk with concentric inner and outer electrical contacts, which can be placed in a magnetic field parallel to its axis. In zero applied field the lines of current are simply radial, but in the presence of an axial magnetic field they lengthen by spiraling. This spiraling occurs because the geometry of the disk is such that the Lorentz force acting on the charge carriers is not counterbalanced by a Hall-effect electric field. The resistance of the disk increases as the field increases, largely as a result of the geometrical magnetoresistance effect associated with the lengthening of the current path. Corbino disks have been used only rarely in practical devices since they have a low overall resistance and correspondingly large power dissipation. *See* HALL EFFECT; MAGNETORESISTANCE. [J.F.He.]

Cordaitales An extinct order of the class Pinopsida comprising a natural grouping of Paleozoic forest trees or shrubs that first appeared in the Lower Pennsylvanian. They became an important component of the tropical vegetation during the Middle and Upper Pennsylvanian and diminished during the basal Permian. The Cordaitales were divided into three families, Cordaitaceae, Pityaceae, and Poroxylaceae. However, members of the Pityaceae and Poroxylaceae are now known to be either seed ferns or progymnosperms, so only the Cordaitaceae remain. Detailed information about these prominent Paleozoic gymnosperms comes from impression-compression fossils and sandstone casts. However, coal balls, which are mineral nodules in which the plants are preserved with three-dimensional anatomy, have been essential to establishing whole-plant concepts of cordaitean species. *See* COAL BALLS; PALEOBOTANY. [M.L.T.]

Cordierite An orthorhombic magnesium aluminosilicate mineral of composition $Mg_2[Al_4Si_5O_{18}]$. The crystal structure is related to beryl. Limited amounts of Fe^{2+} may substitute for Mg^{2+}, and Fe^{3+} for Al^{3+}. The hardness is 7 (Mohs scale); specific gravity 2.6; luster vitreous; cleavage poor; and color greenish-blue, lilac blue, or dark blue, often strongly pleochroic colorless to deep blue. Transparent pleochroic crystals are used as gem material. The disordered cordierite structure, $Mg_2[(Al,Si)_9O_{18}]$, is called indialite and is hexagonal, isotypic with beryl. Osumilite, $KMg_2Al_3[(Al,Si)_{12}O_{30}] \cdot H_2O$, is also related but has a structure built of double six-membered rings of tetrahedrons. Cordierite, indialite, and osumilite are difficult to distinguish. Pale colored varieties are often misidentified as quartz, since these minerals have many physical properties in common. *See* BERYL; SILICATE MINERALS.

Cordierite possesses unusually low thermal expansion, and synthetic material has been applied to thermal-shock-resistant materials, such as insulators for spark plugs and low-expansion concrete.

Cordierite frequently occurs associated with thermally metamorphosed rocks derived from argillaceous sediments. It may occur in aluminous schists, gneisses, and granulites; though usually appearing in minor amounts, cordierite occurs at many localities throughout the world. [P.B.M.]

Cordilleran belt A mountain belt or chain which is an assemblage of individual mountain ranges and associated plateaus and intermontane lowlands. A cordillera is usually of continental extent and linear trend; component elements may trend at angles to its length or be nonlinear.

The term cordillera is most frequently used in reference to the mountainous regions of western South and North America, which lie between the Pacific Ocean and interior lowlands to the east. Farther north, the extensive and geologically diverse mountain terrane of western North America is formally known as the Cordilleran belt or orogen. This belt includes such contrasting elements within the United States as the Sierra Nevada, Central Valley of California, Cascade Range, Basin and Range

Province, Colorado Plateau, and Rocky Mountains. *See* MOUNTAIN SYSTEMS.

Cordilleras represent zones of intense deformation of the Earth's crust produced by the convergence and interaction of large, relatively stable areas known as plates. Mountain belts have been analyzed in terms of different modes of plate convergence. Cordilleran-type mountain belts, such as the North American Cordillera, are contrasted with collision-type belts, such as the Himalayas. The former develop during long-term convergence of an oceanic plate toward and beneath a continental plate, whereas the latter are produced by the convergence and collision of one continental plate with another or with an island arc. Characteristics of cordilleran-type mountain belts include their position along a continental margin, their widespread volcanic and plutonic igneous activity, and their tendency to be bordered on both sides by zones of low-angle thrust faulting directed away from the axis of the belt. *See* OROGENY. [G.A.D.]

Core loss The rate of energy conversion into heat in a magnetic material due to the presence of an alternating or pulsating magnetic field. It may be subdivided into two principal components, hysteresis loss and eddy-current loss. *See* EDDY CURRENT.

The energy consumed in magnetizing and demagnetizing magnetic material is called the hysteresis loss. It is proportional to the frequency and to the area inside the hysteresis loop for the material used. Most rotating machines are stacked with silicon steel laminations, which have low hysteresis losses. The cores of large units are sometimes built up with cold-reduced, grain-oriented, silicon iron punchings having exceptionally low hysteresis loss, as well as high permeability when magnetized along the direction of rolling. *See* MAGNETIZATION.

Induced currents flow within the magnetic material because of variations in the flux; this is called eddy-current loss. For 60-cycle rotating machines, core laminations of 0.014–0.018 in. (0.35–0.45 mm) are usually used to reduce this eddy-current loss. *See* ELECTRIC ROTATING MACHINERY. [L.T.R.]

Coriander A strong-scented annual herb. Coriander is cultivated in many places throughout the world for both seeds and leaves. The two forms are quite different in taste from one another, and both are used for flavor in a variety of foods. Only one species, *Coriandrum sativum*, is cultivated. Coriander is a member of the carrot family, Apiaceae (Umbelliferae), and is closely related to other spice seed plants such as cumin, caraway, anise, dill, and fennel. A number of distinct cultivars have been developed. Some, with longer maturity times and resulting higher leaf yield, are grown for cilantro, also called Chinese parsley. *See* APIALES; SPICE AND FLAVORING. [S.Kir.]

Coriolis acceleration An acceleration which arises as a result of motion of a particle relative to a rotating system. Only the components of motion in a plane parallel to the equatorial plane are influenced. Coriolis accelerations are important to the circulation of planetary atmospheres, and also in ballistics. *See* ACCELERATION; BALLISTICS.

Newton's second law of motion is valid only when the motions and accelerations are those observed in a coordinate system that is not itself accelerating, that is, an inertial reference frame. In order to utilize familiar concepts in mathematical treatment, the Earth is commonly treated as if it were fixed, as it appears to one observing from a point on the surface, and the Coriolis force is introduced to balance the acceleration observed by virtue of the observer's motion in the rotating frame. As with the influenced components of motion, the Coriolis force is directed perpendicularly to the Earth's axis, that is, in a plane parallel to the equatorial plane. Since the direction of its action is also perpendicular to the particle velocity itself, the Coriolis force affects only the direction of motion, not the speed. This is the basis for referring to it as the deflecting force of the Earth's rotation.

A simple illustration of a Coriolis effect in the Northern Hemisphere is afforded by a turntable in counterclockwise rotation, and an external observer who moves a marker steadily in a straight line from the axis to the rim of the turntable. The trace on the turntable is a right-turning curve, and obviously this is also the nature of the path apparent to an observer who rotates with the table. Now consider the contrasting case of an air parcel near the North Pole that moves directly south (away from the Earth's axis of rotation) so that its motion to an observer on the Earth is in a straight line. To a nonrotating observer in space, this same motion appears curved toward the east because of the increased linear velocity of the meridian at lower latitudes. The force necessary to produce the eastward acceleration in the inertial frame is equal to the Coriolis force and would be produced by a gradient of air pressure from west to east, and shown by north-south-oriented isobars. In the absence of the pressure gradient force, the Coriolis force would cause the trajectory of the southward-moving air to curve westward on the Earth's surface. Then an air parcel moving uniformly away from the North Pole along a line which appears straight to an observer in space would appear to earthbound observers to curve westward. *See* GEOSTROPHIC WIND; ISOBAR (METEOROLOGY). [E.Ke.]

Corn *Zea mays* occupies a larger area than any other grain crop in the United States, where 60% of the world production is grown. Although corn is grown in the United States primarily for livestock feed, about 10% is used for the manufacture of starch, sugar, corn meal, breakfast cereals, oil, alcohol, and several other specialized products. In many tropical countries, corn is used primarily for human consumption.

As a crop. The origin of corn is still unsettled, but the most widely held hypothesis assumes that corn developed from its wild relative teosinte (*Z. mexicana*) through a combination of favorable mutations, recognized and selectively propagated by early humans. Corn migrated from its center of origin, presumed to be Mexico or Central America, and was being cultivated by the Indians as far north as New England upon the arrival of the first European colonists, whose survival was due largely to the use of corn as food.

Botanically, corn is a member of the grass family. Each form (botanical variety) is conditioned by fairly few genetic differences, and each may exhibit the full range of differences in color, plant type, maturity, and so on, characteristic of the species. All types have the same number of chromosomes (10 pairs), and all may be intercrossed to produce fertile progeny. Dent corns are the most important in the United States. Sweet corn is grown more extensively in the United States than in any other country. It is eaten as fresh corn or canned or frozen. In other countries, flint, dent, or flour corns may be eaten fresh, but at a much more mature stage than the sweet corn eaten in the United States. The commercial production of popcorn is almost exclusively American. *See* CYPERALES; GENETICS; REPRODUCTION (PLANT).

Corn is a cross-pollinated plant; the staminate (male) and pistillate (female) inflorescences (flower clusters) are borne on separate parts of the same plant (see illustration). Plants of this type are called monoecious. The staminate inflorescence is the tassel; it produces pollen that is carried by the wind to the silks produced on the ears.

The development of varieties and strains of corn made possible the extension of its culture under diverse soil and climatic conditions. However, modern research methods led to the present widespread use of hybrid corn. Hybrid corn is the first generation of cross involving inbred lines. Inbred lines are developed by controlled self-pollination. When continued for several generations, self-pollination leads to reduction in vigor but permits the isolation of types which are genetically pure or homozygous. Intense

A corn plant in full tassel and silk. The tassel produces pollen that is blown by wind to the silks. (*Courtesy of J. W. McManigal*)

selection is practiced during the inbreeding phase to identify and maintain genotypes having the desired plant and ear type and maturity characteristics, and relative freedom from insect and disease attacks. Crosses involving any two unrelated lines will exhibit heterosis, that is, yields above the means of the two parents. *See* BREEDING (PLANT); HETEROSIS.

Planting dates depend upon temperature and soil conditions. Germination is very slow at soil temperatures of 50°F (10°C), and seedling growth is limited at temperatures of 60°F (16°C) or below. Planting rates are influenced by water supply, soil type, and fertility and by the maturity characteristics of the hybrid grown. With planting rates above 16,000 plants per acre (40,000 per hectare), drilling in rows 24–36 in. (60–90 cm) apart has become common practice. The use of nitrogen fertilizer has increased greatly; lesser amounts of phosphorus and potash are applied as needed. *See* AGRICULTURAL SOIL AND CROP PRACTICES.

In the 1930s most corn was husked by hand, and the ears were stored in slatted cribs. The mechanical picker supplanted hand harvesting. The mechanical picker, in turn, has been replaced by the picker-sheller or corn combine, which harvests the crop as shelled grain. When harvested as shelled grain, at a relatively high moisture content (20–30%), the grain must be dried artificially for safe storage. High-moisture corn to be used for livestock feed may be stored in airtight silos or may be treated with certain chemical preservatives such as propionic acid. Corn stored under either of these systems is not suitable either for industrial processing or for seed. *See* AGRICULTURAL MACHINERY. [G.F.S.]

Corn is highly productive largely because it can use solar energy so efficiently. The corn plant grows vegetatively until about silking, after which all weight increase is in the form of grain. Almost the entire grain yield results from photosynthesis during the grain growth period, which runs from silking to maturity. Contrary to much popular opinion, grain yields are highest under cool conditions, when the lengthened grain growth period more than compensates for the slower growth rate. Relationships among solar radiation, temperature, growing-season length, soil moisture, day length, soil fertility, and corn genotype in producing grain yields are complex and not well understood. Attempts to study the system as a whole, using simulation models on digital computers, may add considerably to knowledge of the subject. [W.G.D.]

Processing. Corn kernels (seeds) are subjected to both wet and dry milling. The goal of both processes is to separate the germ, the endosperm, and the pericarp (hull).

Wet milling separates the chemical constituents of corn into starch, protein, oil, and fiber fractions, the primary objective being to produce refined corn starch. Worldwide, the production of nutritive sweeteners is the largest use for the starch obtained from corn. The manufacture of corn sweeteners begins with the wet milling process. The starch is first cooked, or pasted. Then, the starch polymers are hydrolyzed (depolymerized) using an acid, an enzyme, a combination of enzymes, or an acid-enzyme combination. The resulting solutions are refined and concentrated to 70–80% solids. These syrups are known worldwide as glucose syrups, but in the United States are often called corn syrups. When starch is completely hydrolyzed, that is, converted into its monomer units, the only product is D-glucose (dextrose), which can be crystallized from concentrated solutions. Isomerization of some of the D-glucose in a high-glucose hydrolyzate to D-fructose produces high-fructose corn syrups (HFCS), which are known simply as high-fructose syrups (HFS) outside the United States. Fructose is approximately 20% sweeter than sucrose on an equal weight basis.

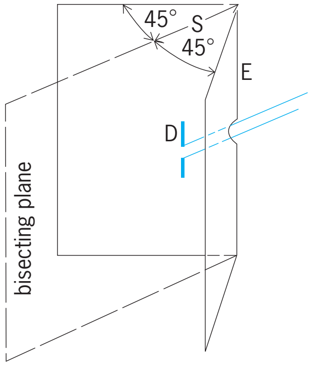
Corn starch is less extensively depolymerized to make products other than sweeteners. Very slight hydrolysis makes products known as acid-modified or thin-boiling starches. A little more modification with an acid produces dextrins. One application is as remoistenable adhesives on envelopes. Hydrolysis catalyzed by acid or enzymes produces starch oligomers, which are known as maltooligosaccharides or maltodextrins. Maltodextrins are used extensively in foods for their bulking and binding properties and the protection they give to frozen foods. Hydrolysis gives mixtures of breakdown products that, when dried, are known as corn syrup solids. Corn syrup solids dissolve rapidly, are mildly sweet, and are used as bulking materials in food.

Most of the processing of dry-milled corn is done by tempering-degerming systems. Cleaned kernels are transferred to a tempering bin, where they are held for various times at various temperatures depending on the miller and the desired product. Tempered kernels are passed through a degerminator, which removes the bran (pericarp) and germ while leaving the endosperm intact. The endosperm may be converted into as many as 16 different fractions. The main products are regular grits, coarse grits, flaking grits, and corn flour. Other products are corn cones and corn meal.

Nixtamalization is the process of cooking and soaking corn kernels in water containing calcium hydroxide (lime) to soften the pericarp and hydrate the protein matrix and starch of the endosperm. The cooked, steeped product, called nixtamal, is then ground, using stone attrition mills. The product, masa, is sheeted, cut into pieces, and baked, producing tortillas, tortilla chips, taco shells, and corn chips. *See* FOOD ENGINEERING; FOOD MANUFACTURING. [J.N.BeM.]

Cornales An order of flowering plants, division Magnoliophyta (Angiospermae), in the superordinal Asteridae group of Eudicotyledon. The order consists of 5 families (Cornaceae, Grubbiaceae, Hydrangeaceae, Hydrostachyaceae, and Loasaceae), approximately 50 genera, and about 600 species. The order is mostly characterized by opposite leaves and flowers with four or five perianth parts that usually grow from the top of the ovary (epigynous). The fruit is either a fleshy berry or dehiscent capsule. The various species of dogwoods (*Cornus*) and sour gum (*Nyssa sylvatica*, family Cornaceae) are well known. Various species of Hydrangeaceae (deutzia, hydrangea, mock-orange) are important cultivated shrubs. *See* ASTERIDAE; DOGWOOD; PLANT KINGDOM; TUPELO. [K.J.Sy.]

Corner reflector antenna A directional antenna consisting of the combination of a reflector comprising two conducting planes forming a dihedral angle and a driven radiator or dipole which usually is in the bisecting plane (see illustration). It is widely used both singly and in arrays, gives good gain in comparison with cost, and covers a relatively wide band of frequency. The distance *S* from the driven radiator *D* to edge *E* need not be critically chosen with respect to wavelength. *See* ANTENNA (ELECTROMAGNETISM). [J.C.S.]



A 90° corner reflector antenna.

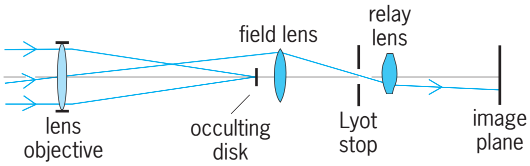
Corona discharge A type of electrical conduction that generally occurs at or near atmospheric pressure in gases. A relatively strong electric field is needed. External manifestations are the emission of light and a hissing sound. The particular characteristics of the discharge are determined by the shape of the electrodes, the polarity, the size of the gap, and the gas or gas mixture. *See* ELECTRICAL CONDUCTION IN GASES.

In some cases corona discharge may be desirable and useful, whereas in others it is harmful and attempts are made to minimize it. The effect is used for voltage division and control in direct-current nuclear particle accelerators. On the other hand, the corona discharge that surrounds a high-potential power transmission line represents a power loss and limits the maximum potential which can be used. Because the power loss due to Joule heating decreases as the potential difference is increased, it is desirable to use the maximum possible voltage.

In the potential current characteristic, the corona region is found above the dark current region and is field-sustained. Near the upper end it goes into a glow discharge or a brush discharge, depending on pressure. Higher pressure favors the brush discharge. *See* GLOW DISCHARGE.

For still higher potential difference, breakdown occurs and a continuously ionized path forms. *See* ELECTRIC SPARK. [G.H.M.]

Coronagraph A specialized astronomical telescope substantially free from instrumentally scattered light, used to observe the solar corona, the faint atmosphere surrounding the Sun. Coronagraphs can record the emission component of the corona (spectral lines emitted by high-temperature ions surrounding the Sun) and the white-light component (solar photospheric light scattered by free electrons surrounding the Sun) routinely from high mountain sites under clear sky conditions. The emission and white-light components are typically only a few millionths the brightness of the Sun itself. Hence, the corona is difficult to observe unless the direct solar light is completely rejected, and unless instrumentally diffracted and scattered light that reaches the final image plane of the coronagraph is small relative to the coronal light. *See* SOLAR CORONA; SUN.

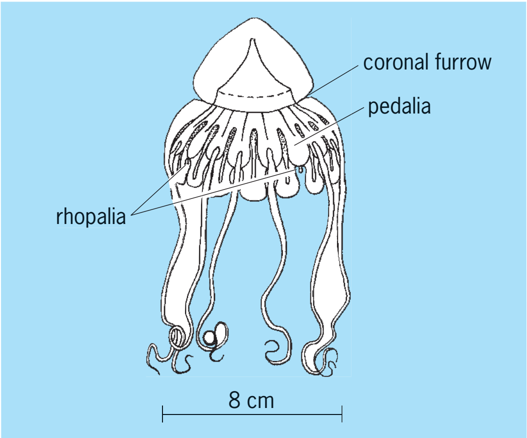


Basic designs of Lyot coronagraph with lens objective.

The basic design (see illustration), as invented by B. Lyot, has an occulting disk in the primary image plane of the telescope to block the image of the Sun itself. In addition, the primary objective (a lens or superpolished mirror) is specially fabricated to minimize scattered light. Also, light diffracted by the objective rim must be suppressed. For this, an aperture (Lyot stop) is placed at an image of the objective as produced by a field lens, with the aperture diameter slightly smaller than that of the objective image. A relay lens behind the Lyot stop forms the coronal image at the final image plane.

The development of superpolished mirror technology allowed the construction of coronagraphs based on mirror objectives, with significant advantages compared with the singlet-lens objectives used in traditional Lyot coronagraphs. [R.N.Sm.]

Coronatae An order of the class Scyphozoa which includes mainly abyssal species. The exumbrella is divided by a circular or coronal furrow into two parts, an upper central disk and a lower coronal part. The central disk is usually domelike, but in *Periphylla* (see illustration) it often narrows toward the top. The coronal part has gelatinous thickenings (pedalia) situated on the radii running from the center of the umbrella to the tentacles and the sensory organs. The pedalia are separated from one another by clefts, running down the radii, that are half-way between each tentacle and rhopalium (a sensory organ). Abyssal forms of this group are dark brown or reddish-purple. The littoral species of *Nausithoë* is reported to show alternation of generations, but the life history of abyssal forms remains unknown. *See* SCYPHOZOA. [T.U.]



***Periphylla*. (*After L. H. Hyman, The Invertebrates, vol. 1, McGraw-Hill, 1940*)**

Coronoidea A small class of “arm”- and brachiole-bearing, stemmed echinoderms in the subphylum Crinozoa, based on five genera known from the Middle Ordovician to Late Silurian of Europe and North America. Coronoids have a crested theca or body with well-developed pentameral symmetry and plate arrangement very similar to that found in blastoids. A thin stem supported the theca above the sea floor, allowing coronoids to live as attached, low- to medium-level suspension feeders. Coronoids had previously been assigned to the blastoids, eocrinoids, or crinoids by different researchers, but they have been elevated in rank to a separate class. Coronoids appear to be most closely related to the Blastoidea and may have been the ancestors of this class. *See* Blastoidea; Crinozoa; Echinodermata; Eocrinoidea. [J.Sp.]

Correspondence principle A fundamental hypothesis according to which classical mechanics can be understood as a limiting case of quantum mechanics; or conversely, many characteristic features in quantum mechanics can be approximated on the basis of classical mechanics, provided classical mechanics is properly reinterpreted. This idea was first proposed by N. Bohr in the early 1920s as a set of rules for understanding the spectra of simple atoms and molecules.

The classical motions in simple dynamical systems can be understood as composed of independent partial motions, each with its own degree of freedom. Each degree of freedom accumulates its own classical action-integral. The frequency of the classical motion for any particular degree of freedom is given by the partial derivative of the energy function with respect to the corresponding action. Bohr noticed that this classical result yields the correct quantum-theoretical result for the light frequency in a transition from one energy level to another, provided the derivative is replaced by the difference in the energies. Moreover, precise information about the possibility of such transitions and their intensities is obtained by analyzing the related classical motion. This information becomes better as the quantum numbers involved become larger. The apparent inconsistencies in Bohr's quantum theory are thereby overcome by a set of rules that came to be called the correspondence principle. *See* Action.

After 1925, the success of the new quantum mechanics, particularly wave mechanics, reduced the correspondence principle to a somewhat vague article of faith among physicists. However, the appeal to classical mechanics is still convenient for some rather crude estimates such as the total number of levels below a given energy. Such estimates help in finding the approximate shape of large atoms and large nuclei in the Thomas-Fermi model.

The correspondence principle, however, has assumed a more profound significance. Experimental techniques in atomic, molecular, mesoscopic, and nuclear physics have improved dramatically. High-precision data for many thousands of energy levels are available where the traditional methods of quantum mechanics are not very useful or informative. However, the basic idea behind the correspondence principle must still be valid: Quantum mechanics must be understandable in terms of classical mechanics for the highly excited states, even in difficult cases like the three-body problem, where the overall behavior seems unpredictable and chaotic. The wider application of Bohr's correspondence principle allows many basic but difficult problems to be seen in a new light. *See* Atomic structure and spectra; Chaos; Mesoscopic physics; Molecular structure and spectra; Quantum mechanics. [M.C.G.]

Corrosion In broad terms, the interaction between a material and its environment that results in a degradation of the physical, mechanical, or even esthetic properties of that material. More specifically, corrosion is usually associated with a change in the oxidation state of a metal, oxide, or semiconductor.

Electrolytic corrosion consists of two partial processes: an anodic (oxidation) and cathodic (reduction) reaction (see illustration). In the absence of any external voltages, the rates of the anodic and cathodic reactions are equal, and there is no external flow of current. The loss of metal that is the usual manifestation of the corrosion process is a result of the anodic reaction, and can be represented by reaction (1).

$$M \rightarrow M^{n+} + ne^{-} \qquad (1)$$

This reaction represents the oxidation of a metal (M) from the elemental (zero valence) state to an oxidation state of M^{n+} with the generation of *n* moles of electrons (e^{-}). The anodic reaction may occur uniformly over a metal surface or may be localized to a specific area. If the dissolved metal ion can react with the solution to form an insoluble compound, then a buildup of corrosion products may accumulate at the anodic site. *See* Oxidation-reduction.

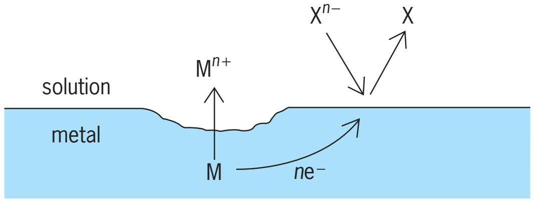


Diagram of a corrosion cell showing the anodic and cathodic partial processes. X^{n-} = cathodic reactant, X = cathodic product, $x^{n-} + ne \rightarrow x$.

In the absence of any applied voltage, the electrons generated by the anodic reaction (1) are consumed by the cathodic reaction. For most practical situations, the cathodic reaction is either the hydrogen-evolution reaction or the oxygen-reduction reaction. The hydrogen-evolution reaction can be summarized as reaction (2).

$$2H^{+} + 2e^{-} \rightarrow H_2 \qquad (2)$$

In this case, protons (H^{+}) combine with electrons to form molecules of hydrogen (H_2). This reaction is often the dominant cathodic reaction in systems at low pH. The hydrogen-evolution reaction can itself cause corrosion-related problems, since atomic hydrogen (H) may enter the metal, causing embrittlement, a phenomenon that results in an attenuation of the mechanical properties and can cause catastrophic failure. *See* Embrittlement.

The second important cathodic reaction is the oxygen-reduction, given by reactions (3) and (4). These represent the

$$O_2 + 4H^{+} + 4e^{-} \rightarrow 2H_2O \qquad (3)$$

$$O_2 + 2H_2O + 4e^{-} \rightarrow 4OH^{-} \qquad (4)$$

overall reactions in acidic and alkaline solutions, respectively. This cathodic reaction is usually dominant in solutions of neutral and alkaline pH. In order for this reaction to proceed, a supply of dissolved oxygen is necessary; hence the rate of this reaction is usually limited by the transport of oxygen to the metal surface.

Reactions (2)–(4) represent the overall reactions which, in practice, may occur by a sequence of reaction steps. In addition, the reaction sequence may be dependent upon the metal surface, resulting in significantly different rates of the overall reaction. The cathodic reactions are important to corrosion processes since many methods of corrosion control depend on altering the cathodic process. Although the cathodic reactions may be related to corrosion processes which are usually unwanted, they are essential for many applications such as energy storage and generation.

Corrosion rates are usually expressed in terms of loss of thickness per unit time. General corrosion rates may vary from on the order of centimeters per year to micrometers per year. Relatively large corrosion rates may be tolerated for some large structures, whereas for other structures small amounts of corrosion may result in catastrophic failure. For example, with the advent of technology for making extremely small devices, future generations of integrated circuits will contain components that are on the order of nanometers (10^{-9} m) in size, and even small amounts of corrosion could cause a device failure.

In some situations, corrosion may occur only at localized regions on a metal surface. This type of corrosion is characterized by regions of locally severe corrosion, although the general loss of thickness may be relatively small.

Pitting corrosion is usually associated with passive metals, although this is not always the case. Pit initiation is usually related to the local breakdown of a passive film and can often be related to the presence of halide ions in solution.

Crevice corrosion occurs in restricted or occluded regions, such as at a bolted joint, and is often associated with solutions that contain halide ions. Crevice corrosion is initiated by a depletion of the dissolved oxygen in the restricted region. As the supply of oxygen within the crevice is depleted, because of cathodic oxygen reduction, the metal surface within the crevice becomes activated, and the anodic current is balanced by cathodic oxygen reduction from the region adjacent to the crevice. The ensuing reactions within the crevice are the same as those described for pitting corrosion: halide ions migrate to the crevice, where they are then hydrolyzed to form metal hydroxides and hydrochloric acid.

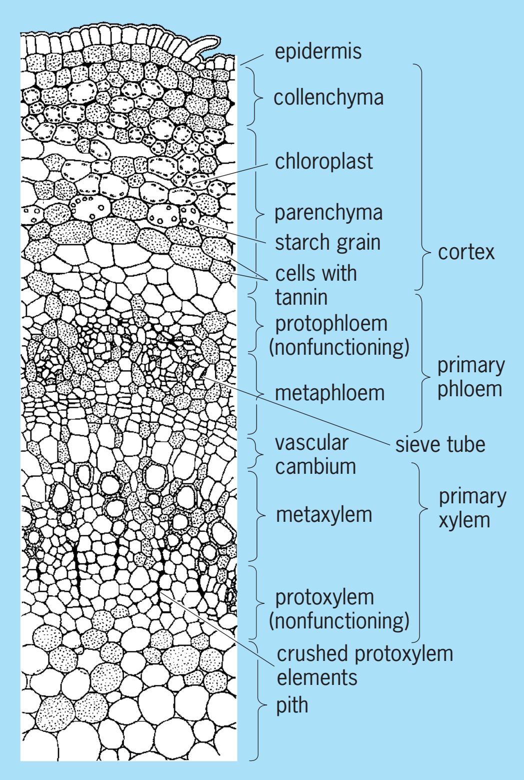
Corrosion can also be accelerated in situations where two dissimilar metals are in contact in the same solution. This form of corrosion is known as galvanic corrosion. The metal with the more negative potential becomes the anode, while the metal with the more positive potential sustains the cathodic reaction. In many cases the table of equilibrium potential can be used to predict which metal of galvanic couple will corrode. For example, aluminum-graphite composites generally exhibit poor corrosion resistance since graphite has a positive potential and aluminum exhibits a highly negative potential. As a result, in corrosive environments the aluminum will tend to corrode while the graphite remains unaffected.

Stress corrosion cracking and hydrogen embrittlement are corrosion-related phenomena associated with the presence of a tensile stress. Stress corrosion cracking results from a combination of stress and specific environmental conditions so that localized corrosion initiates cracks that propagate in the presence of stress. Mild steels are susceptible to stress corrosion cracking in environments containing hydroxyl ions (OH^-; often called caustic cracking) or nitrate ions (NO_3^-). Austenitic stainless steels are susceptible in the presence of chloride ions (Cl^-) and hydroxyl ions (OH^-). Other alloys that are susceptible under specific conditions include certain brasses, aluminum and titanium alloys. Hydrogen embrittlement is caused by the entry of hydrogen atoms into a metal or alloy, resulting in a loss of ductility or cracking if the stress level is sufficiently high. The source of the hydrogen is usually from corrosion (that is, cathodic hydrogen evolution) or from cathodic polarization. In these cases the presence of certain substances in the metal or electrolyte can enhance the amount of hydrogen entry into the alloy by poisoning the formation of molecular hydrogen. Metals and alloys that are susceptible to hydrogen embrittlement include certain carbon steels, high-strength steels, nickel-based alloys, titanium alloys, and some aluminum alloys. *See* ALLOY; STAINLESS STEEL; STEEL.

A reduction in the rate of corrosion is usually achieved through consideration of the materials or the environment. Materials selection is usually determined by economic constraints. The corrosion resistance of a specific metal or alloy may be limited to a certain range of pH, potential, or anion concentration. As a result, replacement metal or alloy systems are usually selected on the basis of cost for an estimated service lifetime. *See* ELECTROCHEMISTRY. [R.M.L.; P.C.Se.]

Cortex (plant) The mass of primary tissue in roots and stems extending inward from the epidermis to the phloem. The cortex may consist of one or a combination of three major tissues: parenchyma, collenchyma, and sclerenchyma. In roots the cortex almost always consists of parenchyma, and is bounded, more or less distinctly, by the hypodermis (exodermis) on the periphery and by the endodermis on the inside.

Cortical parenchyma is composed of loosely arranged thin-walled living cells. Prominent intercellular spaces usually occur in this tissue. In stems the cells of the outer parenchyma may appear green due to the presence of chloroplasts in the cells (see illustration). This green tissue is sometimes called chlorenchyma, and it is probable that photosynthesis takes place in it.



Transverse section of the *Prunus* stem showing the cortex which is composed of collenchyma and parenchyma. (*After K. Esau, Plant Anatomy, 2d ed., 1967*)

In some species the cells of the outer cortex are modified in aerial stems by deposition of hemicellulose as an additional wall substance, especially in the corners or angles of the cells. This tissue is called collenchyma, and the thickening of the cell walls gives mechanical support to the shoot.

The cortex makes up a considerable proportion of the volume of the root, particularly in young roots, where it functions in the transport of water and ions from the epidermis to the vascular (xylem and phloem) tissues. In older roots it functions primarily as a storage tissue.

In addition to being supportive and protective, the cortex functions in the synthesis and localization of many chemical substances; it is one of the most fundamental storage tissues in the plant. The kinds of cortical cells specialized with regard to storage and synthesis are numerous.

Because the living protoplasts of the cortex are so highly specialized, patterns and gradients of many substances occur within the cortex, including starch, tannins, glucosides, organic acids, crystals of many kinds, and alkaloids. Oil cavities, resin ducts, and laticifers (latex ducts) are also common in the midcortex of many plants. [D.S.V.F.]

Corundum A mineral with the ideal composition Al_2O_3. It is one of a large group of isostructural compounds including hematite (Fe_2O_3) and ilmenite ($FeTiO_3$), all of which crystallize in the hexagonal crystal system, trigonal subsystem. Corundum has the high hardness of 9 on Mohs scale and is therefore commonly used as an abrasive, either alone or in the form of the rock called emery, which consists principally of the minerals corundum and magnetite. Crystals occurring in igneous rocks usually have an elongated barrellike shape, while crystals from metamorphic rocks are generally tabular. The specific gravity is approximately 3.98. *See* HEMATITE; ILMENITE.

Pure corundum is transparent and colorless, but most specimens contain some transition elements substituting for aluminum, resulting in the presence of color. Substitution of chromium results in a deep red color; such red corundum is known as ruby. The term “sapphire” is used in both a restricted sense for the “cornflower blue” variety containing iron and titanium, and in a general sense for gem-quality corundums of any color other than red. Star ruby and star sapphire contain tiny needles of the mineral rutile. *See* RUBY; SAPPHIRE.

Corundum occurs as a rock-forming mineral in both metamorphic and igneous rocks, but only in those which are relatively poor in silica, and never in association with free silica. Igneous rocks which most commonly contain corundum include syenites, nepheline syenites, and syenite pegmatites. Both contact and regionally metamorphosed silica-poor rocks may contain corundum. *See* IGNEOUS ROCKS; METAMORPHIC ROCKS. [D.R.P.]

Cosmic background radiation A nearly uniform flux of microwave radiation that is believed to permeate all of space. The discovery of this radiation in 1965 by A. Penzias and R. W. Wilson has had a profound impact on understanding the nature and history of the universe. The interpretation of this radiation as the remnant fireball from the big bang by P. J. E. Peebles, R. H. Dicke, R. G. Roll, and D. T. Wilkinson, and their correct prediction of the spectrum to be that of a blackbody, was one of the great triumphs of cosmological theory. The flight of the *Cosmic Background Explorer (COBE)* satellite has both verified the basic nature of the radiation and given deep insight into the mechanism of formation of galaxy clusters in the early universe and the presence of dark matter.

In the theory of the big bang, the universe began with an explosion 10–15 billion years ago. This big bang was not an explosion of matter into empty space but an explosion of space itself. The early universe was filled with dense, hot, glowing matter; there was no region of space free of matter or radiation. (This state is reflected in the present universe by the fact that space is more or less uniformly filled with galaxies; galaxy clusters and holes between clusters are believed to have grown from gravitational instabilities during the expansion.) The explosion of space increased the volume of the matter and radiation and thus reduced the density and temperature. The initial temperature was so high that even for several hundred thousand years after the initial explosion the universe was still as hot as the surface of the present-day Sun. At this temperature the matter of the universe was in the form of a plasma of electrons, protons, alpha particles (helium nuclei), and photons. The photons were strongly absorbed and reemitted by the electrons, and their spectrum was similar to that of the Sun. About 500,000 years after the initial explosion, the expansion caused the temperature to drop enough that the electrons and protons recombined to form hydrogen atoms. Unlike the previous plasma, which was opaque to light, neutral hydrogen is transparent. From that time (called the time of the decoupling or of recombination) until now, the cosmic photons have been traveling virtually unscattered, carrying information about the nature of the universe at the time of the decoupling. *See* BIG BANG THEORY.

To an observer moving with the plasma, the photons have a blackbody spectrum with a characteristic temperature of a few thousand kelvins. (A blackbody spectrum is the characteristic emission from a perfectly absorbing object heated to the characteristic temperature. The orange glow emitted from a heated pan is approximately blackbody, as is the light emitted from the filament of a light bulb or from the surface of the Sun.) Although the glow from the plasma is in the visible region, as a result of the recessional velocity of the plasma from the Earth the radiation is redshifted from the visible into the microwave region, with a characteristic temperature of 3 K (5°F above absolute zero, −459.67°F). Detection of the radiation is really the observation of the shell of matter that last scattered the radiation. *See* HEAT RADIATION; REDSHIFT.

The microwave radiation is coming from the most distant region of space ever observed, and was emitted earlier in time than any other cosmological signal. The radiation was originally termed cosmic background radiation because the discoverers foresaw that it would cause a background interference with satellite communications, but the term has taken on a vivid new meaning: the radiating shell of matter forms the spatial background in front of which all other astrophysical objects, such as quasars, lie. Until methods are devised to detect the neutrinos or gravity waves that were decoupled earlier, there will be no direct means of viewing beyond this background. *See* GRAVITATIONAL RADIATION; NEUTRINO.

Subsequent to its discovery, experimental work on the microwave background has been concerned primarily with the measurement of the radiation’s color (its spectrum of intensity at different frequencies) and with its isotropy (its intensity as a function of direction in the sky). Results from the *COBE* satellite showed that the spectrum is that of a blackbody, at a temperature above absolute zero of 2.735 ± 0.060 K, to better than 1% accuracy. The lack of deviations places strong limits on the nature of material present at the time of decoupling, just a half million years after the creation of the universe.

Measurements showed that the radiation was isotropic to better than 1%. This uniformity posed a difficult problem for cosmological theory, since according to the simple big bang theory the different parts of the sky that gave rise to the microwave background had not been close enough together to reach an equilibrium temperature. Thus there was no way to understand how the intensity could be uniform. This theoretical problem was solved by a variation on the big bang theory called the inflationary universe model. In this picture the early universe was much smaller than had previously been supposed, giving it time to attain a uniform temperature; the rapid expansion of the universe occurred at a later time, the period of inflation. *See* INFLATIONARY UNIVERSE COSMOLOGY.

A map of intensity produced by the *COBE* satellite displays a smooth yin-yang pattern, which is the cosine variation from the 600-km/s (370-mi/s) motion of the Milky Way Galaxy. The variation is only about 3.4 mK, or about 0.1% as large as the constant 2.7-K past. The velocity of the Milky Way Galaxy is believed to result from its gravitational acceleration toward the center of a large local supercluster of galaxies. *See* DOPPLER EFFECT; GALAXY, EXTERNAL; UNIVERSE.

In 1992 the *COBE* team announced that they had found small variations in the microwave map that appear to be cosmological in origin. The map of intensity with the cosine term removed displays a bright horizontal band which comes from synchrotron emission in the Milky Way Galaxy. The most exciting regions of the plot are the marbled areas above and below the synchrotron stripe, which the *COBE* team called ripples in the radiation. These ripples are believed to be the first indications that the early universe was not completely uniform. The structure has a magnitude of approximately 15–30 μK, a factor of 200,000 times smaller than the 2.7-K radiation itself.

The inflationary universe model accounts for the uniformity of the radiation but still leaves the puzzle that the present universe is highly nonuniform, with most of the mass clumped into stars, galaxies, and clusters of galaxies. Most astrophysicists believe that the clumping came about from the mutual gravitational attraction of the matter created in the big bang. The cosmological anisotropy observed by the *COBE* satellite is interpreted as the early sign of the clumping, taking place a half million years after the creation of the universe.

Theories of galaxy formation must postulate large amounts of dark, unseen matter in order to provide the strong gravitational fields necessary for sufficient clumping. The nature of this matter is unknown, but the matter must be more massive than all that observed in stars and galaxies. The radiation coming from the otherwise unseen clumps undergoes a gravitational redshift, according to the general theory of relativity, and it is this effect that *COBE* is believed to be observing. These residual lumps are consistent in magnitude and form with that predicted by the inflationary universe version of the big bang theory. Thus the ripples observed in the radiation are in fact a map of the distribution of dark matter in the very early universe. *See* COSMOLOGY; GRAVITATIONAL REDSHIFT. [R.A.Mu.]

Cosmic rays Electrons and the nuclei of atoms—largely hydrogen—that impinge upon Earth from all directions of space with nearly the speed of light. These nuclei with relativistic speeds are often referred to as primary cosmic rays, to distinguish them from the cascade of secondary particles generated by their impact against air nuclei at the top of the terrestrial atmosphere. The secondary particles shower down through the atmosphere and are found all the way to the ground and below.

The primary cosmic rays provide the only direct sample of matter from outside the solar system. Measurement of their composition can aid in understanding which aspects of the matter making up the solar system are typical of the Milky Way Galaxy as a whole and which may be so atypical as to yield specific clues to the origin of the solar system. Cosmic rays are electrically charged; hence they are deflected by the magnetic fields which are thought to exist throughout the Galaxy, and may be used as probes to determine the nature of these fields far from Earth. Outside the solar system the energy contained in the cosmic rays is comparable to that of the magnetic field, so the cosmic rays probably play a major role in determining the structure of the field. Collisions between the cosmic rays and the nuclei of the atoms in the tenuous gas which permeates the Galaxy change the cosmic-ray composition in a measurable way and produce gamma rays which can be detected at Earth, giving information on the distribution of this gas.

Cosmic-ray detection. All cosmic-ray detectors are sensitive only to moving electrical charges. Neutral cosmic rays (neutrons, gamma rays, and neutrinos) are studied by observing the charged particles produced in the collision of the neutral primary with some type of target. At low energies the ionization of the matter through which they pass is the principal means of detection. A single measurement of the ionization produced by a particle is usually not sufficient both to identify the particle and to determine its energy. However, since the ionization itself represents a significant energy loss to a low-energy particle, it is possible to design systems of detectors which trace the rate at which the particle slows down and thus to obtain unique identification and energy measurement.

At energies above about 500 MeV per nucleon, almost all cosmic rays will suffer a catastrophic nuclear interaction before they slow appreciably. An ionization measurement is commonly combined with measurements of physical effects which vary in a different way with mass, charge, and energy. Cerenkov detectors and the deflection of the particles in the field of large superconducting magnets or the magnetic field of the Earth itself provide the best means of studying energies up to a few hundred GeV per nucleon. Detectors employing the phenomenon of x-ray transition radiation promise to be useful for measuring composition at energies up to a few thousand GeV per nucleon. *See* CERENKOV RADIATION; SUPERCONDUCTING DEVICES.

Above about 10^{12} eV, direct detection of individual particles is no longer possible since they are so rare. Such particles are studied by observing the large showers of secondaries they produce in Earth's atmosphere. These showers are detected either by counting the particles which survive to strike ground-level detectors or by looking at the flashes of light the showers produce in the atmosphere with special telescopes and photomultiplier tubes. *See* PARTICLE DETECTOR; PHOTOMULTIPLIER.

Atmospheric cosmic rays. The primary cosmic-ray particles coming into the top of the terrestrial atmosphere make inelastic collisions with nuclei in the atmosphere. When a high-energy nucleus collides with the nucleus of an air atom, a number of things usually occur. Rapid deceleration of the incoming nucleus leads to production of pions with positive, negative, or neutral charge. A few protons and neutrons (in about equal proportions) may be knocked out with energies up to a few GeV. They are called knock-on protons and neutrons.

All these protons, neutrons, and pions generated by collision of the primary cosmic-ray nuclei with the nuclei of air atoms are the first stage in the development of the secondary cosmic-ray particles observed inside the atmosphere. Since several secondary particles are produced by each collision, the total number of energetic particles of cosmic-ray origin will increase with depth, even while the primary density is decreasing.

The uncharged π^0 mesons decay into two gamma rays with a life of about 8×10^{-17} s. The two gamma rays each produce a positron-electron pair. Upon passing sufficiently close to the nucleus of an air atom deeper in the atmosphere, the electrons and positrons convert their energy into bremsstrahlung. The bremsstrahlung in turn create new positron-electron pairs, and so on. This cascade process continues until the energy of the initial π^0 has been dispersed into a shower of positrons, electrons, and photons with insufficient individual energies ($\leq$1 MeV) to continue the pair production. The electrons and photons of such showers are referred to as the soft component of the atmospheric (secondary) cosmic rays. *See* ELECTRON-POSITRON PAIR PRODUCTION.

The $\pi^{\pm}$ mesons produced by the primary collisions have a life of about 2.6×10^{-8} s before they decay into muons. Most low-energy $\pi^{\pm}$ decay into muons before they have time to undergo nuclear interactions. Except at very high energy (above 500 GeV), muons interact relatively weakly with nuclei, and are too massive (207 electron masses) to produce bremsstrahlung. They lose energy mainly by the comparatively feeble process of ionizing an occasional air atom as they progress downward through the atmosphere. Because of this ability to penetrate matter, they are called the hard component.

The high-energy nucleons—the knock-on protons and neutrons—produced by the primary-particle collisions and a few pion collisions proceed down into the atmosphere. They produce nuclear interactions of the same kind as the primary nuclei, though of course with diminished energies. This cascade process constitutes the nucleonic component of the secondary cosmic rays.

Solar modulation. The cosmic-ray intensity is lower during the years of high solar activity and sunspot number, which follow an 11-year cycle. This effect has been extensively studied with ground-based and spacecraft instruments.

The primary cause of solar modulation is the solar wind, a highly ionized gas (plasma) which boils off the solar corona and propagates radially from the Sun at a velocity of about 250 mi/s (400 km/s). The wind is mostly hydrogen, with typical density of 80 protons per cubic inch (5 protons per cubic centimeter). This density is too low for collisions with cosmic rays to be important. Rather, the high conductivity of the medium traps part of the solar magnetic field and carries it outward.

In addition to the bulk sweeping action, another effect of great importance occurs in the solar wind, adiabatic deceleration. Because the wind is blowing out, only those particles which chance to move upstream fast enough are able to reach Earth. However, because of the expansion of the wind, particles interacting with it lose energy. Thus, particles observed at Earth with energy of 10 MeV per nucleon actually started out with several hundred MeV per nucleon in nearby interstellar space, and those with initial energy of only 100–200 MeV per nucleon probably never reach Earth at all.

Composition of cosmic rays. Nuclei ranging from protons to lead have been identified in the cosmic radiation. The relative abundances of the elements may be compared with the best estimate of the "universal abundances" obtained by combining measurements of solar spectra, lunar and terrestrial rocks, meteorites, and so forth. Most obvious is the similarity between the two distributions. However, a systematic deviation is quickly apparent: the elements lithium-boron and scandium-manganese as well as most of the odd-charged nuclei are vastly overabundant in the cosmic radiation. This effect has a simple explanation: the cosmic rays travel great distances in the galaxy and occasionally collide with atoms of interstellar gas—mostly hydrogen and helium—and fragment. This fragmentation, or spallation as it is called, produces lighter nuclei from heavier ones but does not change the energy per nucleon very much. Thus the energy spectra of the secondaries are similar to those of the primaries. Calculations involving reaction probabilities determined by nuclear physicists show that the overabundances of the secondary elements can be explained by assuming that cosmic rays pass through an average of about 1 oz per square inch (5 g per square centimeter) of material on their way to Earth.

When spallation has been corrected for, differences between cosmic-ray abundances and solar-system or universal abundances still remain. The most important question is whether these differences are due to the cosmic rays having come from a special kind of material (such as would be produced in a supernova explosion), or simply to the fact that some atoms might be more easily accelerated than others.

Cosmic-ray electron measurements pose other problems of interpretation, partly because electrons are nearly 2000 times lighter than protons, the next lightest cosmic-ray component. Protons with kinetic energy above 1 GeV are about 100 times as numerous as electrons above the same energy, with the relative number of electrons decreasing slowly at higher energies. But it takes about 2000 GeV to give a proton the same velocity as a 1-GeV electron. Viewed in this way electrons are several thousand times more abundant than protons. It is thus quite possible that cosmic electrons have a different source entirely from the nuclei.

Age. Another important result which can be derived from detailed knowledge of cosmic-ray isotopic composition is the "age" of cosmic radiation. Certain isotopes are radioactive, such as beryllium-10 with a half-life of 1.6×10^6 years. Since Be is produced entirely by spallation, study of the relative abundance of ^{10}Be to the other Be isotopes, particularly as a function of energy to utilize the relativistic increase in this lifetime, will yield a number related to the average time since the last nuclear collision. Measurements show that ^{10}Be is nearly absent at low energies and yield an estimate of the age of the cosmic rays of approximately 10^7 years. An implication of this result is that the cosmic rays propagate in a region in space which has an average density of 1.5–3 atoms per cubic inch (0.1–0.2 atom per cubic centimeter). This is consistent with some astronomical observations of the immediate solar neighborhood.

Origin. Although study of cosmic rays has yielded valuable insight into the structure, operation, and history of the universe, their origin has not been determined. The problem is not so much to devise processes which might produce cosmic rays, but to decide which of many possible processes do in fact produce them.

It is thought that cosmic rays are produced by mechanisms operating within galaxies and are confined almost entirely to the galaxy of their production, trapped by the galactic magnetic field. The intensity in intergalactic space would only be a few percent of the typical galactic intensity, and would be the result of a slow leakage of the galactic particles out of the magnetic trap. [P.E.]

Cosmic spherules Solidified droplets of extraterrestrial materials that melted either during high-velocity entry into the atmosphere or during hypervelocity impact of large meteoroids onto the Earth's surface. Cosmic spherules are rounded particles that are millimeter to microscopic in size and that can be identified by unique physical properties. Although great quantities of the spheres exist on the Earth, they are ordinarily found only in special environments where they have concentrated and are least diluted by terrestrial particulates. *See* METEOR.

The most common spherules are ablation spheres produced by aerodynamic melting of meteoroids as they enter the atmosphere. Typical ablation spheres are produced by melting of submillimeter asteroidal and cometary fragments that enter the atmosphere at velocities ranging from 6.5 to 43 mi (11 to 72 km) per second. The spheres are formed near 48 mi (80 km) altitude, where deceleration, intense frictional heating, melting, partial vaporization, and solidification all occur within a few seconds. During formation, the larger particles can be seen as luminous meteors or shooting stars.

Ablation spheres fall to Earth at a rate of one 0.1-mm-diameter sphere per square meter per year, and every rooftop contains these particles. Unfortunately they are usually mixed in with vast quantities of terrestrial particulates, and they are very difficult to locate. They can, however, be easily found in special environments, such as the ocean floor, that do not contain high concentrations of terrestrial particles that could be confused with cosmic spheres larger than 0.004 in. (0.1 mm) in diameter. *See* MARINE SEDIMENTS.

Impact spheres constitute a second and rarer class of particles that are produced when giant meteoroids impact the Earth's surface with sufficient velocity to produce explosion craters that eject molten droplets of both meteoroid and target materials. They are very abundant on the Moon, but they are rare on the Earth, and they have been found in only a few locations. Impacts large enough to produce explosion craters occur on the Earth every few tens of thousands of years, but the spheres and the craters themselves are rapidly degraded by weathering and geological processes. Meteoritic spherules have been found around a number of craters. Silica-rich glass spheroids (microtektites) are found in thin layers that are contemporaneous with the conventional tektites. Microtektites are believed to be shock-melted sedimentary materials that were ejected from large impact craters. They were ejected as plumes that covered substantial fractions of the surface of the Earth. Microspherules of a different composition have been found in the thin iridium-rich layer associated with the global mass extinctions at the Cretaceous–Tertiary boundary. *See* TEKTITE.

Cosmic spherules are of particular scientific interest because they provide information about the composition of comets and asteroids and also because they can be used as tracers to identify debris resulting from the impact of large extraterrestrial objects. In general, cosmic spherules can be confidently identified on the basis of their elemental and mineralogical compositions, which are radically different from nearly all spherical particles of terrestrial origin. [D.E.Br.]

Cosmic string A hypothetical object that may account for large-scale structure in the universe. The problem of the form and origin of such structure is one of the major challenges in science. The hot big bang theory provides a remarkably simple and successful description of the broad features of the universe, but it provides no mechanism through which structure could have formed. *See* BIG BANG THEORY.

Cosmic strings were the earliest theory of the formation of structure in the universe to emerge from high-energy particle theory in the early 1980s. It was realized that certain grand unified theories and superstring theories, which seek to unify the disparate forces of nature within a single theoretical framework, automatically lead to the production of a network of cosmic strings in the very early universe. Eventually, disturbances produced by the srings would lead to the formation of structures like galaxies and galaxy clusters.

Cosmic strings are analogous to defects that form when water is suddenly frozen to form ice. Freezing is an important example of a phase transition in which symmetry is broken. The water is symmetric under rotations; it looks the same from any angle. However, the crystalline structure of ice is not; its crystalline planes pick out definite directions. As the water freezes, at each point in space the crystalline structure of the solid picks an orientation in which to form, but this orientation varies from place to place. At some points, there is a mismatch between the orientation of neighboring crystalline regions. The resulting topological defects can take the form of sheets, lines, or points.

All unified field theories are based on the concept of symmetry breaking. The idea is that at high energies and temperatures the forces of nature should be indistinguishable and matter should exist in a highly symmetric state. However, at low energies the symmetry is broken and the forces are distinct. But the symmetry breaking that occurred as the very hot early universe cooled would have produced defects, just as symmetry breaking produces defects in ice when water freezes. Cosmic strings are closely analogous to the linelike defects in ice, often called dislocation lines. *See* Crystal defects; Inflationary universe cosmology; Symmetry breaking.

Cosmic strings are very thin, approximately 10^{-15} the radius of a proton. They are also very massive; 1 m of grand-unified cosmic string would weigh 10^{20} kg. They can take the form of closed loops, or infinite strings that wander on forever. When the cosmic strings form, around 10^{-34} s after the big bang, most of the string is in very long strings, which wander right across the universe. In effect, the universe is filled with a random, tangled network of spaghetti. As the universe expands, the string network chops itself up into tiny loops, which lose energy by radiating gravity waves until they shrink and disappear. However, the long strings cannot be eliminated, and would survive right up to the present. *See* Cosmology; Gravitational radiation; Universe. [N.T.]

Cosmochemistry The science of the chemistry of the universe, particularly that beyond the Earth. As currently practiced, cosmochemistry is concerned primarily with inferences on pre-solar-system events, solar nebular processes, and early planetary processes as deduced from minerals in meteorites and from chemical and isotopic compositions of meteorites and their parts. *See* Isotope; Meteorite.

Minerals in meteorites. Meteorites provide a great deal of otherwise unobtainable information about the formation and early history of the solar system. The solar system formed from the solar nebula, a large cloud of gas and dust. The chemical composition of the solar system, which can be assumed to be the same as that of the solar nebula, is known in detail from spectroscopic analysis of the Sun, which contains 99.9% of its mass. From a combination of this knowledge, an estimate of temperature and pressure from hydrodynamic models, and thermodynamic data for all possible gas, liquid, and solid species, it can be determined which minerals would have become stable as the gas cloud underwent gravitational collapse, spun down into a disk, and cooled. Pressure in the solar nebula was probably so low that condensation occurred at temperatures below the melting points of the minerals, and they condensed as solids. Different minerals became stable at different temperatures, giving rise to a condensation sequence, which can be calculated. *See* Astronomical spectroscopy; Elements, cosmic abundance of; Hydrodynamics; Protostar; Solar system; Sun; Thermodynamic principles.

Detailed chemical information, however, requires samples, and the Earth is too geologically active to provide samples dating to its formation. Meteorites are therefore studied because, in general, they have undergone much less modification than terrestrial rocks.

A certain type of meteorite, the carbonaceous chondrite, contains millimeter-sized rocklets, or refractory inclusions, that are composed of the very minerals (especially hibonite, perovskite, melilite, spinel, and fassaite) believed to have been among the first to condense from the solar nebula. This finding indicates that assumptions used to calculate the condensation sequence are reasonably accurate. *See* Corundum; Melilite; Perovskite; Spinel.

Some meteorites also contain trace amounts of grains of carbon-rich minerals (silicon carbide, diamond, and graphite) whose condensation requires a gas with a carbon/oxygen ratio greater than 1, whereas that of the Sun is 0.6. This finding, along with very large isotopic anomalies for many elements, provides strong evidence that these grains are interstellar in origin, predating the Sun by as much as about 2.4×10^9 years. These grains should have disappeared by reacting with the solar nebular gas, however; why they did not and how they survived long enough to be incorporated into meteorites are not yet understood. *See* Diamond; Graphite; Interstellar matter; Silicon. [S.B.S.]

Chemical compositions of meteorites. The chemical composition of meteorites and independently formed objects within them have taught much about pre-solar-system events, solar nebular processes, and early planetary processes.

As mentioned above, several types of interstellar grains have been separated from primitive meteorites. Presolar grains identified include silicon carbide, graphite, diamond, titanium carbide, zirconium carbide, molybdenum carbide, aluminum oxide, titanium oxide, hibonite, and spinel. While chemistry alone has not unambiguously identified any of these grains as presolar, chemistry does help to understand the formation conditions of objects whose isotopic composition proves a presolar origin. A good example is silicon carbide, most of which is believed, on the basis of isotopic arguments, to come from the circumstellar envelopes of asymptotic giant branch stars. The silicon carbide with isotope anomalies that is separated from meteorites is enriched in a number of trace elements that are predicted to condense at high temperatures as carbides in reducing environments, such as zirconium, titanium, molybdenum, strontium, barium, and the rare-earth elements. These enrichments are entirely consistent with the proposed origin of silicon carbide by high-temperature condensation in the circumstellar envelopes of carbon-rich stars. *See* Giant star.

Chemistry has been used to infer a number of important processes in the solar nebula. These include high-temperature condensation and vaporization, melting and crystallization of millimeter- to centimeter-sized objects in the solar nebula, separation of metal from silicate grains, and reaction of condensed grains with solar nebular gas. Investigation of these processes helps determine important properties of the solar nebula, such as its temperature, how long it lasted, and what the planets, which formed from the nebula, are made of.

A number of important planetary processes, such as separation and differentiation of a metallic core and differentiation of the silicate portion of a planet into mantle and crust, can be studied through the chemical compositions of meteorites. [A.M.D.]

Isotopic compositions of meteorites. Studies of the relative abundances of isotopes in meteorites provide a unique source of information about the age of the solar system, the time scales for formation of the first solid bodies in the solar system and the growth and evolution of small planets, the prehistory (nucleosynthesis) of the material out of which the solar system formed, and the interaction of solar and galactic cosmic rays with matter. *See* Nucleosynthesis.

The oldest meteoritic samples are the refractory, calcium-aluminum-rich inclusions found in carbonaceous chondrites. The 4.566-billion-year age of these objects provides the best estimate for the condensation of the first solid material in the solar system. Chondrules, millimeter-size spherules of glass and crystals, began to form a few million years after refractory inclusions as the solar nebula cooled. The oldest basaltic meteorites crystallized from molten lavas on small asteroids within roughly 10 million years of this time (that is, ages of 4.562–4.552 billion years). Most chondritic meteorites have less precisely determined ages encompassing the range covered by chondrules and basaltic achondrites. The tight clustering of ages of the oldest meteorites reflects a period of rapid growth during the first 10 million years of solar system history, as millimeter-to-centimeter-size objects collided and coalesced to form meter-to-kilometer-size planetesimals. The younger ages of some meteorites indicate that disturbances due to shock and thermal metamorphism began as early as 4.5 billion years ago and continued for 100–200 million years. Collisions between planetesimals led to coagulation, the growth of larger bodies, and the eventual formation of the terrestrial planets, including the Earth-Moon system, 50– 100 million years after most meteorites. *See* EARTH, AGE OF; ROCK AGE DETERMINATION.

One unusual group, the SNC meteorites, whose appearance and composition is similar to that of terrestrial basalts, is the exception to the rule with much younger crystallization ages of approximately 1.3 billion years. The young ages require an origin on a planetary body larger than the Moon, on which radioactive heating could sustain igneous activity for at least 3 billion years. It is generally believed that this group of meteorites originated on Mars, an argument strengthened by recent evidence that the isotopic compositions of hydrogen, nitrogen, and noble gases in the SNC meteorites and the Martian atmosphere are strikingly similar and distinct from those in the Earth and other meteorites.

Nine short-lived species with half-lives ranging from 0.10 to 103 million years are known to have existed at the birth of the solar system. The evidence of short-lived radionuclides is distributed across all classes of meteorites and provides a compelling argument not only that meteorites are the oldest objects in the solar system but that they formed rather quickly over a very short interval. Although these nuclides can no longer be observed directly, evidence that they were present during the earliest epoch of solar system history is preserved as variations in the relative abundances of the daughter isotopes of the extinct radionuclides. For example, large excesses of ^{26}Mg, produced by the decay of ^{26}Al (half-life of 0.72 million years), are found in aluminum-rich, magnesium-poor minerals in refractory inclusions in carbonaceous chondrites.

The short-lived nuclides are not restricted to primitive chondritic meteorites but are also prominent in meteorites believed to have been produced by planetary-scale melting. The widespread presence of short-lived nuclides indicates that the time interval between nucleosynthesis and the formation of the solar system must be short. Refractory inclusions containing ^{41}Ca, an isotope with a half-life of only 100,000 years, must have formed within a few mean lives, that is, a few hundred thousand years of ^{41}Ca production. This time scale is so short that it suggests the formation of the solar system may have been triggered by a shock wave from a nearby exploding star containing freshly synthesized nuclear material.

Except for the variations in isotopic abundances related to decay of radionuclides discussed above, for the most part there is a close similarity between the isotopic compositions of meteorites, the Moon, and the Earth. For many years this apparent homogeneity was taken as evidence that the solar nebula was chemically and physically well mixed before the formation of the first solid bodies. The development of new analytical techniques permitting the determination of isotopic compositions in small ($<$0.01 mm) constituents of meteorites has, however, led to the discovery of large differences in isotopic abundances for many elements which cannot be explained in terms of radioactive decay or cosmic-ray interactions. These isotope anomalies provide unequivocal evidence that dust grains that condensed around a variety of different stars were incorporated into primitive meteorites and offer a window through which nucleosynthesis and stellar evolution are revealed with unprecedented clarity.

The isotope anomalies found in refractory inclusions represent a mixture of exotic stardust from other stars diluted with normal solar system material; the inclusions themselves clearly are not presolar material. A major new discovery in meteorite research is the identification in primitive chondrites of whole interstellar grains, formed outside the solar system in stellar atmospheres and incorporated into primitive meteorites essentially intact. These grains survived the formation of the solar system and preserve the isotope compositions of the stellar nuclear sources for both major and trace elements. Presolar grains show isotope anomalies for all elements, and the size of the anomalies is at least a factor of 100 times larger than that of anomalies found in refractory inclusions.

Studies of isotope anomalies and presolar grains in primitive meteorites have yielded important new clues to nucleosynthesis and the types of stars contributing material to the nascent solar nebula. The very large range of isotope abundances measured in presolar grains cannot be generated by a single stellar source, and is ample proof that the solar system is the product of contributions from disparate stars. Hydrogen and the bulk of the helium in the solar system are relicts of big bang nucleosynthesis, while the elements carbon through iron were produced dominantly in charged particle reactions in massive stars. The radionuclides ^{129}I, ^{232}Th, ^{235}U, ^{238}U, and ^{244}Pu are all produced by neutron-rich nucleosynthesis in supernovae. The abundance of short-lived radionuclides requires the late addition of fresh nucleosynthetic material, possibly from a massive, red-giant star, to the solar nebula less than a few million years prior to the formation of the first meteorites. *See* BIG BANG THEORY; SUPERNOVA.

[I.D.H.]

Cosmogenic nuclide A rare nuclide produced by nuclear reactions between high-energy cosmic radiation and terrestrial or extraterrestrial material. Cosmogenic nuclides may be used to examine the history of exposure to cosmic rays, and have numerous applications in earth science and archeology.

Primary cosmic radiation is present in space and consists of nuclear particles (mostly protons and alpha particles) with energies that are greater than typical nuclear binding energies. Collisions between cosmic-ray particles and atomic nuclei produce fragments, including cosmogenic nuclides, and also alter the characteristics of the cosmic radiation. As cosmic radiation enters the atmosphere, its flux decreases and its composition becomes dominated by neutrons rather than protons and alpha particles (which react with atmospheric gases). This reduction in flux continues through the atmosphere; at ground level, small but measurable quantities of cosmogenic nuclides are produced in solid material within about 1 m (3.3 ft) of the Earth's surface. The cosmogenic nuclides produced in these two reservoirs (atmosphere and lithosphere) may be employed for examination of different geological processes. Because of their wide range of half-lives and chemical properties, cosmogenic nuclides have a wide range of applications in geological, geomorphological, and biogeochemical studies. *See* ALPHA PARTICLES; COSMIC RAYS; COSMOCHEMISTRY; PROTON.

Numerous nuclides are produced in measurable quantities in the atmosphere. Their half-lives and their chemical reactivities determine their applications in earth science.

Short-lived nuclides, including beryllium-7 (^{7}Be), sodium-22 (^{22}Na), phosphorus-32 (^{32}P), and phosphorus-33 (^{33}P), have been employed in studies of atmospheric circulation, particularly stratospheric-tropospheric exchange. Because of its highly successful applications in dating, carbon-14 (^{14}C; radiocarbon) is the best-known cosmogenic nuclide. Essentially all atmospheric ^{14}C is in the form of gaseous carbon dioxide ($^{14}CO_2$); it thus has an atmospheric residence time long enough for the ratio of ^{14}C to ^{12}C (the stable isotope) to become homogeneous throughout the atmosphere. Living organisms and inorganic carbonates incorporate carbon with an isotope ratio reflecting that of the atmosphere. Upon removal from contact with the atmosphere, the ratio ^{14}C/^{12}C decreases through radioactive decay of ^{14}C. With knowledge of the initial ratio and the half-life of ^{14}C, measurement of ^{14}C/^{12}C allows calculation of the age of a sample. This technique has been extensively used in archeology and geology for samples as old as 4×10^4 years. High-precision ^{14}C dates of inorganic carbon dissolved in seawater are also used to deduce global oceanic circulation rates and patterns by determining the time since a particular water mass had contact with the atmosphere. *See also* OCEAN CIRCULATION; RADIOCARBON DATING; RADIOISOTOPE (GEOCHEMISTRY); SEAWATER.

A small but significant flux of cosmic rays is present at ground level. This radiation produces cosmogenic nuclides within mineral lattices of exposed rock. In-situ-produced cosmogenic nuclides are used to examine geological problems. In-situ-produced cosmogenic nuclides are useful for dating periods of surface exposure. Their production rates decrease by a factor of 2 for every $\gg 40$ cm (16 in.) depth below an exposed rock surface, so accumulation of cosmogenic nuclides can date geological events that bring material to the Earth's surface. For example, the theoretical evolution of the concentration of ^{10}Be as a function of time for various erosion rates can be calculated. The method has been used to date exposure of rocks brought to the surface by processes including glaciation, volcanic activity, and meteor impact. It has also been used to date the formation of geomorphological features (such as alluvial fans or glacial moraines) deposited over active faults and subsequently offset by fault movement. This provides a quantitative approach to determine slip rates on faults and earthquake recurrence intervals. Such results could not have been obtained by conventional methods. *See* GEOMORPHOLOGY.

Because cosmic rays penetrate just a few meters of solid matter, cosmogenic nuclides cannot form deep in the interiors of large bodies such as asteroids. The accumulation of cosmogenic nuclides begins when a collision lifts deep-seated material to the surface or ejects it into space as part of a small body. When a meteorite hits the Earth, the accumulation of cosmogenic nuclides effectively stops. The reason is that the Earth's atmosphere and magnetic field screen out most cosmic rays. The total amounts of the cosmogenic nuclides in a meteorite are related to its exposure age. They also indicate the size of the meteoroid. To get this information, it is necessary to be able to identify cosmogenic nuclides as such and measure their concentrations. [G.F.H.]

Cosmology The study of the structure and the origin of the universe, including the origin of galaxies, the elements, and matter itself.

Structure of the universe. Modern cosmology began in the early twentieth century with theoretical work on the cosmological implications of A. Einstein's theory of general relativity and with the astronomical debate over the nature of spiral nebulae.

Some astronomers contended that these faint nebulae were regions of star formation that were part of the Milky Way Galaxy, while others argued that they were distant galaxies much like the Milky Way. This debate was settled in 1923 by E. Hubble's discovery of 12 Cepheid variable stars in M31, the Andromeda Nebula. There is a simple empirical relationship between the period of the Cepheids and their luminosity. Thus, Hubble's observations allowed him to determine that the Andromeda Nebula was at a very large distance and was a galaxy much like the Milky Way. *See* ANDROMEDA GALAXY; CEPHEIDS; GALAXY, EXTERNAL; MILKY WAY GALAXY.

Hubble continued his study of galaxies and found that most were receding from the Earth. Hubble proposed a simple linear relationship between the distance to a galaxy and its recessional velocity, given by Eq. (1), where v is the recessional velocity of the galaxy, usually measured in kilometers per second,

$$v = Hr \tag{1}$$

and r is the distance to the galaxy, usually measured in megaparsecs (1 Mpc $= 3.26 \times 10^6$ light-years $= 3.1 \times 10^{19}$ km $= 1.9 \times 10^{19}$ mi). Astronomers are still trying to accurately measure H, the Hubble constant. The Hubble Space Telescope has observed Cepheids in the Virgo and Fornax clusters. These observations suggest that the Hubble constant is about 72 (km/s)/Mpc. *See* HUBBLE CONSTANT; SPACE TELESCOPE, HUBBLE.

Age of the universe. The universe ought to be older than any visible star; thus, the inferred ages of the stars in the Milky Way Galaxy place a lower limit on age of the universe. The oldest known stars are in globular clusters, dense concentrations of roughly 100,000 stars, believed to be 12–20 $\times 10^9$ years old. These age estimates are based on models of stellar evolution that predict when a star of a given mass becomes a red giant. *See* STAR CLUSTERS; STELLAR EVOLUTION.

Big bang model. When Einstein proposed his theory of general relativity, the universe was believed to be static. Einstein had to modify his equations so that general relativity would allow a static universe by adding a cosmological constant term. Hubble's observations of the expanding universe then implied that these modifications were unnecessary. In the 1920s, G. Lemaître and A. Friedmann independently proposed a general relativistic model of the expanding universe. One of the simplest solutions to Einstein's relativity equation, it assumes that the universe is homogeneous and expanding. When Lemaître and Friedmann made their proposal, there was no real evidence for their simplifying assumptions. Only since the late 1980s have observations become sensitive enough to confirm their assumptions. *See* RELATIVITY.

The Friedmann-Lemaître model, often called the big bang model, implies that the universe began in an extremely dense state and expanded and cooled. In this model, the Hubble law is predicted as an approximate description of the expansion valid for galaxies within a few hundred megaparsecs of the Milky Way Galaxy. The model implies that radiation is redshifted as the universe expands. Thus, radiation from distant objects should appear at lower frequencies than those at which it was emitted. Observations of atomic lines from distant quasars confirm that radiation is redshifted just as predicted. *See* QUASAR; REDSHIFT.

The Friedmann-Lemaître model, while fully relativistic, can be described in the language of newtonian physics. The Hubble law implies that a shell of galaxies of radius R and mass m expands with velocity HR. Thus, the kinetic energy of the shell is $m(HR)^2/2$. If M is the mass interior to the shell, then the gravitational binding energy of the shell is GMm/R, where G is the newtonian constant of gravitation. The total energy E of the shell is therefore given by Eq. (2). Since it has been assumed that the universe is uniform, the mass M within the shell can be

$$E = \frac{m(HR)^2}{2} - \frac{GMm}{R} \tag{2}$$

replaced with the quantity $4\pi\rho R^3/3$, where ρ is the density of the universe and $4\pi R^3/3$ is the volume of a shell of radius R. Then Eq. (2) can be rewritten as Eq. (3), where Ω is the ratio of the density of the universe to the critical density of the universe,

$$\frac{E}{mR^2} = \frac{H^2}{2}\left(1 - \frac{8\pi G\rho}{3H^2}\right) = \frac{H^2}{2}(1 - \Omega) \tag{3}$$

$3H^2/(8\pi G)$. If $\Omega < 1$, the total energy of the shell is positive, and the universe will continue to expand forever. If $\Omega > 1$, the total energy of the shell is negative, gravity will eventually stop the expansion, and the universe will eventually collapse. Some physicists speculate that this so-called big crunch will be followed by a future big bang. If $\Omega = 1$, the total energy is zero, and the universe stands on the balance between open and closed and corresponds to a special solution called the Einstein-de Sitter model. *See* GRAVITATION.

This simple newtonian model, while accurately describing the dynamics of the expanding universe, can lead to a conceptual error. The newtonian shell has a center, since newtonian theory cannot deal with a uniform mass density. General relativity, however, allows the universe to be isotropic and expanding uniformly without having a special center point. In the Friedmann-Lemaître model, the Milky Way Galaxy is not a special place in the universe.

The density of the universe determines not only the final fate of the universe but also its geometry. If $\Omega > 1$, the universe is closed and its geometry is that of a three-dimensional sphere. If the universe is closed, two light rays sent off in opposite directions from the same starting point will eventually bend toward each other. If $\Omega = 1$, the universe is flat and the two light rays will continue to move away from each other. If $\Omega < 1$, the geometry of the universe is hyperbolic, much like that of a saddle. A common misconception is that if the universe is open it must be spatially infinite. This need not be true, as general relativity does not constrain the topology of the universe. If $\Omega < 1$, the universe could be either infinite or finite and periodic.

Astronomical observations could also potentially measure the geometry of the universe. If the universe is closed, there is less volume associated with a given redshift than if it is open. The implication is that fewer galaxies should be detectable at large distances than in an open universe. The current observational situation is confused; galaxy counts using infrared techniques favor a flat or closed universe, while galaxy counts using optical techniques favor an open universe.

Observations of supernovae are another potential probe of the geometry of the universe. It is suspected that all type Ia supernovae, supernovae produced by the explosive burning of a white dwarf star, have the same luminosity. Thus, observations of distant supernovae can potentially determine the distances to galaxies at high redshift. Since the relation between distance and redshift differs in different cosmologies, this test can be used to measure the geometry of the universe. Current data suggest that the universe is accelerating and has a cosmological constant. Because of uncertainties in dust and evolutionary corrections, these results are uncertain.

One of the most dramatic discoveries of modern physics was the detection of the microwave background radiation by A. Penzias and R. Wilson. Most cosmologists believe that this radiation is the leftover heat from the big bang.

In the hot big bang model, the universe started in an extremely hot dense state. In this state, the universe was composed of electrons, positrons, quarks, neutrinos, and photons. As the universe expanded, most of the matter annihilated with antimatter into photons. These photons then cooled as the universe expanded. Thermal physics predicts that the spectrum of radiation from the big bang would be similar to that emitted by a blackbody, a so-called Planck spectrum. The Friedmann-Lemaître model predicts that this radiation should be uniform since the big bang started in a uniform state. *See* HEAT RADIATION.

The observations of the *Cosmic Background Explorer* (*COBE*) satellite, launched in 1989, provided strong confirmation of the hot big bang model. The observed spectrum of the microwave background radiation agrees closely with the predicted Planck spectrum. The *COBE* experiment also confirmed that the microwave background radiation is uniform to nearly 1 part in 50,000, consistent with the homogeneity assumption of the hot big bang model. *See* COSMIC BACKGROUND RADIATION.

Within the context of the hot big bang model, the conditions in the universe now can be extrapolated back to the first moments after the big bang. The temperature of the cosmic background radiation now is 2.73 kelvins above absolute zero. When the universe was half its present size, the background temperature was twice as high. One second after the big bang, the universe was only 3×10^{-11} of its present size and the temperature of the microwave background was roughly 10^{10} K (1.8×10^{10} °F). At this high temperature, the universe consisted of a thermal sea of photons, electrons, positrons, and neutrinos. In addition, there was a handful of protons and neutrons. There was approximately 1 baryon (proton or neutron) for every 10^{10} photons. *See* BARYON; ELECTRON; NEUTRINO; NEUTRON; POSITRON; PROTON.

As the universe cooled, the protons and neutrons combined to make deuterium. Most of this deuterium then interacted to make helium, while trace amounts combined to make lithium. Most of the deuterium and helium in the early universe is believed to have been produced in the first minutes of the big bang. One of the successes of the big bang model is its ability to account for the observed abundances of light elements. The universe today consists of roughly 28% helium, 70% hydrogen, and 2% other elements. Nucleosynthesis in stars produces roughly equal amounts of helium and heavier elements from hydrogen. Thus, it is difficult to understand the helium abundances without big bang nucleosynthesis. *See* DEUTERIUM; HELIUM; HYDROGEN; LITHIUM.

The amounts of deuterium, helium, and lithium produced in the big bang depend sensitively on the number of baryons per photon in the early universe and on the number of neutrino flavors. Based on the observed abundances of these elements in old stars, it was predicted that there should be only three flavors of neutrinos. Experiments at particle accelerators have confirmed this prediction based on the first moments of the early universe. *See* FLAVOR.

The observed light-element abundances also lead to a prediction for the density of protons and neutrons. The current best estimates suggest that if the universe is made only of protons, neutrons, and electrons, then Ω is between 0.01 and 0.1. Thus, unless there exists some exotic form of matter, big bang nucleosynthesis suggests that the universe is open. *See* BIG BANG THEORY; NUCLEOSYNTHESIS.

Alternatives to the hot big bang. There have been a variety of models proposed as alternatives to the hot big bang. Historically, the most important alternative model is the steady-state model, which assumes a homogeneous expanding universe that is not evolving because matter is continuously being created out of the vacuum. This model has great difficulty accounting for the observed shape of the microwave background radiation and cannot account for the observed abundance of helium. Another alternative is the cold big bang model in which the universe began in a big bang that started at absolute zero. It has been suggested that in this model the microwave background radiation could be due to reemitted light from iron needles. This model requires special dust grains and also cannot explain the abundances of light elements.

Dark-matter problem. Astronomers have been in an embarrassing situation for several decades: the amount of mass measured dynamically in galaxies by observing stellar and gas motions is roughly 10 times the mass observed in dust, gas, and known stars. This discrepancy suggests that either there is a basic flaw in newtonian physics or 90% of the mass in galaxies is in some yet unknown form, usually referred to as the dark matter.

Some of the strongest evidence for existence of dark matter comes from radio observations of hydrogen gas and optical observations of star motions in spiral galaxies like the Milky Way Galaxy. Observations of hot x-ray-emitting gas in elliptical galaxies provide a method for measuring their mass distribution. Since the gas pressure gradients must balance the force of gravity, gas density and temperature profiles can be directly related to the elliptical galaxy mass profiles. Data from x-ray satellites suggest that the galactic dark-matter problem is ubiquitous: all galaxies, whether spiral or elliptical, dwarf or normal, seem to have halos of dark matter. *See* X-RAY ASTRONOMY.

Candidates for the dark matter range in mass from microelectronvolt axions to 10^6-solar-mass black holes. Yet another possibility is that the dark matter consists of some as yet undetected particle. Particle physicists have suggested several possible candidates for the dark matter. The most popular of these particles is predicted in an extension of standard physics called supersymmetry. This particle, named a WIMP (weakly interacting massive particle), could potentially be detected in deep underground experiments. *See* BLACK HOLE; ELEMENTARY PARTICLE; SUPERSYMMETRY; WEAKLY INTERACTING MASSIVE PARTICLE (WIMP).

Origin of large-scale structure. One of the most active areas of research in cosmology has been the attempt to understand the formation of galaxies and the origin of large-scale structure. Most popular models of structure formation are based on gravitational instability. These models assume that there was some initial source of weak density fluctuation. In the expanding universe, these weak density fluctuations grow gravitationally.

The details of the gravitational formation scenario depend upon the nature of the dark matter. If the dark matter is in the form of either baryons or neutrinos, small-scale density fluctuations are erased. In these models, the first objects to form are the rich clusters. Galaxies form later through the fragmentation of rich clusters. If the dark matter is in the form of WIMPs, it can cluster more easily. In these cold dark-matter models, the first structures to form are usually subgalactic objects, which later condense to form galaxies. Galaxies can then agglomerate gravitationally and form clusters. Observations of quasars at high redshifts suggest that at least some small objects must have formed in the early universe and appear to favor models in which small objects formed before very large objects.

Observations of the microwave background radiation probe conditions in the early universe. In most cosmology models, the microwave photons that are detected on Earth last interacted with electrons when the universe was one-thousandth its present size. Thus, fluctuations in the microwave background temperature reflect the density fluctuations in the early universe.

While the gravitational instability picture can explain how initial weak fluctuations grew to form large-scale structure, it does not explain the initial source of these fluctuations. There are several competing theories.

The inflationary universe model is an attractive scenario for simultaneously explaining the homogeneity of the universe on large scales and the fluctuations in density observed on the smaller scales. In this scenario, the universe in its first few moments underwent a period of exponential expansion. This rapid expansion, which took place before nucleosynthesis, stretched out any initial density variations and eliminated any monopoles or other unwanted objects that formed before the inflationary epoch. During this inflationary epoch, quantum fluctuations generated new density fluctuations that are predicted to be the initial source of structure. The inflationary scenarios predict that the density parameter Ω should be extremely close to 1. *See* INFLATIONARY UNIVERSE COSMOLOGY.

Maps of the microwave background fluctuations may eventually reveal the source of the initial fluctuations. Different models make different predictions for the amplitude of microwave fluctuations on different scales. The inflationary model predicts that there should be fluctuations of roughly the same amplitude on all angular scales on the sky. The model also suggests that the fluctuations should be random and show no large-scale coherent edges or peaks. Microwave background observations appear to favor the inflationary structure formation scenario. [D.N.S.]

Cotton A fiber obtained from the cotton plant *Gossypium*, of the order Malvales. It has been used for more than 3000 years, and is the most widely used natural fiber, because of its versatility and comparatively low cost to produce and to manufacture into finished products. Cotton traditionally has been used alone in textile products, but blends with artificial fibers are also important. Chemically, cotton is essentially pure cellulose. The natural waxes occurring on the original fiber surface act as a finish which facilitates spinning. *See* CELLULOSE; MALVALES; NATURAL FIBER; TEXTILE.

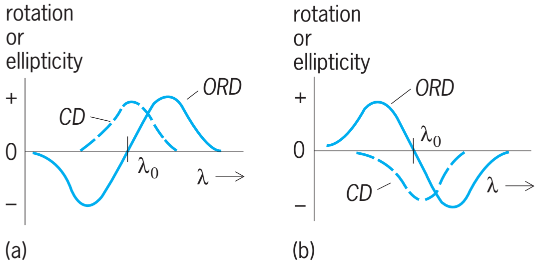
To mature, cotton requires about 180 days of continuously warm weather with adequate moisture and sunlight; frost is harmful and may kill the plant. The plants begin to bloom about 4 months after planting. When the flowers fall off, seed pods grow and become cotton capsules or boils, which must be protected against the boll weevil or other insects. When fully grown, the boils burst, exposing the fleecy white fiber. When the raw cotton is harvested, it contains seeds, leaf fragments, and dirt that must be removed before baling. Cotton seeds alone constitute approximately two-thirds of the weight of the picked cotton.

After harvesting, the fiber, or lint as it is then called, is separated from the seed by gins. The lint is compressed into bales, covered with jute bagging, and bound with metal bands. After baling, the lint is sampled, graded, and sent to cotton mills, where the lint is blended, cleaned, carded, and spun into yams. In the oil mill processing industry, the cottonseed is separated into fuzz or linters, hulls, oil, and protein cake. Each of these products is converted to several subproducts.

The cotton plant is one of the world's major agricultural crops. It is grown in all countries lying within a wide band around the Earth. The limits of this band in the New World are at about 37°N latitude and at about 32°S latitude. In addition to the effects of latitude, suitability of climate for the growth of cotton is also regulated by elevation, wind belts, ocean currents, and mountain ranges. The regions of more intensive culture comprise the Cotton Belt of the United States, the northern valleys of Mexico, India, Pakistan, eastern China, central Asia, Australia, the Nile River valley, eastern Africa, South Africa, northeastern and southern Brazil, northern Argentina, and Peru. Within these regions and outlying districts, 44 countries report data on cotton production. [E.G.N.]

Cotton effect The characteristic wavelength dependence of the optical rotatory dispersion curve or the circular dichroism curve or both in the vicinity of an absorption band.

When an initially plane-polarized light wave traverses an optically active medium, two principal effects are manifested: a change from planar to elliptic polarization, and a rotation of the major axis of the ellipse through an angle relative to the initial direction of polarization. Both effects are wavelength dependent. The first effect is known as circular dichroism, and a plot of its wavelength (or frequency) dependence is referred to as a circular dichroism (CD) curve. The second effect is called optical rotation and, when plotted as a function of wavelength, is known as an optical rotatory dispersion (ORD) curve. In the vicinity of absorption bands, both curves take on characteristic shapes, and this behavior is known as the Cotton effect, which may be either positive or negative (see illustration). There is a Cotton effect associated with each absorption process, and hence a partial CD curve or partial ORD curve is associated with each particular absorption band or process. *See* OPTICAL ROTATORY DISPERSION; POLARIZED LIGHT.



Behavior of the ORD and CD curves in the vicinity of an absorption band at wavelength λ_0, (idealized). (*a*) Positive Cotton effect. (*b*) Negative Cotton effect.

The rotational strengths actually observed vary over quite a few orders of magnitude; this variation in magnitude is useful in stereochemical interpretation of molecular structure. [A.Mo.]

Coulomb excitation Nuclear excitation caused by the time-dependent long-ranged electric field acting between colliding nuclei. Theoretically, the Coulomb force between the positively charged colliding nuclei is well understood, and the interaction is exactly calculable. Coulomb excitation usually is the dominant reaction in nuclear scattering, and even occurs at low bombarding energies where the separation of the nuclei is sufficiently large that the short-ranged nuclear force does not act. *See also* COULOMB'S LAW.

Coulomb excitation plays a vital role in probing the response of both shape and volume collective modes of motion as well as the interplay of single-particle degrees of freedom of the nuclear many-body system. The goal of this work is to develop better models of nuclear structure and to elucidate the underlying nuclear force. *See* NUCLEAR STRUCTURE. [D.Cl.]

Coulomb explosion A process in which a molecule moving with high velocity strikes a solid and the electrons that bond the molecule are torn off rapidly in violent collisions with the electrons of the solid; as a result, the molecule is suddenly transformed into a cluster of charged atomic constituents that then separate under the influence of their mutual Coulomb repulsion. *See* COULOMB'S LAW.

Coulomb explosions are most commonly studied using a particle accelerator, normally employed in nuclear physics research (Van de Graaff generator, cyclotron, and so forth), to produce a beam of fast molecular ions that are directed onto a solid-foil target. The Coulomb explosion of the molecular projectiles begins within the first few tenths of a nanometer of penetration into the foil, continues during passage of the projectiles through the foil, and runs to completion after emergence of the projectiles into the vacuum downstream from the foil. Detectors located downstream make precise measurements of the energies and charges of the molecular fragments together with their angles of emission relative to the beam direction. The Coulomb explosion causes the fragment velocities to be shifted in both magnitude and direction from the beam velocity. *See* PARTICLE ACCELERATOR.

Coulomb explosion experiments serve two main purposes. First, they yield valuable information on the interactions of fast ions with solids. For example, it is known that a fast ion generates a polarization wake that trails behind it as it traverses a solid. This wake can be studied in detail by using diatomic molecular-ion beams, since the motion of a trailing fragment is influenced not only by the Coulomb explosion but also by the wake of its partner. Second, Coulomb-explosion techniques can be used to determine the stereochemical structures of molecular-ion projectiles. *See* ELECTRON WAKE; MOLECULAR STRUCTURE AND SPECTRA; STEREOCHEMISTRY. [D.S.Ge.]

Coulomb's law For electrostatics, Coulomb's law states that the direct force F of point charge q_1 on point charge q_2, when the charges are separated by a distance r, is given by $F = k_0 q_1 q_2 / r^2$, where k_0 is a constant of proportionality whose value depends on the units used for measuring F, q, and r. It is the basic quantitative law of electrostatics. In the rationalized meter-kilogram-second (mks) system of units, $k_0 = 1/(4\pi\epsilon_0)$, where ϵ_0 is called the permittivity of empty space and has the value 8.85×10^{-12} farad/m. Thus, Coulomb's law in the rationalized mks system is as in the equation below, where

$$F = \frac{1}{4\pi\epsilon_0}\frac{q_1 q_2}{r^2}$$

q_1 and q_2 are expressed in coulombs, r is expressed in meters, and F is given in newtons. *See* ELECTRICAL UNITS AND STANDARDS.

The direction of F is along the line of centers of the point charges q_1 and q_2, and is one of attraction if the charges are opposite in sign and one of repulsion if the charges have the same sign. For a statement of Coulomb's law as applied to point magnet poles *see* MAGNETOSTATICS.

Experiments have shown that the exponent of r in the equation is very accurately the number 2. Lord Rutherford's experiments, in which he scattered alpha particles by atomic nuclei, showed that the equation is valid for charged particles of nuclear dimensions down to separations of about 10^{-12} cm. Nuclear experiments have shown that the forces between charged particles do not obey the equation for separations smaller than this. *See* ELECTROSTATICS. [R.P.Wi.]

Coulometer Electrolysis cell in which a product is obtained with 100% efficiency as a result of an electrochemical reaction. The quantity of electricity, that is, the number of coulombs of electricity (Q), can be determined very accurately by weighing the product that is deposited on an electrode in the course of the electrochemical reaction. The relationship between the weight of the product formed in the coulometer and the quantity of electricity used is given by Faraday's laws of electrolysis. When a constant current of i amperes flows through the electrolyte in the coulometer for t seconds, the number of coulombs passed is given by Eq. (1).

$$Q = it \tag{1}$$

If the current varies in the course of the electrolysis, the simple current-time product in Eq. (1) is replaced by the current-time integral, Eq. (2).

$$Q = \int_0^t i\,dt \tag{2}$$

When Q coulombs of electricity are passed through the electrolyte, the weight in grams of the material that is deposited on the electrode (w) is given by Eq. (3), where n is the number

$$w = \frac{QM}{Fn} \tag{3}$$

of electrons transferred per mole of material deposited, M is its molecular weight, and F is the Faraday constant, 96,487 ± 1.6 coulombs.

Equation (3) is fundamental in coulometry and is a mathematical statement of Faraday's laws. This equation is used for the accurate determination of Q, the current-time integral, by weighing or measuring a product that is formed at an electrode by an electrochemical reaction that occurs with 100% current efficiency. The electrolysis cell that is used for this purpose is a coulometer.

Only a few electrode reactions proceed with the 100% current efficiency that is required for the use of Eq. (3). The deposition of silver or copper (in a silver or copper coulometer), the evolution of oxygen and hydrogen (in a gas coulometer), and the oxidation of iodide to iodine (in an iodine coulometer) are examples of electrode reactions that have been successfully employed. One coulomb of electricity will deposit 1.1180 mg of silver at the cathode in a silver coulometer or liberate 1.315 mg of iodine at the anode in an iodine coulometer. Although these classical chemical coulometers are capable of measuring the quantity of electricity with high precision and accuracy, their use is time-consuming and inconvenient; and they have been largely replaced by operational amplifier integrator circuits or digital circuits that display in a direct readout the number of coulombs passed during electrolysis. *See* ELECTROCHEMICAL EQUIVALENT; ELECTROLYSIS. [Q.F.]

Countercurrent exchange (biology) Engineers have known for decades that efficient, almost complete heat or other exchange could be achieved between two fluids flowing in opposite directions in separate tubes. Such countercurrent systems have evolved numerous times in living organisms for all types of exchange function. They are most commonly found in the circulatory, respiratory, and excretory (kidney) systems, serving in heat, oxygen, and ion exchange. Biological countercurrent systems can be classified into two main types: downhill exchanges and hairpin multipliers. In both cases, the basic mechanism is the same-exchange of substance between fluids flowing in opposite directions—but the consequences are very different.

Downhill exchange systems are commonest in the circulatory system where their morphological structure is a rete (network) of closely oppressed sets of small arteries and veins. They are also found in gills of fish and in the minute air tubules of the avian lung. In downhill exchanges, fluids flow in opposite directions in separate tubes with the possibility of exchange, for example, heat flow or diffusion of oxygen, between them. The fluid entering one tube is warmest at that end, while that entering the second tube is coolest at the other end. Heat flows from higher to lower temperature. Although the temperature differential between the two fluids is small at any point along the length of the countercurrent system, almost all the heat contained in the warmer tube is transferred to the cooler tube. Exchange of heat or oxygen occurs by passive diffusion. Most of the heat that entered the countercurrent system at one end leaves the system at the same end.

Retia of blood vessels thus serve as thermal isolating mechanisms within the body. Downhill exchange systems in the gills of fish and in the air tubules of birds permit maximum exchange of oxygen from the environment into the blood. Blood in respiratory capillaries flows against the water or air current and thus can pick up most of the oxygen contained in the external fluid. The advantage of downhill exchangers is that they achieve greater efficiency without extra energy cost simply by arranging flow in a countercurrent rather than in a concurrent fashion.

Hairpin multiplier systems take their name from the structure of the tubes, which have a hairpin turn between the afferent (descending) and the efferent (ascending) limbs. Hairpin countercurrent systems are found in the nephron (the loop of Henle) of the kidney and in the capillary system of the gas gland in the swim bladder of many fish. In contrast to downhill systems, which operate by passive transport, hairpin multipliers must employ active transport of materials. These are always materials pumped out of the efferent limb of the system. *See* KIDNEY; RESPIRATORY SYSTEM; SWIM BLADDER. [W.J.B.]

Countercurrent transfer operations Industrial processes in chemical engineering or laboratory operations in which heat or mass or both are transferred from one fluid to another, with the fluids moving continuously in very nearly steady state or constant manner and in opposite directions through the unit. Other geometrical arrangements for transfer operations are the parallel or concurrent flow, where the two fluids enter at the same end of the apparatus and flow in the same direction to the other end, and the cross-flow apparatus, where the two fluids flow at right angles to each other through the apparatus.

In heat transfer there can be almost complete transfer in countercurrent operation. The limit is reached when the temperature of the colder fluid becomes equal to that of the hotter fluid at some point in the apparatus. At this condition the heat transfer is zero between the two fluids. Most heat transfer equipment has a solid wall between the hot fluid and the cold fluid, so the fluids do not mix. Heat is transferred from the hot fluid through the wall into the cold fluid. Another type of equipment does use direct contact between the two fluids-for example, the cooling towers used to remove heat from a circulating water stream. *See* COOLING TOWER; HEAT BALANCE; HEAT EXCHANGER; HEAT TRANSFER.

Mass transfer involves the changing compositions of mixtures, and is done usually by physical means. A material is transferred within a single phase from a region of high concentration to one of lower concentration by processes of molecular diffusion and eddy diffusion. In typical mass transfer processes, at least two phases are in direct contact in some state of dispersion, and mass (of one or more substances) is transferred from one phase across the interface into the second phase. Mass transfer takes place between two immiscible phases until equilibrium between the two phases is attained. In mass transfer there is seldom an equality of concentration in the two equilibrium phases. This means that a component may be transferred from a phase at low concentration (but at a concentration higher than that at equilibrium) to a second phase of greater concentration. The approach to equilibrium is controlled by diffusion transport across phase boundaries.

Although the two phases may be in concurrent flow or crossflow, usual arrangements have the phases moving in Countercurrent directions. The more dense phase enters near the top of a vertical cylinder and moves downward under the influence of gravity. The less dense phase enters near the bottom of the cylinder and moves upward under the influence of a small pressure gradient. *See* ADSORPTION; CHEMICAL SEPARATION TECHNIQUES; DISTILLATION; ELECTROPHORESIS; EXTRACTION; LEACHING. [F.J.L.]

Couple A system of two parallel forces of equal magnitude and opposite sense. Under a couple's action a rigid body tends only to rotate about a line normal to the couple's plane. This tendency reflects the vector properties of a couple.

The total force of a couple is zero. The total moment **C** of a couple is identical about any point. Accordingly, **C** is the moment of either force about a point on the other and is perpendicular to the couple's plane. *See* RESULTANT OF FORCES; STATICS.

The moment of a couple about a directed line is the component of its total moment in the line's direction. Couples are equivalent whose total moments are equal. [N.S.F.]

Coupled circuits Two or more electric circuits are said to be coupled if energy can transfer electrically or magnetically from one to another. If electric charge, or current, or rate of change of current in one circuit produces electromotive force or affects the voltage between nodes in another circuit, the two circuits are coupled.

Between coupled circuits there is mutual inductance, resistance, or capacitance, or some combination of these. The concept of a mutual parameter is based on the loop method of analysis. A mutual parameter can be one that carries two or more loop currents; such a network has conductive coupling because electricity can flow from one circuit to the other.

Also, there can be purely inductive coupling, which appears if the magnetic field produced by current in one circuit links the other circuit. A two-winding transformer is an application of inductive coupling, with energy transferred through the magnetic field only.

It is also possible to have mutual capacitance, with energy transferred through the electric field only. Examples are the mutual capacitance between grid and plate circuits of a vacuum tube, or the capacitive interference between two transmission lines, as a power line and a telephone line, that run for a considerable distance side by side.

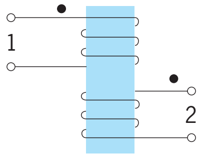


Fig. 1. Polarity of coils.

There are several ways to show the relative polarities of inductive coupling. Figure 1 shows two coils wound on the same core. Current flowing into the upper end of coil 1 would produce magnetic flux upward in the core, and so also would current flowing into the upper end of coil 2. For this reason the upper ends of the two coils are said to be corresponding ends. Dots are placed on a diagram at the corresponding ends of coupled coils. Such dots are shown in Fig. 1, though they are not needed in this figure. Dots are also shown in Fig. 2, where they give the only means of identifying corresponding ends of the coils shown. [H.H.Sk.]

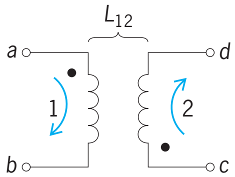

Fig. 2. Mutual inductance L_{12}. Letters *a*, *b*, *c*, and *d* label terminals.

Coupling The mechanical fastening that connects shafts together for power transmission, often to form long sections of shafting or to connect the shaft of a machine to an external drive. Couplings are classified with respect to the kind of alignment and the centerline position of the connecting shafts. Rigid couplings are used where the axes of the shafts are directly in line, flexible couplings where the axes may be at a slight angle and slightly displaced, and universal joint couplings for large angularity or large displacement.

A rigid coupling is suitable for shafts in close alignment or held in alignment without inducing destructive forces in shafts or bearings. For commercial shafting, the coupling may be a sleeve with the shafts pressed into each end, or it may be a clamping sleeve. The sleeve on each shaft end may have an external flange with bolt holes. Couplings for large power machines are bolted together to hold the shafts rigidly; hence the shafts must be accurately aligned before assembly.

Flexible coupling provides the mechanical connection for shafts at a slight angle and displaced somewhat, particularly where power machines may set up vibratory forces. Such couplings are used when alignment is difficult to obtain, when a nonrigid support makes alignment impossible to maintain, or if shaft position changes because of operation. Flexible couplings consist of symmetrical hubs on each end of the joined shafts with a flexible connecting member between. This member may take such forms as the floating gear, the embedded spring, the flexible pin, and the flexible disk. Flexible couplings not only provide for lateral and angular misalignment, but also reduce the transmission of shock loads and change the vibration characteristics and critical speeds of the shafts. Oldham's coupling is the original flexible coupling, and presents the basic principle from which most flexible couplings are derived.

A flexible coupling for connecting shafts that have appreciable permanent angularity is termed a universal joint. *See* CLUTCH; FLUID COUPLING; SHAFTING; UNIVERSAL JOINT. [J.J.R.]

Covellite A mineral having composition CuS and crystallizing in the hexagonal system. It is usually massive or occurs in disseminations through other copper minerals. The luster is metallic and the color indigo blue. The hardness is 1.5 (Mohs scale), the specific gravity 4.7. Covellite is a common though not abundant mineral in most copper deposits. It is a supergene mineral and is thus found in the zone of sulfide enrichment associated with other copper minerals, principally chal-cocite, chalcopyrite, bornite, and enargite, and is derived by their alteration. *See* BORNITE; CHALCOCITE; CHALCOPYRITE; COPPER; ENARGITE. [C.S.Hu.]

Cover crops Unharvested crops grown to improve soil quality or enhance pest management. Increasing numbers of farmers plant cover crops as a means of conserving soil, enhancing production, and reducing off-farm inputs. The sustainable agriculture movement has been a driving force for the increased use of cover crops. Cover cropping can accomplish a wide range of desired benefits, although there can be some drawbacks.

Cover crops play a vital role in controlling erosion by (1) shielding the soil surface from the impact of falling raindrops; (2) holding soil particles in place; (3) preventing crust formation; (4) improving the soil's capacity to absorb water; (5) slowing the velocity of runoff; and (6) removing subsurface water between storms through transpiration. Cover crops also improve soil structure by adding organic matter. Legume cover crops add nitrogen to the soil, which can then be used by crops. Insect, weed, and nematode management can be affected by cover cropping, as cover crops provide a food source to many beneficial insect species. In turn, these beneficial insects may feed on adjacent crop pests.

Cover crops require knowledge and management to attain the desired benefit. If they are not properly selected or managed, there are drawbacks to their use, including depletion of soil moisture, competition with the adjacent crop (when present) for soil moisture and nutrients, increased frost hazard in orchards and vineyards, increased insect, nematode, and weed pests, and added costs to purchase and plant seeds.

Cover crops can be readily grown in humid climates and in arid and semiarid climates where irrigation provides sufficient water that cover crops do not rob the soil of needed moisture. Cover crops that reseed themselves are often sown on rangeland. Long-lived grasses have been widely seeded on many different soil types in the Great Plains.

In cold climates, many common spring-sown crops can be advantageously used as cover crops. Buckwheat (*Fagopyrum esculentum*) can be used as a cover crop to protect the soil and as a smother crop to control weeds; it also improves the soil upon incorporation.

Cover cropping in orchard and vineyard middles is often easier than in annual crops because they are grown between the crop spatially rather than temporally. A wide range of species, mixes, and management systems are used in orchards and vineyards. *See* AGRICULTURAL SOIL AND CROP PRACTICES; NITROGEN FIXATION; SOIL CONSERVATION. [C.In.; P.J.Z.]

Cowpea The legume *Vigna unguiculata* ssp. *unguiculata*, also called southern pea, blackeye pea, or blackeye bean (United States), or niébé (French-speaking Africa). It is an important source of dietary protein for human consumption and of animal feed in the tropics, especially in Africa, Brazil, and India where cowpeas are grown mostly as a subsistence crop for home consumption and are not sold in markets. The cowpea is adapted to hotter, more arid climates and more infertile soils than other food legume crops. Its symbiotic nitrogen-fixing abilities help maintain soil fertility in peasant cropping systems.

The cowpea was domesticated in Africa from one of several wild taxa that belong to the same species as the cultivars and are classified as *V. unguiculata* ssp. *dekindtiana*. Cultivars generally have dark-green, glabrous, shiny leaves. Growth habits include climbing, prostrate, and bush types. Flowers are white or violet with various color patterns. Most cultivars are self-pollinating. Seeds can be kidney or egg shaped, spherical or rhomboid. Pigmentation covers the entire seed (self-colored) or surrounds the hilum (eye). Colors are mottled, speckled, or solid and include white, cream, brown, red, pink, green, and black.

The most important utilization of cowpeas is that of seeds, whether mature (dry seeds or blackeye bean) or immature (southern pea). Seeds are marketed as a dry pack or as a canned or frozen product. Other uses, such as for the yard-long beans, are becoming more available, especially in specialty food markets. *See* LEGUME. [P.Ge.]

Coxsackievirus A large subgroup of the genus *Enterovirus* in the family Picornaviridae. The coxsackieviruses produce various human illnesses, including aseptic meningitis, herpangina, pleurodynia, and encephalomyocarditis of newborn infants. *See* ENTEROVIRUS; PICORNAVIRIDAE.

Coxsackieviruses measure about 28 nanometers in diameter; they resemble other enteroviruses in many biological properties, but differ in their high pathogenicity for newborn mice. At least 23 antigenically distinct types in group A are now recognized, and 6 in group B.

After incubation for 2–9 days, during which the virus multiplies in the enteric tract, clinical manifestations appear which vary widely. Diagnosis is by isolation of virus in tissue culture or infant mice. Stools are the richest source of virus. Neutralizing and complement-fixing antibodies form during convalescence and are also useful in diagnosis. *See* ANTIBODY; COMPLEMENT-FIXATION TEST; NEUTRALIZING ANTIBODY; TISSUE CULTURE.

The coxsackieviruses have worldwide distribution. Infections occur chiefly during summer and early fall, often in epidemic proportions. Spread of virus, like that of other enteroviruses, is associated with family contact and contacts among young children. *See* ANIMAL VIRUS; VIRUS CLASSIFICATION. [J.L.Me.; M.E.Re.]

CPT theorem A fundamental ingredient in quantum field theories, which dictates that all interactions in nature, all the force laws, are unchanged (invariant) on being subjected to the combined operations of particle-antiparticle interchange (so-called charge conjugation, *C*), reflection of the coordinate system through the origin (parity, *P*), and reversal of time, *T*. In other words, the *CPT* operator commutes with the hamiltonian. The operations may be performed in any order; *TCP*, *TPC*, and so forth, are entirely equivalent. If an interaction is not invariant under any one of the operations, its effect must be compensated by the other two, either singly or combined, in order to satisfy the requirements of the theorem. *See* Quantum field theory.

The *CPT* theorem appears implicitly in work by J. Schwinger in 1951 to prove the connection between spin and statistics. Subsequently, G. Lüders and W. Pauli derived more explicit proofs, and it is sometimes known as the Lüders-Pauli theorem. The proof is based on little more than the validity of special relativity and local interactions of the fields. The theorem is intrinsic in the structure of all the successful field theories. *See* Quantum statistics; Relativity; Spin (quantum mechanics).

CPT assumed paramount importance in 1957, with the discovery that the weak interactions were not invariant under the parity operation. Almost immediately afterward, it was found that the failure of *P* was attended by a compensating failure of *C* invariance. Initially, it appeared that *CP* invariance was preserved and, with the application of the *CPT* theorem, invariance under time reversal. Then, in 1964 an unmistakable violation of *CP* was discovered in the system of neutral *K* mesons. *See* Parity (quantum mechanics).

One question immediately posed by the failure of parity and charge conjugation invariance is why, as one example, the π^+ and π^- mesons, which decay through the weak interactions, have the same lifetime and the same mass. It turns out that the equality of particle-antiparticle masses and lifetimes is a consequence of *CPT* invariance and not *C* invariance alone. *See* Elementary particle; Meson; Symmetry laws (physics). [V.F.]

Crab The name applied to arthropods in sections Anomura and Brachyura of the reptantian suborder of the order Decapoda, class Crustacea. The term crab is also sometimes used for two species of sucking lice (order Anoplura) which prey upon humans. *Phthirus pubis* is the crab louse which inhabits the pubic region.

Section Anomura includes over 1400 species in 12 different families. Commonly called hermit, king, sand, or mole crabs, the anomurans have lobsterlike abdomens which bend beneath the cephalothorax in crablike manner, setting them apart in a somewhat ill-defined group.

Section Brachyura encompasses the so-called true crabs, with reduced abdomens folded snugly beneath the cephalothorax. More than 4500 species making up 28 families have been grouped into subsections. In addition to subsections Dromiacea, Gymnopleura, and Oxystomata, the Hapalocarcinidea has one family of the same name containing three genera of small crabs with elongated abdomens. Subsection Brachygnatha is the largest group of brachyurans and includes the most typical crabs. It has 20 families encompassing over 3700 species which occupy a variety of habitats, undergo different types of development, and exhibit contrasting patterns of behavior. *See* Crustacea; Decapoda (crustacea). [M.S.K.]

Crab Nebula The Crab Nebula is the remnant of a tremendous stellar explosion witnessed by Chinese astronomers in 1054. The explosion, called a supernova, occurred at a distance of about 2000 parsecs from the Earth (1 parsec = 1.9×10^{13} mi = 3.1×10^{13} km = 3.26 light-years). *See* Supernova.

The Crab now consists of three components. At the heart of the nebula is what is left of the core of the Crab's giant stellar progenitor. This neutron star has twice the mass of the Sun concentrated into an object only about 20 km (12 mi) across, giving it a density of 10^9 tons per cubic centimeter. The neutron star is spinning at 30 times a second, whipping its powerful (10^8 tesla) magnetic field around with it. Radiation formed in this extreme environment is concentrated into two intense beams directed away from the neutron star's two magnetic poles. As these beams sweep past the direction of the Earth like the beam from a lighthouse, the star appears to wink on and off, earning it the name "pulsar." The Crab pulsar has been seen in all parts of the electromagnetic spectrum from gamma rays through radio waves. *See* Gamma-ray astronomy; Neutron star; Pulsar; Radio astronomy; X-ray astronomy.

Crab Nebula, the 900-year-old remnant of a cataclysmic stellar explosion.

The Crab pulsar's rotational period is slowing by 34 nanoseconds a day, and as it slows it loses 100,000 times more power than is radiated away by the Sun. Most of this energy is carried away from the pulsar by a wind of electrons and positrons moving at close to the speed of light. The wind feeds a vast cloud of highly relativistic particles. This cloud is called the Crab synchrotron nebula because, as the particles spiral through the nebula's magnetic field, they give off the sort of radiation emitted by a synchrotron particle accelerator. *See* Synchrotron radiation.

The third component of the Crab is a complex of filaments made up of gas ejected by the explosion itself (see illustration). The filaments are ionized by ultraviolet radiation from the synchrotron nebula, causing them to glow like the gas in a fluorescent light bulb. *See* Astrophysics, high-energy; Fluorescence. [J.He.]

Crabapple A fruit, represented commercially by such varieties as Martha, Hyslop, and Transcendent, comprising hybrids between *Malus baccata* (Siberian crabapple) and *M. domestica* (cultivated apple).

Trees are very hardy. At one time the fruit of the crabapple was esteemed because of its high pectin content and its usefulness in jam and jelly manufacture. With the introduction of commercial pectin preparations, demand for the crabapple declined sharply. Except for its use as a pickled product, there is little commercial interest in this fruit. *See* Apple; Fruit, tree; Pectin; Rosales. [H.B.T.]

Cracking A process used in the petroleum industry to reduce the molecular weight of hydrocarbons by breaking molecular bonds. Cracking is carried out by thermal, catalytic, or hydrocracking methods. Increasing demand for gasoline and other middle distillates relative to demand for heavier fractions makes cracking processes important in balancing the supply of petroleum products.

Thermal cracking depends on a free-radical mechanism to cause scission of hydrocarbon carbon-carbon bonds and a reduction in molecular size, with the formation of olefins, paraffins, and some aromatics. Side reactions such as radical saturation and polymerization are controlled by regulating reaction conditions. In catalytic cracking, carbonium ions are formed on a catalyst surface, where bond scissions, isomerizations, hydrogen exchange, and so on, yield lower olefins, isoparaffins, isoolefins, and aromatics. Hydrocracking is based on catalytic formation of hydrogen radicals to break carbon-carbon bonds and saturate olefinic bonds. It converts intermediate- and high-boiling distillates to middle distillates high in paraffins and low in cyclics and olefins. *See* HYDROCRACKING. [E.C.L.]

Cranberry The large-fruited American cranberry, *Vaccinium macrocarpon*, a member of the heath family, Ericaceae, is a native plant of open, acid peat bogs in northeastern North America. Well-tended cranberry bogs continue to produce annual crops for a century or more without replanting. Selections from the wild have been cultivated since the early 19th century. It is an evergreen perennial vine producing runners and upright branches with conspicuous terminal flower buds.

Commercial cranberry growing is confined to Massachusetts, New Jersey, Wisconsin, Washington, and Oregon and to several provinces in Canada. Most of the fruit destined for processing is harvested in flood waters, either by machines which pick and deliver the fruit into towed plastic boats or by water reels which detach the berries to float and be driven by wind to shore where they are elevated into bulk trucks. Berries for juice manufacture are usually vine-ripened and deep-frozen for a month or more prior to thawing and extraction.

Good-quality fresh cranberries can be stored for several months, refrigerated, with very little loss to decay. Good-quality cranberries can be kept in deep-freeze storage for several years with only minor moisture loss. Frozen berries on thawing are soft and juicy, unlike the firm fresh berry, and must be utilized promptly.

The special requirements of the cranberry plant for low fertility, acid soil, and winter protection make it a poor choice for home garden cultivation. [C.E.C.]

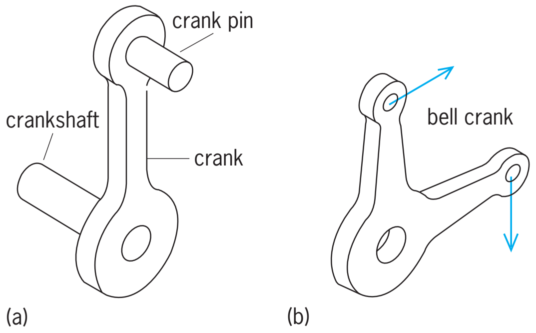
Cranial nerve Any peripheral nerve which has its central nervous system connection with the brain, as opposed to the spinal cord, and reaches the brain through a hole (foramen) in the skull. Nerve fibers are sensory if they carry information from the periphery to the brain, and motor if they carry information from the brain to the periphery. Sensory fibers are classified as (1) somatic sensory (ss) if they come from the skin or muscle sense organs, (2) visceral sensory (vs) if they come from the viscera, and (3) special sensory (sp.s) if they come from special sense organs such as the eye and ear. Motor fibers are classified as (1) somatic motor (sm) if they carry information to somatic striated muscles, (2) general visceral motor (gvm) if they carry information to glands, smooth muscle, or cardiac muscle, and (3) special visceral motor (svm) if they carry information to visceral striated muscle. A cranial nerve may have only one fiber type or several; cranial nerves with several fiber types are called mixed nerves.

In mammals, 12 pairs of cranial nerves, numbered I through XII, are usually described. However, mammals also have an anterior unnumbered nerve, the terminal nerve. Many vertebrates also have two pairs of lateral line nerves (unnumbered), and lack discrete nerves XI and XII. The table summarizes the cranial nerves of vertebrates. *See* BRAIN. [D.B.W.]

Cranial nerves of vertebrates

No.	Name (type)	Peripheral origin or destination
—	Terminal (ss)	Anterior nasal epithelium
I	Olfactory (sp.s)	Olfactory mucosa
—	Vomeronasal (sp.s)	Vomeronasal mucosa
II	Optic (sp.s)	Retina of eye
III	Oculomotor (sm)	Four extrinsic eye muscles
IV	Trochlear (sm)	One extrinsic eye muscle
V	Trigeminal (svm)	Muscles of mandibular arch derivative
	(ss)	Most of head
VI	Abducens (sm)	One extrinsic eye muscle
—	Anterior lateral line (sp.s)	Lateral line organs of head
VII	Facial (svm)	Muscles of hyoid arch derivative
	(gvm)	Salivary glands
	(ss)	Small part of head
	(vs)	Anterior pharynx
	(sp.s)	Taste, anterior tongue
VIII	Vestibulocochlear (sp.)	Inner ear
—	Posterior lateral line (sp.s)	Lateral line organs of trunk
IX	Glossopharyngeal (svm)	Muscles of third branchial arch
	(gvm)	Salivary gland
	(ss)	Skin near ear
	(vs)	Part of pharynx
	(sp.s)	Taste, posterior tongue
X	Vagus (svm)	Muscles of arches 4–6
	(gvm)	Most viscera of entire trunk
	(vs)	Larynx and part of pharynx
	(sp.s)	Taste, pharynx
XI	Spinal accessory (svm)	Some muscles of arches 4–6
XII	Hypoglossal (sm)	Muscles of tongue and anterior throat

Crank In a mechanical linkage or mechanism, a link that can turn about a center of rotation. The crank's center of rotation is in the pivot, usually the axis of a crankshaft, that connects the crank to an adjacent link. A crank is arranged for complete rotation (360°) about its center; however, it may only oscillate or have intermittent motion. A bell crank is frequently used to change direction of motion in a linkage (see illustration). *See* LINKAGE (MECHANISM). [D.P.Ad.]



Cranks (*a*) for changing radius of rotation, and (*b*) for changing direction of translation.

Craton A large, relatively stable portion of the Earth's crust. Although ocean basins originally were considered low cratons, today the term applies only to continents. Continental (high) cratons are the broad heartlands of continents with subdued topography, encompassing the largest areas of most continents. Cratons experience only broad (epeirogenic) warping and occasional faulting in contrast to the much more structurally mobile or unstable zones of continents, which include mountain ranges, such as the Himalaya, and rift zones, such as those of East Africa. The terminology used today to express these contrasts was first proposed by the German geologist L. Kober in 1921. *Kratogen* referred to stable continental platforms, and *orogen* to mountain or orogenic belts. Later authors shortened the former term to kraton or craton. A complementary term, taphrogen, coined in the 1940s, encompasses the rift structures.

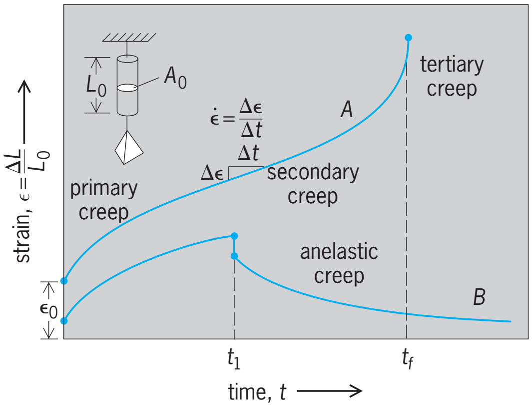
The present North American craton comprises the low continental interior extending from the young Rocky Mountains east to the older Paleozoic Appalachian Mountains, and north to the Paleozoic Franklin mountain belt along the Arctic margin of Canada and Greenland. The Canadian shield is that part of the craton where pre-Paleozoic rocks are widely exposed today. In contrast, the remainder of the craton in the plains of western Canada and most of the central United States has little-deformed younger strata at the surface. Most continents have similar large Phanerozoic cratons. *See* Continents, evolution of; Earth crust.

Cratons are believed to comprise bits of old continental crust, which have had long and complex histories involving the overprinting of many tectonic events. Continents can be viewed as great collages of tectonic elements amalgamated together at different times and in different ways. Therefore, the delineation of both cratons and orogens has an important temporal element: What is now a craton may be made up of interlaced orogens of differing ages, each of which may include bits of mangled older cratons within them. Refined studies of seismic waves that have penetrated the Earth's deep interior indicate that beneath cratons there is anomalous mantle with distinctive compositional or thermal characteristics. Such roots imply a long-term linkage between the evolution of early continental crust and underlying mantle, which somehow contributed to the survival of fragments of cratons older than 2.5–3 billion years. *See* Orogeny; Plate tectonics. [R.H.Dot.]

Creep (materials) The time-dependent strain occurring when solids are subjected to an applied stress. *See* Stress and strain.

Some of the different kinds of creep phenomena that can be exhibited by materials are shown in the illustration. The strain $\epsilon = \Delta L/L_0$, in which L_0 is the initial length of a body and ΔL is its increase in length, is plotted against the time t for which it is subjected to an applied stress. The most common kind of creep response is represented by the curve A. Following the loading strain ϵ_0, the creep rate, as indicated by the slope of the curve, is high but decreases as the material deforms during the primary creep stage. At sufficiently large strains, the material creeps at a constant rate. This is called the secondary or steady-state creep stage. Ordinarily this is the most important stage of creep since the time to failure t_f is determined primarily by the secondary creep rate $\dot{\epsilon}_s$. In the case of tension creep, the secondary creep stage is eventually interrupted by the onset of tertiary creep, which is characterized by internal fracturing of the material, creep acceleration, and finally failure. The creep rate is usually very temperature-dependent. At low temperatures or applied stresses the time scale can be thousands of years or longer. At high temperatures the entire creep process can occur in a matter of seconds. Another kind of creep response is shown by curve B. This is the sort of strain-time behavior observed when the applied stress is partially or completely removed in the course of creep. This results in time-dependent or anelastic strain recovery.

Creep of materials often limits their use in engineering structures. The centrifugal forces acting on turbine blades cause them to extend by creep. In nuclear reactors the metal tubes that contain the fuel undergo creep in response to the pressures and forces exerted on them. In these examples the occurrence of creep is brought about by the need to operate these systems at the highest possible temperatures. Creep also occurs in ordinary structures. An example is found in prestressed concrete beams, which are held in compression by steel rods that extend through them. Creep and stress relaxation in the steel rods eventually leads to a reduction of the compression force acting in the beam, and this can result in failure. *See* Prestressed concrete.



Typical creep curves for materials.

The mechanism of creep invariably involves the sliding motion of atoms or molecules past each other. In amorphous materials such as glasses, almost any atom or molecule within the material is free to slide past its neighbor in response to a shear stress. In plastics, the long molecular chains can slide past each other only to a limited extent. Such materials typically show large anelastic creep effects (curve B in the illustration).

For crystalline materials, creep deformation also involves the sliding of atoms past each other, but here the sliding can occur only within the cores of crystal dislocations. Thus, creep of metals and ceramics is usually governed by the motion of dislocations.

It is possible to design materials with superior creep resistance. When solute atoms are added to metals, they are attracted to the strain fields of the dislocations. There they inhibit dislocation motion and in this way improve the creep resistance. Many of the aluminum alloys used for aircraft structures are strengthened in this way. The addition of second-phase particles to alloys is another way to improve the creep resistance. The most effective strengthening phases are oxides, carbides, or intermetallic phases, because they are usually much stronger than the host metal and therefore create strong obstacles to dislocation motion. Materials containing finely dispersed, strong particles of a stable phase are usually very creep-resistant. Nickel-based superalloys, used in gas-turbine engines, derive their creep resistance from these effects. *See* Aluminum alloys; Crystal defects; Diffusion; High-temperature materials; Metal, mechanical properties of; Plasticity; Rheology. [W.D.N.; J.G.C.; K.J.He.]

Creeping flow Fluid at very low Reynolds number. In the flow of fluids, a Reynolds number (density · length · velocity/viscosity) describes the relative importance of inertia effects to viscous effects. In creeping flow the Reynolds number is very small (less than 1) such that the inertia effects can be ignored in comparison to the viscous resistance. Creeping flow at zero Reynolds number is called Stokes flow.

Mathematically, viscous fluid flow is governed by the Navier-Stokes equation. In creeping flow the nonlinear momentum terms are unimportant, and the Navier-Stokes equation can be linearized. *See* Fluid flow; Fluid-flow principles; Fluid mechanics; Navier-Stokes equation; Reynolds number; Viscosity.

Examples of creeping flow include very small objects moving in a fluid, such as the settling of dust particles and the swimming of microorganisms. Other examples include the flow of fluid (ground water or oil) through small channels or cracks, such as in hydrodynamic lubrication or the seepage in sand or rock formations. The flow of high-viscosity fluids may also be described by creeping flow, such as the extrusion of melts or the transport of paints, heavy oils, or food-processing materials. [C.Y.W.]

Creodonta An extinct order of mammals containing the dominant carnivores in North America, Europe, Asia, and Africa during much of the Cenozoic. Its members roamed the Earth for more than 50 million years, then became extinct less than 9 million years ago. Creodonts were not part of the order Carnivora, but they independently evolved carnivorous specializations in their teeth and limbs. They ranged from tiny (*Isohyaenodon* from Africa was the size of a small weasel) to gigantic (*Hyainailouros* from Europe and Asia was one of the largest land-dwelling mammalian carnivores ever). The wolflike genus *Hyaenodon* is probably the most familiar creodont among the more than 180 known species. Most lived in North America and

Europe, but new species from Africa and Asia are being described at an incredible rate. *See* Dentition.

There are two major families within Creodonta: Hyaenodontidae and Oxyaenidae. Hyaenodontids are the more diverse, with more than 140 known species. Oxyaenids were less diverse (only about 40 species are known).

The formal classification of Creodonta has changed considerably. Improved knowledge about the relationships of placental mammals has resulted in many former creodont families being moved to other orders so that only oxyaenids and hyaenodontids remain. It is unclear how Hyaenodontidae and Oxyaenidae are related to one another, and their grouping as Creodonta may turn out to be unjustified.

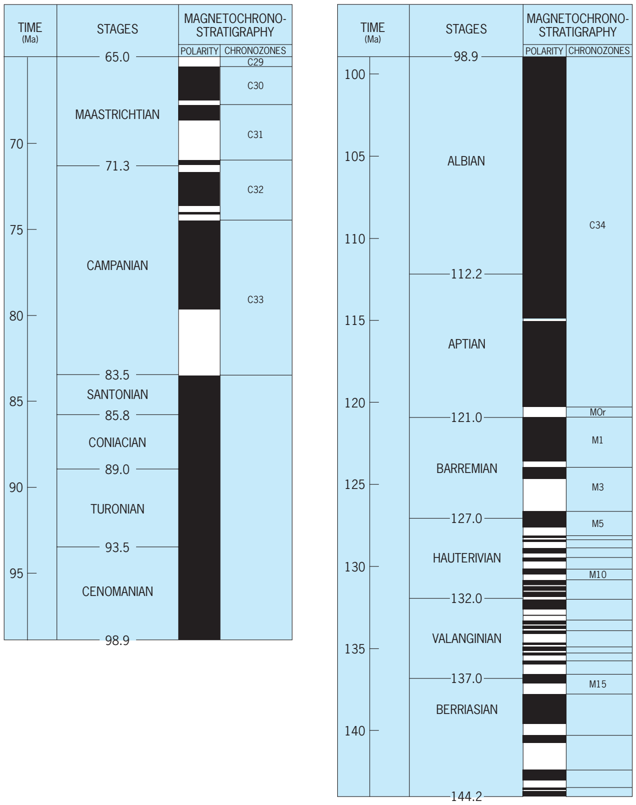
It was long thought that the extinction of the creodonts was caused by competition from better-adapted members of the order Carnivora. However, the timing of creodont evolution does not support this theory. It is more likely that chance and changing conditions, including the evolution and extinction of creodont prey species, explain their slow demise. *See* Carnivora; Mammalia. [P.D.P.]

Cress A prostrate hardy perennial crucifer of European origin belonging to the plant order Capparales. Watercress (*Nasturtium officinale*) is generally grown in flooded soil beds and used for salads and garnishing. Virginia is an important producing state. Garden cress (*Lepidium sativum*) is a cool-season annual crucifer of western Asian origin grown for its flavorful leaves. Of lesser commercial importance is upland or spring cress (*Barbarea verna*), a biennial crucifer of European origin. *See* Capparales. [H.J.C.]

Cretaceous In geological time, the last period of the Mesozoic Era, preceded by the Jurassic Period and followed by the Tertiary Period. The rocks formed during Cretaceous time constitute the Cretaceous System. Omalius d'Halloys first recognized the widespread chalks of Europe as a stratigraphic unit. W. O. Conybeare and W. Phillips (1822) formally established the period, noting that whereas chalks were remarkably widespread deposits at this time, the Cretaceous System includes rocks of all sorts and its ultimate basis for recognition must lie in its fossil remains. *See* Chalk; Fossil; Jurassic; Rock age determination; Stratigraphy; Tertiary.

The parts of the Earth's crust that date from Cretaceous time include three components: a large part of the ocean floor, formed by lateral accretion; sediments and extrusive volcanic rocks that accumulated in vertical succession on the ocean floor and on the continents; and intrusive igneous rocks such as the granitic batholiths that invaded the crust of the continents from below or melted it in situ. The sedimentary accumulations contain, in fossils, the record of Cretaceous life. The plutonic and volcanic rocks are the chief source of radiometric data from which actual ages can be estimated, and suggest that the Cretaceous Period extended from 144 million years to 65 ± 0.5 million years before present (see illustration).

There are 12 globally recognized subdivisions, or stages, in the Cretaceous, based on species development (see illustration). In marine sediments the appearance and disappearance of individual, widely distributed species allows further time resolution by so-called zones. Initially these zones were largely based on ammonites, a now extinct group of cephalopods, closest to the squids and octopuses but resembling the pearly nautilus. Due to the provinciality of some ammonite species and the rarity of many, the dating of Cretaceous marine sediments now mainly devolves on microscopic fossils of calcareous plankton. The most important of these are protozoans. Their shells, in the range of 0.1–1 mm, occurring by hundreds if not thousands in a handful of chalk, have furnished about 38 pantropical zones. Next in importance are the even tinier (0.01-mm) armor plates of "nanoplanktonic" coccolithophores. Thousands may be present in a pinch of chalk, and 24 zones have been recognized. *See* Cephalopoda; Coccolithophorida; Foraminiferida; Marine sediments; Micropaleontology; Paleontology; Phytoplankton; Protozoa; Zooplankton.



Stages of the Cretaceous Period, their estimated ages in years before present, and polarity chrons representing the alternation between episodes of normal (black) and reversed (white) orientations of the Earth's magnetic field. (*After F. M. Gradstein et al., in W. A. Berggren et al., eds., Geochronology, Time Scales and Global Stratigraphic Correlations, SEPM Spec. Publ., no. 54, 1995*)

The Earth's magnetic field reversed about 60 times during Cretaceous time, and the resulting polarity chrons have been recorded in the remanent magnetism of many rock types (illustration). The actual process of reversal occurs in a few thousand years and affects the entire Earth simultaneously, providing geologically instantaneous time signals by which the continental and volcanic records can be linked to marine sequences and their fossil zonation. Noteworthy here is the occurrence of a very long (32-million-year) interval during which the field remained in normal polarity. *See* Paleomagnetism.

During Cretaceous time the breakup of Gondwana, the great late Paleozoic-Triassic supercontinent, became complete. Laurasia had already separated from Africa by the development of Tethys and became split into North America and Eurasia by the opening of the North Atlantic. These new, deep oceanic areas continued to grow in Cretaceous time. India broke away from Australia and Australia from Antarctica. South America tore away from Africa by the development of the South Atlantic Ocean, while India brushed past Madagascar on its way north to collide with southeast Asia. As these new oceanic areas grew, comparable areas of old ocean floor plunged into the mantle in subduction zones such as those that still ring the Pacific Ocean, marked by deep oceanic trenches and by the development of mountain belts and volcanism on adjacent continental margins. *See also* Continents, evolution of; Plate tectonics; Subduction zones.

The face of the globe was also affected by changes in sea level. Sea level at times in the early Cretaceous stood at levels comparable to the present, but subsequently the continents were flooded with relatively shallow seas to an extent probably not attained since Ordovician-Silurian times. Maximal flooding, in the Turonian Stage, inundated at least 40% of present land area. Cretaceous seas covered most of western Europe, though old mountain belts such as the Caledonides of Scandinavia and Scotland remained dry and archipelagos began to emerge in the Alpine belt. In America, seas flooded the southeastern flank of the Appalachian Mountains, extended deep into what is now the Mississippi Valley, and advanced along the foredeep east of the rising Western Cordillera to link at times the Gulf of Mexico with the Arctic Ocean.

Large seas extended over parts of Asia, Africa, South America, and Australia. The wide spread of the chalk facies is essentially due to this deep inundation of continents, combined with the trapping of detrital sediments near their mountain-belt sources, in deltas or in turbidite-fed deep-water fans. At the same time, carbonate platforms were still widespread, and the paratropical dry belts were commonly associated with evaporite deposits. *See* PALEOGEOGRAPHY; SALINE EVAPORITES.

In parts of early Cretaceous time, ice extended to sea level in the polar regions. But during most of Cretaceous time, climates were in the hothouse or greenhouse mode, showing lower latitudinal temperature gradients. Tropical climates may have been much like present ones, and paratropical deserts existed as they do now, but terrestrial floras and faunas suggest that nearly frost-free climates extended to the polar circles as did abundant rainfall, and no ice sheets appear to have reached sea level.

On land, flowering plants (angiosperms) first appeared in early Cretaceous time, as opportunistic plants in marginal settings, and then spread to the understory of woodlands, replacing cycads and ferns. In late Cretaceous time, evergreen angiosperms, including palms, thus came to dominate the tropical rainforests. Evergreen conifers maintained dominance in the drier mid-latitude settings, while in the moist higher latitudes forests of broad-leaved deciduous trees dominated. Insects became highly diverse, and many modern families have their roots in the Cretaceous. Amphibians and small reptiles were present. Larger land animals included crocodiles and crocodilelike reptiles, turtles, and dinosaurs. The mammals remained comparatively minor elements in the Cretaceous faunas. In early Cretaceous time, egg-laying and marsupial mammals were joined by placentals, but Cretaceous mammals were in general small, and lack of color vision in most modern mammalians suggests a nocturnal ancestry and a furtive existence in a dinosaurian world. Birds had arisen, from dinosaurs in Jurassic time, but their fossil record from the Cretaceous is poor and largely one of water birds. More common are the remains of flying reptiles, the pterosaurs. *See* DINOSAUR; MAMMALIA; MARSUPIALIA; PTEROSAURIA.

About 65 million years ago, during the reversed magnetic interval known as chron 29R, a collision with an asteroid or comet showered the entire Earth with impact debris, preserved in many places as a thin “boundary clay” enriched in the trace element iridium. This event coincided with the great wave of extinctions—the K/T crisis—which serve to bound the Cretaceous (Kreide) Period against the Tertiary.

Global effects of the impact must have included earthquake shock many orders of magnitude greater than any found in human history; associated land slips and tidal waves; a dust blackout of sunlight that must have taken many months to clear; a sharp drop in temperatures that would have brought frost to the tropics; changes in atmospheric and water chemistry; and disturbance of existing patterns of atmospheric and oceanic circulation. It is possible that earthquakes influenced volcanic eruptions. Different biotic communities were affected to different degrees. The pelagic community, sensitive to photosynthetic productivity, was severely struck, with coccolithophores and planktonic foraminiferans reduced to a few species, while ammonites, belemnites, plesiosaurs, and mosasaurs were eliminated. Dinoflagellates, endowed with the capacity to encyst under stress, suffered no great loss. Benthic life was only moderately damaged, excepting destruction of the reef community. While North American trees underwent far more extinction at the specific level than formerly believed, land floras escaped with little damage, presumably because they were generally equipped to handle stress by dormancy and seed survival. The plant-fodder-dependent dinosaurs perished, as did their predators and scavengers. The fresh-water community, buffered by ground water against temperature change and food-dependent mainly on terrestrial detritus, was little affected. While a great many individual organisms must have been killed by the immediate effects of the impact, the loss of species and higher taxa must have occurred on land and in shallowest waters mainly in the aftermath of darkness, chill, and starvation, and in the deeper waters in response to changed regimes in currents, temperatures, and nutrition. The Cretaceous crash led above all to an evolutionary outburst of the mammals, which in the succeeding tens of millions of years not only filled and multiplied the niches left by dinosaurs but also invaded the seas. [A.G.F.]

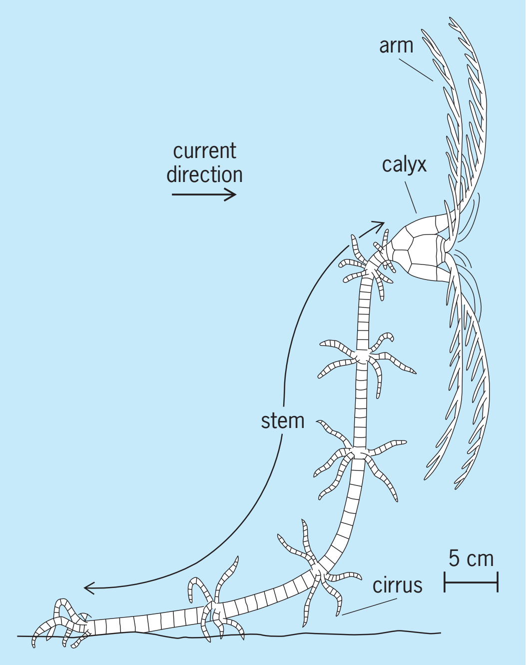
Criminalistics Criminalistics is the science and profession dealing with the recognition, collection, identification, individualization, and interpretation of physical evidence, and the application of the natural sciences to law-science matters. It is not possible for a single person to become proficient in the examination and analysis of all types of physical evidence. Increasingly, criminalists and other workers in forensic science laboratories are specializing in the examination of one or a few types of physical evidence. For example, forensic biologists analyze the biological or genetic properties of evidence, trace evidence analysts identify material that is transferred between two objects and determine its origin, and firearms and toolmark experts examine firearms, ammunition components, and tools and marks left by them. *See* FORENSIC MEDICINE.

A wide variety of techniques are used by criminalists for the location and collection of evidence at crime scenes as well as for the examination and analysis of that evidence in the laboratory. Crime scene techniques may involve the use of lasers or other light sources to locate biological stains or minute fibers or paint particles, chemical tests for lead around suspected bullet holes, electrostatic devices to recover a dusty shoe sole impression from a floor, or special reagents for the development of latent fingerprints.

Many techniques used in the forensic laboratory are the same ones that are used by analytical chemists, molecular biologists, materials scientists, and so on. Often these techniques are adapted to the special requirements of the forensic science laboratory. Infrared spectroscopy, mass spectrometry, gas chromatography, optical and electron microscopy, and a host of other standard analytical chemistry techniques find common use by criminalists.

Routine techniques and procedures have been developed by forensic scientists which have little or no application outside the forensic laboratory. Examples are the determination of genetic markers in minute fragments of dried biological material, the determination of the refractive index of microscopic glass fragments, the microscopic comparison of individual human hairs, and the microscopic comparison of markings on the surface of bullets. [P.D.B.]

Crinoidea A class of exclusively suspension-feeding echinoderms with long, slender arms arranged radially around the calyx, a rigid cuplike structure composed of calcareous plates. The radial arm arrangement gives crinoids a flowerlike appearance (*see* illustration). Two basic adult body types are recognized: the sea lilies, with a long, anchored stem vertically supporting the calyx and arms above the sea bottom; and the stemless featherstars, or comatulids, with a whorl of flexible appendages on the calyx. Crinoids have a worldwide distribution and can be found in all seas except the Black and Baltic. They occupy depths



Schematic diagram of a stemmed crinoid in feeding posture.

ranging from just below sea level to a depth of over 9000 m (29,500 ft). Sea lilies are found only at depths greater than 100 m (330 ft), whereas comatulids are most abundant and diverse in shallow, tropical coral reef environments. *See* BLASTOIDEA; PELMATOZOA.

Over 500 species of living comatulids have been described, and many of these can be extremely abundant locally, yet fewer than 100 species of living sea lilies are known. These patterns contrast starkly with the fossil record of crinoids, which is dominated by stemmed crinoids: of the more than 5000 described fossil species, more than 90% have stems.

Living crinoids have no economic importance and are not used for food by humans. However, their fossil remains are often the dominant constituent of building limestone (for example, Indiana limestone) which is highly valued.

Adult crinoids range in size from a few centimeters for some of the stemless forms to several meters from base of the stem to tip of the arms for the largest stemmed crinoids. They also vary in color from the largely bland whites and grays of the deep-water forms to the brilliant reds, yellows, and purples of the shallow-water tropical featherstars. In spite of the size range, color differences, and stemmed or stemless condition as adults, all crinoids share a suite of morphological traits that can be traced back to the Ordovician age, nearly 500 million years ago. *See* ORDOVICIAN.

Crinoids are exclusively passive suspension feeders, extracting food particles from the ambient water. Crinoids are indiscriminate feeders, and the tube feet capture organic and inorganic particles with a median size of about 50 micrometers and rarely larger than 500 μm. The organic food component consists primarily of phytoplankton, protozoa, and crustacea. Crinoid morphology and behavior strongly reflect their total reliance on water movement for nutrient supply. Crinoids avoid slack-water environments, living in areas dominated by currents, wave action, or multidirectional flows.

Crinoids have a long and rich fossil record, and at times in Earth history they were numerically one of the dominant members of the benthic marine ecosystem. The first undisputed crinoids were found in rocks of the Ordovician Period. The Mississippian Period, known as the Age of Crinoids, represents the peak in their abundance and diversity. Crinoids remained an important component of marine communities until the Permo-Triassic extinction event that signaled the end of the Paleozoic Era. This event led to a great reduction in crinoid diversity. A single genus, *Holocrinus*, found in Lower Triassic rocks, is the most primitive member of the Articulata, a subclass that includes all post-Paleozoic crinoids. *See* ARTICULATA (ECHINODERMATA); CRINOZOA; ECHINODERMATA. [T.K.B.]

Crinozoa A subphylum of the Echinodermata including radially symmetrical echinoderms showing a partly meridional pattern of growth. This tends to produce an aboral cup-shaped theca and a partly radially divergent pattern of growth, forming appendages, called brachioles or arms and bearing ambulacral grooves. Included in the subphylum are the blastoids, cystoids, edrioblastoids, eocrinoids, parablastoids, and paracrinoids. *See* BLASTOIDEA; CRINOIDEA; ECHINODERMATA; EOCRINOIDEA. [H.B.F.]

Critical care medicine The treatment of acute, life-threatening disorders, usually in intensive care units. Critical care medicine has been practiced informally for many decades in trauma centers, postanesthesia recovery rooms, coronary care units, delivery rooms, emergency rooms, and postoperative areas. The facilities and trained personnel available in the intensive care unit (ICU) permit extensive monitoring of physiological variables, organization of complex, multidisciplinary diagnostic and therapeutic plans, administration of therapy to predetermined goals, and expert nursing care.

Critical care thus runs counter to the traditional division of specialties by organ or organ system. Specialists in critical care undergo training beyond a primary qualification (internal medicine, surgery, anesthesia, or pediatrics), and must be able to manage acute respiratory, cardiovascular, metabolic, cerebral, and renal problems, as well as infections. The patients may be newborns, children, or adults suffering from trauma or acute life-threatening disease. Patients having failure of multiple organs, complicated medical problems, disorders falling into several medical specialities, or a need for 24-h care often become the responsibility of the critical care specialist.

The intensive care unit is the most labor-intensive, technically complex, and expensive part of hospital care. The intensive care unit, however, may be crucial to the patient's survival. Perhaps the single most useful function of the intensive care unit is to provide life-support systems for desperately ill patients who would not survive without them. Such systems include mechanical ventilation; cardiopulmonary resuscitation; peritoneal dialysis and hemodialysis; circulatory support with intraaortic balloon pumping; and extracorporeal membrane oxygenation.

Another aspect of critical care is the provision of life-sustaining therapy. Components include administration of intravenous fluids, provision of nutritional support, and control of infections. [W.C.Sh.]

Critical mass The amount of fissile material (uranium-233, uranium-235, or plutonium-239) that supports a self-sustaining nuclear chain reaction. Critical mass is a definitive feature of nuclear reactors and nuclear explosives. It is increased by the presence of such neutron-absorptive materials as admixed uranium-238, aluminum pipes for flow of coolant, zirconium fuel-element cladding, and boron, cadmium, or gadolinium control rods. It is reduced by a moderator, such as graphite, heavy water, or light water, which slows down the neutrons, inhibits their escape, and thus improves the probability of producing fission in the fuel. Without a moderator, natural uranium cannot reach criticality. *See* CHAIN REACTION.

Critical mass also depends on the density of the fissile component, its geometry, and the immediate surroundings. In a reactor the critical mass is not a static quantity because specific nuclear phenomena activate and influence the chain reaction. *See* NUCLEAR REACTOR.

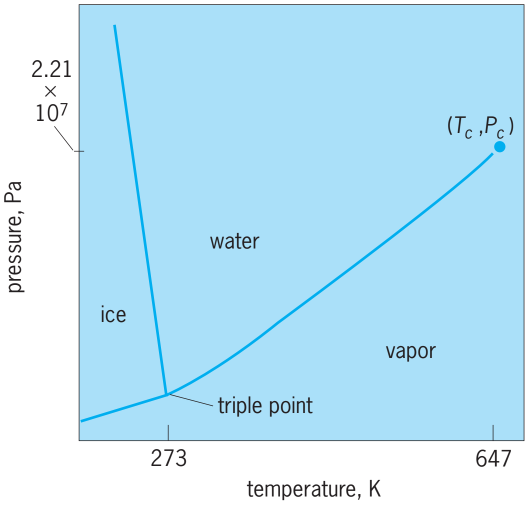
An explosive, supercritical condition can be deliberately created by rapid introduction of reactivity in excess of the requirements for a critical mass. This is the basis for nuclear explosions, which rely on sudden explosively driven densification of a subcritical fissile component. *See* ATOMIC BOMB; HYDROGEN BOMB; NUCLEAR EXPLOSION. [A.DeV.]

Critical phenomena The unusual physical properties displayed by substances near their critical points. The study of critical phenomena of different substances is directed toward a common theory.

Ideally, if a certain amount of water (H_2O) is sealed inside a transparent cell and heated to a high temperature T, for instance, $T > 647$ K (374°C or 705°F), the enclosed water exists as a transparent homogeneous substance. When the cell is allowed to cool down gradually and reaches a particular temperature, namely the boiling point, the enclosed water will go through a phase transition and separate into liquid and vapor phases. The liquid phase, being more dense, will settle into the bottom half of the cell. This sequence of events takes place for water at most moderate densities. However, if the enclosed water is at a density close to $322.2\ \mathrm{kg \cdot m^{-3}}$, rather extraordinary phenomena will be observed. As the cell is cooled toward 647 K (374°C or 705°F), the originally transparent water will become increasingly turbid and milky, indicating that visible light is being strongly scattered. Upon slight additional cooling, the turbidity disappears and two clear phases, water and vapor, are found. This phenomenon is called the critical opalescence, and the water sample is said to have gone through the critical phase transition. The density, temperature, and pressure at which this transition happens determine the critical point and are called respectively the critical density ρ_c, the critical temperature T_c, and the critical pressure P_c. For water $\rho_c = 322.2\ \mathrm{kg \cdot m^{-3}}$, $T_c = 647$ K (374°C or 705°F), and $P_c = 2.21 \times 10^7$ pascals. *See* OPALESCENCE.

Different fluids, as expected, have different critical points. Although the critical point is the end point of the vapor pressure curve on the pressure-temperature (P-T) plane (see illustration), the critical phase transition is qualitatively different from that of the ordinary boiling phenomenon that happens along the vapor pressure curve. In addition to the critical opalescence, there are other highly unusual phenomena that are manifested near the critical point; for example, both the isothermal compressibility and heat capacity diverge to infinity as the fluid approaches T_c. *See* THERMODYNAMIC PROCESSES.

Many other systems, for example, ferromagnetic materials such as iron and nickel, also have critical points. The ferromagnetic critical point is also known as the Curie point. As in the case of fluids, a number of unusual phenomena take place near the critical point of ferromagnets, including singular heat capacity and divergent magnetic susceptibility. The study of critical phenomena is directed toward describing the various anomalous and interesting types of behavior near the critical points of these diverse and different systems with a single common theory. *See* CURIE TEMPERATURE; FERROMAGNETISM. [M.H.W.C.]



Phase diagram of water (H_2O) on pressure-temperature (P-T) plane.

Crocodile The common name used for 14 species of large reptiles included in the family Crocodylidae (order Crocodylia) which also includes the alligators, caimans, and the gharial (also known as the gavial). Like all crocodilians, the crocodiles are primarily distributed throughout the tropical regions of the world. Species occur in both saltwater and freshwater habitats. Crocodiles are generally omnivorous, feeding on invertebrates, fish, other reptiles and amphibians, birds, and mammals—practically any animal they can overpower. A few, very narrow-snouted species are believed to subsist primarily on fish. Crocodiles are primarily aquatic and nocturnal, leaving the water only to bask by day or to build their nests. Some species construct burrows into the banks of rivers or lakes where they spend part of their time.

These animals are powerful predators with large teeth and strong jaws. Large adults of some species may exceed 20 ft (6 m) in length and are capable of overpowering and eating large grazing mammals, even occasionally humans. The webbed feet, flattened tail, and placement of the nostrils, eyes, and ears on raised areas of the head are adaptations for an aquatic existence. The raised nostrils, eyes, and ears allow the animals to float almost completely submerged while still monitoring their environment.

Reproduction in crocodiles is the most elaborate of the reptiles. Courtship and mating occur in the water. The female digs a hole in the soil for the 30 or so eggs. Nests are often guarded by the female. The young may remain together as a pod with the female for a year or more. Hearing and vocal communication are well developed in the crocodiles, and a variety of bellows, snarls, and grunts are utilized in their elaborate social behavior.

Crocodiles are considered very valuable for the leather obtained from their hides, and all species are becoming very rare owing to hunting and to the loss of their habitats through land development for other uses. Most countries with native crocodile populations are implementing conservation measures, and international efforts are being made to regulate trade in a crocodile products. *See* ALLIGATOR; CROCODYLIA; REPTILIA. [H.W.C.]

Crocodylia An order of the class Reptilia (subclass Archosauria) which is composed of large, voracious, aquatic species which include the alligators, caimans, crocodiles, and gavials. The group has a long fossil history from Late Triassic times and its members are the closest living relatives of the extinct dinosaurs and the birds. The 21 or 22 living species are found in tropic areas of Africa, Asia, Australia, and the Americas. One form, the salt-water crocodile (*Crocodylus porosus*), has traversed oceanic barriers from the East Indies as far east as the Fiji Islands. *See* ARCHOSAURIA.

The order is distinguished from other living reptiles in that it has two temporal foramina, an immovable quadrate, a bony secondary palate, no shell, a single median penis in males, socketed teeth, a four-chambered heart, and an oblique septum that completely separates the lung cavities from the peritoneal region. Certain of these unique features and other salient characteristics of the Crocodylia are intimately associated with their aquatic life. For example, there is a special pair of fleshy flaps at the posterior end of the mouth cavity which form a valvular mechanism which separates the mouth from the region where the air passage opens into the throat. This complex arrangement allows crocodilians to breathe even though most of the head is under water, or the mouth is open holding prey or full of water.

During the breeding season male crocodylians set up territories on land which they defend against intruders of the same species. Fertilization is internal and the hard-shelled eggs are deposited in excavations in the sand or in large nests of decaying vegetation, depending upon the species.

The living species are placed in two families and eight genera. The family Crocodylidae contains two subgroups: the true crocodiles, Crocodylinae, including the genera *Crocodylus* found in all tropic areas, *Osteolaemus* in central Africa, and the false gavial (*Tomistoma*) in Malaya and the East Indies; the alligators and caimans, Alligatorinae, including the genera *Alligator* of the southeastern United States and near Shanghai, China, the *Caiman* from Central and South America, and *Melanosuchus* and *Paleosuchus* of South America. The gavial (*Gavialis gangeticus*) of India and north Burma is the only living member of the family Gavialidae. Crocodiles differ most obviously from alligators and caimans in head shape and in the position of the teeth, although other technical details also separate them. *See* ALLIGATOR; CROCODILE; GAVIAL.

Crocodylians first appear in deposits of Late Triassic or possibly Early Jurassic age in North America and South Africa. They formerly were much more widely distributed in temperate latitude than today; abundant paleobotanical evidence confirms a warmer climate in mid-latitudes at this time, It seems probable that the restriction of crocodilians to the tropics was a direct result of cooling climate in the late Cenozoic. *See* REPTILIA. [J.T.G.]

Crocoite A mineral with the chemical composition $PbCrO_4$. Crocoite occurs in yellow to orange or hyacinth red, monoclinic, prismatic crystals with adamantine to vitreous luster; it is also massive granular. Hardness is 2.5–3 on Mohs scale and specific gravity is 6.0. Streak, or color of the mineral powder, is orangish-yellow. It fuses easily.

Crocoite is a secondary mineral associated with other secondary minerals of lead such as pyromorphite and of zinc such as cerussite. It has been found in mines in California and Colorado. *See* LEAD. [E.C.T.C.]

Crossing-over (genetics) The process whereby one or more gene alleles present in one chromosome may be exchanged with their alternative alleles on a homologous chromosome to produce a recombinant (crossover) chromosome which contains a combination of the alleles originally present on the two parental chromosomes. Genes which occur on the same chromosome are said to be linked, and together they are said to compose a linkage group. In eukaryotes, crossing-over may occur during both meiosis and mitosis, but the frequency of meiotic crossing-over is much higher. *See* ALLELE; CHROMOSOME; GENE; LINKAGE (GENETICS).

Crossing-over is a reciprocal recombination event which involves breakage and exchange between two nonsister chromatids of the four homologous chromatids present at prophase I of meiosis; that is, crossing-over occurs after the replication of chromosomes which has occurred in premeiotic interphase. The result is that half of the meiotic products will be recombinants, and half will have the parental gene combinations. Using maize chromosomes which carried both cytological and genetical markers, H. Creighton and B. McClintock showed in 1931 that genetic crossing-over between linked genes was accompanied by exchange of microscopically visible chromosome markers. *See* RECOMBINATION (GENETICS).

In general, the closer two genes are on a chromosome, that is, the more closely linked they are, the less likely it is that crossing-over will occur between them. Thus, the frequency of crossing-over between different genes on a chromosome can be used to produce an estimate of their order and distances apart; this is known as a linkage map. *See* GENETIC MAPPING.

Since each chromatid is composed of a single deoxyribonucleic acid (DNA) duplex, the process of crossing-over involves the breakage and rejoining of DNA molecules. Although the precise molecular mechanisms have not been determined, it is generally agreed that the following events are necessary: (1) breaking (nicking) of one of the two strands of one or both nonsister DNA molecules; (2) heteroduplex (hybrid DNA) formation between single strands from the nonsister DNA molecules; (3) formation of a half chiasma, which is resolved by more single-strand breakages to result in either a reciprocal crossover, a noncrossover, or a nonreciprocal crossover (conversion event). [C.B.G.]

Crossopterygii An infraclass of the bony fishes (class Osteichthyes), also known as fringe-finned fishes, that forms one of the two major divisions of the lobe-finned fishes (Sarcopterygii). The group first appeared as fossils in the Early Devonian; in the Paleozoic they were mostly small to medium-sized carnivorous fish living in shallow tropical seas, estuaries, and fresh waters. There were two principal groups: a diverse set of fishes termed Rhipidista and the Coelacanthini. Their principal radiations were in the Devonian, and by the Mississippian they were in sharp decline. The Rhipidista were wholly extinct by the Middle Permian, but the coelacanths underwent a second, smaller, Mesozoic radiation and managed to survive to the present day as the most famous lobe-fin of all, the living species *Latimeria chalumnae*. Crossopterygii are characterized by a unique hinge in the skull that allowed the front portion to be raised and lowered during feeding and respiratory movements. *See* SARCOPTERYGII.

Members of the order Rhipidistia were principally fusiform, fast-swimming carnivores that flourished in the rivers and lakes of the Late Devonian. They could breathe air, and the use of lungs as well as gills gave them an advantage in warm, shallow-water environments where dissolved oxygen was often low. Members of the order Coelacanthini are characterized by a special trifid tail and scales ornamented with tubercles. They are not thought to be close to the ancestors of tetrapods. *See* OSTEICHTHYES. [K.T.]

Crosstalk Interference in a communications channel (disturbed channel) caused by activity in other communications channels (disturbing channels). The term was originally used to denote the presence in a telephone receiver of unwanted speech signals from other conversations, but its scope has been extended by common usage to include like effects in other types of communications.

The cause of crosstalk is some form of coupling mechanism between the disturbed channel and the disturbing channels. Communications channels are normally segregated by space, frequency, time, code, or polarization division, or by some combination of the five, to avoid such coupling, but economic and other constraints often preclude complete segregation.

In space-division segregation, each communication channel is assigned its own transmission medium, for example, a pair of wires is a multipair cable or a separate radio propagation path. Coupling between channels is caused by the physical proximity and relative orientation of the transmission media. The coupling is usually electromagnetic, a linear phenomenon that is independent of signal level in the channels. *See* ELECTROMAGNETIC COMPATIBILITY.

Crosstalk is classified in a variety of ways. The type of coupling (electromagnetic, intermodulation, or common impedance) indicates the mechanism. The terms near-end crosstalk (NEXT) and far-end crosstalk (FEXT) indicate the relative directions of signal propagation in the disturbed and disturbing channels. The terms direct crosstalk, where the disturbing channel couples directly to the disturbed channel, and indirect crosstalk, where the coupling path between disturbing and disturbed channels involves a third, or tertiary, channel, are often used to further describe crosstalk caused by electromagnetic coupling. Interaction crosstalk (IXT) is a term used to further describe indirect crosstalk that couples from the disturbing channel to the tertiary channel at one place, propagates along the tertiary channel, and subsequently couples into the disturbed channel at another place. Transverse crosstalk is a term that includes all direct and indirect crosstalk that is not interaction crosstalk. Intelligible crosstalk is understood by the receiver of the disturbed channel, whereas nonintelligible crosstalk is not.

Most remedies for reducing crosstalk entail some technique for decreasing coupling among the communications channels involved. The use of twisted pairs in multipair cables, of shielding for each pair, or of coaxial conductors and optical fibers in place of pairs are common techniques for reducing electromagnetic coupling where space division alone is not adequate. Improved control of signal levels and improved linearity in amplifiers are effective for frequency-division systems. Often such improvements are made possible by advances in technology. Selection of the appropriate type of modulation (AM, FM, PM) is also important. Crosstalk within multichannel digital systems that transport digital versions of analog signals can be reduced with the help of a separate coder-decoder for each analog channel in place of a common, time-shared coder-decoder for all channels. Signal processing in the disturbed channel can sometimes be effective in reducing crosstalk. *See* ELECTRICAL COMMUNICATIONS; ELECTRICAL INTERFERENCE; ELECTRICAL SHIELDING; OPTICAL FIBERS; TELEPHONE SERVICE. [J.W.S.]

Crown gall A neoplastic disease of primarily woody plants, although the disease can be reproduced in species representing more than 90 plant families. The disease results from infection of wounds by the free-living soil bacterium *Agrobacterium tumefaciens* which is commonly associated with the roots of plants.

The first step in the infection process is the site-specific attachment of the bacteria to the plant host. Up to half of the bacteria become attached to host cells after 2 h. At 1 or 2 weeks after infection, swellings and overgrowths take place in tissue surrounding the site of infection, and with time these tissues proliferate into large tumors (see illustration). If infection takes place around the main stem or trunk of woody hosts, continued tumor proliferation will cause girdling and may eventually kill the host. Crown gall is therefore economically important, particularly in nurseries where plant material for commercial use is propagated and disseminated.

Crown gall on peach.

Unlike healthy normal cells, crown gall tumor cells do not require an exogenous source of phytohormones (auxins and cytokinin) for growth in culture because they readily synthesize more than sufficient quantities for their own growth. They also synthesize basic amino acids, each conjugated with an organic acid, called opines. The tumor cells also grow about four times faster and are more permeable to metabolities than normal cells.

These cellular alterations, such as the synthesis of opines and phytohormone regulation, result from bacterial genes introduced into host plant cells by *A. tumefaciens* during infection. Although it is not understood how these genes are introduced into the plant cell, the genes for the utilization of these opines and for regulating phytohormone production have been found to be situated on an extrachromosomal element called the pTi plasmid. This plasmid, harbored in all tumor-causing *Agrobacterium* species, also carries the necessary genetic information for conferring the tumor-inducing and host-recognition properties of the bacterium.

Crown gall is consequently a result of this unique bacteria-plant interaction, whereby *A. tumefaciens* genetically engineers its host to produce undifferentiated growth in the form of a large tumor, in which there is the synthesis of a unique food source in the form of an opine for specific use by the bacterial pathogen. *See* BACTERIAL GENETICS; GENETIC ENGINEERING; PLANT HORMONES; PLANT PATHOLOGY. [C.J.Ka.]

Crushing and pulverizing The reduction of materials such as stone, coal, or slag to a suitable size for their intended uses such as road building, concrete aggregate, or furnace firing. Reduction in size is accomplished by five principal methods: (1) crushing, a slow application of a large force; (2) impact, a rapid hard blow as by a hammer; (3) attrition, a rubbing or abrasion; (4) sudden release of internal pressure; and (5) ultrasonic forces. The last two methods are not in common use.

Crushing and pulverizing are processes in ore dressing needed to reduce valuable ores to the fine size at which the valueless gangue can be separated from the ore. These processes are also used to reduce cement rock to the fine powder required for burning, to reduce cement clinker to the very fine size of portland cement, to reduce coal to the size suitable for burning in pulverized form, and to prepare bulk materials for handling in many processes. *See* MATERIALS-HANDLING EQUIPMENT.

Equipment suitable for crushing large lumps as they come from the quarry or mine cannot be used to pulverize to fine powder, so the operation is carried on in three or more stages called primary crushing, secondary crushing, and pulverizing. The three stages are characterized by the size of the feed material, the size of the output product, and the resulting reduction ratio of the material. The crushing-stage output may be screened for greater uniformity of product size.

There are four principal types of primary crushers. The Blake jaw crusher uses a double toggle to move the swinging jaw and is built in a variety of sizes from laboratory units to large sizes having a feed inlet 84 by 120 in. (213 by 305 cm). The Dodge jaw crusher uses a single toggle or eccentric and is generally built in smaller sizes. The Gates gyratory crusher has a cone or mantle that does not rotate but is moved eccentrically by the lower bearing sleeve. The Symons cone crusher also has a gyratory motion, but has a much flatter mantle or cone than does the gyratory crusher. The top bowl is spring-mounted. It is used as a primary or secondary crusher.

Secondary crushers include the single-roll crusher and the double-roll crusher which have teeth on the roll surface and are used mainly for coal. Smooth rolls without teeth are sometimes used for crushing ores and rocks. The hammer crusher is the type of secondary crusher most generally used for ore, rock, and coal. The reversible hammer mill can run alternately in either direction, thus wearing both sides of the hammers.

In open-circuit pulverizing, the material passes through the pulverizer once with no removal of fines or recirculation. In closed-circuit pulverizing, the material discharged from the pulverizer is passed through an external classifier where the finished product is removed and the oversize is returned to the pulverizer for further grinding.

Ball and tube mills, rod mills, hammer mills, and attrition mills are pulverizers operating by impact and attrition. In ball race and roller pulverizers, crushing and attrition are used. *See* Ball-and-race-type pulverizer; Buhrstone mill; Pebble mill; Tumbling mill. [R.M.H.]

Crustacea A highly variable, species-rich group of arthropods that have inhabited marine environments since the beginning of the Cambrian Period. Within the marine realm the crustaceans occupy as diverse a spectrum of habitats as the insects inhabit on land.

The hierarchical rank of the Crustacea is a matter of continuing debate. The Crustacea are regarded as a phylum, distinct from other arthropods, by proponents of the concept of polyphyly in the Arthropoda. Alternatively, they are given the rank of subphylum or superclass by those who view the Arthropoda as a monophyletic taxon.

Species of Crustacea such as the shrimp, prawn, crab, or lobster are familiar. However, there are many more with less common vernacular names such as the water fleas, beach fleas, sand hoppers, fish lice, wood lice, sow bugs, pill bugs, barnacles, scuds, slaters, and krill or whale food. The Crustacea are one of the most difficult animal groups to define because of their great diversity of structure, habit, habitat, and development. No one character or generalization will apply equally well to all.

Crustaceans have segmented, chitin-encased bodies; articulated appendages; mouthparts known as mandibles during some stage of their life, however modified they may be for cutting, chewing, piercing, sucking, or licking; and two pairs of accessory feeding organs, the maxillules and maxillae. One or the other pair is sometimes vestigial or may be lacking. The Crustacea are unique in having two pairs of antennae: the first pair, or antennules, and the second pair, the antennae proper. The latter, are almost always functional at some stage of every crustacean's life.

Taxonomy. Not only is there a lack of agreement on the rank of the Crustacea per se, but there is no consensus on hierarchial levels of subordinate taxa. The classification presented here is restricted to extant taxa and is, at best, a compromise among opposing opinions.

- Superclass Crustacea
  - Class Cephalocarida
  - Class Branchiopoda
    - Order: Anostraca
      - Spinicaudata
      - Laevicaudata
      - Ctenopoda
      - Anomopoda
      - Onychopoda
    - Order: Haplopoda
      - Notostraca
  - Class Remipedia
  - Class Ostracoda
    - Subclass Myodocopa
      - Order: Myodocopida
        - Halocyprida
    - Subclass Podocopa
      - Order: Platyocopida
        - Podocopida
  - Class Maxillopoda
    - Subclass Mystacocarida
    - Subclass Cirripedia
      - Order: Ascothoracica
        - Thoracica
        - Acrothoracica
        - Rhizocephala
    - Subclass Copepoda
      - Order: Calanoida
        - Harpacticoida
        - Cyclopoida
        - Poecilostomatoida
        - Siphonostomatoida
        - Monstrilloida
        - Misophrioida
        - Mormonilloida
    - Subclass Branchiura
    - Subclass Tantulocarida
  - Class Malacostraca
    - Subclass Phyllocarida
      - Order: Leptostraca
    - Subclass Hoplocarida
      - Order: Stomatopoda
    - Subclass Eumalacostraca
      - Superorder Syncarida
      - Order: Bathynellacea
        - Anaspidacea
    - Superorder Peracarida
      - Order: Spelaeogriphacea
        - Mysidacea
        - Mictacea
        - Amphipoda
        - Isopoda
        - Tanaidacea
        - Cumacea

See Branchiopoda; Cephalocarida; Malacostraca; Maxillopoda; Ostracoda; Remipedia.

General morphology. The true body segments, the somites or metameres, are usually somewhat compressed or depressed. Each typically includes one pair of biramous appendages. The linear series of somites making up the body of a crustacean are more or less distinctly organized into three regions or tagmata: the head, thorax, and abdomen. Where regional organization of the postcephalic somites is not clearly marked, they collectively form the trunk. The somites are variously fused with one another in diagnostic combinations in different groups of the Crustacea.

Body. A dorsal shield or carapace of variable length arises from the dorsum of the third cephalic somite and covers the cephalon and cephalothorax to varying extent. The carapace reaches its greatest development in the malacostracan Decapoda (shrimps, lobsters, and crabs). *See* Decapoda (crustacea).

The chitinous cuticle covering the crustacean body is its external skeleton (exoskeleton). The chitin is flexible at the joints, in foliaceous appendages, and throughout the exoskeletons of many small and soft-bodied species, but it is often thickened and stiff in others. It becomes calcified in many species as a result of the deposition of lime salts.

The paired appendages are typically biramous and consist of two branches: the endopod and exopod. The endopod is definitely segmented in the higher Crustacea. The endopods are variously modified to serve a variety of functions and needs such as sensory perception, respiration, locomotion, prehension and comminution of food, cleansing, defense, offense, reproduction, and sex recognition and attraction. If retained in the adult, the exopod may remain leaf- or paddlelike, or become flagellated structures, facilitating swimming or aiding respiration.

The digestive system is a relatively straight tube that curves dorsally from the mouth, which is situated on the underside of the head between the mandibles. In the alimentary tract three regions are recognizable: the foregut, midgut, and hindgut. The anterior part of the foregut often is esophageal in nature, whereas the posterior and greater part usually consists of two parts. In the anterior portion in the Eucarida, a complex and elaborate grinding mechanism, the gastric mill, is developed. The posterior chamber is divided into dorsal and ventral filtering compartments for the straining of food. The midgut in most cases is provided with several ceca or diverticula which produce digestive secretions or serve as organs for the absorption of food. When these ceca are present in considerable number, they become organized into a sizable gland, the midgut gland of higher Crustacea. The hindgut is typically short and terminates in a muscular anus on the underside of the telson.

Most crustaceans have a heart perforated by openings, or ostia, which admit venous blood from the pericardial sinus in which it is located. The heart may be elongated and tubular and extend through the greater part of the body, but generally it is a more compact organ. It pumps blood through an arterial system or through connecting sinuses or lacunae within the body tissues. Some lower Crustacea do not have a heart, and the muscular movements of the animal or its alimentary tract circulate the blood through the body cavities or sinuses. The blood of the great majority of the crustaceans is bluish because it contains the respiratory pigment hemocyanin. A few crustaceans have red blood as a result of the presence of erythrocrurion. *See* RESPIRATORY PIGMENTS (INVERTEBRATE).

Crustacea take up oxygen by means of gills, the general body surface, or special areas of it. Some of the few species that have become more or less terrestrial in their habits have developed modifications of their branchial mechanism such as water-retaining recesses which when sufficiently moist enable them to breathe air. Some sow or pill bugs have special tracheal developments in their abdominal appendages for the same purpose.

In the crustacean nervous system a supraesophageal ganglion somewhat larger than the other ganglia is considered to be the brain. It is connected by circumesophageal commissures to a double ventral nerve cord with segmentally arranged ganglia. These become reduced in number and, in the brachyuran crabs, form a large ganglionic mass centered in the thorax.

The organs of special sense are the eyes, the antennules, and the antennae. Crustacean eyes (photoreceptors) are of two types: the median (nauplius eye) and simple eyes (frontal organs); and compound eyes. Simple and median eyes and lateral eyes consist only of light sensory cells. In contrast, compound eyes are composed of many subunits (ommatidia), each having separate optical elements. Compound eyes, therefore, provide varying amounts of actual vision, and in at least some species color differentiation. The antennules and antennae are provided with a variety of sensory structures for the reception of chemical and mechanical stimuli. Taste chemoreceptors are usually found on the mouthparts and the pereiopods, or walking legs. Many of the hairs (setae) and bristles found on the crustacean body and appendages act as mechanoreceptors. Organs of balance (statocysts) are also present on basal segments of the antennules in many crustaceans. *See* CHEMORECEPTION; EYE (INVERTEBRATE); PHOTORECEPTION.

Those glands recognized as definite excretory organs are the maxillary and antennal glands in the adult crustaceans. They are located in the cephalon and rarely are both present at the same time. Many crustaceans, especially deep-sea forms, have phosphorescent or luminous organs. The barnacles and some other crustaceans have cement glands. Species that produce encysted or drought-resistant eggs have other glands of special secretion. The most studied crustacean gland is the sinus gland of the eyestalks. This gland is part of a neurosecretory system producing hormones that control color change and pattern, molting cycle, oogenesis, and egg development within the ovary. *See* ENDOCRINE SYSTEM (INVERTEBRATE); NEUROSECRETION.

Reproductive system. The sexes are separate in most Crustacea and usually can be differentiated from each other by secondary sex characters. Chief among these characters are the size and shape of the body, appendages, or both, and placement of the genital apertures. Hermaphroditism is the rule in the Cephalocarida, Remipedia, some ostracods, sessile Cirripedia (barnacles), in isolated cases in other crustaceans, and in certain parasitic forms. Parthenogenesis (eggs developing and hatching without prior fertilization) occurs frequently in some of the lower crustaceans that have what might be called an alternation of generations. The parthenogenetic generations alternate with a generation produced by fertilized eggs. *See* CIRRIPEDIA.

The eggs of most crustaceans are carried attached to the female until hatched. Some females develop brood pouches in which the young are retained for a time. A nutrient secretion which sustains the young until they are released is produced in some species having a brood chamber. Penaeid shrimp and a few of the lower Crustacea deposit their eggs in the medium in which they live, in some cases attaching them to aquatic vegetation.

Development. The nauplius larva is characteristic of Crustacea. This first larval stage is common in the lower forms, but in many of the higher forms it occurs during development in the egg, and the young are hatched as a different and more advanced larva or, as in many Malacostraca, in a form similar to the adult. Life histories vary from the simple to the complex within the different groups of Crustacea.

Molting (ecdysis). This process involves several steps: (1) preparation, which includes some degree of resorption of the old cuticle; (2) the formation of a new, temporarily soft and thin one within it; (3) the accumulation and storing of calcium in the midgut gland or as lenticular deposits (gastroliths). The preparatory period is less complicated in the thinly chitinous forms. The actual molt follows. The old shell or cuticle splits at predetermined places, permitting the crustacean within, already enclosed in new but still soft exoskeleton, to withdraw. A temporary absorption of water enables the animal to split or crack its housing. Upon withdrawal of the entire animal, absorption of water again rapidly takes place with a pronounced increase in body size. The chitinous lining of the foregut and hindgut as well as the endophragmal skeleton are shed along with the exoskeleton. In the immediate postmolt period the crustacean is quite helpless and, if unsheltered, is at the mercy of its enemies. The tender new cuticle is reinforced rapidly by the resorbed chitin, and hardened by whatever reserves of calcium the animal may have stored, supplemented and extended by the far more plentiful supplies in solution in the sea which may be absorbed or ingested by the growing crustacean. Molting takes place quite frequently in the larval stages when growth is rapid, but becomes less frequent as the animal ages. In many species there is a terminal molt at maturity. Hormones from the sinus gland play an important role in both initiating and inhibiting molting. *See* GASTROLITH.

Autotomy and regeneration. The mechanisms of autotomy and regeneration are developed in the crustaceans to minimize injury or loss to an enemy. When an appendage is broken, it is cast off or broken at the fracture or breaking plane. This sacrifice often enables the victim to escape. Even more remarkable is the fact that crustaceans, by voluntary muscular contraction, can part with a limb which may be injured. Crustacea also have the ability to regenerate lost parts. Although the regenerated parts are not always the same size as the original in the first molt after injury, increase in size in successive molts soon restores a lost limb to virtually its former appearance.

Geologic history. Exceptionally well-preserved arthropods have been discovered in Late Cambrian rocks. The oldest true crustaceans are ostracods, dating from 570 million years ago (Ma). Although the ostracods are not the most primitive crustaceans, their remains constitute the oldest authentic record of the Crustacea. The appearance of more primitive crustaceans later in geologic history, the reverse of what would be expected, is more related to their preservation potential than to their evolutionary history. The more advanced classes, the Maxillopoda and the Malacostraca, appeared in the fossil record, respectively, in the Middle Cambrian, about 530 Ma, and the Late Devonian, about 370 Ma. *See* CEPHALOCARIDA.

Bionomics and economics. Crustacea are ubiquitous. They live at almost all depths and levels of the sea, in fresh waters at elevations up to 12,000 ft (3658 m), in melted snow water, in the deepest of the sea's abysses more than 6 mi (9 km) down, and in waters of 0°C (32°F) temperature. Some species live on land, although most must descend to salt water areas again to spawn their young. Some live in strongly alkaline waters and others in salt water which is at the saturation point, still others in hot springs and hydrothermal vents with temperatures in excess of 55°C (131°F).

Crustacea are of all sizes, ranging from copepods 0.01 in. (0.25 mm) long to huge spider crabs of Japan, which span 12 ft (3.7 m) from tip to tip of the laterally extended legs. The American lobster, the heaviest so far known, tops all crustaceans at $44\frac{1}{2}$ lb (20 kg).

Most crustaceans are omnivorous and essentially scavengers. Many are filter feeders and screen particulate life, plankton, and organic detritus from the waters in which they live; others are largely carnivorous, still others vegetarian. Among the vegetarians are the grazers of the ocean meadows which convert the microscopic plant life (diatoms) into flesh and food for larger animals which in turn are harvested as food for humans.

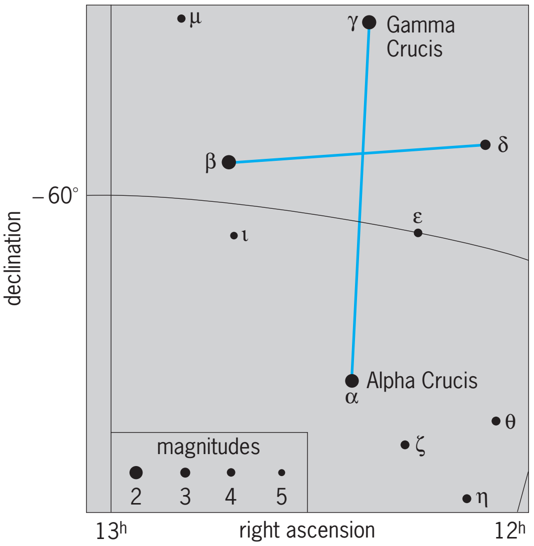
Crux The Southern Cross in astronomy, the most celebrated of the constellations of the far south. The four principal bright stars of the group, α, γ, β and δ form the figure of a cross, giving the constellation its name (see illustration). The brightest star in Crux is Alpha Crucis at the foot of the cross, which has received the artificial name Acrux. This is a navigational star. *See* CONSTELLATION; CYGNUS.

[C.-S.Y.]



Line pattern of the constellation Crux. The grid lines represent the coordinates of the sky. The apparent brightness, or magnitude, of the stars is shown by the sizes of dots, graded by appropriate numbers as indicated.

Cryobiology The use of low-temperature environments in the study of living plants and animals. The principal effects of cold on living tissue are destruction of life and preservation of life at a reduced level of activity. Both of these effects are demonstrated in nature. Death by freezing is a relatively common occurrence in severe winter storms. Among cold-blooded animals winter weather usually results in a comalike sleep that may last for a considerable length of time.

In cryobiological applications much lower temperatures are used than are present in natural environments. The extreme cold of liquid nitrogen (boiling at −320°F or −196°C) can cause living tissue to be destroyed in a matter of seconds or to be preserved for years and possibly for centuries with essentially no detectable biochemical activity. The result achieved when heat is withdrawn from living tissue depends on processes occurring in the individual cells. Basic knowledge of the causes of cell death, especially during the process of freezing, and the discovery of methods which circumvent these causes have led to practical applications both for long-term storage of living cells or tissue (cryopreservation) and for calculated and selective destruction of tissue (cryosurgery).

The biochemical constituents of a cell are either dissolved or suspended in water. During the physical process of freezing, water tends to crystallize in pure form, while the dissolved or suspended materials concentrate in the remaining liquid. In the living cell, this process is quite destructive. In a relatively slow freezing process ice first begins to form in the fluid surrounding the cells, and the concentration of dissolved materials in the remaining liquid increases. A concentration gradient is established across the cell wall, and water moves out of the cell in response to the osmotic force. As freezing continues, the cell becomes quite dehydrated. Salts may concentrate to extremely high levels. In a similar manner the acid-base ratio of the solution may be altered during the concentration process. Dehydration can affect the gross organization of the cell and also the molecular relationships, some of which depend on the presence of water at particular sites. Cellular collapse resulting from loss of water may bring in contact intracellular components normally separated to prevent destructive interaction. Finally, as the ice crystals grow in size, the cell walls may be ruptured by the ice crystals themselves or by the high concentration gradients which are imposed upon them.

By speeding the freezing process to the point that temperature drop is measured in degrees per second, some of these destructive events can be modified. However, most of the destructive processes will prevail. To prevent dehydration, steps must be taken to stop the separation of water in the form of pure ice so that all of the cell fluids can solidify together. The chief tools used to accomplish this are agents that lower the freezing point of the water. Glycerol, a polyalcohol which is compatible with other biochemical materials in living cells, is frequently used in cell preservation. Besides the antifreeze additive, refrigeration procedures are designed to control the rate of decline in temperature to the freezing point, through the liquid-solid transition, and below, to very low temperatures.

Cryopreservation. The earliest commercial application of cryopreservation was in the storage of animal sperm cells for use in artificial insemination. The microorganisms used in cheese production can be frozen, stored, and transported without loss of lactic acid–producing activity. Pollen from various plants can be frozen for storage and transport, facilitating plant-breeding experiments. Among the most valuable applications of cryopreservation is the storage of whole blood or separated blood cells.

Cryosurgery. Cellular destruction from freezing can be used to destroy tissue as a surgical procedure. One of the significant advantages of cryosurgery is that the apparatus can be employed to cool the tissue to the extent that the normal or the aberrant function is suppressed; yet at this stage the procedure can be reversed without permanent effect. When the surgeon is completely satisfied that he or she has located the exact spot to destroy, the temperature can be lowered enough to produce irreversible destruction. This procedure is of particular assistance in neurosurgery.

A second major advantage of cryosurgery is that the advancing front of reduced temperatures tends to cause the removal of blood and the constriction of blood vessels in the affected area. This means that little or no bleeding results from cryosurgical procedures.

A third major advantage of cryosurgery is that cryosurgery equipment currently employs a freezing apparatus that can be placed in contact with area to be destroyed with a minimum incision to expose the affected area. [A.W.F.]

Cryogenics The science and technology of phenomena and processes at low temperatures, defined arbitrarily as below 150 K (−190°F). Phenomena that occur at cryogenic temperatures include liquefaction and solidification of ambient gases; loss of ductility and embrittlement of some structural materials such as carbon steel; increase in the thermal conductivity to a maximum value, followed by a decrease as the temperature is lowered further, of relatively pure metals, ionic compounds, and crystalline dielectrics (diamond, sapphire, solidified gases, and so forth); decrease in the thermal conductivity of metal alloys and plastics; decrease in the electrical resistance of relatively pure metals; decrease in the heat capacity of solids; decrease in thermal noise and disorder of matter; and appearance of quantum effects such as superconductivity and superfluidity. *See* ELECTRICAL RESISTIVITY; SPECIFIC HEAT OF SOLIDS; SUPERCONDUCTIVITY; SUPERFLUIDITY; THERMAL CONDUCTION IN SOLIDS.

Low-temperature environments are maintained with cryogens (liquefied gases) or with cryogenic refrigerators. The temperature afforded by a cryogen ranges from its triple point to slightly below its critical point. Commonly used cryogens are liquid helium-4 (down to 1 K), liquid hydrogen, and liquid nitrogen. Less commonly used because of their expense are liquid helium-3 (down to 0.3 K) and neon. The pressure maintained over a particular cryogen controls its temperature. Heat input—both the thermal load and the heat leak due to imperfect insulation—boils away the cryogen, which must be replenished. *See* LIQUID HELIUM; THERMODYNAMIC PROCESSES; TRIPLE POINT.

A variety of techniques are available for prolonged refrigeration. Down to about 1.5 K, refrigeration cycles involve compression and expansion of appropriately chosen gases. At lower temperatures, liquid and solids serve as refrigerants. Adiabatic demagnetization of paramagnetic ions in solid salts is used in magnetic refrigerators to provide temperatures from around 4 K down to 0.003 K. Nuclear spin demagnetization of copper can achieve 5×10^{-8} K. Helium-3/helium-4 dilution refrigerators are frequently used for cooling at temperatures between 0.3 and 0.002 K, and adiabatic compression of helium-3 (Pomeranchuk cooling) can create temperatures down to 0.001 K. *See* ADIABATIC DEMAGNETIZATION.

Both the latent heat of vaporization and the sensible heat of the gas (heat content of the gas) must be removed to liquefy a gas. Of the total heat that must be removed to liquefy the gas, the latent heat is only 1.3% for helium and 46% for nitrogen. Consequently, an efficient liquefier must supply refrigeration over the entire temperature range between ambient and the liquefaction point, not just at the liquefaction temperature. The Collins-Claude refrigeration cycle forms the basis (with a multitude of variations) of most modern cryogenic liquefiers. Gas is compressed isothermally and cooled in a counterflow heat exchanger by the colder return stream of low-pressure gas. During this cooling, a fraction of the high-pressure stream (equal to the rate of liquefaction) is split off and cooled by the removal of work (energy) in expansion engines or turbines. This arrangement provides the cooling for the removal of the sensible heat. At the end of the counterflow cooling, the remaining high-pressure stream is expanded in either a Joule-Thomson valve or a wet expander to give the liquid product and the return stream of saturated vapor. *See* LIQUEFACTION OF GASES.

The work input required to produce refrigeration is commonly given in terms of watts of input power per watt of cooling, that is, W/W. Cooling with a refrigerator is more efficient (that is, requires a lower W/W) than cooling with evaporating liquid supplied from a Dewar because the refrigerator does not discard the cooling available in the boil-off gas. *See* REFRIGERATION; REFRIGERATION CYCLE; THERMODYNAMIC CYCLE. [D.E.D.]

Cryolite A mineral with chemical composition Na_3AlF_6. It crystallizes in the monoclinic system. Hardness is $2^1/_2$ on Mohs scale and the specific gravity is 2.95. Crystals are usually snow-white but may be colorless and more rarely brownish, reddish, or even black. The mean refraction index is 1.338, approximately that of water, and thus fragments become invisible when immersed in water.

Cryolite was once used as a source of metallic sodium and aluminum, but now is used chiefly as a flux in the electrolytic process in the production of aluminum from bauxite. *See* ALUMINUM. [C.S.Hu.]

Cryotron A current-controlled switching device based on superconductivity for use primarily in computer circuits. The early version has been superseded by the tunneling cryotron, which consists basically of a Josephson junction. In its simplest form the device has two electrodes of a superconducting material (for example, lead) which are separated by an insulating film only about 10 atomic layers thick. Switching is accomplished by a magnetic field generated by sending a current through the control line on top of the junction. The tunneling cryotron is still in the research stage, but various computer circuits have already been realized. *See* SUPERCONDUCTING DEVICES; SUPERCONDUCTIVITY. [P.Wo.]

Cryptobiosis A state of life in which the metabolic rate of an organism is reduced to an imperceptible level. The several kinds of cryptobiosis ("hidden life") include anhydrobiosis (life without water), cryobiosis (life at low temperatures), and anoxybiosis (life without oxygen). The most is known about anhydrobiosis.

States of anhydrobiosis occur in early developmental stages of various organisms, including seeds of plants, spores of bacteria and fungi, cysts of certain crustaceans, and larvae of certain insects; they occur in both developmental and adult stages of certain soil-dwelling micrometazoans (rotifers, tardigrades, and nematodes), mosses, lichens, and certain ferns.

A central question in the study of anhydrobiosis has been whether metabolism actually ceases. Available evidence strongly suggests that dry anhydrobiotes are ametabolic. In that case, a philosophical question immediately arises concerning the nature of life. This philosophical quandary can be avoided by applying the definition of life adopted by most students of anhydrobiosis: an organism is alive, provided its structural integrity is maintained. When that integrity is violated, it is dead. *See* METABOLISM. [J.H.Cr.]

Cryptography The various methods for writing in secret code or cipher. As society becomes increasingly dependent upon computers, the vast amounts of data communicated, processed, and stored within computer systems and networks often have to be protected, and cryptography is a means of achieving this protection. It is the only practical method for protecting information transmitted through accessible communication networks such as telephone lines, satellites, or microwave systems. Cryptographic procedures can also be used for message authentication, personal identification, and digital signature verification for electronic funds transfer and credit card transactions. *See* DATA COMMUNICATIONS; DIGITAL COMPUTER; ELECTRICAL COMMUNICATIONS.

Cryptography helps resist decoding or deciphering by unauthorized personnel; that is, messages (plaintext) transformed into cryptograms (codetext or ciphertext) have to be able to withstand intense cryptanalysis. Transformations can be done by using either code or cipher systems. Code systems rely on code books to transform the plaintext words, phrases, and sentences into ciphertext code groups. To prevent cryptanalysis, there must be a great number of plaintext passages in the code book and the code group equivalents must be kept secret, making it difficult to utilize code books in electronic data-processing systems.

Cipher systems are more versatile. Messages are transformed through the use of two basic elements: a set of unchanging rules or steps called a cryptographic algorithm, and a set of variable cryptographic keys. The algorithm is composed of enciphering (**E**) and deciphering (**D**) procedures which usually are identical or simply consist of the same steps performed in reverse order, but which can be dissimilar. The keys, selected by the user, consist of a sequence of numbers or characters. An enciphering key (Ke) is used to encipher plaintext (X) into ciphertext (Y) as in Eq. (1), and a deciphering key (Kd) is used to decipher ciphertext (Y) into plaintext (X) as in Eq. (2).

$$\mathbf{E}_{\mathrm{Ke}}(\mathrm{X}) = \mathrm{Y} \qquad (1)$$

$$\mathbf{D}_{\mathrm{Kd}}[\mathbf{E}_{\mathrm{Ke}}(\mathrm{X})] = \mathbf{D}_{\mathrm{Kd}}(\mathrm{Y}) = \mathrm{X} \qquad (2)$$

Algorithms are of two types—conventional and public-key. The enciphering and deciphering keys in a conventional algorithm either may be easily computed from each other or may be identical [Ke = Kd = K, denoting $\mathbf{E}_{\mathrm{k}}(\mathrm{X}) = \mathrm{Y}$ for encipherment and $\mathbf{D}_{\mathrm{K}}(\mathrm{Y}) = \mathrm{X}$ for decipherment]. In a public-key algorithm, one key (usually the enciphering key) is made public, and a different key (usually the deciphering key) is kept private. In such an approach it must not be possible to deduce the private key from the public key.

When an algorithm is made public, for example, as a published encryption standard, cryptographic security completely depends on protecting those cryptographic keys specified as secret.

Unbreakable ciphers. Unbreakable ciphers are possible. But the key must be randomly selected and used only once, and its length must be equal to or greater than that of the plaintext to be enciphered. Therefore such long keys, called one-time tapes, are not practical in data-processing applications. To work well, a key must be of fixed length, relatively short, and capable of being repeatedly used without compromising security. In theory, any algorithm that uses such a finite key can be analyzed; in practice, the effort and resources necessary to break the algorithm would be unjustified.

Strong algorithms. Fortunately, to achieve effective data security, construction of an unbreakable algorithm is not necessary. However, the work factor (a measure, under a given set of assumptions, of the requirements necessary for a specific analysis or attack against a cryptographic algorithm) required to break the algorithm must be sufficiently great. Included in the set of assumptions is the type of information expected to be available for cryptanalysis. For example, this could be ciphertext only; plaintext (not chosen) and corresponding ciphertext; chosen plaintext and corresponding ciphertext; or chosen ciphertext and corresponding recovered plaintext.

A strong cryptographic algorithm must satisfy the following conditions: (1) The algorithm's mathematical complexity prevents, for all practical purposes, solution through analytical methods. (2) The cost or time necessary to unravel the message or key is too great when mathematically less complicated methods are used, because either too many computational steps are involved (for example, in trying one key after another) or because too much storage space is required (for example, in an analysis requiring data accumulations such as dictionaries and statistical tables).

To be strong, the algorithm must satisfy the above conditions even when the analyst has the following advantages: (1) Relatively large amounts of plaintext (specified by the analyst, if so desired) and corresponding ciphertext are available. (2) Relatively large amounts of ciphertext (specified by the analyst, if so desired) and corresponding recovered plaintext are available. (3) All details of the algorithm are available to the analyst; that is, cryptographic strength cannot depend on the algorithm remaining secret. (4) Large high-speed computers are available for cryptanalysis.

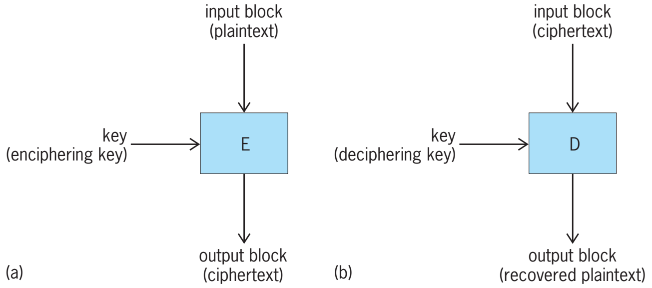


Fig. 1. Block cipher. (*a*) Enciphering. (*b*) Deciphering.

Digital signatures. Digital signatures authenticate messages by ensuring that: the sender cannot later disavow messages; the receiver cannot forge messages or signatures; and the receiver can prove to others that the contents of a message are genuine and that the message originated with that particular sender. The digital signature is a function of the message, a secret key or keys possessed by the sender of the message, and sometimes data that are nonsecret or that may become nonsecret as part of the procedure (such as a secret key that is later made public).

Digital signatures are more easily obtained with public-key than with conventional algorithms. When a message is enciphered with a private key (known only to the originator), anyone deciphering the message with the public key can identify the originator. The latter cannot later deny having sent the message. Receivers cannot forge messages and signatures, since they do not possess the originator's private key.

Since enciphering and deciphering keys are identical in a conventional algorithm, digital signatures must be obtained in some other manner. One method is to use a set of keys to produce the signature. Some of the keys are made known to the receiver to permit signature verification, and the rest of the keys are retained by the originator in order to prevent forgery.

Data Encryption Standard. Regardless of the application, a cryptographic system must be based on a cryptographic algorithm of validated strength if it is to be acceptable. The Data Encryption Standard (DES) is such a validated conventional algorithm already in the public domain. This procedure enciphers a 64-bit block of plaintext into a 64-bit block of ciphertext under the control of a 56-bit key. The National Bureau of Standards accepted this algorithm as a standard, and it became effective on July 15, 1977.

Block ciphers. A block cipher (Fig. 1) transforms a string of input bits of fixed length (termed an input block) into a string of output bits of fixed length (termed an output block). In a strong block cipher, the enciphering and deciphering functions are such that every bit in the output block jointly depends on every bit

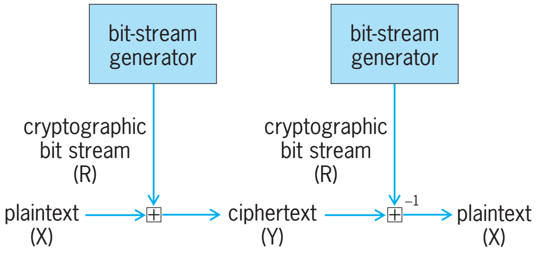

Fig. 2. Stream cipher concept. (*After C.H. Meyer and S. M. Matyas, Cryptography: A New Dimension in Computer Data Security, 1980*).

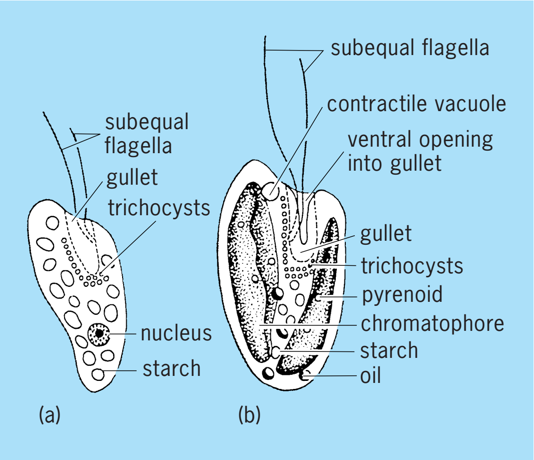
in the input block and on every bit in the key. This property is termed intersymbol dependence.

Stream ciphers. A stream cipher (Fig. 2) employs a bit-stream generator to produce a stream of binary digits (0's and 1's) called a cryptographic bit stream, which is then combined either with plaintext (via the $\boxplus$ operator) to produce ciphertext or with ciphertext (via the $\boxplus^{-1}$ operator) to recover plaintext. [C.H.M.; S.M.M.]

Cryptomonadida

Cryptomonadida An order of the class Phytamastigophorea, also known as the Cryptomonadina. Cryptomonads are considered to be protozoans by zoologists and algae by botanists. Most species occur in fresh water. They are olivegreen, blue, red, brown, or colorless. All flagellated members have two subequal flagella inserted in a gullet opening through an obliquely truncate anterior end (see illustration). Although few in genera and species, Cryptomonadida form extensive marine and fresh-water blooms. *See* PROTOZOA. [J.B.L.]



Examples of cryptomonads. (*a*) *Chilomonas paramecium*. (*b*) *Cryptomonas erosa*.

Cryptophyceae

Cryptophyceae A small class of biflagellate unicellular algae (cryptomonads) in the chlorophyll *a*–*c* phyletic line (Chromophycota). In protozoological classification, these organisms constitute an order, Cryptomonadida, of the class Phytomastigophora. Cryptomonads are 4–80 micrometers long, ovoid or bean-shaped, and dorsiventrally flattened. The cell is bounded by a moderately flexible periplast comprising the plasmalemma and underlying rectangular or polygonal proteinaceous plates. A tubular invagination (gullet, groove, or furrow) traverses the ventral cytoplasm and opens just below the apex of the cell. A pair of subequal flagella, which are covered with hairs and small scales, arise from the center or apical end of the gullet. Cryptomonads may be photosynthetic, osmotrophic, or phagotrophic. In photosynthetic species, chloroplasts occur singly or in pairs.

Photosynthetic pigments include chlorophyll a and c, α-carotene and β-carotene (the former being predominant, an unusual ratio for algae), and red and blue phycobiliproteins closely related to those in red algae but occurring in the intrathylakoidal space rather than forming phycobilisomes. The color of the chloroplasts, and thus the color of the cryptomonad, depends upon pigment composition and may be green, olive, brown, yellow, red, or blue. Pigment composition is affected by environmental conditions.

Cryptomonads are found in fresh, brackish, marine, and hypersaline bodies of water, sometimes in great abundance. Several species are endosymbionts of marine ciliates and invertebrates, and of fresh-water dinoflagellates. *See* ALGAE; CHROMOPHYCOTA; CRYPTOMONADIDA. [P.C.Si.; R.L.Moe]

Cryptostomata

Cryptostomata An extinct order of Bryozoa in the class Stenolaemata. Cryptostomes had basally attached, erect, calcified colonies made of sheets or delicate branches composed of short tubular or box-shaped feeding zooids (individual units that constitute these colonial organisms) and commonly extrazooidal skeletal deposits. Overall colony morphology is the basis for dividing cryptostomes into four subgroups that commonly are treated as orders: Rhabdomesina, Ptilodictyina, Fenestellina, and Timanodictyina.

Cryptostomes were exclusively marine and lived in a wide variety of relatively low-energy environments on continental shelves and seas. They were important contributors to the growth of organic mounds during the Late Ordovician and early Carboniferous.

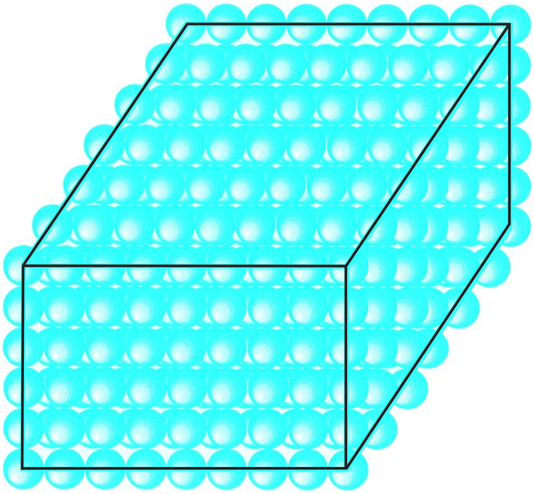
Phylogenetic relationships among the four subgroups are not clear. Probably the Rhabdomesina is paraphyletic and gave rise to the other three groups, each of which apparently is monophyletic. *See* BRYOZOA; STENOLAEMATA. [F.K.McK.]

Crystal

Crystal A solid in which the atoms or molecules are arranged periodically. Within a crystal, many identical parallelepiped unit cells, each containing a group of atoms, are packed together to fill all space (see illustration). In scientific nomenclature, the term crystal is usually short for single crystal, a single periodic arrangement of atoms. Most gems are single crystals. However, many materials are polycrystalline, consisting of many small grains, each of which is a single crystal. For example, most metals are polycrystalline. *See* SINGLE CRYSTAL.

In electronics, the term crystal is restricted to mean piezoelectric crystal. Piezoelectric crystals contract or expand under application of electric voltages, and conversely they generate voltages when compressed. They are used for oscillators, pressure sensors, and position actuators. *See* PIEZOELECTRICITY.

The anisotropic microscopic structure of a crystal is often reflected in its external form, consisting of flat faces and sharp edges. Crystal structure is generally determined via diffraction of x-rays, neutrons, or electrons. Unlike disordered materials such as glasses or liquids, the diffraction pattern of a periodic array of atoms consists of individual sharp spots. The symmetry and structure of the crystal can be inferred from the symmetry of the diffraction pattern and the intensities of the diffracted



Structure of a simple crystal. Spheres, representing atoms, are packed together into a cubic lattice. This crystal has 4-fold symmetry axes passing through the front face; after a 90° rotation the structure appears unchanged.

beams. *See* ELECTRON DIFFRACTION; NEUTRON DIFFRACTION; X-RAY DIFFRACTION.

A crystal can be characterized by the symmetry operations that leave its structure invariant. These can include rotation about an axis through a specific angle, reflection through a plane, inversion through a point, translations by a unit cell dimension, and combinations of these. For a periodic structure, the only allowable rotational symmetries are 2-fold, 3-fold, 4-fold, and 6-fold. A quasicrystal is a solid which yields a sharp diffraction pattern but has rotational symmetries (such as 5-fold or 10-fold) which are inconsistent with a periodic arrangement of atoms. *See* QUASICRYSTAL.

A plastic crystal is generally composed of organic molecules which are rotationally disordered. The centers of the molecules lie at well-defined, periodically spaced positions, but the orientations of the molecules are random. Plastic crystals are often very soft and may flow under their own weight.

A liquid crystal is a material which is intermediate in structure between a liquid and a solid. Liquid crystals usually flow like liquids but have some degree of internal order. They are generally composed of rodlike organic molecules, although in some cases they are composed of disklike molecules. In a nematic liquid crystal, the rods all have the same general orientation, but the positions of the rods are disordered. In a smectic liquid crystal, rodlike molecules are ordered into sheets, within which there is only liquidlike order. A smectic can thus be thought of as being crystalline in one dimension and liquid in the other two. In a discotic liquid crystal, disklike molecules are ordered into columnar arrays; there is short-range liquidlike order within the columns, but the columns form a two-dimensional crystal. *See* CRYSTAL DEFECTS; CRYSTAL GROWTH; CRYSTAL STRUCTURE; CRYSTALLOGRAPHY; LIQUID CRYSTALS. [P.A.He.]

Crystal absorption spectra The wavelength or energy dependence of the attenuation of electromagnetic radiation as it passes through a crystal, due to its conversion to other forms of energy in the crystal. When atoms are grouped into an ordered array to form a crystal, their interaction with electromagnetic radiation is greatly modified. Free atoms absorb electromagnetic radiation by transitions between a few electronic states of well-defined energies, leading to absorption spectra consisting of sharp lines. In a crystal, these states are broadened into bands, and the cores of the atoms are constrained to vibrate about equilibrium positions. The ability of electromagnetic radiation to transfer energy to bands and ionic vibrations leads to broad absorption spectra that bear little resemblance to those of the free parent atoms. *See* ABSORPTION OF ELECTROMAGNETIC RADIATION; ATOMIC STRUCTURE AND SPECTRA; BAND THEORY OF SOLIDS; LATTICE VIBRATIONS. [D.E.As.]

Crystal counter A device, more correctly described as a crystal detector, that detects ionizing radiation of all types and is adaptable to measuring neutrons. The sensitive element is a single crystal with a dc resistance normally higher than 10^{12} ohms. The crystals are small and are cut or grown to volumes ranging from less than 1 mm^3 to approximately 200 mm^3.

Crystal detectors fall into two categories: Certain crystals act as thermoluminescent detectors, of which lithium fluoride (LiF), lithium borate ($Li_2B_4O_7$), and calcium sulfate ($CaSO_4$) are among the best known. Other crystals, for example, cadmium telluride (CdTe) and mercury iodide (HgI_2), act as conduction detectors, delivering either pulses or a dc signal, depending upon the associated electronic circuitry. *See* IONIZATION CHAMBER; THERMOLUMINESCENCE.

Diamond is a unique crystal that functions as a thermoluminescent detector or, if suitable contacts are made, as a conduction detector. The efficiency of the diamond detector in the thermoluminescent or conduction mode is strongly dependent on the impurity atoms included within the crystal lattice, with nitrogen and boron playing dominant roles. Not all diamonds are good detectors; only the rare and expensive natural types IB or IIA are appropriate. Besides being stable and nontoxic, diamond has an additional attractive feature as a detector. As an allotrope of carbon, it has the atomic number $Z = 6$. Human soft tissue has an effective $Z = 7.4$, so that diamond is a close tissue-equivalent material, an essential characteristic for biological dosimetry, for example, in measurements in living organisms. *See* DIAMOND.

Good crystal detectors are insulators and therefore have significant band-gap energies. A large band gap impedes the spontaneous excitation of charge carriers between the valence and conduction bands, thus lowering leakage currents and movement of charge carriers to trapping centers. Room temperature devices are consequently possible. *See* BAND THEORY OF SOLIDS; ELECTRIC INSULATOR; TRAPS IN SOLIDS.

In thermoluminescent detectors, the crystal is heated at a controlled rate on a metal tray by means of an electric current. The photon emission from the crystal is monitored by a photomultiplier the output of which is directed toward an appropriate recording device. The result is a “glow curve”, the area of which correlates with the number of traps depopulated, which are in turn directly related to the radiation-field intensity. The integrated light output therefore becomes a direct measure of the total radiation dose. *See* DOSIMETER; PHOTOMULTIPLIER.

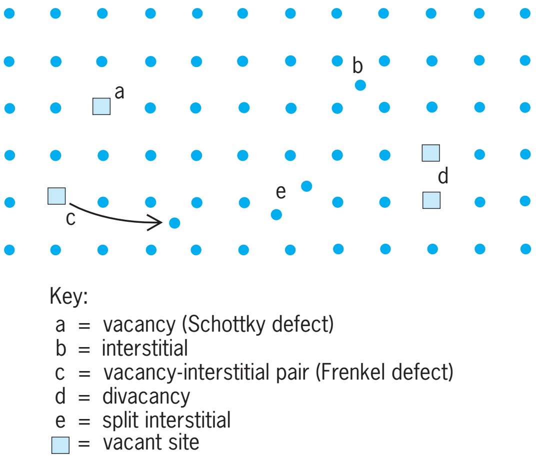
In a conduction detector, a charged particle entering the crystal transfers its kinetic energy to the bulk of the crystal by creating charge carriers (electron-hole pairs). A photon of sufficient energy interacts with the crystal atoms, losing all or part of its energy through the photoelectric effect, the Compton effect, or pair production. In each of these processes, electrons are either liberated or created, and they in turn have their energy dissipated in the bulk of the crystal by creating charge carriers. When the carrier pair is created, the individual carriers move under the influence of the electric field toward the oppositely charged contacts. On arriving at the contacts, the charges can be measured at the output point either as a dc or as a pulse signal, depending upon the circuitry. It is, however, necessary for full efficiency of the counting system that both types of carriers are collected equally. *See* COMPTON EFFECT; ELECTRON-POSITRON PAIR PRODUCTION; GAMMA-RAY DETECTORS; PHOTOEMISSION.

In the thermoluminescent mode the crystals measure the total dose of the applied radiation, whereas in the conduction mode they measure the instantaneous dose rate; in both cases it is ultimately the crystal itself that limits the sensitivity and resolution of the system. Present methods of synthesis for crystals permit the detection of radiation fields down to nearly background values (0.1 microgray/h or 10^{-5} rad/h) even with crystals as small as 1 mm^3. Small crystals make detectors possible that are capable of very high spatial resolution. This feature is important in electron radiation therapy. *See* PARTICLE DETECTOR; RADIATION BIOLOGY; RADIOLOGY. [R.J.K.]

Crystal defects Departures of a crystalline solid from a regular array of atoms or ions. A “perfect” crystal of NaCl, for example, would consist of alternating Na^+ and Cl^- ions on an infinite three-dimensional simple cubic lattice, and a simple defect (a vacancy) would be a missing Na^+ or Cl^- ion. There are many other kinds of possible defects, ranging from simple and microscopic, such as the vacancy and other structures shown in the illustration, to complex and macroscopic, such as the inclusion of another material, or a surface.

Natural crystals always contain defects, due to the uncontrolled conditions under which they were formed. The presence of defects which affect the color can make these crystals valuable as gems, as in ruby (Cr replacing a small fraction of the Al in Al_2O_3). Crystals prepared in the laboratory will also always contain defects, although considerable control may be exercised over their type, concentration, and distribution.

The importance of defects depends upon the material, type of defect, and properties which are being considered. Some properties, such as density and elastic constants, are proportional to



Some simple defects in a lattice.

the concentration of defects, and so a small defect concentration will have a very small effect on these. Other properties, such as the conductivity of a semiconductor crystal, may be much more sensitive to the presence of small numbers of defects. Indeed, while the term defect carries with it the connotation of undesirable qualities, defects are responsible for many of the important properties of materials, and much of solid-state physics and materials science involves the study and engineering of defects so that solids will have desired properties. A defect-free silicon crystal would be of little use in modern electronics; the use of silicon in devices is dependent upon small concentrations of chemical impurities such as phosphorus and arsenic which give it desired electronic properties.

An important class of crystal defect is the chemical impurity. The simplest case is the substitutional impurity, for example, a zinc atom in place of a copper atom in metallic copper. Impurities may also be interstitial; that is, they may be located where atoms or ions normally do not exist. In metals, impurities usually lead to an increase in the electrical resistivity. Impurities in semiconductors are responsible for the important electrical properties which lead to their widespread use. The energy levels associated with impurities and other defects in nonmetals may also lead to optical absorption in interesting regions of the spectrum.

Even in a chemically pure crystal, structural defects will occur. These may be simple or extended. One type of simple defect is the vacancy, but other types exist (see illustration). The atom which left a normal site to create a vacancy may end up in an interstitial position, a location not normally occupied. Or it may form a bond with a normal atom in such a way that neither atom is on the normal site, but the two are symmetrically displaced from it. This is called a split interstitial. The name Frenkel defect is given to a vacancy-interstitial pair, whereas an isolated vacancy is a Schottky defect.

The simplest extended structural defect is the dislocation. An edge dislocation is a line defect which may be thought of as the result of adding or subtracting a half-plane of atoms. A screw dislocation is a line defect which can be thought of as the result of cutting partway through the crystal and displacing it parallel to the edge of the cut. Dislocations are of great importance in determining the mechanical properties of crystals. A dislocation-free crystal is resistant to shear, because atoms must be displaced over high-potential-energy barriers from one equilibrium position to another. It takes relatively little energy to move a dislocation (and thereby shear the crystal), because the atoms at the dislocation are barely in stable equilibrium. Such plastic deformation is known as slip. *See* PLASTICITY.

For both scientific and practical reasons, much of the research on crystal defects is directed toward the dynamic properties of defects under particular conditions, or defect chemistry. Much of the motivation for this arises from the often undesirable effects of external influences on material properties, and a desire to minimize these effects. Examples of defect chemistry abound, including one as familiar as the photographic process, in which incident photons cause defect modifications in silver halides or other materials. Properties of materials in nuclear reactors is another important case. [W.B.F.]

Crystal growth The growth of crystals, which can occur by natural or artificial processes. Crystal growth generally comes about by means of the following processes occurring in series: (1) diffusion of the atoms (or molecules, in the case of molecular crystals such as hydrocarbons or polymers) of the crystallizing substance through the surrounding environment (or solution) to the surface of the crystal, (2) diffusion of these atoms over the surface of the crystal to special sites on the surface, (3) incorporation of atoms into the crystal at these sites, and (4) diffusion of the heat of crystallization away from the crystal surface. The rate of crystal growth may be limited by any of these four steps. The initial formation of the centers from which crystal growth proceeds is known as nucleation. *See* CRYSTALLIZATION; NUCLEATION.

During its growth into a fluid phase, a crystal often develops and maintains a definite polyhedral form which may reflect the characteristic symmetry of the microscopic pattern of atomic arrangement in the crystal. The bounding faces of this form are those which are perpendicular to the directions of slowest growth. How this comes about is illustrated in Fig. 1, in which it is seen that the faces *b*, normal to the faster-growing direction, disappear, and the faces *a*, normal to the slower-growing directions, become predominant. Growth forms, like that shown, are not necessarily equilibrium forms, but they are likely to be most regular when the departures from equilibrium are not large. *See also* CRYSTAL STRUCTURE.

The atomic binding sites on the surface of a crystal can be of several kinds. Thus an atom must be more weakly bound on a perfectly developed plane of atoms at the crystal surface (site A) than at a ledge formed by an incomplete plane one atom thick (site B). Atom A binds with only three neighboring atoms, whereas atom B binds to five neighbors. (An atom in the middle of the island monolayer has bonds with nine neighbors.) Therefore, the binding of atoms in an island monolayer on the crystal surface will be less per atom than it would be within a completed surface layer.

The potential energy of a crystal is most likely to be minimum in forms containing the fewest possible ledge sites. This means that, in a regime of regular crystal growth, dilute fluid, and moderate departure from equilibrium, the crystal faces of the growth form are likely to be densely packed and atomically smooth. There will be a critical size of monolayer, which will be a decreasing function of supersaturation, such that all monolayers smaller than the critical size tend to shrink out of existence, and

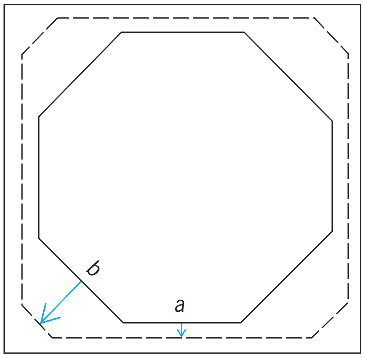


Fig. 1. Schematic representation of cross section of crystal at three stages of regular growth.

those which are larger will grow to a complete layer. The critical monolayers form by a fluctuation process. Kinetic analyses indicate that the probability of critical fluctuations is so small that in finite systems perfect crystals will not grow, except at substantial departures from equilibrium. That, in ordinary experience, finite crystals do grow in a regular regime only at infinitesimal departures from equilibrium is explained by the screw dislocation theory. According to this theory, growth is sustained by indestructible surface ledges which result from the emergence of screw dislocations in the crystal face. *See* CRYSTAL DEFECTS.

When the departures from equilibrium (supersaturation or undercooling) are sufficiently large, the more regular growth shapes become unstable and cellular (grasslike) or dendritic (treelike) morphologies develop. Essentially, the development of protuberances on an initially regular crystal permits more efficient removal of latent heat or of impurities, but at the cost of higher interfacial area and the associated excess surface energy. When the supersaturation becomes so great that the energy associated with the increase in interfacial area is unimportant, protuberances proliferate and the crystal grows in a multibranched form that is even more complicated; its shape is characterized by fractal geometry. *See* FRACTALS. [M.J.A.; D.T.]

The advent of semiconductor-based technology generated a demand for large, high-quality single crystals, not only of semiconductors but also of associated electronic materials. With increasing sophistication of semiconductor devices, an added degree of freedom in materials properties was obtained by varying the composition of major components of the semiconductor crystal over very short distances. Thin, multilayered single-crystal structures, and even structures that vary in composition both normal and lateral to the growth direction, are often required.

Bulk single crystals are usually grown from a liquid phase. The liquid may have approximately the same composition as the solid; it may be a solution consisting primarily of one component of the crystal; or it may be a solution whose solvent constitutes at most a minor fraction of the crystal's composition. The most important bulk crystal growth technique is the crystal-pulling or Czochralski method, in which a rotating seed crystal is dipped into the melt (Fig. 2). Rotation reduces radial temperature gradients, and slow withdrawal of the rotating seed results in growth of a cylinder of single-crystal material. Crystal diameter and length depend upon the details of the temperature and pulling rate, and the dimensions of the melt container. Crystal quality depends very critically upon minimization of temperature gradients that enhance the formation of dislocations. Pulled silicon crystals 6 in. (15 cm) in diameter are important for the semiconductor industry. Ruby, sapphire, and group 13–15 compound semiconductor crystals are among the many crystals that are routinely grown by the Czochralski technique.

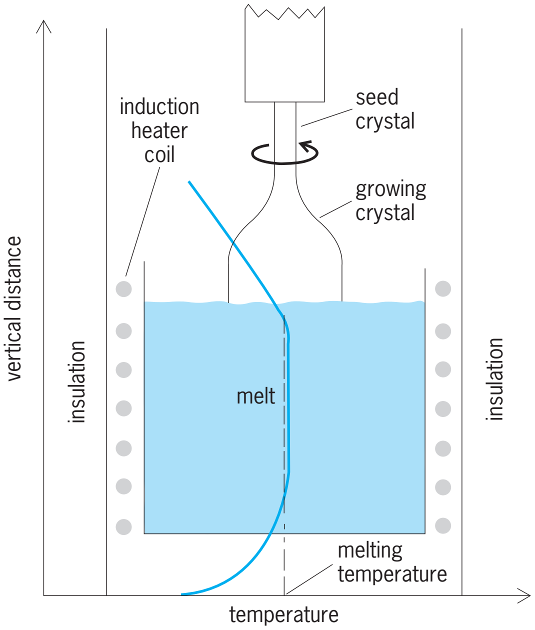

Fig. 2. Czochralski crystal growth and temperature distribution.

The evolution of methods for the growth of very thin but very high-quality epitaxial layers has resulted largely from the need for such layers of semiconductors and magnetic garnets. The technique most closely related to the methods used for bulk crystal growth is liquid-phase epitaxy. For a typical binary semiconductor, growth is done onto a substrate single-crystal wafer from a solution rich in the component with the lowest partial pressure. For a binary compound, the grown layers may differ only in impurity concentrations to modify their electrical characteristics. More often, multilayered structures with layers differing in major component composition but having the same crystal structure and lattice parameter are required. The simplest example of liquid-phase epitaxy with major composition changes in layers is the growth of layers of aluminum gallium arsenide ($Al_xGa_{1-x}As$; $1 > x > 0$) on a gallium arsenide (GaAs) substrate.

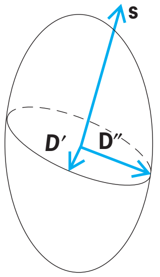
Growth by liquid-phase epitaxy is done in an apparatus in which the substrate wafer is sequentially brought into contact with solutions that are at the desired compositions and may be supersaturated or cooled to achieve growth. For crystalline solid solutions other than $Al_xGa_{1-x}As$, very precise control over solution compositions is required to achieve a lattice match. Typically, structures grown by liquid-phase epitaxy have four to six layers ranging widely in composition and having thickness from 10^{-7} to 10^{-6} m.

The desirability of highly reproducible growth and even thinner epitaxial layers of 13–15 compounds on large wafer areas has led to the development of molecular-beam epitaxy and several forms of chemical-vapor deposition. Molecular-beam epitaxy is an ultrahigh-vacuum technique in which beams of atoms or molecules of the constituent elements of the crystal provided by heated effusion ovens, impinge upon a heated substrate crystal. It has been used for epitaxial layers as thin as 0.5 nanometer. Molecular-beam epitaxy has also been used for group 12–16 compounds and for silicon. *See* ARTIFICIALLY LAYERED STRUCTURES; MOLECULAR BEAMS; SEMICONDUCTOR; SEMICONDUCTOR HETEROSTRUCTURES; VAPOR DEPOSITION. [M.B.P.]

Crystal optics The study of the propagation of light, and associated phenomena, in crystalline solids. For a simple cubic crystal the atomic arrangement is such that in each direction through the crystal the crystal presents the same optical appearance. The atoms in anisotropic crystals are closer together in some planes through the material than in others. In anisotropic crystals the optical characteristics are different in different directions. In classical physics the progress of an electromagnetic wave through a material involves the periodic displacement of electrons. In anisotropic substances the forces resisting these displacements depend on the displacement direction. Thus the velocity of a light wave is different in different directions and for different states of polarization. The absorption of the wave may also be different in different directions. *See* DICHROISM; TRICHROISM.

In an isotropic medium the light from a point source spreads out in a spherical shell. The light from a point source embedded in an anisotropic crystal spreads out in two wave surfaces, one of which travels at a faster rate than the other. The polarization of the light varies from point to point over each wave surface, and in any particular direction from the source the polarization of the two surfaces is opposite. The characteristics of these surfaces can be determined experimentally by making measurements on a given crystal.

In the most general case of a transparent anisotropic medium, the dielectric constant is different along each of three orthogonal



Index ellipsoid, showing construction of directions of vibrations of *D* vectors belonging to a wave normal *s*. (*After M. Born and E. Wolf, Principles of Optics, 7th ed., Cambridge University Press, 1999*)

axes. This means that when the light vector is oriented along each direction, the velocity of light is different. One method for calculating the behavior of a transparent anisotropic material is through the use of the index ellipsoid, also called the reciprocal ellipsoid, optical indicatrix, or ellipsoid of wave normals. This is the surface obtained by plotting the value of the refractive index in each principal direction for a linearly polarized light vector lying in that direction (see illustration). The different indices of refraction, or wave velocities associated with a given propagation direction, are then given by sections through the origin of the coordinates in which the index ellipsoid is drawn. These sections are ellipses, and the major and minor axes of the ellipse represent the fast and slow axes for light proceeding along the normal to the plane of the ellipse. The length of the axes represents the refractive indices for the fast and slow wave, respectively. The most asymmetric type of ellipsoid has three unequal axes. It is a general rule in crystallography that no property of a crystal will have less symmetry than the class in which the crystal belongs.

Accordingly, there are many crystals which, for example, have four- or sixfold rotation symmetry about an axis, and for these the index ellipsoid cannot have three unequal axes but is an ellipsoid of revolution. In such a crystal, light will be propagated along this axis as though the crystal were isotropic, and the velocity of propagation will be independent of the state of polarization. The section of the index ellipsoid at right angles to this direction is a circle. Such crystals are called uniaxial and the mathematics of their optical behavior is relatively straightforward.

In crystals of low symmetry the index ellipsoid has three unequal axes. These crystals are termed biaxial and have two directions along which the wave velocity is independent of the polarization direction. These correspond to the two sections of the ellipsoid which are circular. *See* CRYSTALLOGRAPHY.

The normal to a plane wavefront moves with the phase velocity. The Huygens wavelet, which is the light moving out from a point disturbance, will propagate with a ray velocity. Just as the index ellipsoid can be used to compute the phase or wave velocity, so can a ray ellipsoid be used to calculate the ray velocity. The length of the axes of this ellipsoid is given by the velocity of the linearly polarized ray whose electric vector lies in the axis direction. *See* PHASE VELOCITY.

The refraction of a light ray on passing through the surface of an anisotropic uniaxial crystal can be calculated with Huygens wavelets in the same manner as in an isotropic material. For the ellipsoidal wavelet this results in an optical behavior which is completely different from that normally associated with refraction. The ray associated with this behavior is termed the extraordinary ray. At a crystal surface where the optic axis is inclined at an angle, a ray of unpolarized light incident normally on the surface is split into two beams: the ordinary ray, which proceeds through the surface without deviation; and the extraordinary ray, which is deviated by an angle determined by a line drawn from the center of one of the Huygens ellipsoidal wavelets to the point at which the ellipsoid is tangent to a line parallel to the surface. The two beams are oppositely linearly polarized. [B.H.Bi]

Crystal structure The arrangement of atoms, ions, or molecules in a crystal. Crystals are solids having, in all three dimensions of space, a regular repeating internal unit of structure.

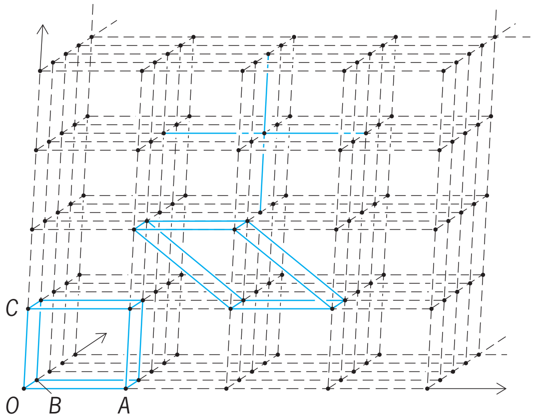
Crystals have been studied using x-rays, which excite signals from the atoms. The signals are of different strengths and depend on the electron density distribution about atomic cores. Light atoms give weaker signals and hydrogen is invisible to x-rays. However, the mutual atomic arrangements that are called crystal structures can be derived once the chemical formulas and physical densities of solids are known, based on the knowledge that atomic positions are not arbitrary but are dictated by crystal symmetry, and that the diffraction signals received are the result of systematic constructive interference between the scatterers within the regularly repeating internal unit of pattern. *See* CRYSTALLOGRAPHY; POLYMORPHISM (CRYSTALLOGRAPHY); X-RAY CRYSTALLOGRAPHY; X-RAY DIFFRACTION.

Crystals are defined in terms of space, population, and mutual arrangement. Crystal space is represented as an indefinitely extended lattice of periodically repeating points. The periodicity of the lattice is defined by the lengths and mutual orientations of three lattice vectors that enclose the pattern. Population is defined as the total number and kind of fundamental units of structure that form the pattern. The order and periodicity of crystals must extend to about 100 nanometers in all three dimensions of space to give the sharply defined diffraction signals required for mapping structural details by x-rays. Intermediate states of order are seen in liquid crystals, which have long molecules as fundamental units of structure. These are arranged with their lengths parallel to each other, but without periodicity, in the nematic state. In the smectic state there is orientation in equally spaced planes but no sideways periodicity, like traffic moving freely on a multilane highway. *See* LIQUID CRYSTALS.

In reality crystal space is not, in general, perfect. The growth process is characterized by constraints and turbulences, and by the dynamic interaction between the crystal and its environment. The process is reflected within the structures formed as an assemblage of atoms is collected and made relatively immobile by releasing the energy known as the heat of crystallization. The resulting crystal lattices resemble a mosaic of slightly misaligned adjacent regions. This is fortunate for research in x-ray crystallography. Perfect alignment would result in subtraction of energy by interference with the primary beam, due to a 180° phase reversal of the reflected beam (primary extinction). Internally diffracted beams would also be attenuated by internal reflection from regions above them (secondary extinction). *See* CRYSTAL GROWTH.

Each of the spatially misaligned mosaic blocks of a single crystal is assumed to maintain lattice periodicity within it. This assumption is confirmed by the sharp diffraction patterns observed. There are some "wrong" atoms, vacant lattice sites, trapped gas atoms, and so forth, and the atomic occupants jiggle about while also vibrating cooperatively and synchronously in complex internal modes of motion. Intricate patterns of electron exchange are enacted, and systematic changes in spin orientations can occur for an atom with a magnetic moment. Details like these are important for understanding the relationships between structure determination on the atomic and molecular levels and the cooperative behavior that determines bulk properties and functions. *See* CRYSTAL DEFECTS; LATTICE VIBRATIONS.

A rectangular space lattice with two possible cells is outlined in the illustration. These have the same cell volumes but different symmetries. Since crystallographic unit cells are completely defined by three lattice vectors, the crystal symmetry referenced to this lattice can be no higher than orthorhombic: $a \neq b \neq c$ ($OA \neq OB \neq OC$), and all angles equal to 90°. This and a possible monoclinic cell, with the same vectors a and b (OA and



A space lattice, two possible unit cells, and the environment of a point.

OB) and one angle not equal to 90°, are outlined. If the *OAB* plane is rotated and the vector *a* (*OA*) is extended to terminate at the next lattice point, then all angles differ from 90° and the crystal symmetry represented becomes triclinic. The mutual arrangement and atom coordinates of the cell population must be such that the environment, seen from every point of the space lattice, remains the same.

Screw axes combine the rotation of an ordinary symmetry axis with a translation parallel to it and equal to a fraction of the unit distance in this direction. If screw axes are present in crystals, it is clear that the displacements involved are of the order of a few tenths of nanometer and that they cannot be distinguished macroscopically from ordinary symmetry axes. The same is true for glide mirror planes, which combine the mirror image with a translation parallel to the mirror plane over a distance that is half the unit distance in the glide direction. The handedness of screw axes is a very important feature of many biological and mineral structures. *See* STEREOCHEMISTRY.

Space groups are indefinitely extended arrays of symmetry elements disposed on a space lattice. A space group acts as a three-dimensional kaleidoscope: An object submitted to its symmetry operations is multiplied and periodically repeated in such a way that it generates a number of interpenetrating identical space lattices. Space groups are denoted by the Hermann-Mauguin notation preceded by a letter indicating the Bravais lattice on which it is based. For example, $P\ 2_12_12_1$ is an orthorhombic space group; the cell is primitive and three mutually perpendicular screw axes are the symmetry elements. J. D. H. Donnay and D. Harker have shown that it is possible to deduce the space group from a detailed study of the external morphology of crystals.

In general, metallic structures are relatively simple, characterized by a close packing and a high degree of symmetry. Manganese, gallium, mercury, and one form of tungsten are exceptions. A characteristic of metallic structures is the frequent occurrence of allotropic forms; that is, the same metal can have two or more different structures which are most frequently stable in a different temperature range. The forces which link the atoms together in metallic crystals are nondirectional. This means that each atom tends to surround itself by as many others as possible. This results in a close packing, similar to that of spheres of equal radius, and yields three distinct systems: close-packed (face-centered) cubic, hexagonal close-packed, and body-centered cubic.

Simple crystal structures are usually named after the compounds in which they were first discovered (diamond or zinc sulfide, cesium chloride, sodium chloride, and calcium fluoride). Many compounds of the types A^+X^- and $A^{2+}X_2{}^-$ have such structures. They are highly symmetrical, the unit cell is cubic, and the atoms or ions are disposed at the corners of the unit cell and at points having coordinates that are combinations of 0, 1, $^1/_2$, or $^1/_4$.

The sodium chloride structure is an arrangement in which each positive ion is surrounded by six negative ions, and vice versa. The centers of the positive and the negative ions each form a face-centered cubic lattice. Systematic study of the dimensions of the unit cells of compounds having this structure has revealed that:

1. Each ion can be assigned a definite radius. A positive ion is smaller than the corresponding atom and a negative ion is larger.
2. Each ion tends to surround itself by as many others as possible of the opposite sign because the binding forces are nondirectional.

In the cesium chloride structure each of the centers of the positive and negative ions forms a primitive cubic lattice; the centers are mutually shifted. Contact of the ions of opposite sign here is along the cube diagonal. In the diamond structure, each atom is in the center of a tetrahedron formed by its nearest neighbors. The 4-coordination follows from the well-known bonds of the carbon atoms.

The calcium fluoride structure is divided into eight equal cubelets, calcium ions are situated at corners and centers of the faces of the cell. The fluorine ions are at the centers of the eight cubelets. [D.Ev.]

Crystal whiskers Single crystals that have grown in filamentary form. Some grow from their base: either these are extruded to relieve pressure in the base material or they grow as a result of a chemical reaction at the base. In both cases, the growth occurs at a singularity in the base material. Other crystal whiskers grow at their tip, into a supersaturated medium, and the filamentary growth results from a strong anisotropy in the growth rate. *See* SINGLE CRYSTAL; SUPERSATURATION.

Great interest in whiskers developed after it was discovered that the strength exhibited by some whiskers approached that expected theoretically for perfect crystals. This great strength results from the internal and surface perfection of the whiskers, whereas the strength of most materials is limited by defects. The interest in the high strength of the whiskers centered on the possibility of using them in composites to increase the strength of more ductile matrix materials. Fibers of silica, boron, and carbon, which are much easier to fabricate in large quantity than whiskers, exhibit similarly high strengths, and are now used in composites. *See* COMPOSITE MATERIAL; CRYSTAL DEFECTS. [K.A.J.; R.S.Wa.]

Crystallization The formation of a solid from a solution, melt, vapor, or a different solid phase. Crystallization from solution is an important industrial operation because of the large number of materials marketed as crystalline particles. Fractional crystallization is one of the most widely used methods of separating and purifying chemicals. In fractional crystallization it is desired to separate several solutes present in the same solution. This is generally done by picking crystallization temperatures and solvents such that only one solute is supersaturated and crystallizes out. By changing conditions, other solutes may be crystallized subsequently. Repeated crystallizations are necessary to achieve desired purities when many inclusions are present or when the solid solubility of other solutes is significant. For a discussion of crystallization in glass, a supercooled melt, *see* GLASS. Polymer crystals obtained from solutions are used to study the properties of these crystals, while crystallization of polymer melts dramatically influences polymer properties; *see* POLYMER. For methods of preparing large crystals *see* SINGLE CRYSTAL. For crystallization from vapors *see* SUBLIMATION. For solubility and other relationships between solid and liquid phases *see* PHASE EQUILIBRIUM; SOLUTION. *See* also CRYSTAL; CRYSTALLOGRAPHY; NUCLEATION. [W.R.W.]

Crystallography The branch of science that deals with the geometric forms of crystals. How to describe, classify, and measure such forms are the first questions of crystallography. Revealing the forces that made them and the activities within them are the modern directions of the field. Crystallography is essential to progress in the applied sciences and technology and developments in all materials areas, including metals and alloys, ceramics, glasses, and polymers, as well as drug design. It is equally vital to progress in fundamental physics and chemistry, mineralogy and geology, and computer science, and to understanding of the dynamics and processes of living systems. *See* CRYSTAL STRUCTURE; POLYMORPHISM (CRYSTALLOGRAPHY).

The external morphology of crystals reflects their growth rates in different directions. These directions remain constant during the course of the growth process, and are represented mathematically as the normals to sets of parallel planes that are imagined as being added on as growth proceeds. The faces that meet and define an edge belong to a zone, a zone being a set of planes that share one common direction, the zone axis. The invariance of interfacial angles, measured by rotation about an axis that is defined by the zone direction, was discovered in the seventeenth century. *See* CRYSTAL GROWTH.

Interfacial angles are calculated from spherical geometry. Figure 1 illustrates the procedure for a crystal having well-developed faces of which three are mutually perpendicular. The normals to these faces are the natural directions for constructing an orthogonal frame of reference for measurement. The crystal is imagined to be shrunk and placed at the center of a sphere with coordinates (0,0,0). The face normals, labeled [100], [010], and [001], define the directions of an orthogonal reference system. Normals to the same set of planes, but oppositely directed, are labeled $[\bar{1}00]$, $[0\bar{1}0]$, $[00\bar{1}]$. The reversal of sign indicates that the crystal must be rotated 180° to obtain the same view. Rotation about the [001] direction interchanges the positions of [100] and $[\bar{1}00]$ faces and their bounding edges. Rotation about [010] turns these faces upside down. Correct designations for group movements and symmetry operations are clearly essential for establishing and maintaining orientation in crystal space. The directions of face normals determine points at which the imagined sphere is pierced. The solid angles between an array of such points, all lying on the same great circle of the sphere, belong to a zone.

Optical measurements and stereographic projections established the constancy of interfacial angles, independent of how well developed the faces are. Such properties as the cleavage of large rhombohedral crystals of calcite ($CaCO_3$) into little rhombs suggested that the large crystal could be represented by geometrically identical smaller units stacked together, by translation, to fill space. The 14 lattices of Bravais (Fig. 2) enlarged the seven crystal systems of optical mineralogy by adding centering points to them: body (I), face (F), and base (C) centers. The 14 lattices define three-dimensional distributions of mathematical points such that the environments of all points of the lattice are identical. They also define the symmetries of frameworks for constructing mathematical models to represent the observed and measured realities—models made from cells of the smallest volume, but also highest symmetry, that stack together by translation to fill space.

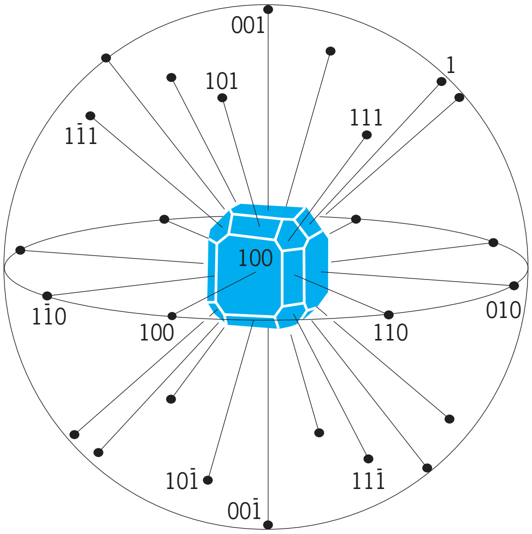


Fig. 1. Spherical projection of normals to crystal faces.

Bravais lattice cells	Axes and interaxial angles	Examples
 Cubic P Cubic I Cubic F	Three axes at right angles; all equal: $a = b = c;\ \alpha = \beta = \gamma = 90°$	Copper (Cu), silver (Ag), sodium chloride (NaCl)
 Tetragonal P Tetragonal I	Three axes at right angles; two equal: $a = b \neq c;\ \alpha = \beta = \gamma = 90°$	White tin (Sn), rutile (TiO_2), β-spodumene ($LiAlSi_2O_6$)
 P C I F Orthorhombic	Three axes at right angles; all unequal: $a \neq b \neq c;\ \alpha = \beta = \gamma = 90°$	Gallium (Ga), perovskite ($CaTiO_3$)
 Monoclinic P Monoclinic C	Three axes, one pair not at right angles, of any lengths: $a \neq b \neq c;\ \alpha = \gamma = 90° \neq \beta$	Gypsum ($CaSO_4 \cdot 2H_2O$)
 Triclinic P	Three axes not at right angles, of any lengths: $a \neq b \neq c;\ \alpha \neq \beta \neq \gamma \neq 90°$	Potassium chromate (K_2CrO_7)
 Trigonal R (rhombohedral)	Rhombohedral: three axes equally inclined, not at right angles; all equal: $a = b = c;\ \alpha = \beta = \gamma \neq 90°$	Calcite ($CaCO_3$), arsenic (As), bismuth (Bi)
 Trigonal and hexagonal C (or P)	Hexagonal: three equal axes coplanar at 120°, fourth axis at right angles to these: $a_1 = a_2 = a_3 \neq c;$ $\alpha = \beta = 90°,\ \gamma = 120°$	Zinc (Zn), cadmium (Cd), quartz (SiO_2) [P]

Fig. 2. The 14 Bravais lattices, derived by centering of the seven crystal classes (P and R) defined by symmetry operators.

Stacking of model cells does not imply that a crystal grows by stacking identical bricks; a lattice of identically surrounded mathematical points does not imply that any real objects, atoms or molecules, are located at the points; and filling space by translation of identical cells does not imply that the space defined by the cells is filled. Rather, the Bravais lattices are a formalism for representing observed geometries and symmetries of real crystals by three-dimensional lattices of identically surrounded points.

The lattices also provide the means to identify imaginary planes within the cell; these are called Miller indices (*h*,*k*,*l*). They consist of small whole numbers. For example, each of the six faces of a simple cube, with the origin of a coordinate frame of reference at the cube body center, is normal to one of the reference axes and parallel to the plane defined by the two others. The six faces are indexed as their normals in Fig. 1—(100), $(\bar{1}00)$, (010), $(0\bar{1}0)$, (001), and $(00\bar{1})$—to represent a face that intercept the *x*, *x* axis but not the *y* and *z*; the *y*, *y* axis but not the *x* and *z*; and so forth. Hypothetical parallel planes with 1/2 the interplanar spacing are represented as (200), $(\bar{2}00)$, (020), and so forth.

A complete mathematical formalism exists for modeling an external morphological form and the symmetry relations between imagined units of structure within it. The symmetry operators include rotation axes, glide and mirror planes, and left- and right-handed screw axes which will simultaneously rotate and translate a three-dimensional object to create its clone in a different spatial position and orientation. The operators minimize the detail required to specify the spatial arrangements of patterns and objects that fill two-dimensional and three-dimensional space. The so-called color space groups of crystallography greatly increase the number of distinguishably different symmetries beyond the classical 230 by adding a fourth coordinate to the three space coordinates. This is done to encode a real difference that will be manifested in some property. The different directions of the magnetic moments of chemically identical atoms of an element such as iron provide an example of the need for representing a difference on the atomic level between cells that are otherwise identical.

The sharp x-ray line spectra characteristic of the bombarded element are the primary probes for determining interior structural detail of crystals. Cameras with cylindrical film and enclosed powdered samples record all diffraction lines as arcs of concentric circles. This fundamental powder method has endured since 1917 and is now employed with improved beam purity and optics, improved diffractometers which couple sample and detector rotation, electronic detection, rapid sequential recording, and computer indexing programs that provide patterns of compounds, mixtures of phases, and dynamic changes that occur when crystals are subjected and respond to external stress. The method is applied to single crystals, polycrystalline aggregates, and multiple-phase mixtures, randomly disposed either in space or in geometrically designed composite materials. *See* X-RAY CRYSTALLOGRAPHY; X-RAY POWDER METHODS.

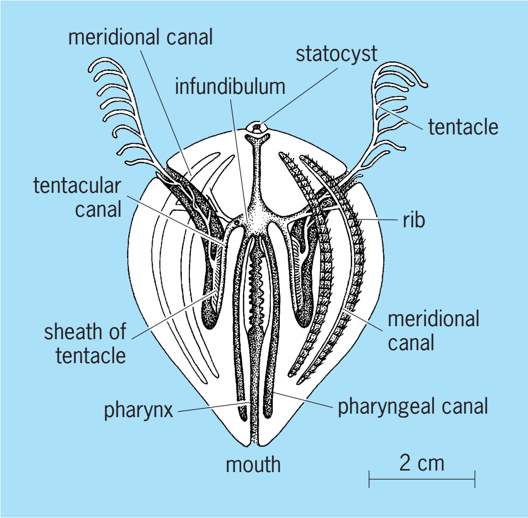
The dynamics of living systems, the difficulties in distinguishing light elements, and the inherent ambiguities of measuring, decoding, and mapping crystal structures are continuing challenges. Major achievements of crystallography include the determination of the structures of deoxyribonucleic acid (DNA), proteins, other biological compounds, and boranes; the development of direct methods of phase determination; and the determination of the structure and mechanism of a photosynthetic center. *See* BORANE; DEOXYRIBONUCLEIC ACID (DNA); PHOTOSYNTHESIS; PROTEIN. [D.Ev.]

Ctenophora A phylum of exclusively marine organisms, formerly included in the jellyfish and polyps as coelenterates. These animals, the so-called comb jellies, possess a biradial symmetry of organization and have eight rows of comblike plates as the main locomotory structures. Most are pelagic, but a few genera are creeping. Many are transparent and colorless; others are faintly to brightly colored. Almost all are luminescent. Many of these organisms are hermaphroditic. Development is biradially symmetrical, with a cydippid larval stage. Five orders constitute this phylum as follows:

Phylum Ctenophora
  Order: Cydippida
    Lobata
    Cestida
    Platyctenida
    Beroida

The body is gelatinous and extremely fragile; its form may be globular, pyriform, or bell- or helmet-shaped. Some species resemble a ribbon. Their size ranges from $\frac{1}{8}$ to 20 in. (3 mm to 50 cm). The axis of symmetry is determined by the mouth and the organ of equilibrium, or statocyst (see illustration). The mouth leads into the flattened, elongated pharynx. The sagittal plane is thus referred to as the stomodeal plane. The other plane of symmetry is perpendicular to the sagittal plane and is marked (Beroida excepted) by tentacles. Eight meridional combplate rows or ribs stretch from the aboral pole on the surface of the body. The comb plates, which are used as oars during locomotion, are the most characteristic structure of the ctenophores, possessed by all members of the phylum. Each plate consists of a great number of very long related cilia.

Fertilization usually occurs in seawater. Pelagic ctenophores are self-fertile, but cross-fertilization might also take place inside a swarm of ctenophores. Ctenophores have high powers of regeneration. Asexual reproduction (in a few platyctenid genera) is by regeneration of an entire organism from a small piece of the adult body.



Structure of a cydippid ctenophore.

The ctenophores feed on zooplankton. They are themselves important plankton organisms. They are quite common and have a worldwide distribution in all seas, where they can appear in enormous swarms. Some genera stand great changes in the seawater salinity. Because of their voracity as predators of zooplankton, they play an important role in plankton equilibrium and in fisheries. [J.M.F.]

Ctenopoda An order of branchiopod crustaceans formerly included in the order Cladocera. The body is up to about 4 mm (0.2 in.) in length. Although superficially similar to the large order Anomopoda in the protection of the trunk and its limbs by a functionally bivalved carapace, in the nature of the eye, in the use of antennae for swimming, and in the possession of a somewhat similar postabdomen, ctenopods differ in various ways. *See* ANOMOPODA.

The six trunk limbs are all constructed on a similar plan but differ in detail among themselves. They beat with a metachronal rhythmn and by so doing draw in suspended food particles. Some species have become planktonic; *Holopedium* surrounds itself by a sphere of jelly to assist flotation. Others are sedentary; *Sida* attaches itself by a sucker at the back of the head.

Reproduction is mostly by parthenogenesis. Most species occur in fresh water, where they are widely distributed, but *Penilia* is marine. *See* BRANCHIOPODA. [G.Fr.]

Ctenostomata A paraphyletic order of Bryozoa in the class Gymnolaemata. Ctenostomes have entirely cuticular body walls, and colonies consist of feeding zooids only or of feeding zooids plus spine- or stolon-shaped zooids. *See* GYMNOLAEMATA.

Feeding zooids possess tentacles that collectively form a circular, feeding, bell-shaped lophophore centered on the mouth. Most ctenostomes grow as encrusting or erect, ramifying, thin branches that consist entirely of zooids or of individual zooids or zooid groups connected by stolons. Others grow as densely packed zooids that form flexible encrustations or thick, erect, branched growths. A few branching ctenostomes are endolithic borers.

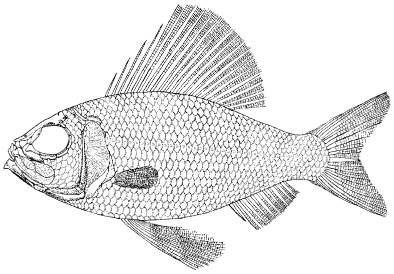
Colonies are hermaphroditic. Fertilized eggs are usually brooded as embryos in the space normally occupied by the retracted tentacles of feeding zooids. In other species, brooding may be within specialized invaginations or within the coelom. A few species release fertilized eggs directly into the sea. The free-swimming larvae attach to a substrate for metamorphosis.

Then is formed the first feeding zooid of the colony, from which all subsequent zooids within the developing colony are budded.

Most ctenostomes are marine, although several species are tolerant to lower salinity than any other marine bryozoans and a few live in fresh water.

The fossil record of endolithic ctenostomes extends back to the Late Ordovician. The lack of a mineralized skeleton diminishes chances of preservation of nonboring ctenostomes. Ctenostome bryozoans are relatively primitive in their lack of calcification, small number of zooid types, lack of brooding in some species, and other features. The oldest known Cheilostomata are Late Jurassic and have zooidal shapes and encrusting colony growth habits that are close to morphologies known in extant ctenostomes and apparently are derived from ctenostomes. The class Stenolaemata may have originated from ctenostomes. *See* BRYOZOA; STENOLAEMATA. [F.K.McK.]

Ctenothrissiformes A small order of teleostean fishes that are of particular interest because they seem to be on or near the main evolutionary line leading from the generalized, soft-rayed salmoniforms to the spiny-rayed beryciforms and perciforms, dominant groups among higher bony fishes. Ctenothrissiformes lack fin spines but they share many characters with primitive beryciforms. The few fishes confidently assigned to the Ctenothrissiformes, *Ctenothrissus* (Ctenothrissidae; see illustration) and *Aulolepis* and *Pateroperca* (Aulolepidae), are known as Upper Cretaceous marine fossils from Europe and southwestern Asia. Two little-known genera of Recent oceanic fishes, *Macristium* and *Macristiella* (Macristiidae), are assigned by some authors to the order but some doubt attends this placement. *See* BERYCIFORMES; PERCIFORMES; SALMONIFORMES. [R.M.B.]

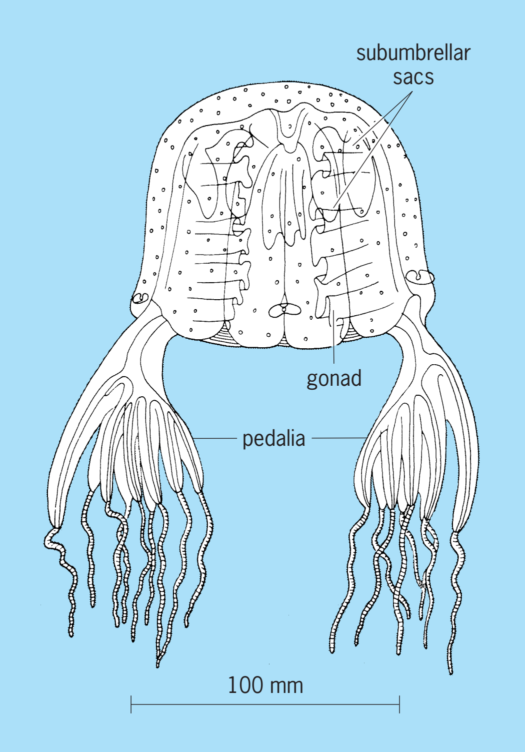


Cretaceous ctenothrissid, *Ctenothrissus radians.* (*After C. Patterson, Phil. Trans. Roy. Soc. London, Ser. B, Biol. Sci., no. 739, vol. 247, 1964*)

Cube A parallelepiped whose six faces are all squares. The cube is one of the five regular solids known to the ancient Greeks. A cube has eight vertices and twelve edges. Each vertex is on three edges and three faces, each edge is on two vertices and two faces, and each plane is on four vertices and four edges. *See* POLYHEDRON; REGULAR POLYTOPES. [L.M.Bl.]

Cubeb The dried, nearly ripe fruit (berries) of a climbing vine, *Piper cubeba*, of the pepper family (Piperaceae). This species is native to eastern India and Indomalaysia. The crushed berries are smoked, and the inhaled smoke produces a soothing effect in certain respiratory ailments. Cubebs are used in medicine as a stimulant, expectorant, and diuretic. Medicinal properties of cubeb are due to the presence of a volatile oil which formerly was thought to stimulate healing of mucous membranes. *See* PIPERALES. [P.D.St./E.L.C.]

Cubomedusae An order of the class Scyphozoa. Their distribution is mostly tropical. The umbrella is cubic, and a pedalium, a gelatinous leaf-shaped body, is present at the base of each ridge of the exumbrella (see illustration). A well-developed tentacle, or a cluster of tentacles, arises from each pedalium. No connecting stage between polyp and medusa is known. *See* SCYPHOZOA. [T.U.]



Cubomedusan, *Chiropsalmus quadrumanni.* (*After L. Hyman, The Invertebrates, vol. 1, McGraw-Hill, 1940*)

Cuculiformes An order of birds with zygodactyl feet in which the outer fourth toe is reversed. The order is divided into the suborder Musophagi, containing the single family Musophagidae (touracos; 18 species), and the suborder Cuculi, with the lone family Cuculidae (cuckoos; 129 species).

Touracos are African woodland birds with a loose green, gray, or brown plumage with patches of bright yellow, red, or violet. The nest is a bulky platform placed in a tree, with incubation and care of the chicks shared by the parents. The young leave the nest at an early age (about 10 days) and crawl about the trees before being able to fly.

Cuckoos are diverse. They are mostly arboreal, but some are terrestrial, and some, such as the American roadrunners (*Geococcyx*) are fast runners with top speeds of about 15 mi/h (25 km/h) and fly rarely. Most cuckoos are secretive, sulking in heavy vegetation. They are strong fliers but do not fly often. Temperate species are migratory. Cuckoos feed on insects, small vertebrates, other animals, and rarely on fruit. Most are solitary, but the anis (Crotophaginae) live in flocks and build a cooperative nest housing several females. Many Old World species (Cuculinae) are nest parasites. *See* AVES. [W.J.B.]

Cucumber A warm-season annual cucurbit (*Cucumis sativus*) native to India and belonging to the plant order Campanulales. The cucumber is grown for its immature fleshy fruit which is used primarily for pickling and for slicing as a salad. The development of gynoecious (bearing only female flowers) and hybrid varieties (cultivars) with increased disease resistance is resulting in a continuing change in the varieties of both pickling and slicing cucumbers. Important producing states are Florida and South Carolina for fresh market and Michigan and Wisconsin for pickling. *See* CAMPANULALES. [H.J.C.]

Culture The cultivation of cells in the laboratory. Bacteria and yeasts may be grown suspended in a liquid medium or as colonies on a solid medium; molds grow on moist surfaces; and animal and plant cells (tissue cultures) usually adhere to the glass or plastic beneath a liquid medium. Cultures must provide sources of energy and raw material for biosynthesis, as well as a suitable physical environment.

The materials supplied determine which organisms can grow out from a mixed inoculum. Some bacteria (prototrophic) can produce all their constituents from a single organic carbon source; hence they can grow on a simple medium. Other cells (auxotrophic) lack various biosynthetic pathways and hence require various amino acids, nucleic acid bases, and vitamins. Obligatory or facultative anaerobes grow in the absence of O_2; many cells require elevated CO_2. Cultures isolated from nature are usually mixed; pure cultures are best obtained by subculturing single colonies. Viruses are often grown in cultures of a host cell, and may be isolated as plaques in a continuous lawn of those cells. In diagnostic bacteriology, species are ordinarily identified by their ability to grow on various selective media and by the characteristic appearance of their colonies on test media. *See* BACTERIAL GROWTH.

Laboratory cultures are often made in small flasks, test tubes, or covered flat dishes (petri dishes). Industrial cultures for antibiotics or other microbial products are usually in fermentors of 10,000 gallons (37,850 liters) or more. The cells may be separated from the culture fluid by centrifugation or filtration.

Specific procedures are employed for isolation, cultivation, and manipulation of microorganisms, including viruses and rickettsia, and for propagation of plant and animal cells and tissues. A relatively minute number of cells, the inoculum, is introduced into a sterilized nutrient environment, the medium. The culture medium in a suitable vessel is protected by cotton plugs or loose-fitting covers with overlapping edges so as to allow diffusion of air, yet prevent access of contaminating organisms from the air or from unsterilized surfaces. The transfer, or inoculation, usually is done with the end of a flamed, then cooled, platinum wire. Sterile swabs may also be used and, in the case of liquid inoculum, sterile pipets.

The aqueous solution of nutrients may be left as a liquid medium or may be solidified by incorporation of a nutritionally inert substance, most commonly agar or silica gel. Special gas requirements may be provided in culture vessels closed to the atmosphere, as for anaerobic organisms. Inoculated vessels are held at a desired constant temperature in an incubator or water bath. Liquid culture media may be mechanically agitated during incubation. Maximal growth, which is visible as a turbidity or as masses of cells, is usually attained within a few days, although some organisms may require weeks to reach this stage. *See* CHEMOSTAT; EMBRYONATED EGG CULTURE; TISSUE CULTURE. [B.D.D.]

Cumacea An order of the class Crustacea, subclass Malacostraca. All have a well-developed carapace which is fused dorsally with at least the first three thoracic somites and which overhangs the sides to enclose a branchial cavity. The telson may be free or may appear lacking because it is fused with the last abdominal somite. Eyes are sessile and, except for a few genera, are coalesced in a single median organ or wholly wanting. There are eight pairs of thoracic appendages. There is no free larval stage. In the few species whose life history has been investigated there are five to seven molts after release from the brood pouch. There is always some sexual dimorphism in adults, but immature males resemble females until the later stages.

The order is rather uniform and classification is based on trivial characters. Seven families are recognized. Affinities are probably closer to the Mysidacea than to the Tanaidacea. A few fossils are now known.

Cumacea are found in all seas and in some estuaries and areas of brackish water, including the Caspian Sea. Most inhabit water shallower than 660 ft (200 m), but many occur in great depths. They normally burrow in sand or mud with the front protruding. They feed on organic detritus or very small organisms and may themselves form part of the diet of various fishes. *See* MALACOSTRACA. [N.S.J.]

Cumin *Cuminum cyminum*, a plant for which the whole or ground dried ripe fruit, commonly called seed, is a popular spice. It is a major ingredient in both chili powder and curry, and is added to meat sauces, rice, bread, pickles, soups, and other foods. Roman caraway is another common name for this member of the parsley family (Apiaceae). The only species in its genus, cumin exhibits a variety of plant types depending on the seed source. A small annual herb about 1–2 ft (0.3–0.6 m) tall, cumin grows upright as a single slender stem with many branches. *See* APIALES.

The strong, pungent green-spicy odor and flavor of cumin is attributable largely to cuminaldehyde, the main constituent of the essential oil, and other aldehydes.

This herb is native to the Mediterranean region. Presently cumin is commercially grown in Iran, southern Russia, China, India, Morocco, and Turkey. The three major types of cumin seed, Iranian, Indian, and Middle Eastern, vary in seed color, essential oil quantity, and flavor. Upon distillation cumin seed yields 2.5–5% essential oil, used in both perfumery and flavoring liqueurs. Cumin is also used medicinally. *See* SPICE AND FLAVORING. [S.Kir.]

Cummingtonite An amphibole (a double-chain silicate mineral) with the idealized chemical formula $Mg_7Si_8O_{22}(OH)_2$ that crystallizes with monoclinic symmetry. Naturally occurring samples generally are solid solutions between $Mg_7Si_8O_{22}(OH)_2$ and the corresponding iron (Fe)-end member with the general formula $(Mg,Fe)_7Si_8O_{22}(OH)_2$. The name cummingtonite (derived from the location Cummington, Massachusetts) is applied to all solid solutions with $Mg/(Mg + Fe^{2+}) \geq 0.5$, whereas those with $Mg/(Mg + Fe^{2+}) < 0.5$ are termed grunerite. Up to a total of 1.0 (Ca + Na) atom per formula unit may also be present in cummingtonite.

Cummingtonite commonly occurs as aggregates of fibrous crystals, often in radiating clusters. It is transparent to translucent, varies in color from white to green to brown, and may be pale to dark depending primarily on the iron content. Hardness is 5–6 on Mohs scale; density is 3.1–3.6 g/cm^3 (1.8–2.1 oz/in.^{3}), increasing with increasing iron content.

Cummingtonite is generally considered to be a metamorphic mineral, but it has been found in silicic volcanic rocks and, rarely, plutonic igneous rocks. It occurs in a variety of metamorphic rock types (amphibolite, schist, gneiss, granulite) that have undergone medium- to high-grade metamorphism. It commonly occurs in the calcium- and aluminum-poor environment of metamorphosed iron formation. It can also be a constituent of metamorphosed mafic and ultramafic igneous rocks, where it may coexist with other amphibole minerals such as hornblende, tremolite, and anthophyllite. With increasing intensity of metamorphism, cummingtonite is commonly replaced by pyroxene-bearing mineral assemblages. *See* AMPHIBOLE; HORNBLENDE; IGNEOUS ROCKS; METAMORPHIC ROCKS; TREMOLITE. [R.K.P.]

Cuprite A mineral having composition Cu_2O and crystallizing in the isometric system. Cuprite is commonly in crystals showing the cube, octahedron, and dodecahedron. It is various shades of red and a fine ruby red in transparent crystals which have a metallic to adamantine luster. The hardness is 3.5–4 (Mohs scale) and the specific gravity is 6.1.

Cuprite is a widespread supergene copper ore. Fine crystals have been found at Cornwall, England, and Chessy, France. It has served as an ore in the Congo, Chile, Bolivia, and Australia. In the United States it has been found at Clifton, Morenci, Globe, and Bisbee, all in Arizona. *See* COPPER. [C.S.Hu.]

Curie temperature The critical or ordering temperature for a ferromagnetic or a ferrimagnetic material. The Curie temperature T_C is the temperature below which there is a spontaneous magnetization M in the absence of an externally applied magnetic field, and above which the material is paramagnetic. In the disordered state above the Curie temperature, thermal energy overrides any interactions between the local magnetic moments of ions. Below the Curie temperature, these interactions are predominant and cause the local moments to order or align so that there is a net spontaneous magnetization.

In the ferromagnetic case, as temperature T increases from absolute zero, the spontaneous magnetization decreases from M_0, its value at $T = 0$. At first this occurs gradually, then with increasing rapidity until the magnetization disappears at the Curie temperature. In ferrimagnetic materials the course of magnetization with temperature may be more complicated, but the spontaneous magnetization disappears at the Curie temperature.

In antiferromagnetic materials the corresponding ordering temperature is termed the Néel temperature. Below the Néel temperature the magnetic sublattices have a spontaneous magnetization, though the net magnetization of the material is zero. Above the Néel temperature the material is paramagnetic. *See* ANTIFERROMAGNETISM.

The ordering temperatures for magnetic materials vary widely. The ordering temperature for ferroelectrics is also termed the Curie temperature, below which the material shows a spontaneous electric moment. *See* FERROMAGNETISM; PYROELECTRICITY. [J.F.Di.]

Curie-Weiss law A relation between magnetic or electric susceptibilities and the absolute temperature which is followed by ferromagnets, antiferromagnets, nonpolar ferroelectrics and antiferroelectrics, and some paramagnets. The Curie-Weiss law is usually written as the equation below, where χ is the suscepti-

$$\chi = C/(T - \theta)$$

bility, C is a constant for each material, T is the absolute temperature, and θ is called the Curie temperature. Antiferromagnets and antiferroelectrics have a negative Curie temperature. The Curie-Weiss law refers to magnetic and electric behavior above the transition temperature of the material in question. It is not always precisely followed, and it breaks down in the region very close to the transition temperature. Often the susceptibility will behave according to a Curie-Weiss law in different temperature ranges with different values of C and θ. *See* CURIE TEMPERATURE; ELECTRIC SUSCEPTIBILITY; MAGNETIC SUSCEPTIBILITY. [E.A.; F.Ke.]

Curium A chemical element, Cm, in the actinide series, with an atomic number of 96. Curium does not exist in the terrestrial environment, but may be produced artificially. The chemical properties of curium are so similar to those of the typical rare earths that, if it were not for its radioactivity, it might easily be mistaken for one of these elements. The known isotopes of curium include mass numbers 238–250. The isotope ^{244}Cm is of particular interest because of its potential use as a compact, thermoelectric power source, through conversion to electrical power of the heat generated by nuclear decay. *See* PERIODIC TABLE.

Metallic curium may be produced by the reduction of curium trifluoride with barium vapor. The metal has a silvery luster, tarnishes in air, and has a specific gravity of 13.5. The melting point has been determined as 2444 ± 72°F (1340 ± 40°C). The metal dissolves readily in common mineral acids with the formation of the tripositive ion.

A number of solid compounds of curium have been prepared and their structures determined by x-ray diffraction. These include CmF_4, CmF_3, CmC_3, $CmBr_3$, CmI_3, Cm_2O_3, and CmO_2. Isostructural analogs of the compounds of curium are observed in the lanthanide series of elements. *See* ACTINIDE ELEMENTS; TRANSURANIUM ELEMENTS. [G.T.S.]

Currant A fruit (berry) in the genus *Ribes* in the family Saxifragaceae. Cultivated black and red currants and gooseberries all belong to this genus. *Ribes* species having prickles or spines are called gooseberries, and those that do not are called currants. The berries are produced in clusters on bushes, and cultivars ripen in midsummer.

Ribes are not widely grown commercially for fruit in the United States, but red currants and gooseberries are popular in home gardens for use in jellies and pies. Several *Ribes* species, particularly golden currant (*R. aureum*) and fuchsia-flowered gooseberry (*R. speciosum*), are used as shrubs in landscaping. In Europe cultivars of the black currant (*R. nigrum*) are extensively grown commercially for juice concentrate. Wild *Ribes* species occur widely in the United States, and desirable, edible types are sometimes gathered during the season when the fruit is locally abundant. *See* GOOSEBERRY; ROSALES. [R.H.Co.]

Current comparator An instrument for determining the ratio of two currents, based on Ampère's laws. The application of the current comparator, unlike the voltage ratio transformer, is not limited to alternating currents but can be used with direct currents as well. *See* INSTRUMENT TRANSFORMER.

The current comparator is based on Ampère's circuital law, which states that the integral of the magnetizing force around a closed path is equal to the sum of the currents which are linked with that path. Thus, if two currents are passed through a toroid by two windings of known numbers of turns, and the integral of the magnetizing force around the toroid is equal to zero, the current ratio is exactly equal to the inverse of the turns ratio. *See* AMPÈRE'S LAW.

For alternating-current comparators, the ampere-turn unbalance is given by the voltage at the terminals of a uniformly distributed detection winding on a magnetic core. Direct-current comparators use two magnetic cores which are modulated by alternating current in such a way that the dc ampere-turn unbalance is indicated by the presence of even harmonics in the voltage. Neither method is an exact measure of the integral of the magnetizing force, and various design features are added to overcome this deficiency. The most important of these are the magnetic shields, which are configured as hollow toroids. They protect the magnetic core and detection winding from the leakage fluxes of the current-carrying windings and ambient magnetic fields, and they are responsible for an improvement in accuracy of about three orders of magnitude. The copper shields supplement this action at higher frequencies and also provide mechanical protection for the magnetic steels.

Applications of the ac comparator include current and voltage transformer calibration, measurement of losses in large capacitors, inductive reactors and power transformers, resistance measurement, and the calibration of active and reactive power and energy meters. Further, the current comparator, like the current transformer, has the advantage of being applicable to measurements involving high-voltage, high-power circuits as well as being the basis for very accurate high-current-transconductance amplifiers.

In dc applications, the current comparator provides the means to resolve the first three or four most significant digits of a balance by turns-count, thus eliminating problems associated with switch contact resistance and thermal electromotive forces. Its uses include eight-decade resistance and thermometry bridges, a seven-decade potentiometer, and high current ratio standards. It also provides the means for generating highly accurate direct-current voltages and currents. *See* CURRENT MEASUREMENT; ELECTRICAL MEASUREMENTS. [W.J.M.M.; N.L.K.; E.So.]

Current density A vector quantity equal in magnitude to the instantaneous rate of flow of electric charge, perpendicular to a chosen surface, per unit area per unit time. If a wire of cross-sectional area A carries a current I, the current density J is I/A.

The units of *J* in the rationalized meter-kilogram-second system are amperes per square meter. [J.W.St.]

Current measurement The measurement of the rate of passage of electric charges in a circuit. The unit of measurement, the ampere (A), is one of the base units of the International System of Units (SI). It is defined as that constant current which, if maintained in two straight parallel conductors of infinite length, of negligible circular cross section, and placed 1 m apart in vacuum, would produce between these conductors a force equal to 2×10^{-7} newton per meter of length.

In order to establish an electrical unit in accordance with the SI definition, it is necessary to carry out an experimental determination. The ampere cannot be realized exactly as defined. Electromagnetic theory has to be used to relate a practical experiment to the definition. *See* CURRENT BALANCE.

Since January 1, 1990, working standards of voltage and resistance have provided the foundations of practical electrical measurements. The standard of voltage is based on the alternating-current (ac) Josephson effect, in which voltage is related to frequency. By international agreement the value 483 597.9 GHz/V for the Josephson constant is now used throughout the world. The working unit of resistance is maintained through the quantum Hall effect, with an agreed value of 25 812.807 ohms for the voltage-to-current ratio obtained under certain defined experimental conditions. These values have been chosen to provide the best known approximations to the SI units and have the advantage of reproducibility at the level of 1 part in 10^8. The working standard of current is derived from measurements of voltage across a known resistor. *See* ELECTRICAL UNITS AND STANDARDS; HALL EFFECT; JOSEPHSON EFFECT.

The moving-coil (d'Arsonval) meter measures direct currents (dc) from 10 microamperes to several amperes. The accuracy is likely to be a few percent of the full-scale indication, although precision instruments can achieve 0.1% or even better. Above 1 milliampere a shunt usually carries the major part of the current; only a small fraction is used to deflect the meter. Since the direction of deflection depends on the direction of the current, the d'Arsonval movement is suitable for use only with unidirectional currents. Rectifiers are used to obtain dc and drive the meter from an ac signal. The resulting combination is sensitive to the rectified mean value of the ac waveform.

In the moving-iron meter, two pieces of soft magnetic material, one fixed and one movable, are situated inside a single coil. When current flows, both pieces become magnetized in the same direction and accordingly repel each other. The moving piece is deflected against a spring or gravity restoring force, the displacement being indicated by a pointer. As the repulsive force is independent of current direction, the instrument responds to low-frequency ac as well as dc. The natural response of such a movement is to the root-mean-square (rms) value of the current. The accuracy of moving-iron meters is less than that of moving-coil types. *See* AMMETER.

For radio-frequency applications it is essential that the sensing element be small and simple to minimize inductive and capacitive effects. In a thermocouple meter the temperature rise of a short, straight heater wire is measured by a thermocouple and the corresponding current is indicated by a d'Arsonval movement. In a hot-wire ammeter the thermal expansion of a wire heated by the current is mechanically enhanced and used to deflect a pointer. Both instruments, based on heating effects, respond to the rms value of the current. Above 100 MHz, current measurements are not made directly, as the value of current is likely to change with position owing to reflections and standing waves. *See* MICROWAVE MEASUREMENTS; THERMOCOUPLE.

Above 50 A the design of shunts becomes difficult. For ac, current transformers can be used to reduce the current to a level convenient for measurement. At the highest accuracy, current comparators may be used in which flux balance is detected when the magnetizing ampere-turns from two signals are equal and opposite. Direct-current comparators are available in which dc flux balance is maintained and any unbalance is used to servo a second, or slave, current signal. For the highest accuracy, second-harmonic modulators are used, and for lower precision, Hall effect sensors. Electronically balanced ac and dc current comparators make clip-around ammeters possible, in which an openable magnetic core can be closed around a current-carrying conductor. This allows the meter to be connected into and removed from the circuit without breaking it or interrupting the current. *See* CURRENT COMPARATOR; INSTRUMENT TRANSFORMER.

The obvious method for measuring a very small current is to determine the voltage drop across a large resistor. A sensitive voltage detector having very low offset current is required, for example, an electrometer. Electrometers based on MOSFET (metal-oxide-semiconductor field-effect transistor) devices have overtaken other designs where the very highest resolution is required, as they can have offset current drifts less than 10^{-16} A. In order to provide a low impedance to the measured current, it is preferable to use the electrometer device in an operational-amplifier configuration. The input becomes a virtual ground, and so stray capacitance across the input connection does not degrade the rate of response of the circuit as seriously as in the simple connection. *See* TRANSISTOR. [R.B.D.K.]

Current sources and mirrors A current source is an electronic circuit that generates a constant direct current which flows into or out of a high-impedance output node. A current mirror is an electronic circuit that generates a current which flows into or out of a high-impedance output node, which is a scaled replica of an input current, flowing into or out of a different node.

Most specifications of analog integrated circuits depend almost uniquely on the technological parameters of the devices, and on the direct or alternating current that flows through them. The voltage drop over the devices has much less impact on performance, as long as it keeps the devices in the appropriate mode of operation (linear or saturation). High-performance analog integrated-circuit signal processing requires that currents be generated and replicated (mirrored) accurately, independent of supply voltage and of those device parameters that are least predictable (such as current gain ß in a bipolar transistor). Hence, current sources and mirrors occupy a large portion of the total die area of any analog integrated circuit. They are also used, but less often, in discrete analog circuits. *See* INTEGRATED CIRCUITS; TRANSISTOR. [P.M.VanP.]

Curve fitting A procedure in which the basic problem is to pass a curve through a set of points, representing experimental data, in such a way that the curve shows as well as possible the relationship between the two quantities plotted. It is always possible to pass some smooth curve through all the points plotted, but since there is assumed to be some experimental error present, such a procedure would ordinarily not be desirable. *See* INTERPOLATION.

The first task in curve fitting is to decide (1) how many degrees of freedom (number of unspecified parameters, or independent variables) should be allowed in fitting the points, and (2) what the general nature of the curve should be. Since there is no known way of answering these questions in a completely objective way, curve fitting remains something of an art. It is clear, however, that one must make good use of any background knowledge of the quantities plotted in order to answer the two questions. Thus, if one knew that a discontinuity might occur at some value of the abscissa, one would try to fit the points above and below that value by separate curves.

Against this background knowledge of what the curve should be expected to look like, one may observe the way the points fall on the paper. One may even find it advantageous to make a few rough attempts to draw a reasonable curve "through" the points.

A knowledge of the accuracy of the data is needed to help answer the question of the number of degrees of freedom to be permitted in fitting the data, If the data are very accurate, one may use as many degrees of freedom as there are points. The curve can then be made to pass through all the points, and it serves only the function of interpolation. At the opposite extreme when the data are very rough, one may attempt to fit the data by a straight line representing a linear relation, Eq. (1), between

$$y = ax + b \tag{1}$$

y and x. Using the above information and one's knowledge of the functions that have been found useful in fitting various types of experimental curves, one selects a suitable function and tries to determine the parameters left unspecified. At this point there are certain techniques that have been worked out to choose the optimum value of the parameters.

One of the most general methods used for this purpose is the method of least squares. In this method one chooses the parameters in such a way as to minimize the sum, Eq. (2), where

$$S = \sum_{i=1}^{n} [y_i - f(x_i)]^2 \tag{2}$$

y_i is the ordinate of ith point and $f(x_i)$ the ordinate of the point on the curve having the same abscissa x_i as this point. *See* LEAST-SQUARES METHOD. [K.S.K.]

Cutaneous sensation The sensory quality of skin. The skin consists of two main layers, the epidermis and the dermis. Sensory receptors in or beneath the skin are peripheral nerve-fiber endings that are differentially sensitive to one or more forms of energy. The sensory endings can be loosely categorized into three morphological groups: endings with expanded tips, such as Merkel's disks found at the base of the epidermis; encapsulated endings, such as Meissner's corpuscles (particularly plentiful in the dermal papillae), and other organs located in the dermis or subcutaneous tissue, such as Ruffini endings, Pacinian corpuscles, Golgi-Mazzoni corpuscles, and Krause's end bulb; and bare nerve endings that are found in all layers of the skin (some of these nerve endings are found near or around the base of hair follicles).

There is a remarkable relationship between the response specificities of cutaneous receptors and five primary qualities of cutaneous sensation, the latter commonly described as touch-pressure (mechanoreceptors), cold and warmth (thermoreceptors), pain, and itch. Each quality is served by a specific set of cutaneous peripheral nerve fibers. More complex sensations must result from an integration within the central nervous system of information from these sets of nerve fibers. Exploration of the skin surface with a rounded metal point reveals that there exist local sensory spots on the skin, stimulation of which evokes only one of the five qualities of sensation. Thus, there may be plotted maps of pressure, warm, cold, pain, or itch spots. *See* MECHANORECEPTORS; PAIN; SKIN; SOMESTHESIS. [R.LaM.]

Cyanamide A term used to refer to the free acid hydrogen cyanamide, H_2NCN, or commonly to the calcium salt of this acid, calcium cyanamide, $CaCN_2$. Calcium cyanamide is manufactured by the cyanamide process, in which nitrogen gas is passed through finely divided calcium carbide at a temperature of 1832°F (1000°C). Most calcium cyanamide is used in agriculture as a fertilizer; some is used as a weed killer, as a pesticide, and as a cotton defoliant.

Hydrogen cyanamide is prepared from calcium cyanamide by treating the salt with acid. It is used in the manufacture of dicyandiamide and thiourea. [E.E.W.]

Cyanate A compound containing the —OCN group, typically a salt or ester of cyanic acid (HOCN). The cyanate ion is ambidentate, that is, it has two reactive sites, because it can bind through the oxygen (O) or the nitrogen (N). Cyanate is commonly N-bonded with most nonmetallic elements, presumably because of the small charge density on the oxygen. Cyanic acid has the structure H—O═C≡N, but it may exist in an isomeric form known as isocyanic acid, H—N═C═O. The cyanates are isomeric with fulminates, where the carbon and the nitrogen are transposed (—ONC).

Cyanic acid is a volatile liquid, and it polymerizes upon standing to form cyamelide acid and cyanuric acid. In water cyanic acid undergoes hydrolysis to ammonia and carbon dioxide. However, dilute solutions in ice water may be kept for several hours. Both cyanic acid and isocyanic acid are prepared from cyanuric acid. The linear —OCN ion may be prepared by mild oxidation of aqueous cyanide ion (CN^-) using lead oxide (PbO) and potassium cyanide (KCN).

The primary use for cyanates is in the synthesis of a number of organic compounds such as unsubstituted carbamates (R—NH═C═OOR′). These compounds are used as derivatives of alcohols. Other important reactions include addition to amines to give substituted ureas. *See* CARBON; CYANIDE; NITROGEN; THIOCYANATE. [T.J.Me.]

Cyanide A compound containing the —CN group, for example, potassium cyanide, KCN; calcium cyanide, $Ca(CN)_2$; and hydrocyanic (or prussic) acid, HCN. Chemically, the simple inorganic cyanides resemble chlorides in many ways. Organic compounds containing this group are called nitriles, for example, acrylonitrile, CH_2CHCN. *See* ACRYLONITRILE.

HCN is a weak acid. In the pure state, it is a highly volatile liquid, boiling at 26°C (78.8°F). HCN and the cyanides are highly toxic to animals and humans.

The cyanide ion forms a variety of coordination complexes with transition-metal ions, a property responsible for several of the commercial uses of cyanides. The cyanide process T is the most widely used method for extracting gold and silver from the ores. In silver-plating, a smooth adherent deposit is obtained on a metal cathode when electrolysis is carried out in the presence of an excess of cyanide ion. *See* ELECTROPLATING OF METALS; GOLD METALLURGY; SILVER METALLURGY.

$Ca(CN)_2$ is extensively used in pest control and as a fumigant in the storage of grain. In finely divided form, it reacts slowly with the moisture in the air to liberate HCN.

In case hardening of metals, an iron or steel article is immersed in a bath of molten sodium or potassium cyanide containing sodium chloride or carbonate. The cyanide decomposes at the surface, forming a deposit of carbon which combines with and penetrates the metal. *See* COORDINATION CHEMISTRY. [F.J.J.]

Cyanobacteria A large and heterogeneous group of photosynthetic microorganisms, formerly referred to as blue-green algae. They had been classified with the algae because their mechanism of photosynthesis is similar to that of algal and plant chloroplasts; however, the cells are prokaryotic, whereas the cells of algae and plants are eukaryotic. The name cyanobacteria is now used to emphasize the similarity in cell structure to other prokaryotic organisms. *See* ALGAE; CELL PLASTIDS.

All cyanobacteria can grow with light as an energy source through oxygen-evolving photosynthesis; carbon dioxide (CO_2) is fixed into organic compounds via the Calvin cycle, the same mechanism used in green plants. Thus, all species will grow in the absence of organic nutrients. However, some species will assimilate organic compounds into cell material if light is available, and a few isolates are capable of growth in the dark by using organic compounds as carbon and energy sources. Some cyanobacteria can shift to a different mode of photosynthesis, in which hydrogen sulfide rather than water serves as the electron donor. Molecular oxygen is not evolved during this process, which is similar to that in purple and green photosynthetic sulfur bacteria. The photosynthetic pigments of cyanobacteria include chlorophyll *a* (also found in algae and plants) and phycobiliproteins. *See* Chlorophyll; Photosynthesis.

Cyanobacteria are extremely diverse morphologically. Species may be unicellular or filamentous. Both types may aggregate to form macroscopically visible colonies. The cells range in size from those typical of bacteria (0.5–1 micrometer in diameter) to 60 μm.

When examined by electron microscopy, the cells of cyanobacteria appear similar to those of gram-negative bacteria. Many species produce extracellular mucilage or sheaths that promote the aggregation of cells or filaments into colonies.

The photosynthetic machinery is located on internal membrane foldings called thylakoids. Chlorophyll *a* and the electron transport proteins necessary for photosynthesis are located in these lipid membranes, whereas the water-soluble phycobiliprotein pigments are arranged in particles called phycobilisomes which are attached to the lipid membrane.

Several other types of intracellular structures are found in some cyanobacteria. Gas vesicles, which may confer buoyancy on the organisms, are often found in cyanobacteria that grow in the open waters of lakes. Polyhedral bodies, also known as carboxysomes, contain large amounts of ribulose bisphosphate carboxylase, the key enzyme of CO_2 fixation via the Calvin cycle. Several types of storage granules may be found.

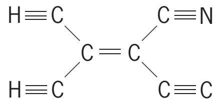
Cyanobacteria can be found in a wide variety of fresh-water, marine, and soil environments. They are more tolerant of environmental extremes than are eukaryotic algae. For example, they are the dominant oxygenic phototrophs in hot springs (at temperatures up to 72°C or 176°F) and in hypersaline habitats such as may occur in marine intertidal zones.

Cyanobacteria are often the dominant members of the phytoplankton in fresh-water lakes that have been enriched with inorganic nutrients such as phosphate. It is now known that high population densities of small, single-celled cyanobacteria occur in the oceans, and that these are responsible for 30–50% of the CO_2 fixed into organic matter in these environments. About 8% of the lichens involve a cyanobacterium, which can provide both fixed nitrogen and fixed carbon to the fungal partner. *See* Lichens; Phytoplankton.

Cyanobacteria are thought to be the first oxygen-evolving photosynthetic organisms to develop on the Earth, and hence responsible for the conversion of the Earth's atmosphere from anaerobic to aerobic about 2 billion years ago. This development permitted the evolution of aerobic bacteria, plants, and animals. *See* Bacteria; Cyanophyceae; Prebiotic organic synthesis. [A.Ko.]

Cyanocarbon A derivative of hydrocarbon in which all of the hydrogen atoms are replaced by the —C≡N group. However, the term cyanocarbon has been applied to compounds which do not strictly follow the above definition: tetracyanoethylene oxide, tetracyanothiophene, tetracyanofuran, tetracynopyrrole, tetracyanobenzoquinone, tetracyanoquinodimethane, tetrayanodithiin, pentacyanopyridine, diazomalononitrile, and diazotetracyanocyclopentadiene.

Tetracyanoethylene (with the formula below), the simplest



olefinic cyanocarbon, is a colorless, thermally stable solid, having a melting range of 198–200°C (388–392°F), and readily forming stable complexes with most aromatic systems. Cyanocarbon acids are among the strongest protonic organic acids known and are usually isolated only as the cyanocarbon anion salt. [O.W.W.]

Cyanogen A colorless, highly toxic gas having the molecular formula C_2N_2. Structurally, cyanogen is written N≡C—C≡N. Cyanogen belongs to a class of compounds known as pseudohalogens, because of the similarity of their chemical behavior to that of the halogens. Liquid cyanogen boils at −21.17°C (−6.11°F) and freezes at −27.9°C (−18.2°F) at 1 atm (101.325 kilopascals).

Cyanogen reacts with hydrogen at elevated temperatures in a manner analogous to the halogens, forming hydrogen cyanide, HCN. With hydrogen sulfide, H_2S, cyanogen forms thiocyanoformamide or dithiooxamide. Cyanogen burns in oxygen, producing one of the hottest flames known from a chemical reaction. It is considered to be a promising component of high-energy fuels. *See* Cyanide. [F.J.J.]

Cyanophyceae A class of prokaryotic organisms coextensive with the division Cyanophycota of the kingdom Monera. Because these organisms have chlorophyll *a* and carry out oxygen-evolving photosynthesis, they have traditionally been aligned with algae and, with regard for their characteristic color, called blue-green algae. Microbiologists have emphasized the prokaryotic structure of these organisms and aligned them with bacteria, as the Cyanobacteria. Other names applied to these organisms include Cyanophyta at the level of division and Myxophyceae or Schizophyceae at the level of class. Blue-greens range in form from unicells 1–2 micrometers in diameter to filaments 10 cm (4 in.) long. *See* Cyanobacteria.

Unicellular forms, which may aggregate in colonies or loosely constructed filaments and which reproduce by binary fission or spores, constitute the order Chroococcales, from which two additional orders, Chamaesiphonales and Pleurocapsales, are sometimes segregated. Filamentous forms, which reproduce by hormogonia, constitute the order Nostocales (= Hormogonales or Oscillatoriales). The Nostocales may be restricted to unbranched or falsely branched forms (in which the ends of a trichome adjacent to a rupture grow out as a pair of branches), while those forms in which cells divide in more than one plane (true branching) constitute the order Stigonematales.

Geographically and ecologically, blue-green algae are nearly as ubiquitous as bacteria. They are especially abundant in the plankton of neutral or alkaline eutrophic fresh waters and tropical seas, often forming blooms. Habitats for benthic forms include hot springs, snow and ice, soil, rocks, tree trunks, and buildings. Cyanophyceae live symbiotically with a large variety of animals and plants. They constitute the phycobiont of many lichens.

In addition to contributing to food chains, blue-green algae play specific beneficial roles. Nitrogen-fixing forms greatly enrich rice paddies. On the other hand, blue-green algae are often a nuisance. They clog filters, impart undesirable tastes and odors to domestic water supplies, and make unusable or at least unattractive many swimming pools, aquariums, and fountains. Cyanophycean blooms are often toxic to fish, birds, and livestock.

Blue-green algae were pioneers on Earth and are known from rocks at least as old as 2.3 billion years. They are believed to have been responsible for the accumulation of oxygen in the primeval atmosphere and to have been involved in the formation of laminated reeflike structures called stromatolites. *See* Algae; Stromatolite. [P.C.Si.; R.L.Moe.]

Cybernetics The study of communication and control within and between humans, machines, organizations, and society. This is a modern definition of the term cybernetics, which was first utilized by N. Wiener in 1948 to designate a broad subject area he defined as "control and communication in the animal and the machine." A distinguishing feature of this broad field is the use of feedback information to adapt or steer the entity toward a goal. When this feedback signal is such as to cause changes in the structure or parameters of the system itself, it appears to be self-organizing. *See* Adaptive control.

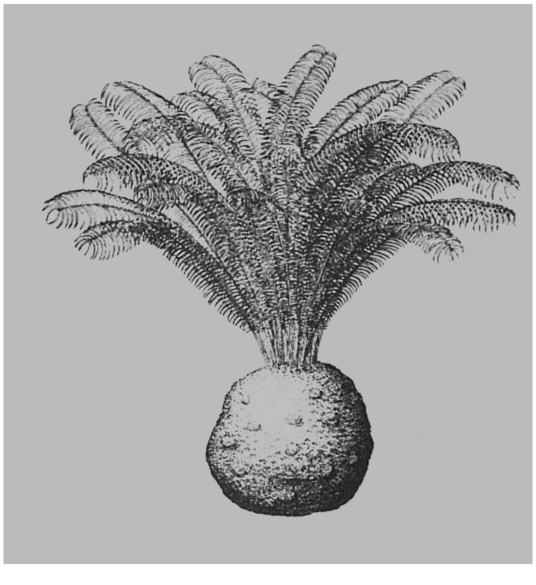
Wiener developed the statistical methods of autocorrelation, prediction, and filtering of time-series data to provide a mathematical description of both biological and physical phenomena.

The use of filtering to remove unwanted information or noise from the feedback signal mimics the selectivity shown in biological systems in which imprecise information from a diversity of sensors can be accommodated so that the goal can still be reached. *See* ESTIMATION THEORY; HOMEOSTASIS; STOCHASTIC CONTROL THEORY. [D.W.Bo.]

Cycadales An order of the class Cycadopsida of the division Pinophyta (gymnosperms) consisting of four families, Cycadaceae, Stangeriaceae, Zamiaceae, and Boweniaceae, with perhaps 100 species. The order dates from the upper Carboniferous and has few living representatives. The cycads were distributed worldwide in the Mesozoic, but today are restricted to subtropical and tropical regions, with the plants occurring in small colonies; few have broad distributions.

The cycads, often incorrectly referred to as palms, range from a few inches (*Zamia*) to 65 ft (20 m; *Macrozamia*) tall. The stems are cylindrical and often branched; in some the stem is subterranean, in others it is mainly above the ground. The pinnate (or bipinnate in *Bowenia*) leaves are borne at the apex of the stems. Microsporophylls and megasporophylls are borne in cones of highly varied appearance. Male and female cones appear on separate plants (dioecious). *See* CYCADOPSIDA; PINOPHYTA; PLANT KINGDOM. [T.A.Z.]

Cycadeoidales An order of extinct plants that formed a conspicuous part of the landscape during the Triassic, Jurassic, and Cretaceous periods. The Cycadeoidales (or Bennettitales) had unbranched or sparsely branched trunks with a terminal crown of leaves (family Cycadeoidaceae; see illustration), or they were branched, at times profusely (family Williamsoniaceae).



Reconstruction of a plant of the genus *Cycadeoidea*, showing terminal crown of leaves, persistent leaf bases, and positions of the fruiting structures. (*Courtesy of T. Delevoryas*)

No known relatives of the Cycadeoidales exist at the present time, although members of the order Cycadales show some resemblances to the extinct group. *See* CYCADALES; EMBRYOBIONTA. [T.D.]

Cycadopsida A class of the division Cycadophyta consisting of a single order, Cycadales, dating back to the Triassic and most abundant in the Jurassic. There are 100–150 living species of cycads in two families, Cycadaceae with one genus and Zamiaceae with ten genera. Most cycads are tropical, but some extend into warm temperate regions. Wild cycads are threatened by collection for horticulture so they are protected by international treaties. They were used as traditional foods in some places but contain potent carcinogens and neurotoxins. *See* CYCADALES; GNETALES; WELWITSCHIALES.

Pinnately compound leaves on massive, usually unbranched trunks emerge in flushes, sometimes with the rachis or leaflets coiled like fiddleheads. Large pollen and seed cones crown different individuals. Pollen cones have numerous wedge-shaped scales, each covered below with clustered microsporangia. Seed cones of Zamiaceae are similar, with two seeds on each scale, but megasporophylls of Cycadaceae are leaflike, with two to eight seeds. As in *Ginkgo*, fertilization is by swimming sperm. *See* PINOPHYTA; PLANT KINGDOM. [J.E.E.]

Cyclanthales An order of flowering plants, division Magnoliophyta (Angiospermae), sometimes called Synanthae or Synanthales, in the subclass Arecidae of the class Liliopsida (monocotyledons). The order consists of the single tropical American family Cyclanthaceae, with about 180 species. They are herbs or, seldom, more or less woody plants, with characteristic leaves that have a basal sheath, a petiole, and an expanded, usually bifid (cleft into two equal parts) blade which is often folded lengthwise (plicate) like that of a palm leaf. One of the species, *Carludovicia palmata*, is a principal source of fiber for panama hats. *See* ARECIDAE. [A.Cr.]

Cyclic nucleotides Derivatives of nucleic acids that control the activity of several proteins within cells to regulate and coordinate metabolism. They are members of a group of molecules known as intracellular second messengers; their levels are regulated by hormones and neurotransmitters, which are the extracellular first messengers in a regulatory pathway. Cyclic nucleotides are found naturally in all living cells.

Two major forms of cyclic nucleotides are characterized: 3′,5′-cyclic adenosine monophosphate (cyclic AMP or cAMP) and 3′,5′-cyclic guanosine monophosphate (cyclic GMP or cGMP). Like all nucleotides, cAMP and cGMP contain three functional groups: a nitrogenous aromatic base (adenine or guanine), a sugar (ribose), and a phosphate. Cyclic nucleotides differ from other nucleotides in that the phosphate group is linked to two different hydroxyl (3′ and 5′) groups of the ribose sugar and hence forms a cyclic ring. This cyclic conformation allows cAMP and cGMP to bind to proteins to which other nucleotides cannot.

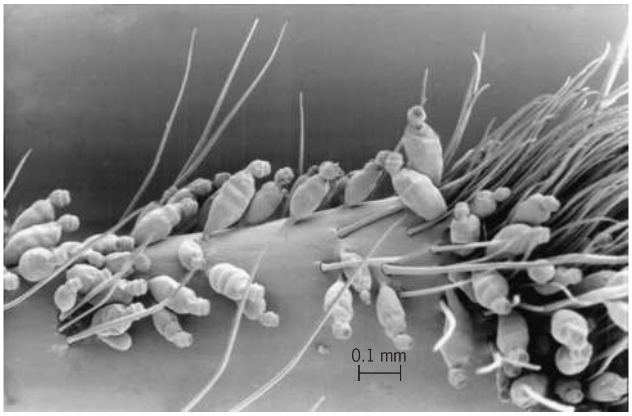
An increase in cAMP or cGMP triggered by hormones and neurotransmitters can have many different effects on any individual cell. The type of effect is dependent to some extent on the cellular proteins to which the cyclic nucleotides may bind. Three types of effector proteins are able to bind cyclic nucleotides: protein kinases, ion channels, and cyclic nucleotide phosphodiesterases.

Protein kinases are enzymes which are able to transfer a phosphate group to (phosphorylate) individual amino acids of other proteins. This action often changes the function of the phosphorylated protein. Ion channels are proteins found in the outer plasma membrane of some cells; binding of cyclic nucleotides to them can alter the flow of sodium ions across the cell membranes. Cyclic nucleotide phosphodiesterases are enzymes responsible for the degradation of cyclic nucleotides.

In bacteria, cAMP can bind to a fourth type of protein, which can also bind to deoxyribonucleic acid (DNA). This catabolite gene activator protein (CAP) binds to specific bacterial DNA sequences, stimulating the rate at which DNA is copied into ribonucleic acid (RNA) and increasing the amount of key metabolic enzymes in the bacteria.

In humans, cyclic nucleotides acting as second messengers play a key role in many vital processes and some diseases. For example, in the brain, cAMP and possibly cGMP are critical in the formation of both long-term and short-term memory. In the liver, cAMP coordinates the function of many metabolic enzymes to control the level of glucose and other nutrients in the bloodstream. *See* Adenosine triphosphate (ATP); Enzyme; Nucleic acid; Nucleoprotein; Nucleotide; Protein. [M.D.U.]

Cycliophora A recently described phylum in the animal kingdom. Only one microscopic species, *Symbion pandora*, has been described. Its sessile stage is approximately 0.3 mm in length and 0.1 mm wide. All known occurrences are from the mouth limbs of the Norwegian lobster, which can be totally encrusted with thousands of the sessile stage of the animal (see illustration).

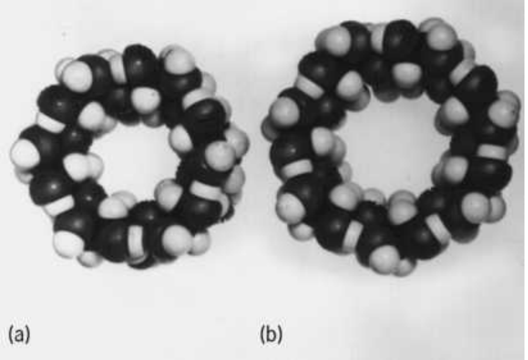


Scanning electron micrograph of the Norwegian lobster's mouthpart with numerous feeding stages of *Symbion pandora*. (*Courtesy of P. Funch and R. M. Kristensen*)

The sessile animal has a circular mouth surrounded by a ring of cilia, which is used for filtering small food particles, such as bacteria or algae. The anatomy is relatively simple, with a U-shaped gut, similar to what is found in bryozoans or some sessile rotiferans. It is the extremely complex life cycle of *S. pandora* that makes the phylum unique. The life cycle consists of an asexual and a sexual generation with no less than two types of free-swimming larva, dwarf male and female; two stages of sessile feeding animals, which brood the male and female; and one type of larva (Pandora larva) inside a brooding chamber (called a marsupium). Furthermore, the sessile animal has internal budding, whereby it grows by loss of the head itself and replacement of the old gut and feeding system with a new bud coming from embryonic cells in the basal part of the body. [R.M.Kr.]

Cycloamylose Any of a group of cyclic oligomers of glucose in the normal C-1 conformation in which the individual glucose units are connected by 1,4 bonds. They are called Schardinger dextrins (after the discoverer), cyclodextrins (to emphasize their cyclic character), or cycloamyloses (to emphasize both their cyclic character and their amylose origin). The most common ones are cyclohexaamylose (which has six glucose units in a cyclic array) and cycloheptaamylose (which has seven glucose units in a cyclic array). The toroidal shape of these molecules has been determined by x-ray analysis (see illustration). The molecular weights are around 1000.

In water or in a mixture of water and dimethyl sulfoxide, cycloamyloses form 1:1 complexes with many organic molecules and most benzenoid derivatives. X-ray and spectroscopic evidence indicates that the guest molecule (usually a small organic molecule) is bound tightly in the cavity of the host molecule (the cycloamylose) just like a key fitting into a lock. The result is an inclusion complex, which is what is formed by enzymes when they first bind the molecules whose reactions they subsequently catalyze. Inclusion complex formation is probably the most important similarity between cycloamyloses and enzymes.



Molecular models of cycloamyloses viewed from the secondary hydroxyl side of the torus. (*a*) Cyclohexaamylose. (*b*) Cycloheptaamylose. (*From M. L. Bender and M. Komiyama, Cyclodextrin Chemistry, Springer, 1978*)

Cycloamyloses have been used to mimic many enzymes, such as ribonuclease, transaminase, and carbonic anhydrase. They have also been used to effect selectivity in several chemical reactions. Cycloamyloses are the premier example of chemical compounds that act like enzymes in inclusion complex formation followed by reaction. *See* Catalysis; Clathrate compounds; Enzyme; Stereospecific catalyst. [M.L.Be.]

Cyclocystoidea A class of small, disk-shaped echinozoans in which the lower surface of the body probably consisted of a suction cap for adhering to substrate, and the upper surface was covered by separate plates arranged in concentric rings. The mouth lay at the center of the upper surface, and the anus, also on the upper surface, lay some distance between the margin and the mouth. Little is known of the habits of cyclocystoids. They occur in rocks of middle Ordovician to middle Devonian age in Europe and North America. *See* Echinodermata; Echinozoa. [H.B.F.]

Cycloid A curve traced in the plane by a point on a circle that rolls, without slipping, on a line. If the line is the x axis of a rectangular coordinate system, at whose origin O the moving point P touches the axis, parametric equations of the cycloid are $x = a(\theta - \sin\theta)$, $y = a(1 - \cos\theta)$, when a is the radius of the rolling circle, and the parameter θ is the variable angle through which the circle rolls (see illustration). *See* Analytic geometry. [L.M.Bl.]

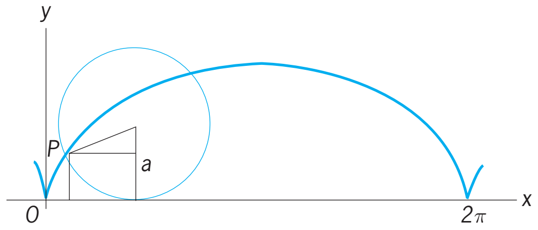


Diagram of a cycloid.

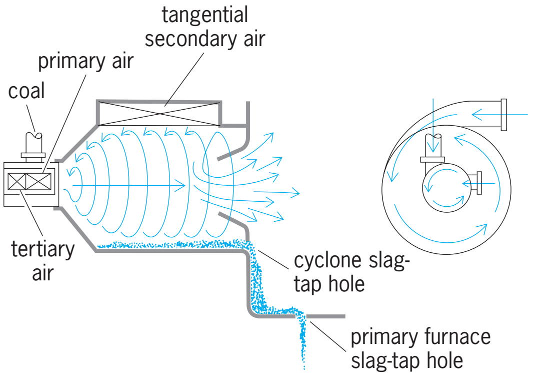
Cyclone An atmospheric circulation system in which the sense of rotation of the wind about the local vertical is the same as that of the Earth's rotation. Thus, a cyclone rotates clockwise in the Southern Hemisphere and counterclockwise in the Northern Hemisphere. In meteorology the term cyclone is reserved for circulation systems with horizontal dimensions of hundreds (tropical cyclones) or thousands (extratropical cyclones) of kilometers. For such systems the Coriolis force due to the Earth's rotation, which is directed to the right of the flow in the Northern Hemisphere, and the pressure gradient force, which is directed toward low pressure, are in opposite directions. Thus, there must be a pressure minimum at the center of the cyclone, and cyclones are sometimes simply called lows. *See* Air pressure.

Extratropical cyclones are the common weather disturbances which travel around the world from west to east in mid-latitudes. They are generally associated with fronts, which are zones of rapid transition in temperature. Extratropical cyclones arise due to the hydrodynamic instability of the upper-level jet stream flow. *See* Front; Jet stream.

Tropical cyclones, by contrast, derive their energy from the release of latent heat of condensation in precipitating cumulus clouds. Over the tropical oceans, where moisture is plentiful, tropical cyclones can develop into intense vortical storms (hurricanes and typhoons), which can have wind speeds in excess of 200 mi/h ($100\ \mathrm{m \cdot s^{-1}}$). *See* Hurricane; Storm; Wind. [J.R.H.]

Cyclone furnace A water-cooled horizontal cylinder in which fuel (coal, gas, or oil) is fired and heat is released at extremely high rates. When firing coal, the crushed coal is introduced tangentially into the burner at the front end of the cyclone (see illustration). About 15% of the combustion air is used as primary and tertiary air to impart a whirling motion to the particles of coal. The whirling, or centrifugal, action on the fuel is further increased by the tangential admission of high-velocity secondary air into the cyclone.



Schematic diagram of cyclone furnace. (*From T. Baumeister, ed., Standard Handbook for Mechanical Engineers, 8th ed., McGraw-Hill, 1978*)

The products of combustion are discharged through a water-cooled reentrant throat at the rear of the cyclone into the boiler furnace. Essentially, the fundamental difference between cyclone furnaces and pulverized coal–fired furnaces is the manner in which combustion takes place. In pulverized coal–fired furnaces, particles of coal move along with the gas stream; consequently, relatively large furnaces are required to complete the combustion of the suspended fuel. With cyclonic firing, the coal is held in the cyclone and the air is passed over the fuel. Thus, large quantities of fuel can be fired and combustion completed in a relatively small volume, and the boiler furnace is used to cool the products of combustion. *See* Boiler; Steam-generating furnace; Steam-generating unit. [G.W.K.]

Cyclophane A molecule composed of two building blocks: an aromatic ring (most frequently a benzene ring) and an aliphatic unit forming a bridge between two (or more) positions of the aromatic ring. Those cyclophanes that contain heteroatoms in the aromatic part are generally called phanes, as "cyclo" in cyclophanes more strictly means that only benzene rings are present in addition to aliphatic bridges. Phane molecules containing hetero atoms in the aromatic ring (for example, nitrogen or sulfur) are called heterophanes, while in heteraphanes they are part of the aliphatic bridge.

Cyclophanes usually are not at all planar molecules; they exhibit an interesting stereochemistry (arrangement of atoms in three-dimensional space); molecular parts are placed and sometimes fixed in unusual orientations toward each other, and often the molecules are not rigid but (conformationally) flexible. Ring strain and, as a consequence, deformation of the benzene rings out of planarity are often encountered. Electronic interactions between aromatic rings fixed face to face can take place. In addition, influence on substitution reactions in the aromatic rings results; that is, substitutents in one ring induce transannular electronic effects in the other ring, often leading to unexpected products. *See* Chemical bonding; Conformational analysis; Stereochemistry.

Cyclophanes have become important in host-guest chemistry and supramolecular chemistry as they constitute host compounds for guest particles because of their cavities. Recognition processes at the molecular level are understood to mean the ability to design host molecules to encompass or attach selectively to smaller, sterically complementary guests in solution—by analogy to biological receptors and enzymes. For this reason, water-soluble cyclophanes were synthesized; they have the ability to include nonpolar guest molecules in aqueous solution. *See* Cage hydrocarbon; Molecular recognition; Polar molecule.

Cyclophanes also exist in nature as alkaloids, cytotoxic agents, antibiotics, and many cyclopeptides. With the possibility of locating groups precisely in space, cyclophane chemistry has provided building units for molecular niches, nests, hollow cavities, multifloor structures, helices, macropolycycles, macro-hollow tubes, novel ligand systems, and so on. Cyclophane chemistry has become a major component of supramolecular chemistry, molecular recognition, models for intercalation, building blocks for organic catalysts, receptor models, and variation of crown ethers and cryptands. *See* Macrocyclic compound; Supramolecular chemistry. [F.Vo.; M.Boh.]

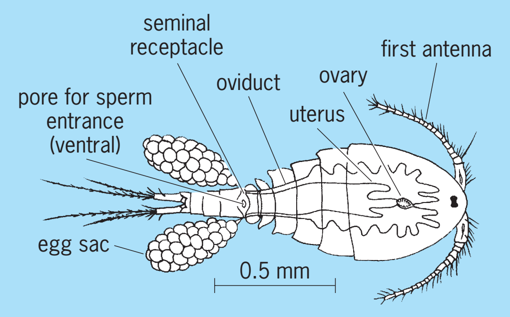
Cyclophyllidea The order which includes most tapeworms that inhabit the gut of warm-blooded vertebrates. They are frequently referred to as the Taenioidea. Each worm has a head, or scolex, and a segmented body, called the strobila. The scolex typically has an apical rostellum, or muscular pad and hooks, and two pairs of lateral suckers. New segments are produced immediately posterior to the scolex, so that the oldest segment is at the hind end. As a segment is pushed further from the scolex, the male and female reproductive organs mature and open on the lateral margin. Ova, fertilized by sperm from the same or another segment, gather in a uterus. The ripe terminal segments containing infectious eggs are shed into gut contents of the host.

A number of tapeworms occur in humans and domestic animals, either as adults or immature stages, the metacestodes, but rarely in both stages. *See* Coenurosis; Platyhelminthes. [R.S.F.]

Cyclopoida An order of small copepod Crustacea. The abundant fresh-water and salt-water species form an important link in the food chains of aquatic life, consuming tiny plants, animals, and detritus and, in turn, furnishing food for small fish, some large fish, and other organisms. Some species are important intermediate hosts for human parasites.

The front part of the body is oval and sharply separated from the tubular hind end, which bears two caudal rami with distinctly unequal setae (see illustration). Usually 10 body segments are present in the male, and 9 in the female because of fusion of two to form a genital segment.

Cyclopoids are intermediate hosts of the parasitic guinea worm (*Drucunculus medinensis*), and sometimes the fish tapeworm (*Dibothriocephalus latus*). Most fresh-water species live



***Cyclops vernalis*, female, dorsal view.**

in shallow water, swimming from plant to plant, but salt-water species are generally water-treaders. Food is not secured by filtration, but is seized and eaten with the biting mouthparts. Many species have a world wide distribution. *See* COPEPODA. [H.C.Y.]

Cyclostomata (Bryozoa) An order of bryozoans in the class Stenolaemata. Cyclostomes tend to have delicate colonies composed of relatively isolated, loosely bundled, or tightly packed, comparatively simple, long, slender, and tubular zooecia, with thin, highly porous, calcareous walls. Cyclostome colonies most commonly are small and delicate, but some are moderately large and massive. They may be inconspicuous encrusting threadlike networks, thin encrusting sheets, nodular masses, or erect tufflike, twiglike, or frondlike growths. Individual cyclostome zooecia are straight to slightly curved long tubes. The walls of adjacent zooecia may be either distinctly separate or fused together.

Exclusively marine, cyclostomes (occasionally termed Stenostomata) are known first from the Late Ordovician, when they may possibly have evolved from cystoporates (which were formerly included in the Cyclostomta). Rare and inconspicuous throughout the rest of the Paleozoic and Triassic, cyclostomes became moderately common in Jurassic and Cretaceous seas, but have since (including today) been less numerous. *See* BRYOZOA; CYSTOPORATA; STENOLAEMATA. [R.J.Cu.]

Cyclothem A vertical sequence of several different kinds of distinctive sedimentary rock units that is repeated upward through the stratigraphic succession. Originally defined in the rock succession of Pennsylvanian age in the Illinois Basin in the 1930s, the rock types include coal, limestone, sandstone, and several types of shale and mudstone. Cyclothems were soon recognized elsewhere in rocks of this age in the central and eastern United States. Those in the Midcontinent (Kansas and states to the northeast) are dominated by several types of limestone and shale, with less coal and sandstone. Those in the Appalachian region are dominated by coal, mudstone, shale, and sandstone, with less limestone. One proposed reason for the Pennsylvanian cyclothems is the periodic rise and fall of sea level (eustacy) that was driven by repeated episodes of continental glaciation in the southern continents of that time. *See* PENNSYLVANIAN; SEDIMENTARY ROCKS; STRATIGRAPHY.

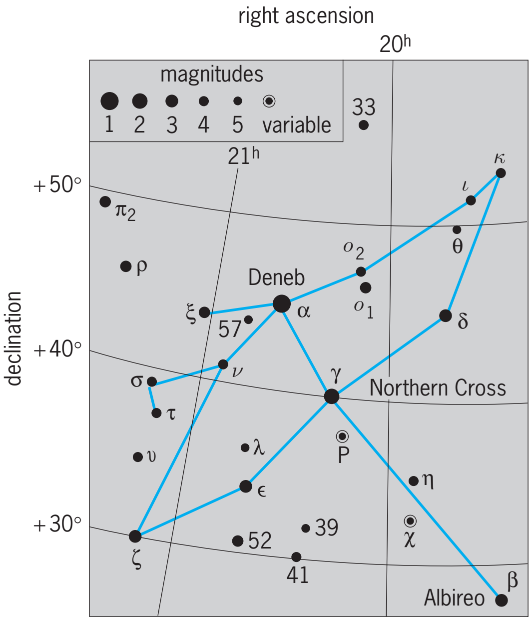
Cyclothems were first noticed in the United States because of the many distinctive rock types involved. These resulted from the interplay between the then tropical to equatorial humid climate with ready access to detrital sand and mud and the marine circulation changes caused by the changing water depth of the sea. Coal-rich cyclothems were soon recognized in strata of the same age in western Europe. Currently, cyclothems without coal are being identified in late Paleozoic strata elsewhere in the world. *See* PALEOZOIC. [P.H.H.]

Cyclotron resonance experiments The measurement of charge-to-mass ratios of electrically charged particles from the frequency of their helical motion in a magnetic field. Such experiments are particularly useful in the case of conducting crystals, such as semiconductors and metals, in which the motions of electrons and holes are strongly influenced by the periodic potential of the lattice through which they move. Under such circumstances the electrical carriers often have "effective masses" which differ greatly from the mass in free space; the effective mass is often different for motion in different directions in the crystal. Cyclotron resonance is also observed in gaseous plasma discharges and is the basis for a class of particle accelerators. *See* BAND THEORY OF SOLIDS; PARTICLE ACCELERATOR.

Cyclotron resonance is most easily understood as the response of an individual charged particle; but, in practice, the phenomenon involves excitation of large numbers of such particles. Their net response to the electromagnetic radiation may significantly affect the overall dielectric behavior of the material in which they move. Thus, a variety of new wave propagation mechanisms may be observed which are associated with the cyclotron motion, in which electromagnetic energy is carried through the solid by the spiraling carriers. These collective excitations are generally referred to as plasma waves. In general, for a fixed input frequency, the plasma waves are observed to travel through the conducting solid at magnetic fields higher than those required for cyclotron resonance. The most easily observed of these excitations is a circularly polarized wave, known as a helicon, which travels along the magnetic field lines. It has an analog in the ionospheric plasma, known as the whistler mode and frequently detected as radio interference. There is, in fact, a fairly complete correspondence between the resonances and waves observed in conducting solids and in gaseous plasmas. Cyclotron resonance is more easily observed in such low-density systems since collisions are much less frequent there than in solids. In such systems the resonance process offers a means of transferring large amounts of energy to the mobile ions, a necessary condition if nuclear fusion reactions are to occur. *See* NUCLEAR FUSION; PLASMA (PHYSICS). [W.M.W.]

Cydippida The largest order of the phylum Ctenophora, comprising 5 families (Bathyctenidae, Haeckelidae, Lampeidae, Mertensidae, and Pleurobrachiidae) and 11 genera. The body of cydippids is usually globular or cylindrical in shape; sizes range from a few millimeters to about 15 cm (6 in.). Most cydippids are colorless and transparent, but some deep-sea species are pigmented dark red. Adult cydippids retain the larval morphology common to all ctenophores (except Beroida) and are usually thought to be the most primitive order. All forms have two main tentacles. Cydippids catch prey on the outstretched tentacles, contracting them to bring it to the mouth. The well-known genus *Pleurobrachia* is widely distributed in temperate coastal waters and estuaries, where it can be a major predator of copepods and larval fish. Many other species of cydippids occur in oceanic waters, from the surface to mesopelagic depths. *See* BEROIDA; CTENOPHORA. [L.P.M.]

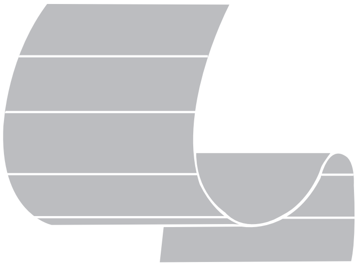
Cygnus The Swan, in astronomy, is a conspicuous northern summer constellation. The five major stars of the group, α, γ, β, ϵ, and δ, are arranged in the form of a cross (see illustration). Hence Cygnus is often called the Northern Cross, to distinguish it from the Southern Cross of the constellation Crux. The constellation is represented by a swan with widespread wings flying southward. The bright star Deneb is the tail of the swan: it lies at the head of the cross. Albireo, a beautiful double star of contrasting orange and blue colors, is the head of the swan. The



Line pattern of constellation Cygnus. Grid lines represent coordinates of sky. Apparent brightness, or magnitudes, of stars is shown by sizes of "dots," which are graded by appropriate numbers as indicated.

whole constellation lies in, and parallel to, the path of the Milky Way. *See* CONSTELLATION; CRUX. [C.-S.Y.]

Cylinder The solid of revolution obtained by revolving a rectangle about a side is called a cylinder, or more precisely a right circular cylinder. More generally the word cylinder is used in solid geometry to describe any solid bounded by two parallel planes and a portion of a closed cylindrical surface. In analytic geometry, however, the word cylinder refers not to a solid but to a cylindrical surface (see illustration). This is a surface generated by a straight line which moves so that it always intersects a given plane curve called the directrix, and remains parallel to a fixed line that intersects the plane of the directrix. Cylinders whose right sections are circles, ellipses, parabolas, or hyperbolas are called circular cylinders, elliptic cylinders, parabolic cylinders, or hyperbolic cylinders, respectively. All these are quadric cylinders. *See* EUCLIDEAN GEOMETRY. [J.S.F.]



Cylindrical surface.

Cyperales An order of flowering plants, division Magnoliophyta (Angiospermae), in the subclass Commelinidae of the class Liliopsida (monocotyledons). The names Glumiflorae, Graminales, and Poales have also been used for this order. There are only two families, the Poaceae (Gramineae), with about 8000 species, and the Cyperaceae, with nearly 4000. The Cyperales are Commelinidae with reduced, mostly wind-pollinated or self-pollinated flowers that have a unilocular, two-or three-carpellate ovary bearing a single ovule. The flowers are arranged in characteristic spikes or spikelets representing reduced inflorescences. The perianth is represented only by a set of bristles or tiny scales, or is completely missing. The leaves generally have a well-defined sheath and a narrow blade, often with a small adaxial appendage (the ligule) at the junction of the two.

The Cyperaceae, or sedge family, includes the bulrushes (*Scirpus*) and the papyrus (*Cyperus papyrus*) of Egypt, as well as the sedges (*Carex*). The Poaceae, or grass family, embraces all true grasses, including bamboos and the cereal grains such as wheat, maize, oats, and rye. The two families differ in a number of more or less consistent technical characters of the inflorescence, fruits, stems, and leaves. *See* COMMELINIDAE; FLOWER; GRASS CROPS; LILIOPSIDA; MAGNOLIOPHYTA. [A.Cr.; T.M.Ba.]

Cypress The true cypress (*Cupressus*), which is very close botanically to the cedars (*Chamaecyparis*). All of the species of *Cupressus* in the United States are western and are found from Oregon to Mexico. The Arizona cypress (*Cupressus arizonica*) of the southwestern United States and the Monterey cypress (*Cupressus macrocarpa*) of California are medium-sized trees and are chiefly of ornamental value. The Italian cypress (*Cupressus sempervirens*) and its varieties are handsome ornamentals, but usually do well only in the southern parts of the United States. Other trees are also called cypress, such as the Port Orford cedar (*Chamaecyparis lawsoniana*) known also as the Lawson cypress, and the Alaska cedar (*Chamaecyparis nootkatensis*), known also as the Nootka cypress or cedar.

The bald cypress (*Taxodium distichum*) is an entirely different tree that is found in the swamps of the South Atlantic and Gulf coastal plains and in the lower Mississippi Valley. The soft needlelike leaves and short branches are deciduous; hence, they drop off in winter and give the tree its common name. Also known as the southern or red cypress, this tree yields a valuable decay-resistant wood used principally for building construction, especially for exposed parts or where a high degree of resistance to decay is required as in ships, boats, greenhouses, railway cars, and railroad ties. *See* CEDAR; PINALES. [A.H.G./K.P.D.]

Cypriniformes An order of actinopterygian fishes which ranks second in size only to the Perciformes. The order Cypriniformes (or Eventognathi) includes the characins, minnows, and their allies. The Weberian apparatus of the Cypriniformes involves only the first four vertebrae. The body is typically invested in cycloid scales, although these are sometimes lost. In further contrast to catfishes, the Cypriniformes have parietal, suboperculum, symplectic, and intercalar bones; they lack a pectoral spine (present in most catfishes); and they have intermuscular bones.

The 8 families of the Cypriniformes, numbering about 3000 species, may be arranged in 3 suborders: Characoidei, Gymnotoidei, and Cyprinoidei. The suborder Characoidei includes the single family Characidae (split by some authors into several smaller families) or characins. They are primarily fresh-water fishes that abound in South America, where they have undergone an extensive adaptive radiation resulting in perhaps 850 species. The Gymnotoidei includes a single family, Gymnotidae, consisting of about 16 genera and perhaps 40 or 45 species that inhabit fresh waters of South and Central America. They are eel-shaped fishes that seem to be capable of producing an electric shock. The electric eel is the largest species. Cyprinoidei includes about 6 families of primarily fresh-water fishes. The Cyprinidae, including minnows and carps, are the largest family of fishes, with about 275 genera and more than 1500 species. The center of abundance and diversity of form of this group is in southeastern Asia. The family is well represented in Africa, Europe, Asia, and North America (about 230 species), but there are none in Central or South America, Madagascar, Australia, or in that part of the East Indies lying east of Lombok.

In the mountainous regions of southeastern Asia are found 3 other small families of the Cyprinoidei: the Homalopteridae, the Gastromyzontidae with 16 genera, and the Gyrinocheilidae. All are adapted to life in torrential streams. *See* ACTINOPTERYGII; CARP; EEL; SILURIFORMES. [R.M.B.]

Cyrtosoma A subphylum of the Mollusca comprising members of the classes Monoplacophora, Gastropoda, and Cephalopoda. Each class has, in turn, been the most diverse molluscan group. In the Ordovician the cephalopods succeeded the monoplacophorans as the most diverse molluscan class, and they held this position until the close of the Mesozoic. They were followed by the gastropods, which by then had diversified into a great variety of aquatic and terrestrial habitats.

Primitive members of the Cyrtosoma have, or had, a conical univalved shell, often twisted into a spiral. Although primitive cyrtosomes, including the only living shelled cephalopod, *Nautilus*, are shell-bearing animals, many advanced cyrtosomes have either lost or greatly reduced their shells (examples include slugs, nudibranchs, squids, and octopuses). Consequently, it is not any particular shell form which unites all members of the Cyrtosoma; rather, it is a knowledge of their evolutionary history. *See* CEPHALOPODA; GASTROPODA; MOLLUSCA; MONOPLACOPHORA. [B.Ru.]

Cystoporata An extinct order of bryozoans in the class Stenolaemata. Cystoporates tend to have robust colonies composed of relatively simple, long, slender, and tubular zooecia, separated by blisterlike vesicles stacked upon one another. *See* BRYOZOA; STENOLAEMATA.

Cystoporate colonies range from small and delicate to large and massive; they can be thin encrusting sheets, tubular or nodular masses, or erect twiglike or frondlike growths.

The cystoporates may possibly have evolved from the earliest ctenostomes. Cystoporates first appeared late in the Early Ordovician, somewhat earlier than representatives of other stenolaemate orders; thus, the cystoporates may possibly have in turn given rise to those orders, although all these forms may simply share a common ancestor further back in time. Apparently marine, the cystoporates became moderately common by Mid-Ordovician time—contributing to building small reefs, as well as to level-bottom communities—and remained so until they died out in the latest Permian. *See* BRYOZOA; STENOLAEMATA. [R.J.Cu.]

Cytochalasin A class of lipophilic antibiotics produced by fungi. The cytochalasins elicit in animal and plant cells a puzzling diversity of membrane phenomena. There is evidence that numerous chemicals, including cytochalasins, interact directly with plasma membrane components, modulate activity of membrane-bound enzymes, and often produce changes in membrane structure.

In animals, cytochalasins inhibit cytokinesis, cell movement, and embryonic morphogenesis, as well as intracellular movement such as the transport of melanin granules. In addition, nuclear extrusion is induced; lymphocyte-mediated destruction of target cells is inhibited; and there is selective "pulverization" of certain chromosomes, which are converted to the unraveled, interphase form, while the other chromosomes in the cell remain in the condensed, metaphase form.

In plants, intracellular movements such as cytoplasmic streaming and chloroplast movements are inhibited. Cytochalasins also inhibit root growth and water uptake in onion seedlings; cells become more spherical in shape.

The great value of the cytochalasins as research tools is that they appear to achieve their reversible impact on cell behavior with a minimum of undesirable side effects such as inhibition of respiration or protein synthesis. Cytochalasin is extensively applied as a chemical "scalpel" to enucleate mammalian cells rapidly, precisely, and efficiently in studies of nuclear-cytoplasmic relations and in cell hybridization and nuclear transplant work. Another major application is in examining the consequences of arrested cytoplasmic movement. [D.D.S.T.]

Cytochemistry The science concerned with the chemistry of cells. Specifically, the macromolecules of subcellular structures can be treated chemically to form microscopically visible end products. For example, proteins, enzymes, lipids, carbohydrates, and nucleic acids can be directly visualized in cell nuclei, membranes, and organelles by cytochemical methods which generate images that can be viewed by either bright field or light, fluorescence, confocal, or electron microscopes. *See* ELECTRON MICROSCOPE; FLUORESCENCE MICROSCOPE; INTERFERENCE MICROSCOPE; PHASE-CONTRAST MICROSCOPE; SCANNING ELECTRON MICROSCOPE.

Enzyme cytochemical methods detect enzymes associated with subcellular structures. The method employs a substrate specifically cleaved by an enzyme in the cell to liberate a product which is transformed into a visible precipitate. For example, to localize the enzyme acid phosphatase in lysosomes, a subcellular organelle, a lead sulfide precipitate is produced by splitting a phosphate (product) from cytidine monophosphate (substrate) and transforming the phosphate product initially into lead phosphate and subsequently into lead sulfide; the latter is visible as a brown-black precipitate in the light microscope. Other methods employ azo dye or formazan precipitates rather than lead to produce a visible product. The number of enzymes that can be detected are limited by the availability and specificity of substrates. *See* ENZYME.

Immunocytochemical methods are used to detect specific proteins associated with subcellular structures. The methods are based on the immunologic principle of the built-in specificity of antibody-antigen interactions. An antigen in a tissue or a cell is detected by employing either a direct or indirect method. The direct method requires a specific antibody linked to a molecule that produces a visible signal; the antibody-molecule complex is applied to a tissue or cells for antigen binding. The indirect method employs an unlabeled primary antibody which is applied to a tissue or cells. The antibody binds to the antigen. The bound primary antibody is then detected by application of a secondary antibody that yields a visible signal. Second antibodies can be labeled with fluorescent probes, enzymes, metals, and high-affinity complexes that are detectable with the appropriate microscope (such as bright-field light, fluorescence, confocal, and electron), in some cases, after application of other reagents to generate a visible product.

Double or triple label immunocytochemistry methods allow multiple antigens to be localized within a tissue or cells. Multiple antigens can be detected at the same time by using different antibodies labeled with probes that fluoresce at different wavelengths. Multiple antibodies can also be labeled with different enzymes or with different size gold particles. Fluorescent probes are detected with conventional fluorescence microscopy or with confocal microscopy using either appropriate filters or lasers. Enzyme probes and gold probes are detected with light and electron microscopy. *See* IMMUNOCHEMISTRY; IMMUNOFLUORESCENCE; PROTEIN.

Autoradiographic methods employ radioactive labeled molecules to identify sites within cells where synthesis of macromolecules occurs. This method is based on the property that an isotope emits ionizing particles during radioactive decay. Radioactive labeled precursor molecules (building blocks of molecules) become incorporated into specific cellular sites after injection into living organisms or cells, producing a radioactive product. To establish the location of the radioactive product in tissues or cells, a photographic emulsion is placed over tissues or cells in the dark for a period of time, followed by a photographic developer solution to reveal sites containing the radioactive product. [P.M.N.]

Cytochrome Any of a group of proteins that carry as prosthetic groups various iron porphyrins called hemes. Hemes also constitute prosthetic groups for other proteins, but the function of prosthetic groups in the cytochromes is largely restricted to oxidation to the ferric heme, with the iron in the 3^+ valence state, and reduction to ferrous heme with a 2^+ iron. Thus, by alternate oxidation and reduction the cytochromes can transfer electrons to and from each other and other substances, and can operate in the oxidation of substrates. The energy released in their oxidation reactions is conserved by using it to drive the formation of the energy-rich compound adenosine triphosphate (ATP) from adenosine diphosphate (ADP) and inorganic phosphate. This process of coupling the oxidation of substrates to phosphorylation of ADP is called oxidative phosphorylation. In cells of eukaryotic organisms, the cytochromes have rather uniform properties; they are part of the respiratory chain and are located in the mitochondria. In contrast, prokaryotes exhibit much more varied cytochromes. Cytochromes are found even in metabolic pathways that employ oxidants other than oxygen. *See* ADENOSINE DIPHOSPHATE (ADP); ADENOSINE TRIPHOSPHATE (ATP); MITOCHONDRIA; PROTEIN.

Respiratory chain. There are four cytochromes in the respiratory chain of eukaryotes, termed respectively aa_3, b, c, and c_1. Cytochrome aa_3, also called cytochrome oxidase, functions by oxidizing reduced cytochrome c (ferrocytochrome c) to the ferric form. It then transfers the reducing equivalents acquired in this reaction to molecular oxygen, reducing it to water. The cytochrome oxidase reaction is probably the most important reaction in biology since it drives the entire respiratory chain and takes up over 95% of the oxygen employed by organisms, thus providing nearly all of the energy needed for living processes. *See* RESPIRATION.

The energy released during oxidation is utilized to actively pump protons (H^+) from the matrix of the mitochondrion through the inner membrane into the intermembrane space. This creates a proton gradient across the membrane, with the matrix space having a lower proton concentration and the outside having a higher proton concentration. This chemical and potential gradient can be released by allowing protons to flow down the gradient and back into the mitochondrial matrix, thereby driving the formation of ATP. A pair of electrons flowing down the respiratory chain yields three molecules of ATP, a remarkable feat of energy conservation. This is called the chemiosmotic mechanism of oxidative phosphorylation, which is generally considered a true picture of respiratory chain function.

Cytochrome oxidase. The cytochrome oxidase of eukaryotes is a very complex protein assembly containing from 8 to 13 polypeptide subunits, two hemes, a and a_3, and two atoms of copper. The two hemes are chemically identical but are placed in different protein environments, so that heme a can accept an electron from cytochrome c and heme a_3 can react with oxygen. When cytochrome oxidase has accepted four electrons, one from each of four molecules of reduced cytochrome c, both its hemes and both its copper atoms are in reduced form, and it can transfer the electrons in a series of reactions to a molecule of oxygen to yield two molecules of water.

Cytochrome oxidase straddles the inner membrane of mitochondria, part of it on the matrix side, part within the membrane, and part on the outer surface or cytochrome c side of the inner membrane. *See* CELL MEMBRANES.

Cytochrome c. Cytochrome c is the only protein member of the respiratory chain that is freely mobile in the mitochondrial intermembrane space. It is a small protein consisting of a single polypeptide chain of 104 to 112 amino acid residues, wrapped around a single heme prosthetic group. The cytochromes c of eukaryotes are all positively charged proteins, with strong dipoles, while the systems from which cytochrome c accepts electrons, cytochrome reductase, and to which cytochrome c delivers electrons, cytochrome oxidase, are negatively charged. There is good evidence that this electrostatic arrangement correctly orients cytochrome c as it approaches the reductase or the oxidase, so that electron transfer can take place very efficiently, even though the surface area at which the reaction occurs is less than 1% of the total surface of the protein.

The amino acid sequences of the cytochromes c of eukaryotes have been determined for well over 100 different species, from yeast to humans, and have provided some very interesting correlations between protein structure and the evolutionary relatedness of different taxonomic groups. The extensive degree of similarity over the entire range of extant organisms has been taken as evidence that this is an ancient structure, developed long before the divergence of plants and animals, which in the course of its evolutionary descent has been adapted to serve a variety of electron transfer functions in different organisms. *See* PROTEINS, EVOLUTION OF.

Cytochrome reductase. Like cytochrome oxidase, the cytochrome reductase complex is an integral membrane protein system. There are numerous subunits, consisting of two molecules of cytochrome b, one molecule of a nonheme iron protein, and one molecule of cytochrome c_1. As in the case of the oxidase, the two cytochrome b hemes are chemically identical, but are present in somewhat different protein environments. The reductase complex is reduced by reaction with the reduced form of the fat-soluble coenzyme Q, dissolved within the inner mitochondrial membrane, which is itself reduced by the succinate dehydrogenase, the NADH dehydrogenase, and other systems. *See* COENZYME.

Other cytochromes. In addition to the mitochondrial respiratory chain cytochromes, animals have a heme protein, termed cytochrome P450, located in the liver and adrenal gland cortex. In the liver it is part of a mono-oxygenase system that can utilize oxygen and the reduced coenzyme NADPH, to hydroxylate a large variety of foreign substances and drugs and thus detoxify them; in the adrenal it functions in the hydroxylation of steroid precursors in the normal biosynthesis of adrenocortical hormones. *See* ADRENAL GLAND; LIVER.

Two varieties of cytochrome b, termed b_{563} and b_{559}, and one of cytochrome c, c_{552}, are involved in the photosynthetic systems of plants. Other plant cytochromes occur in specialized tissues and certain species. *See* BIOLOGICAL OXIDATION; PHOTOSYNTHESIS.

[E.Ma.]

Cytokine Any of a group of soluble proteins that are released by a cell to send messages which are delivered to the same cell (autocrine), an adjacent cell (paracrine), or a distant cell (endocrine). The cytokine binds to a specific receptor and causes a change in function or in development (differentiation) of the target cell. Cytokines are involved in reproduction, growth and development, normal homeostatic regulation, response to injury and repair, blood clotting, and host resistance (immunity and tolerance). Unlike cells of the endocrine system, many different types of cells can produce the same cytokine, and a single cytokine may act on a wide variety of target cells. Further, several cytokines may produce the same effect on a target, so the loss of one type of cytokine may have few if any consequences for the organism; this situation is called redundancy. Finally, the response of a target cell may be altered by the context in which it receives a cytokine signal. The context includes other cytokines in the milieu, and extracellular matrix. Thus has developed the concept of cytokines as alphabet letters that combine to spell words which make up a molecular language.

Types of cytokines. Cytokines may be divided into six groups: interleukins, colony-stimulating factors, interferons, tumor necrosis factor, growth factors, and chemokines.

Interleukins are proteins that are produced by one type of lymphocyte or macrophage and act on other leukocytes. At least 18 types of this important class, with varying origin and function, exist. Production of interleukins is now known not to be confined to lymphocytes or macrophages.

Colony-stimulating factors are produced by lymphoid and nonlymphoid cells. These factors provide a mechanism whereby cells that are distant from bone marrow can call for different types of hemopoietic progeny. There are also growth-promoting actions of locally produced colony-stimulating factors within the bone marrow to stimulate progenitors to differentiate into macrophages, granulocytes, or colonies containing both cell types.

Interferons classically interfere with the virus replication mechanisms in cells. Interferon-α (produced by leukocytes) and interferon-β (produced by fibroblasts) activate cytotoxicity in natural killer cells. Interferon-γ also activates natural killer cells, and is a potent activator of macrophages as well.

Tumor necrosis factor-α (TNF-α) is produced by a variety of cell types, but activated macrophages represent the dominant source. TNF-α activates natural killer cell cytotoxicity, enhances generation of cytotoxic T-lymphocytes, and activates natural killer cells to produce interferon-γ. TNF-α also acts on vascular endothelium to promote inflammation and thrombosis. TNF-α may also induce apoptosis in cells such as trophoblasts. TNF-β is a product of Th1 T-cells; in addition to providing help in proinflammatory cell-mediated immune responses, these cells produce delayed-type hypersensitivity reactions where macrophages are locally recruited and activated to kill intracellular pathogens, such as certain bacteria. TNF-β has interferon-type activity and a narrower spectrum of action than TNF-α.

Transforming growth factors (TGFs) have the ability to promote unrestrained proliferation of cells which otherwise has a benign behavior phenotype. These factors have therefore been implicated in development of cancer. There are two groups of transforming growth factors. TGF-α is a 5-kilodalton peptide produced by a variety of cells and collaborates with TGF-β, a 25-kD peptide, in promoting unrestrained tumorlike growth. TGF-β has potent pleiotropic effects on a wide variety of tissues and is a potent fibrogenic and immunosuppressive agent.

Chemokines are chemoattractant cytokines of small (7–14 kD) heparin-binding proteins that are subdivided into four families: CXC, CC, C, and CX_3C. Chemokines are produced by macrophages stimulated by bacterial endotoxins, and control the nature and magnitude of cell infiltration in inflammation.

Wound healing. Wound healing is probably the most common phenomenon in which the importance of cytokines is seen. Cytokines ensure that the restorative sequences are carried out in the appropriate order by signaling blood cells and vascular endothelium to coagulate and fill in a wound opening, recruiting and signaling macrophages and neutrophils to engulf microbes, and guiding protective skin epidermal cells to grow over the wounded area. If the damage is more extensive, cytokines stimulate production of new skin cells, blood vessels (angiogenesis), connective tissue, and bone. *See* CELLULAR IMMUNOLOGY. [D.A.C.]

Cytokinesis The physical partitioning of a plant or animal cell into two daughter cells during cell reproduction. There are two modes of cytokinesis: by a constriction (the cleavage furrow in animal cells and some plant cells) or from within by an expanding cell plate (the phragmoplast of many plant cells). In either mode, cytokinesis requires only a few minutes, beginning at variable times after the segregation of chromosomes during mitosis (nuclear division). In the vast majority of cases the resulting daughter cells are completely separated. Since they are necessarily smaller cells as a result of cytokinesis, most cells grow in volume between divisions.

Occasionally, cytokinesis is only partial, permitting nutrients and metabolites to be shared between cells. Should cytokinesis fail to occur at all, mitosis may cause more than one nucleus to accumulate. Such a cell is a syncytium. Some tissues normally contain syncytia, for example, binucleate cells in the liver and multinucleate plant endosperm. Some whole organisms such as slime molds are syncytial.

Cytokinesis is precisely and indispensably linked to mitosis, yet the timing and actual mechanisms are distinct. The plane of cell partitioning is perpendicular to the axis of mitosis and coincides with the plane previously occupied by the chromosomes at metaphase. Despite the reliability of this correlation, the chromosomes themselves are not essential for cytokinesis. Experiments performed upon living cells have shown that it is the cell's machinery for chromosome separation, the mitotic apparatus, that provides the essential positional signal to other parts of the cytoplasm which initiates cytokinesis. Subsequently, the mitotic apparatus is no longer involved in cytokinesis and can be destroyed or even sucked out without affecting cytokinesis. *See* CHROMOSOME; MITOSIS.

A cleavage furrow develops by circumferential contraction of the peripheral cytoplasm, usually at the cell's equator. The mechanism of furrowing is very similar among a wide diversity of cell types in lower and higher animals and certain plants. The physical forces of contraction exhibited by a cleavage furrow are evidently greater than the forces of resistance elsewhere. Electron microscopic analysis of the peripheral cytoplasm beneath the cleavage furrow consistently reveals a specialization called the contractile ring. This transient cell organelle is composed of numerous long, thin protein fibers oriented circumferentially within the plane of furrowing. These microfilaments are about 5 nanometers in thickness, appear to attach to the cell membrane, and are known to be composed of actin intermixed with myosin. Both of these proteins are intimately involved in force generation in muscle cells. Thus, the present theory of cytokinesis by furrowing implicates the contractile ring as a transient, localized intracellular "muscle" that squeezes the cell in two. *See* MUSCLE PROTEINS.

In plant cells the dominant mode of cytokinesis involves a phragmoplast, a structure composed of fibrous and vesicular elements that resemble parts of the mitotic apparatus. Microtubules (the fibers) appear to convey a stream of small membranous vesicles toward the midline where they fuse into a pair of partitioning cell membranes. Cellulose cell walls are subsequently secreted between these membranes to solidify the separation between daughter cells. This mode of cytokinesis is well suited to plant cells whose stiff cell walls cannot participate in furrowing. Surprisingly, however, there are instances among the algae where cleavage furrows are the normal mode of cytokinesis. Occasionally, both cleavage furrows and phragmoplasts are employed in the same cell. *See* CELL WALLS (PLANT); PLANT CELL. [T.E.S.]

Cytokinins A group of plant hormones (phytohormones) that, together with other plant hormones, induces plant growth and development. Since the isolation of the first naturally occurring cytokinin, zeatin, from corn seeds in 1961, more than 25 different cytokinins have been isolated from plants. In addition, more than 150 different analogs have been synthesized from kinetin, the first nonplant substance found (in 1954) to stimulate plant cell division.

Oversynthesis of cytokinins in plant tissue causes abnormal growth: crown gall tumor disease caused by the bacterium *Agrobacterium tumefaciens* is an example of excessive production of cytokinins in local tumor tissue. Tissue from crown gall tumors can grow on a simple medium lacking plant hormones because the tumor tissue overproduces both cytokinin and auxin. This is due to the insertion of a piece of bacterial plasmid DNA into the plant nuclear genomes causing activation of the gene responsible for the regulation of cytokinin production. Roots have been shown to be the major site of cytokinin biosynthesis, but stems and leaves are also capable of synthesizing cytokinins. It is possible that all actively dividing cells are capable of cytokinin biosynthesis. *See* CROWN GALL.

Cytokinins exhibit a wide range of physiological effects when applied externally to plant tissues, organs, and whole plants. Exogenous applications of this hormone induce cell division in tissue culture in the presence of auxin. The formation of roots or shoots depends on the relative concentrations of auxin and cytokinin added to the culture medium. High auxin and low cytokinin concentrations lead to root formation, while low auxin and high cytokinin concentrations give shoots. Tissue culture techniques have been employed by plant biotechnologists to grow genetically engineered plant cells into whole plants. Cytokinins appear to be necessary for the correlated phenomena of mitosis and nucleic acid synthesis. Cytokinins delay the aging process in detached leaves by slowing the loss of chlorophyll. Cytokinin effects also include breaking of dormancy, promotion of seed germination, stimulation and nutrient mobilization, enhanced anthocyanin and flavanoid synthesis, increased resistance to disease, and stimulation of the opening of stomates. *See* AUXIN; DORMANCY; PLANT PHYSIOLOGY; TISSUE CULTURE.

The mechanism of action of cytokinin on plant growth and development is poorly understood. It has been demonstrated that specific proteins are induced, enhanced, reduced, or suppressed by the hormone. Some of the enzymes or proteins regulated by cytokinins have been identified. Initial evidence suggests that cytokinins regulate, at least in part, the transcriptional process of gene expression by turning on or off specific genes and stimulating or suppressing the synthesis of specific mRNAs. Another possible action of cytokinins is the regulation of a posttranscriptional process such as stabilization of mRNA. Scientists also demonstrated that cytokinins specifically increase the rate of protein synthesis and the effect seems to be on the translation of mRNA into proteins. *See* PLANT GROWTH; PLANT HORMONES. [C.M.C.]

Cytolysis An important immune function involving the dissolution of certain cells. There are a number of different cytolytic cells within the immune system that are capable of lysing a broad range of cells. The most thoroughly studied of these cells are the cytotoxic lymphocytes, which appear to be derived from different cell lineages and may employ a variety of lytic mechanisms. Cytotoxic cells are believed to be essential for the elimination of oncogenically or virally altered cells, but they can also play a detrimental role by mediating graft rejection or autoimmune disease. There are two issues regarding cytotoxic lymphocytes that are of concern: one is the target structure that is being recognized on the target cell, that is, the cell that is killed, which triggers the response; and the other is the lytic mechanism. *See* CELLULAR IMMUNOLOGY.

When freshly isolated, large granular lymphocytes from peripheral blood are tested in cytotoxicity assays, they spontaneously lyse certain tumor cells. These cytotoxic cells are called natural killer cells, and they are important mediators of innate immunity as a first line of defense against invading pathogens. They are unique in that no previous sensitization is required for them to kill. It now appears that a number of different receptors on natural killer cells are capable of activating the lytic machinery. Recently, it has been found that these cells also express inhibitory receptors that actually inhibit cell lysis, thus adding another level of complexity to the regulation of cytolysis by these cells.

Another killer cell, called the lymphokine-activated killer cell can lyse any target cell, including cells from freshly isolated tumors, and are employed in cancer therapy. Lymphokine-activated killer cells may also be important in mounting a vigorous response under conditions of extreme immunological stress. Very little is known about the mechanisms by which these cells recognize and lyse the target cell.

The last group of cytotoxic cells is the cytotoxic T lymphocyte. These are T cells that can lyse any target cell in an antigen-specific fashion. That is, as a population they are capable of lysing a wide range of target cells, but an individual cytotoxic T lymphocyte is capable of lysing only those target cells which bear the appropriate antigen. These are truly immune cells in that they require prior sensitization in order to function. These cells are thought to mediate graft rejection, mount responses against viral infections and intracellular bacterial infections, and play a major role in tumor destruction.

Cytotoxic cell-mediated lysis is divided into three distinct steps. The first step is conjugation, when the killer cell determines if the target cell expresses the appropriate antigen and binds to it via a complex array of adhesion molecules. The second step involves the programming for lysis in which the lytic event is triggered. The third step is the destruction of the target cell.

Direct cell contact between the target cell and the killer cell is absolutely required for initiating the lytic mechanism. Killer cells remain unscathed during the lytic event, suggesting that the killer cell must either employ a unidirectional lytic mechanism or be resistant to the lytic mechanism. Also, when many, but not all, target cells die after cytotoxic T-lymphocyte interaction, nuclear damage with rapid DNA fragmentation precedes detectable plasma membrane damage. *See* ANTIGEN; HISTOCOMPATIBILITY.

It is becoming clear that cytotoxic lymphocytes employ multiple mechanisms designed to initiate target cell destruction. If cytolysis exists to protect the organism from invading pathogens, there should be redundancies in the system so that, if the pathogen has a mechanism for escaping one cytolytic pathway, alternative mechanisms would still be functional. Two mechanisms are the degranulation of cytolytic granules and the triggering of death receptors found on target cells. In the degranulation mechanism of killing, cytotoxic cells release the contents of cytotoxic granules after specific interaction with the target cell. This results in the leakage of salts, nucleotides, and proteins from the target cell, leading to cell death.

On virtually all cells of the body a number of receptors have been identified that are able to trigger apoptosis when engaged. These receptors are called death receptors. The most studied, and relevant to cytolytic cells, is a receptor called Fas. Fas, when engaged by its ligand (FasL), triggers the caspase cascade leading to the hallmark signs of apoptosis, which include membrane blebbing, chromosomal condensation, nuclear disintegration, DNA fragmentation, and cell death. [H.L.O.; M.M.Ba.]

Cytomegalovirus infection A common asymptomatic infection caused by cytomegalovirus, which can produce life-threatening illnesses in the immature fetus and in immunologically deficient subjects.

Cytomegalovirus is a member of the herpesvirus group, which asymptomatically infects 50–100% of the normal adult population. Such infections usually take place during the newborn period when the virus can be transmitted from the mother to the baby if the virus is present in the birth canal or in breast milk. Toddlers may also acquire the infection in nurseries. Later in life, the virus may be transmitted by heterosexual or male homosexual activity. After infection, cytomegalovirus remains latent in the body because it cannot be completely eradicated even by a competent immune system. It may be activated and cause illnesses when there is a breakdown of the immune system.

Congenital or transplacental cytomegalovirus infection is also a fairly common event. With rare exceptions, it too is usually asymptomatic. Congenital cytomegalovirus disease results from transplacental transmission of the virus, usually from a mother undergoing initial or primary cytomegalovirus infection, during pregnancy. Its manifestations range from subtle sensory neural hearing loss detectable only later in life, to a fulminating multisystem infection and eventual death of the newborn. This important congenital disease occurs in about 1 in 1000 pregnancies.

The only cytomegalovirus illness clearly described in mature, immunologically normal subjects is cytomegalovirus mononucleosis. This is a self-limited illness like infectious mononucleosis, the main manifestation of which is fever. *See* INFECTIOUS MONONUCLEOSIS.

Otherwise, cytomegalovirus illnesses are usually seen only when cellular immunity is deficient. They constitute the most important infection problem afterbone marrow and organ transplantations. Manifestations vary from the self-limited cytomegalovirus mononucleosis to more serious organ involvement such as pneumonia, hepatitis, gastrointestinal ulcerations, and widespread dissemination. The virus causing these illnesses may come from activation of the patient's own latent infection, or it may be transmitted from an outside source, usually from latent cytomegalovirus infecting the graft from a donor. *See* IMMUNOLOGICAL DEFICIENCY; TRANSPLANTATION BIOLOGY.

Cytomegalovirus illnesses are also serious, fairly frequent complications of the acquired immunodeficiency syndrome (AIDS). One reason is that most individuals with human immunodeficiency virus (HIV) infection are already infected with cytomegalovirus. Disease manifestations are similar to what is seen in transplant cases, except they may be more severe. Cytomegalovirus retinitis is a typical problem associated with advanced AIDS. Without treatment, the retina is progressively destroyed such that blindness of one or both eyes is inevitable. *See* ACQUIRED IMMUNE DEFICIENCY SYNDROME (AIDS).

Cytomegalovirus diseases can be treated with two antivirals, ganciclovir or foscarnet, with varying degrees of success. Cytomegalovirus pneumonia in the bone marrow transplant recipient cannot be cured by antivirals alone because it probably has an immunopathologic component. Cytomegalovirus diseases in persons with AIDS can be contained but not cured by specific treatment. For example, ganciclovir treatment of cytomegalovirus retinitis is effective only as long as maintenance therapy is continued. *See* ANIMAL VIRUS. [Mo.H.]

Cytoplasm That portion of living cells bordered externally by the plasma membrane (cell membrane) and internally by the nuclear envelope. In the terminology of classical cytology, the substance in living cells and in living organisms not compartmentalized into cells was called protoplasm. It was assumed at the time that the protoplasm of various cells was similar in structure and chemistry. Results of research on cell chemistry and ultrastructure after about 1960 showed that each cell type had a recognizably different "protoplasm." Primarily for that reason, the term protoplasm gradually fell into disuse in contemporary biology. The terms cytoplasm and nucleoplasm have been retained and are used descriptively; they are used almost synonymously with the terms cytosome (body of cytoplasm) and nucleus, respectively.

Many cells, especially the single-celled organisms or protistans, have regional cytoplasmic differentiation. The outer region is the cortex or ectoplasm, and the inner region is the endoplasm. In many cases the cortical layer is a gel made up of a meshwork of cytoskeletal fibers.

Cytoplasm contains mostly water, from 80 to 97% in different cells, except for spores and other inactive forms of living material, in which water may be present in lesser amounts. The dry mass of cells consists mainly of macromolecules: proteins, carbohydrates, nucleic acids, and lipids associated with membranes. The small molecules present in cells are mainly metabolites or metabolic intermediates. The principal ions other than the hydrogen and hydroxyl ions of water are the cations of potassium, sodium, magnesium, and calcium, and the anions chloride and bicarbonate. Many other elements are present in cytoplasm in smaller amounts. Iron is found in cytochrome pigments in mitochondria; magnesium is present in chlorophyll in chloroplasts; copper, zinc, iodine, bromine, and several other elements are present in trace quantities. *See* CYTOCHEMISTRY.

Sedimentation of cells by centrifugation shows that organelles and inclusions can be separated from the ground cytoplasm, the fluid phase of the cytoplasm in which they are suspended. The ground cytoplasm in turn has been shown to consist of a cytoskeletal network and the cytosol, the fluid in which the cytoskeleton is bathed. The cytoskeleton consists of several biopolymers of wide distribution in cells. Microtubules have been observed in electron micrographs of a vast number of different cell types. They consist of the protein tubulin, and are frequently covered by a fuzzy layer of microtubule-associated proteins. *See* CYTOSKELETON.

In most cells the smaller particles exhibit Brownian motion due to thermal agitation. In some cells lacking extensive cytoskeletal structure, particles can be moved freely around the cell by Brownian motion. In others they are restricted by their surrounding cytoskeletal elements. Particles of various types may also undergo saltatory motions which carry them farther than Brownian motion possibly could. Such excursions result from the interaction of a particle with an element of the cytoskeleton such as one or more microtubules or microfilaments. *See* CELL (BIOLOGY). [R.D.Al.]

Cytoskeleton A system of filaments found in the cytoplasm of cells and responsible for the maintenance of and changes in cell shape, cell locomotion, movement of various elements in the cytoplasm, integration of the major cytoplasmic organelles, cell division, chromosome organization and movement, and the adhesion of a cell to a surface or to other cells.

Three major classes of filaments have been resolved on the basis of their diameter and cytoplasmic distribution: actin filaments (or microfilaments) each with an average diameter of 6 nanometers, microtubules with an average diameter of 25 nm, and intermediate filaments whose diameter of 10 nm is intermediate to that of the other two classes. The presence of this system of filaments in all cells, as well as their diversity in structure and cytoplasmic distribution, has been recognized only in the modern period of biology.

A technique that has greatly facilitated the visualization of these filaments, as well as the analysis of their chemical composition, is immunofluorescence applied to cells grown in tissue culture. *See* IMMUNOFLUORESCENCE.

Actin is the main structural component of actin filaments in all cell types, both muscle and nonmuscle. Actin filaments assume a variety of configurations depending on the type of cell and the state it is in. They extend a considerable distance through the cytoplasm in the form of bundles, also known as stress fibers since they are important in determining the elongated shape of the cell and in enabling the cell to adhere to the substrate and spread out on it. Actin filaments can exist in forms other than straight bundles. In rounded cells that do not adhere strongly to the substrate (such as dividing cells and cancer cells), the filaments form an amorphous meshwork that is quite distinct from the highly organized bundles. The two filamentous states, actin filament bundles and actin filament meshworks, are interconvertible polymeric states of the same molecule. Bundles give the cell its tensile strength, adhesive capability, and structural support, while meshworks provide elastic support and force for cell locomotion.

Microtubules are slender cylindrical structures that exhibit a cytoplasmic distribution distinct from actin filaments. Microtubules originate in structures that are closely associated with the outside surface of the nucleus known as centrioles. The major structural protein of these filaments is known as tubulin. Unlike the other two classes of filaments, microtubules are highly unstable structures and appear to be in a constant state of polymerization-depolymerization. *See* CENTRIOLE.

Intermediate filaments function as the true cytoskeleton. Unlike microtubules and actin filaments, intermediate filaments are very stable structures. They have a cytoplasmic distribution independent of actin filaments and microtubules. In the intact cell, they anchor the nucleus, positioning it within the cytoplasmic space. During mitosis, they form a filamentous cage around the mitotic spindle which holds the spindle in a fixed place during chromosome movement. [E.L.]

D

Dacite Aphanitic (very finely crystalline or glassy) rock of volcanic origin, composed chiefly of sodic plagioclase (oligoclase or andesine) and free silica (quartz or tridymite) with subordinate dark-colored (mafic) minerals (biotite, amphibole, or pyroxene). If alkali feldspar exceeds 5% of the total feldspar, the rock is a quartz latite. As quartz decreases in abundance, dacite passes into andesite. Thus, dacite is roughly intermediate between andesite and quartz latite. *See* ANDESITE. [C.A.C.]

D'Alembert's paradox A theorem in fluid mechanics which states that no forces act on a body moving at constant velocity in a straight line through a large mass of incompressible, inviscid fluid which was initially at rest (or in uniform motion). This seemingly paradoxical theorem can be understood by first realizing that inviscid fluids do not exist. If such fluids did exist, there would be no internal physical mechanism for dissipating energy into heat; hence there could be no force acting on the body, because work would then be done on the fluid with no net increase of energy in the fluid. *See* FLUID FLOW. [A.E.Br.]

D'Alembert's principle The principle that the resultant of the external forces $\mathbf{F}$ and the kinetic reaction acting on a body equals zero. The kinetic reaction is defined as the negative of the product of the mass m and the acceleration $\mathbf{a}$. The principle is therefore stated as $\mathbf{F} - m\mathbf{a} = 0$. While D'Alembert's principle is merely another way of writing Newton's second law, it has the advantage of changing a problem in kinetics into a problem in statics. The techniques used in solving statics problems may then provide relatively simple solutions to some problems in dynamics; D'Alembert's principle is especially useful in problems involving constraints. *See* CONSTRAINT. [P.W.S.]

Dalitz plot Pictorial representation in high-energy nuclear physics for data on the distribution of certain three-particle configurations. Many elementary-particle decay processes and high-energy nuclear reactions lead to final states consisting of three particles (which may be denoted by a, b, c, with mass values m_a, m_b, m_c). Well-known examples are provided by the K-meson decay processes, Eqs. (1) and (2), and by the K- and $\overline{K}$-meson reactions with hydrogen, Eqs. (3) and (4). For definite total

$$K^+ \rightarrow \pi^+ + \pi^+ + \pi^- \tag{1}$$

$$K^+ \rightarrow \pi^0 + \mu^+ + \nu \tag{2}$$

$$K^+ + p \rightarrow K^0 + \pi^+ + p \tag{3}$$

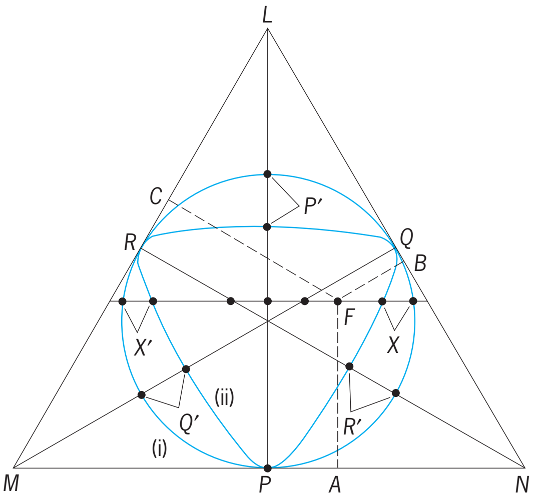
$$K^- + p \rightarrow \Lambda + \pi^+ + \pi^- \tag{4}$$

energy E (measured in the barycentric frame), these final states have a continuous distribution of configurations, each specified by the way this energy E is shared among the three particles. (The barycentric frame is the reference frame in which the observer finds zero for the vector sum of the momenta of all the particles of the system considered.) *See* ELEMENTARY PARTICLE.

If the three particles have kinetic energies T_a, T_b, and T_c (in the barycentric frame), Eq. (5) is obtained.

$$T_a + T_b + T_c = E - m_a c^2 - m_b c^2 - m_c c^2 = Q \tag{5}$$

As shown in the illustration, this energy sharing may be represented uniquely by a point F within an equilateral triangle LMN of side $2Q/\sqrt{3}$, such that the perpendiculars FA, FB, and FC to its sides are equal in magnitude to the kinetic energies T_a, T_b, and T_c. The most important property of this representation is that the area occupied within this triangle by any set of configurations is directly proportional to their volume in phase space.



Configuration of a three-particle system (*abc*) in its barycentric frame is specified by a point *F* such that the three perpendiculars *FA*, *FB*, and *FC* to the sides of an equilateral triangle *LMN* (of height *Q*) are equal in magnitude to the kinetic energies *T*$_a$, *T*$_b$, *T*$_c$, where *Q* denotes their sum.

Not all points F within the triangle LMN correspond to configurations realizable physically, since the a, b, c energies must be consistent with zero total momentum for the three-particle system. With nonrelativistic kinematics and with equal masses m for a, b, c, the only allowed configurations are those corresponding to points F lying within the circle inscribed within the triangle, shown as (i) in the illustration. More generally, with relativistic kinematics, the limiting boundary is distorted as illustrated by the boundary curve (ii), drawn for the $\omega \rightarrow 3\pi$ decay process, where the final masses are equal. [R.H.D.]

Dallis grass A general term for a genus of grasses of which the most important species is the deeply rooted perennial *Paspalum dilatatum*. Dallis grass is widely used in the southern United States, mostly for pasture, and remains productive indefinitely if well managed. Dallis grass does best on fertile soils and responds to lime and fertilizer. On heavier soils it remains green throughout the winter unless checked by heavy frosts. Ergot-bearing seed heads are very toxic to livestock, and Dallis grass must be so managed as to prevent consumption of infected heads by livestock. *See* CYPERALES; ERGOT. [H.B.S.]

Dalton's law The total pressure of a mixture of gases is the sum of the partial pressures of each gas in the mixture. The law was established by John Dalton (1766–1844). In his original formulation, the partial pressure of a gas is the pressure of the gas if it alone occupied the container at the same temperature. Dalton's law may be expressed as $P = P_A + P_B + \cdots$, where P_J is the partial pressure of the gas J, and P is the total pressure of the mixture; this formulation is strictly valid only for mixtures of ideal gases. For real gases, the total pressure is not the sum of the partial pressures (except in the limit of zero pressure) because of interactions between the molecules.

In modern physical chemistry the partial pressure is defined as $P_J = x_J P$, where x_J is the mole fraction of the gas J, the ratio of its amount in moles to the total number of moles of gas molecules present in the mixture. With this definition, the total pressure of a mixture of any kind of gases is the sum of their partial pressures. However, only for an ideal gas is the partial pressure (as defined here) the pressure that the gas would exert if it alone occupied the container. *See* GAS; KINETIC THEORY OF MATTER; THERMODYNAMIC PRINCIPLES. [P.W.A.]

Dam A barrier or structure across a stream, river, or waterway for the purpose of confining and controlling the flow of water. Dams vary in size from small earth embankments for farm use to high, massive concrete structures for water supply, hydropower, irrigation, navigation, recreation, sedimentation control, and flood control. As such, dams are cornerstones in the water resources development of river basins. Dams are now built to serve several purposes and are therefore known as multipurpose. The construction of a large dam requires the relocation of existing highways, railroads, and utilities from the river valley to elevations above the reservoir. The two principal types of dams are embankment and concrete. Appurtenant structures of dams include spillways, outlet works, and control facilities; they may also include structures related to hydropower and other project purposes. *See* ELECTRIC POWER GENERATION; IRRIGATION (AGRICULTURE); WATER SUPPLY ENGINEERING.

Dams are built for specific purposes. In ancient times, they were built only for water supply or irrigation. Early in the development of the United States, rivers were a primary means of transportation, and therefore navigation dams with locks were constructed on the major rivers. Dams have become more complex to meet large power demands and other needs of modern countries.

In addition to the standard impounded reservoir and the appurtenant structures of a dam (spillway, outlet works, and control facility), a dam with hydropower requires a powerhouse, penstocks, generators, and switchyard. The inflow of water into the reservoir must be monitored continuously, and the outflow must be controlled to obtain maximum benefits. Under normal operating conditions, the reservoir is controlled by the outlet works, consisting of a large tunnel or conduit at stream level with control gates. Under flood conditions, the reservoir is maintained by both the spillway and outlet works. *See* RESERVOIR.

All the features of a dam are monitored and operated from a control room. The room contains the necessary monitors, controls, computers, emergency equipment, and communications systems to allow project personnel to operate the dam safely under all conditions. Standby generators and backup communications equipment are necessary to operate the gates and other reservoir controls in case of power failure. Weather conditions, inflow, reservoir level, discharge, and downstream river levels are also monitored. In addition, the control room monitors instrumentation located in the dam and appurtenant features that measures their structural behavior and physical condition.

All dams are designed and constructed to meet specific requirements. First, a dam should be built from locally available materials when possible. Second, the dam must remain stable under all conditions, during construction, and ultimately in operation, both at the normal reservoir operating level and under all flood and drought conditions. Third, the dam and foundation must be sufficiently watertight to control seepage and maintain the desired reservoir level. Finally, it must have sufficient spillway and outlet works capacity as well as freeboard to prevent floodwater from overtopping it.

Dams are classified by the type of material from which they are constructed. In early times, the materials were earth, large stones, and timber, but as technology developed, other materials and construction procedures were used. Most modern dams fall into two categories: embankment and concrete. Embankment dams are earth or rock-fill; other gravity dams and arch and buttress dams are concrete. *See* ARCH; CONCRETE.

The type of dam for a particular site is selected on the basis of technical and economic data and environmental considerations. In the early stages of design, several sites and types are considered. Drill holes and test pits at each site provide soil and rock samples for testing physical properties. In some cases, field pumping tests are performed to evaluate seepage potential. Preliminary designs and cost estimates are prepared and reviewed by hydrologic, hydraulic, geotechnical, and structural engineers, as well as geologists. Environmental quality of the water, ecological systems, and cultural data are also considered in the site-selection process.

Factors that affect the type are topography, geology, foundation conditions, hydrology, earthquakes, and availability of construction materials. The foundation of the dam should be as sound and free of faults as possible. Narrow valleys with shallow sound rock favor concrete dams. Wide valleys with varying rock depths and conditions favor embankment dams. Earth dams are the most common type. *See* ENGINEERING GEOLOGY; FAULT AND FAULT STRUCTURES.

The designers of a dam must consider the stream flow around or through the damsite during construction. Stream flow records provide the information for use in determining the largest flood to divert during the selected construction period. One common practice for diversion involves constructing the permanent outlet works, which may be a conduit or a tunnel in the abutment, along with portions of the dam adjacent to the abutments, in the first construction period. The stream is diverted into the outlet works by a cofferdam high enough to prevent overtopping during construction. A downstream cofferdam is also required to keep the damsite dry. *See* COFFERDAM.

Personnel responsible for operation and maintenance of the dam are familiar with the operating instructions and maintenance schedule. A schedule is established for collection and reporting of data for climatic conditions, rainfall, snow cover, stream flows, and water quality of the reservoir, as well as the downstream reaches. All these data are evaluated for use in reservoir regulation. Another schedule is established for the collection of instrumentation data used to determine the structural behavior and physical condition of the dam. These data are evaluated frequently. Routine maintenance and inspection of the dam and appurtenant structures are ongoing processes. The scheduled maintenance is important to preserve the integrity of the mechanical equipment.

The frequency with which instrumentation data are obtained is an extremely important issue and depends on operating conditions. Timely collection and evaluation of data are critical for periods when the loading changes, such as during floods and after earthquakes. Advances in applications of remote sensing to instrumentation have made real-time data collection possible. This is a significant improvement for making dam safety evaluations.

Throughout history there have been instances of dam failure and discharge of stored water, sometimes causing considerable loss of life and great damage to property. Failures have generally involved dams that were designed and constructed to engineering standards acceptable at the time. Most failures have occurred with new dams, within the first five years of operation. [A.H.Wa.]

Damping A term broadly used to denote either the dissipation of energy in, and the consequent decay of, oscillations of all types or the extent of the dissipation and decay. The energy losses arise from frictional (or analogous) forces which are unavoidable in any system or from the radiation of energy to space or to other systems. For sufficiently small oscillations, the analogous forces are proportional to the velocity of the vibrating member and oppositely directed thereto; the ratio of force to velocity is $-R$, the mechanical resistance. For the role of damping in the case of forced oscillations, where it is decisive for the frequency response, see Forced oscillation; Resonance (acoustics and mechanics). *See also* Harmonic motion; Mechanical vibration; Oscillation; Vibration.

An undamped system of mass m and stiffness s oscillates at an angular frequency $\omega_0 = (s/m)^{1/2}$. The effect of a mechanical resistance R is twofold: It produces a change in the frequency of oscillation, and it causes the oscillations to decay with time. If u is one of the oscillating quantities (displacement, velocity, acceleration) of amplitude A, then Eq. (1) holds in the damped case, whereas in the undamped case Eq. (2) holds. The reciprocal time

$$u = Ae^{-\alpha t}\cos\omega_d t \tag{1}$$

$$u = A\cos\omega_0 t \tag{2}$$

$1/\alpha$ in Eq. (1) may be called the damping constant.

The damped angular frequency ω_d in Eq. (1) is always less than ω_0. According to Eq. (1), the amplitude of the oscillation decays exponentially; the time required for the amplitude to decrease to the fraction $1/e$ of its initial value is equal to $1/\alpha$.

A common measure of the damping is the logarithmic decrement δ, defined as the natural logarithm of the ratio of two successive maxima of the decaying sinusoid. If T is the period of the oscillation, then Eq. (3) holds. Then $1/\delta$ is the number of cycles

$$\delta = \alpha T \tag{3}$$

required for the amplitude to decrease by the factor $1/e$ in the same way that $1/\alpha$ is the time required.

The Q of a system is a measure of damping usually defined from energy considerations. The Q is π times the ratio of peak energy stored to energy dissipated per cycle and is equal to π/δ.

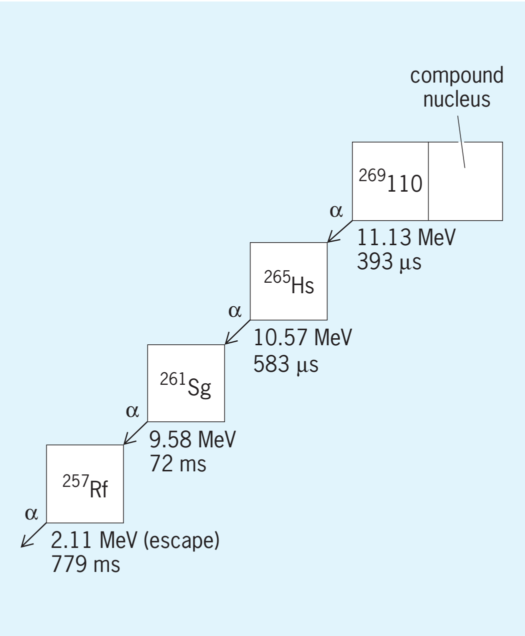
If α in Eq. (1) exceeds ω_0, then the system is not oscillatory and is said to be overdamped. If the mass is displaced, it returns to its equilibrium position without overshoot, and the return is slower as the ratio α/ω_0 increases. If $\alpha = \omega_0$ (that is, $Q = 1/2$), the oscillator is critically damped. In this case, the motion is again nonoscillatory, but the return to equilibrium is faster than for any overdamped case. [M.Gr.]

Daphniphyllales An order of flowering plants, division Magnoliophyta (Angiospermae), in the subclass Hamamelidae of the class Magnoliopsida (dicotyledons). The order consists of a single family with but one genus, *Daphniphyllum*, containing about 35 species. All are dioecious trees or shrubs native to eastern Asia and the Malay region. The plants produce a unique type of alkaloid (daphniphylline group); they often accumulate aluminum and sometimes produce iridoid compounds. The leaves are simple and entire, alternate or sometimes closely clustered at the ends of the branches. The flowers are small and inconspicuous, unisexual, regular, and hypogynous. Usually there are 2–6 sepals, or sometimes the sepals are absent; petals are lacking. *Daphniphyllum* has sometimes been included in the Euphorbiales of the subclass Rosidae, but structural details such as the very tiny embryo make it highly aberrant there. *See* Hamamelidae; Magnoliopsida; Plant kingdom. [T.M.Ba.]

Dark current An ambiguous term used in connection with both gaseous-discharge devices and photoelectric cells or tubes. In gaseous-conduction tubes it refers to the region of operation known as the Townsend discharge. When applied to photoelectric devices, the term refers to background current. This is current which may be present as the result of thermionic emission or other effects when there is no light incident on the photosensitive cathode. *See* Electrical conduction in gases; Townsend discharge. [G.H.M.]

Darmstadtium The eighteenth of the synthetic transuranium elements. Element 110 should be a heavy homolog of the elements platinum, palladium, and nickel (group 10). It is the eighth element in the 6*d* shell. The various isotopes of element 110 have been reliably documented by the observation of at least two atoms with half-lives in the range of milliseconds, a time too short for the application of chemical methods, verifying its position in the periodic system. *See* Half-life; Nickel; Palladium; Periodic table; Platinum; Radioisotope.

Searches for this element began in 1985. With the finding of the isotope ^{269}110 (the isotope of element 110 with mass number 269) in late 1994 at Gesellschaft für Schwerionenforschung (GSI), Darmstadt, Germany, its discovery became conclusive.



Sequence of decay chains that document the discovery of element 110. Numbers below boxes are alpha energies and correlation times. Element 110 is produced in the reaction ^{62}Ni + ^{208}Pb → ^{269}110 + 1*n*.

After an extensive search for the optimum bombarding energy on November 9, 1994, a decay chain was observed which proved the existence of the isotope ^{269}110. The isotopes were produced in a fusion reaction of a nickel-62 projectile with a lead-208 target nucleus. The fused system, with an excitation energy of 13 MeV, cooled down by emitting one neutron and forming ^{269}110, which by sequential alpha decays transformed to hassium-265, seaborgium-261, rutherfordium-257, and nobelium-253. All of these daughter isotopes were already known, and four decay chains observed in the following 12 days corroborated without any doubt the discovery of the element. The illustration shows the first decay chain observed, which ended in ^{257}Rf. The isotope ^{269}110 has a half-life of 0.2 ms, and is produced with a cross section of about 3×10^{-36} cm^2. *See* Alpha particles; Neutron; Nuclear structure; Rutherfordium. [P.Ar.]

Dasheen Common name for the plant *Colocasia esculenta*, including the variety *antiquorum* (taro). These plants are among the few edible members of the aroid family (Araceae). Native to southeastern Asia and Malaysia, the plants supply the people with their most important food. A main dish in the Polynesian menu is poi, a thin, pasty gruel of taro starch, often fermented, which is frequently formed into cakes for baking or toasting. The raw corms (underground stems) are baked or boiled to eliminate an irritating substance present in the cells. *See* ARALES. [P.D.St./E.L.C.]

Dasycladales An order of green algae (Chlorophyceae) in which the plant body (thallus) is composed of a nonseptate axis, attached by rhizoids and bearing whorls of branches. The walls utilize a partially crystalline mannan (polymer of mannose) as the skeletal component and usually are impregnated with aragonite, a form of calcium carbonate, causing these algae to be easily fossilized. Among green algae, only the Dasycladales have a fossil record sufficient to permit meaningful phylogenetic speculation. About 140 extinct genera have been described from limestones as old as the Ordovician, with three peaks of abundance and diversity—Carboniferous, Jurassic-Cretaceous, and Eocene. Only about 11 genera comprising 50 species are extant, with 3 of the genera extending from the Cretaceous. All are confined to warm marine waters except *Batophora*, which occurs as a relict in brackish sinkholes in New Mexico in addition to having a normal Caribbean distribution.

The extant Dasycladales are usually placed in a single family, Dasycladaceae, but those forms in which fertile and sterile whorls alternate or only one fertile whorl is produced may be segregated as the Acetabulariaceae (or Polyphysaceae). *See* ALGAE; CHLOROPHYCEAE. [P.C.Si.; R.L.Moe]

Data communications The conveyance of information from a source to a destination. Data means the symbolic representation of information, generally in a digital (that is, discrete) form. (Analog information refers to information encoded according to a continuous physical parameter, such as the height or amplitude of a waveform, while digital information is encoded into a discrete set of some parameter.) Usually, this digital information is composed of a sequence of binary digits (ones and zeros), called bits. The binary system is used because its simplicity is universally recognizable and because digital data have greater immunity to so-called noise than analog information and allow flexible processing of the information. Groups of eight bits create a data byte or character. These characters make up the so-called alphabets (including alphabetic, numeric, and special symbols) which are used in data communications. The most common data sources and destinations are computers and computer peripherals, and the data represent groups of characters to form text, hypertext (text organized according to topic rather than linear sequence), or multimedia information, including audio, graphics, animation, and video information. *See* BIT; COMPUTER; COMPUTER GRAPHICS; COMPUTER PERIPHERAL DEVICES; DIGITAL COMPUTER; MULTIMEDIA TECHNOLOGY.

Data communications may be accomplished through two principal functions, data transmission and data switching.

Data transmission always involves at least three elements: a source of the information, a channel for the transmission of the information, and a destination for the information. In addition, sometimes the data are encoded. The codes can be used for error detection and correction, compression of the digital data, and so forth. *See* DATA COMPRESSION.

The communications channel is carried over a transmission medium. Such media can be wired, as in the cases of twisted-pair telephone wires, coaxial cables, or fiber-optic cables, or they can be wireless, where the transmission is not confined to any physical medium, such as in radio, satellite, or infrared optical transmission. Sometimes, even when the source of the information is digital, the transmission medium requires analog signaling, and modems (modulators-demodulators) are required to convert the digital signals to analog, and vice versa. For example, data communication between personal computers transmitted over telephone lines normally uses modems. *See* COAXIAL CABLE; COMMUNICATIONS CABLE; COMMUNICATIONS SATELLITE; MODEM; OPTICAL COMMUNICATIONS; OPTICAL FIBERS; RADIO; TELEPHONE SERVICE.

The directionality of the information can be either one-way (simplex communications) or two-way. Two-way communications can be either half-duplex (information goes both ways over the communications link, but not at the same time) or full-duplex (information goes both ways at the same time).

The data channel can be a serial channel, in which the bits are transmitted one after another across a single physical connection; or a parallel channel, in which many bits are transmitted simultaneously (for instance, over parallel wires). Generally, parallel channels are used for short-distance links (less than 300 ft or 100 m), whereas serial links are used for larger distances and high data rates.

At low data rates (less than a few hundred kilobits per second) communications channels are typically dedicated, whereas at higher data rates, because of the cost of high-speed transmitters and receivers, shared channels are used by multiplexing the data streams. For example, two independent data streams with constant data rates of 10 megabits per second (Mb/s) could use a shared channel having a data-rate capability of 20 Mb/s. The multiplexing system would select one bit from each of the two channels to time-multiplex the data together. *See* MULTIPLEXING AND MULTIPLE ACCESS.

In many cases, the source, the destination, and the path taken by the data may vary; thus switching is required.

The two primary types of switching employed in data communications are circuit switching and packet switching. In circuit-switched data communications, an end-to-end connection is established prior to the actual transmission of the data and the communications channel is open (whether or not it is in use) until the connection is removed.

A packet is a group of data bytes which represents a specific information unit with a known beginning and end. The packet can be formed from either a fixed or variable number of bytes. Some of these bytes represent the information payload, while the rest represent the header, which contains address information to be used in routing the packet. In packet switching, unlike circuit switching, the packets are sent only when information transmission is required. The channel is not used when there is no information to be sent. Sharing the channel capacity through multiplexing is natural for packet-switched systems. Furthermore, the packet switches allow for temporary loading of the network beyond the transmission capacity of the channel. This information overload is stored (buffered) in the packet switches and sent on when the channel becomes available.

In order to transfer information from a sender to a receiver, a common physical transmission protocol must be used. Protocols can range from very simple to quite complex. The Open Systems Interconnect (OSI) model, developed by the International Standards Organization, reduces protocol complexity by breaking the protocol into smaller functional units which operate in conjunction with similar functional units at a peer-to-peer level. Each layer performs functions for the next higher layer by building on the functions provided by the layer below. The advantage of performing communications based on this model is that at the application layers (user processes) there is no concern with the communications mechanisms. *See* ELECTRICAL COMMUNICATIONS; INTEGRATED SERVICES DIGITAL NETWORK (ISDN); PACKET SWITCHING; SWITCHING SYSTEMS (COMMUNICATIONS); TELEPROCESSING. [M.S.Go.]

Data compression The process of transforming information from one representation to another, smaller representation from which the original, or a close approximation to it, can be recovered. The compression and decompression processes are often referred to as encoding and decoding. Data compression has important applications in the areas of data storage and data transmission. Besides compression savings, other parameters of concern include encoding and decoding speeds and workspace requirements, the ability to access and decode partial files, and error generation and propagation.

The data compression process is said to be lossless if the recovered data are assured to be identical to the source; otherwise the compression process is said to be lossy. Lossless compression techniques are requisite for applications involving textual data. Other applications, such as those involving voice and image data, may be sufficiently flexible to allow controlled degradation in the data.

Data compression techniques are characterized by the use of an appropriate data model, which selects the elements of the source on which to focus; data coding, which maps source elements to output elements; and data structures, which enable efficient implementation.

Information theory dictates that, for efficiency, fewer bits be used for common events than for rare events. Compression techniques are based on using an appropriate model for the source data in which defined elements are not all equally likely. The encoder and the decoder must agree on an identical model. *See* INFORMATION THEORY.

A static model is one in which the choice of elements and their assumed distribution is invariant. For example, the letter "e" might always be assumed to be the most likely character to occur. A static model can be predetermined with resulting unpredictable compression effect, or it can be built by the encoder by previewing the entire source data and determining element frequencies. The benefits of using a static model include the ability to decode without necessarily starting at the beginning of the compressed data.

An alternative dynamic or adaptive model assumes an initial choice of elements and distribution and, based on the beginning part of the source stream that has been processed prior to the datum presently under consideration, progressively modifies the model so that the encoding is optimal for data distributed similarly to recent observations. Some techniques may weight recently encountered data more heavily. Dynamic algorithms have the benefit of being able to adapt to changes in the ensemble characteristics. Most important, however, is the fact that the source is considered serially and output is produced directly without the necessity of previewing the entire source.

In a simple statistical model, frequencies of values (characters, strings, or pixels) determine the mapping. In the more general context model, the mapping is determined by the occurrence of elements, each consisting of a value which has other particular adjacent values. For example, in English text, although generally "u" is only moderately likely to appear as the "next" character, if the immediately preceding character is a "q" then "u" would be overwhelmingly likely to appear next.

The use of a model determines the intended sequence of values. An additional mapping via one coding technique or a combination of coding techniques is used to determine the actual output. Several data coding techniques are in common use. [D.S.Hi.]

Digitized audio and video signals. The information content of speech, music, and television signals can be preserved by periodically sampling at a rate equal to twice the highest frequency to be preserved. This is referred to as Nyquist sampling. However, speech, music, and television signals are highly redundant, and use of simple Nyquist sampling to code them is inefficient. Reduction of redundancy and application of more efficient sampling results in compression of the information rate needed to represent the signal without serious impairment to the quality of the remade source signal at a receiver. For speech signals, redundancy evident in pitch periodicity and in the format (energy-peaks) structure of the signal's spectrum along with aural masking of quantizing noise is used to compress the information rate. In music, which has much wider bandwidth than speech and far less redundancy, time-domain masking and frequency-domain masking are principally used to achieve compression. For television, redundancy evident in the horizontal and vertical correlation of the pixels of individual frames and in the frame-to-frame correlation of a moving picture, combined with visual masking that obscures quantizing noise resulting from the coding at low numbers of bits per sample, is used to achieve compression. *See* SPEECH; TELEVISION.

Compression techniques may be classified into two types: waveform coders and parametric coders. Waveform coders replicate a facsimile of a source-signal waveform at the receiver with a level of distortion that is judged acceptable. Parametric coders use a synthesizer at the receiver that is controlled by signal parameters extracted at the transmitter to remake the signal. The latter may achieve greater compression because of the information content added by the synthesizer model at the receiver.

Waveform compression methods include adaptive differential pulse-code modulation (ADPCM) for speech and music signals, audio masking for music, and differential encoding and sub-Nyquist sampling of television signals. Parametric encoders include vocoders for speech signals and encoders using orthogonal transform techniques for television. [S.J.C.]

Data mining

The development of computational algorithms for the identification or extraction of structure from data. This is done in order to help reduce, model, understand, or analyze the data. Tasks supported by data mining include prediction, segmentation, dependency modeling, summarization, and change and deviation detection. Database systems have brought digital data capture and storage to the mainstream of data processing, leading to the creation of large data warehouses. These are databases whose primary purpose is to gain access to data for analysis and decision support. Traditional manual data analysis and exploration requires highly trained data analysts and is ineffective for high dimensionality (large numbers of variables) and massive data sets. *See* DATABASE MANAGEMENT SYSTEM.

A data set can be viewed abstractly as a set of records, each consisting of values for a set of dimensions (variables). While data records may exist physically in a database system in a schema that spans many tables, the logical view is of concern here. Databases with many dimensions pose fundamental problems that transcend query execution and optimization. A fundamental problem is query formulation: How is it possible to provide data access when a user cannot specify the target set exactly, as is required by a conventional database query language such as SQL (Structured Query Language)? Decision support queries are difficult to state. For example, which records are likely to represent fraud in credit card, banking, or telecommunications transactions? Which records are most similar to records in table A but dissimilar to those in table B? How many clusters (segments) are in a database and how are they characterized? Data mining techniques allow for computer-driven exploration of the data, hence admitting a more abstract model of interaction than SQL permits.

Data mining techniques are fundamentally data reduction and visualization techniques. As the number of dimensions grows, the number of possible combinations of choices for dimensionality reduction explodes. For an analyst exploring models, it is infeasible to go through the various ways of projecting the dimensions or selecting the right subsamples (reduction along columns and rows). Data mining is based on machine-based exploration of many of the possibilities before a selected reduced set is presented to the analyst for feedback. [U.F.]

Data reduction

The transformation of information, usually empirically or experimentally derived, into corrected, ordered, and simplified form.

The term data reduction generally refers to operations on either numerical or alphabetical information digitally represented, or to operations which yield digital information from empirical observations or instrument readings. In the latter case data reduction also implies conversion from analog to digital form either by human reading and digital symbolization or by mechanical means. *See* ANALOG-TO-DIGITAL CONVERTER; DIGITAL COMPUTER.

In applications where the raw data are already digital, data reduction may consist simply of such operations as editing, scaling, coding, sorting, collating, and tabular summarization.

More typically, the data reduction process is applied to readings or measurements involving random errors. These are the indeterminate errors inherent in the process of assigning values to observational quantities. In such cases, before data may be coded and summarized, the most probable value of a quantity must be determined. Provided the errors are normally distributed, the most probable (or central) value of a set of measurements is given by the arithmetic mean or, in the more general case, by the weighted mean. *See* STATISTICS.

Data reduction may also involve operations of smoothing and interpolation, because the results of observations and measurements are always given as a discrete set of numbers, while the phenomenon being studied may be continuous in nature. [R.J.Ne.]

Data structure

A means of storing a collection of data. Computer science is in part the study of methods for effectively using a computer to solve problems, or in other words, determining exactly the problem to be solved. This process entails (1) gaining an understanding of the problem; (2) translating vague descriptions, goals, and contradictory requests, and often unstated desires, into a precisely formulated conceptual solution; and (3) implementing the solution with a computer program. This solution typically consists of two parts: algorithms and data structures.

Relation to algorithms. An algorithm is a concise specification of a method for solving a problem. A data structure can be viewed as consisting of a set of algorithms for performing operations on the data it stores. Thus algorithms are part of what constitutes a data structure. In constructing a solution to a problem, a data structure must be chosen that allows the data to be operated upon easily in the manner required by the algorithm.

Data may be arranged and managed at many levels, and the variability in algorithm design generally arises in the manner in which the data for the program are stored, that is (1) how data are arranged in relation to each other, (2) which data are calculated as needed, (3) which data are kept in memory, and (4) which data are kept in files, and the arrangement of the files. An algorithm may need to put new data into an existing collection of data, remove data from a collection, or query a collection of data for a specific purpose. *See* ALGORITHM.

Abstract data types. Each data structure can be developed around the concept of an abstract data type that defines both data organization and data handling operations. Data abstraction is a tool that allows each data structure to be developed in relative isolation from the rest of the solution. The study of data structure is organized around a collection of abstract data types that includes lists, trees, sets, graphs, and dictionaries. *See* ABSTRACT DATA TYPE.

Primitive and nonprimitive structures. Data can be structured at the most primitive level, where they are directly operated upon by machine-level instructions. At this level, data may be character or numeric, and numeric data may consist of integers or real numbers.

Nonprimitive data structures can be classified as arrays, lists, and files. An array is an ordered set which contains a fixed number of objects. No deletions or insertions are performed on arrays. At best, elements may be changed. A list, by contrast, is an ordered set consisting of a variable number of elements to which insertions and deletions can be made, and on which other operations can be performed. When a list displays the relationship of adjacency between elements, it is said to be linear; otherwise it is said to be nonlinear. A file is typically a large list that is stored in the external memory of a computer. Additionally, a file may be used as a repository for list items (records) that are accessed infrequently.

File structures. Not all information that is processed by a computer necessarily resides in immediately accessible memory because some programs and their data cannot fit into the main memory of the computer. Large volumes of data or records and archival data are commonly stored in external memory as entities called files. Any storage other than main memory may be loosely defined as external storage. This includes tapes, disks, and so forth. *See* COMPUTER STORAGE TECHNOLOGY.

Virtual memory. This is a system that provides an extension to main memory in a logical sense. In a virtual system, all currently active programs and data are allocated space or virtual addresses in virtual memory. The program and data may not in fact reside in main memory but in an external storage. References to virtual addresses are translated dynamically by the operating system into real addresses in main memory. *See* DIGITAL COMPUTER. [A.O.T.]

Database management system

A collection of interrelated data together with a set of programs to access the data, also called database system, or simply database. The primary goal of such a system is to provide an environment that is both convenient and efficient to use in retrieving and storing information.

A database management system (DBMS) is designed to manage a large body of information. Data management involves both defining structures for storing information and providing mechanisms for manipulating the information. In addition, the database system must provide for the safety of the stored information, despite system crashes or attempts at unauthorized access. If data are to be shared among several users, the system must avoid possible anomalous results due to multiple users concurrently accessing the same data.

Examples of the use of database systems include airline reservation systems, company payroll and employee information systems, banking systems, credit card processing systems, and sales and order tracking systems.

A major purpose of a database system is to provide users with an abstract view of the data. That is, the system hides certain details of how the data are stored and maintained. Thereby, data can be stored in complex data structures that permit efficient retrieval, yet users see a simplified and easy-to-use view of the data. The lowest level of abstraction, the physical level, describes how the data are actually stored and details the data structures. The next-higher level of abstraction, the logical level, describes what data are stored, and what relationships exist among those data. The highest level of abstraction, the view level, describes parts of the database that are relevant to each user; application programs used to access a database form part of the view level.

The overall structure of the database is called the database schema. The schema specifies data, data relationships, data semantics, and consistency constraints on the data.

Underlying the structure of a database is the logical data model: a collection of conceptual tools for describing the schema.

The entity-relationship data model is based on a collection of basic objects, called entities, and of relationships among these objects. An entity is a "thing" or "object" in the real world that is distinguishable from other objects. For example, each person is an entity, and bank accounts can be considered entities. Entities are described in a database by a set of attributes. For example, the attributes account-number and balance describe one particular account in a bank. A relationship is an association among several entities. For example, a depositor relationship associates a customer with each of her accounts. The set of all entities of the same type and the set of all relationships of the same type are termed an entity set and a relationship set, respectively.

Like the entity-relationship model, the object-oriented model is based on a collection of objects. An object contains values stored in instance variables within the object. An object also contains bodies of code that operate on the object. These bodies of code are called methods. The only way in which one object can access the data of another object is by invoking a method of that other object. This action is called sending a message to the object. Thus, the call interface of the methods of an object defines that object's externally visible part. The internal part of the object—the instance variables and method code—are not visible externally. The result is two levels of data abstraction, which are important to abstract away (hide) internal details of objects. Object-oriented data models also provide object references which can be used to identify (refer to) objects.

In record-based models, the database is structured in fixed-format records of several types. Each record has a fixed set of fields. The three most widely accepted record-based data models are the relational, network, and hierarchical models. The latter two were widely used once, but are of declining importance. The relational model is very widely used. Databases based on the relational model are called relational databases.

The relational model uses a collection of tables (called relations) to represent both data and the relationships among those data. Each table has multiple columns, and each column has a unique name. Each row of the table is called a tuple, and each column represents the value of an attribute of the tuple.

The size of a database can vary widely, from a few megabytes for personal databases, to gigabytes (a gigabyte is 1000 megabytes) or even terabytes (a terabyte is 1000 gigabytes) for large corporate databases.

The information in a database is stored on a nonvolatile medium that can accommodate large amounts of data; the most commonly used such media are magnetic disks. Magnetic disks can store significantly larger amounts of data than main memory, at much lower costs per unit of data.

To improve reliability in mission-critical systems, disks can be organized into structures generically called redundant arrays of independent disks (RAID). In a RAID system, data are organized with some amount of redundancy (such as replication) across several disks. Even if one of the disks in the RAID system were to be damaged and lose data, the lost data can be reconstructed from the other disks in the RAID system. *See* COMPUTER STORAGE TECHNOLOGY.

Logically, data in a relational database are organized as a set of relations, each relation consisting of a set of records. This is the view given to database users. The underlying implementation on disk (hidden from the user) consists of a set of files. Each file consists of a set of fixed-size pieces of disk storage, called blocks. Records of a relation are stored within blocks. Each relation is associated with one or more files. Generally a file contains records from only one relation, but organizations where a file contains records from more than one relation are also used for performance reasons.

One way to retrieve a desired record in a relational database is to perform a scan on the corresponding relation; a scan fetches all the records from the relation, one at a time.

Accessing desired records from a large relation using a scan on the relation can be very expensive. Indices are data structures that permit more efficient access of records. An index is built on one or more attributes of a relation; such attributes constitute the search key. Given a value for each of the search-key attributes, the index structure can be used to retrieve records with the specified search-key values quickly. Indices may also support other operations, such as fetching all records whose search-key values fall in a specified range of values.

A database schema is specified by a set of definitions expressed by a data-definition language. The result of execution of data-definition language statements is a set of information stored in a special file called a data dictionary. The data dictionary contains metadata, that is, data about data. This file is consulted before actual data are read or modified in the database system. The data-definition language is also used to specify storage structures and access methods.

Data manipulation is the retrieval, insertion, deletion, and modification of information stored in the database. A data-manipulation language enables users to access or manipulate data as organized by the appropriate data model. There are basically two types of data-manipulation languages: Procedural data-manipulation languages require a user to specify what data are needed and how to get those data; nonprocedural data-manipulation languages require a user to specify what data are needed without specifying how to get those data.

A query is a statement requesting the retrieval of information. The portion of a data-manipulation language that involves information retrieval is called a query language. Although technically incorrect, it is common practice to use the terms query language and data-manipulation language synonymously.

Database languages support both data-definition and data-manipulation functions. Although many database languages have been proposed and implemented, SQL has become a standard language supported by most relational database systems. Databases based on the object-oriented model also support declarative query languages that are similar to SQL.

SQL provides a complete data-definition language, including the ability to create relations with specified attribute types, and the ability to define integrity constraints on the data.

Query By Example (QBE) is a graphical language for specifying queries. It is widely used in personal database systems, since it is much simpler than SQL for nonexpert users.

Forms interfaces present a screen view that looks like a form, with fields to be filled in by users. Some of the fields may be filled automatically by the forms system. Report writers permit report formats to be defined, along with queries to fetch data from the database; the results of the queries are shown formatted in the report. These tools in effect provide a new language for building database interfaces and are often referred to as fourth-generation languages (4GLs). *See* HUMAN-COMPUTER INTERACTION.

Often, several operations on the database form a single logical unit of work, called a transaction. An example of a transaction is the transfer of funds from one account to another. Transactions in databases mirror the corresponding transactions in the commercial world.

Traditionally database systems have been designed to support commercial data, consisting mainly of structured alphanumeric data. In recent years, database systems have added support for a number of nontraditional data types such as text documents, images, and maps and other spatial data. The goal is to make databases universal servers, which can store all types of data. Rather than add support for all such data types into the core database, vendors offer add-on packages that integrate with the database to provide such functionality. [H.F.Ko.; A.Si.; S.Su.]

Date The fruit of the date palm (*Phoenix dactylifera*), one of the oldest cultivated tree crops. It provides a staple food for many populations in the Middle East and North Africa, and also is highly valued for feed, fiber, and shelter.

The date palm is in the family Palmaceae. *Phoenix* is distinguished from other palm species by the production of offshoots, columnar-circular trunks, pinnate leaves, and distinctively furrowed seeds. Date palms are monocotyledons and have a single bud or growing point. The date trunk also lacks the cambium growth layer typically found in dicotyledon fruit trees, which is important for true secondary growth.

The date palm species is dioecious: male palms produce staminate flowers and female palms produce pistillate flowers. Both male and female flower clusters are enclosed in protective sheaths. Bees and insects go to the male flowers but not to the female blooms. The date palm is dependent on humans for pollination. Pollen from the staminate flowers must be collected and manually applied to the pistallate inflorescence every season for commercial date production. Windblown pollination results in poor fruit set and in fruit that do not mature properly. One male tree can provide enough pollen for 30–40 female trees. Because the inner layer of the fruit wall is fleshy, the date fruit is classified as a berry, like a tomato. *See* Arecales; Fruit; Fruit, tree. [J.L.A.]

Dating methods Relative and quantitative techniques used to arrange events in time and to determine the numerical age of events in history, geology, paleontology, archeology, paleoanthropology, and astronomy. Relative techniques allow the order of events to be determined, whereas quantitative techniques allow numerical estimates of the ages of the events. Most numerical techniques are based on decay of naturally occurring radioactive nuclides, but a few are based on chemical changes through time, and others are based on variations in the Earth's orbit. Once calibrated, some relative techniques also allow numerical estimates of age. *See* Archeology; Astronomy; Geology; Radioisotope.

Relative dating methods rely on understanding the way in which physical processes in nature leave a record that can be ordered. Once the record of events is ordered, each event is known to be older or younger than each other event. In most cases the record is contained within a geological context, such as a stratigraphic sequence; in other cases the record may be contained within a single fossil or in the arrangement of astronomical bodies in space and time. The most important relative dating methods are stratigraphic dating and paleontologic dating. Other relative dating methods include paleomagnetic dating, dendrochronology, and tephrostratigraphy. *See* Dendrochronology; Paleomagnetism; Sequence stratigraphy; Stratigraphy.

Several chemical processes occur slowly, producing changes over times of geological interest; among these are the hydration of obsidian, and the conversion of L- to D-amino acids (racemization or epimerization). Determination of age requires measurement of a rate constant for the process, knowledge of the temperature history of the material under study, and (particularly for amino acid racemization) knowledge of the chemical environment of the materials. *See* Amino acid dating; Obsidian; Racemization.

Unlike chemical methods, in which changes depend both on time and on environmental conditions, isotopic methods which are based on radioactive decay depend only on time. A parent nuclide may decay to one stable daughter in a single step by simple decay [for example, rubidium decays to strontium plus a beta particle ($^{87}\text{Rb} \rightarrow {}^{87}\text{Sr} + \beta$)]; to two daughters by branched decay through different processes [for example, potassium captures an electron to form argon, or loses a beta particle to form calcium ($^{40}\text{K} + e^- \rightarrow {}^{40}\text{Ar}$; $^{40}\text{K} \rightarrow {}^{40}\text{Ca} + \beta$)]; to one stable daughter through a series of steps (chain decay); or into two unequal-sized fragments by fission. In all cases, the number of parent atoms decreases as the number of daughter atoms increases, so that for each method there is an age-sensitive isotopic ratio of daughter to parent that increases with time. Many different isotopes have been exploited for measuring the age of geological and archeological materials. For example, the table shows parent isotopes, their half-lives, and the resulting daughter products. *See* Gerontology; Half-life.

Astronomers have estimated the age of the universe, and of the Milky Way Galaxy, by various methods. It is well known that the universe is expanding equally from all points, and that the velocity of recession of galaxies observed from Earth increases with distance. The rate of increase of recession velocity with distance is called the Hubble constant; and knowing the recession rate and distance of galaxies at some distance, it is simple to find how long it took them to get there. Initial estimates for the age of the universe were approximately 20 billion years; but as the rate of expansion decreases with time, revised estimates are nearer 13 billion years. By contrast, the Earth and other bodies in the solar system are only about 4.5 billion years old. Comparison of present-day osmium isotope ratios with theoretically estimated initial ratios yields estimates of 8.6–15.7 billion years for the age of the Galaxy. *See* Cosmochemistry; Cosmology; Milky Way Galaxy; Universe. [F.S.B.]

Principal parent and daughter isotopes used in radiometric dating

Radioactive parent isotope	Stable daughter isotope	Half-life, years
Carbon-14	Nitrogen-14	5730
Potassium-40	Argon-40	1.25×10^{9}
Rubidium-87	Strontium-87	4.88×10^{10}
Samarium-147	Neodymium-143	1.06×10^{11}
Lutetium-176	Hafnium-176	3.5×10^{10}
Rhenium-187	Osmium-187	4.3×10^{10}
Thorium-232	Lead-208	1.4×10^{10}
Uranium-235	Lead-207	7.04×10^{8}
Uranium-238	Lead-206	4.47×10^{9}

Datolite A mineral nesosilicate, composition $CaBSiO_4(OH)$, crystallizing in the monoclinic system. It usually occurs in crystals showing many faces and having an equidi-mensional habit. It may also be fine granular or compact and massive. Hardness is $5\text{–}5^{1}/_{2}$ on Mohs scale; specific gravity is 2.8–3.0. The luster is vitreous, the crystals colorless or white with a greenish tinge. Datolite is found in the Harz Mountains, Germany; Bologna, Italy; and Arendal, Norway. In the United States fine crystals have come from Westfield, Massachusetts; Bergen Hill, New Jersey; and various places in Connecticut. In Michigan, in the Lake Superior copper district, datolite occurs in fine-grained porcelainlike masses which may be coppery red because of inclusions of native copper. *See* Silicate minerals. [C.S.Hu.]

Dawsoniidae A subclass of the true mosses (Bryopsida) largely limited to the South Pacific. The subclass consists of a single genus, *Dawsonia*, of nine species. The plants are coarse and rigid in loose dark green or brownish tufts. They are simple or occasionally forked, grow erect from a procumbent base, and sometimes achieve a height of 26 in. (65 cm), much more than any other mosses. The stems may have a central strand of homogeneous fiberlike cells or both xylemlike and phloemlike cells. The leaves are long-linear or long-lanceolate from a relatively short, oblong-sheathing base. The limb, which may be as long as 1.6 in. (40 mm), is concave-tubulose and spreading or flat and spirally twisted when dry. It is coarsely toothed at the margins and at back. The inflorescences are dioecious and terminal. Male plants repeatedly form new growth through the perigonial bud. *See* Bryophyta; Bryopsida; Polytrichidae. [H.Cr.]

Day A unit of time equal to the period of rotation of Earth. Different sorts of day are distinguished, according to how the period of rotation is reckoned with respect to one or another direction in space. A day is normally defined as 86,400 SI (Système International) seconds [86,400 s/d = (60 s/min) × (60 min/h) × (24 h/d)], where SI seconds are measured by atomic processes. *See* Physical measurement.

The apparent solar day is the interval between any two successive meridian transits of the Sun. It varies through the year, reaching about 24 h 30 s of ordinary clock time in December and about 23 h 59 min 39 s in September.

The mean solar day is the interval between any two successive meridian transits of an imagined point in the sky that moves along the celestial equator with a uniform motion equal to the average rate of motion of the Sun along the ecliptic. Ordinary clocks are regulated to advance 24 h during a mean solar day. Because of irregularities in the Earth's rotation, leap seconds are occasionally added to keep the day in terms of seconds of atomic time (Coordinated Universal Time, or UTC) in step with the day based on rotation (UT1).

The sidereal day is the interval between any two successive upper meridian transits of the vernal equinox. Similarly, as for the solar day, a distinction is made between the apparent sidereal day and the mean sidereal day which, however, differ at most by a small fraction of a second. The difference between sidereal time and solar time arises from the Earth's revolution around the Sun, which results in a year containing one more sidereal day than solar day. A mean sidereal day comprises 23 h 56 min 4.09053 s of a mean solar day.

The mean solar day and the sidereal day vary together in consequence of variations in the speed of rotation of Earth, which are of three sorts: seasonal, irregular, and secular. *See* EARTH ROTATION AND ORBITAL MOTION; TIME. [G.M.C.; J.M.P.]

Dead reckoning A form of navigation that determines position of a craft by advancing a previous position to a new one on the basis of assumed distance and direction moved. The parameters of dead reckoning are direction of motion and distance traveled. The intended direction of travel, the course, may differ from the direction steered because of the anticipated offsetting effect of wind (called leeway) or current, or both. When it is desired to distinguish between the two directions, mariners call the second the course steered, or heading, while aviators refer to it as the heading. A compass is used to indicate direction. Distance is usually determined indirectly by measurement of speed and time, but it may be measured directly.

In addition to several magnetic compasses, nearly all naval vessels and ocean liners are equipped with one or more north-seeking gyrocompasses. Gyrocompasses have replaced magnetic compasses as the primary source of directional information on many modern vessels. *See* GYROCOMPASS; MAGNETIC COMPASS.

Aboard ship, distance or speed is measured by means of a log or by an engine revolution counter. The pitometer log uses a pitot-static tube. The Forbes log uses a small rotor in a tube projecting below the bottom of the vessel. An electromagnetic log has a sensing element which produces a voltage directly proportional to speed through the water.

In aircraft, speed through the air is measured by means of an airspeed indicator or Mach meter. The latter provides an indication of speed in units of the speed of sound, which varies with density of the atmosphere. For measurement of air speed a pitot-static tube is generally used with a suitable registering device.

To determine position by dead reckoning, air and land navigators, and some marine navigators, use the best estimate of direction and distance traveled over the surface. Many marine navigators, however, prefer to use course steered and estimated speed through the water, without allowance for leeway, for their dead reckoning; they consider positions determined by allowance of estimated effects of wind and current as estimated positions.

The uncertainty of a dead-reckoning position, however determined, increases with time and, if there is an error in direction measurement, it also increases with distance traveled. From time to time an independent determination of position is made by means of external references. When a reliable position, called a fix, is so obtained, a new dead reckoning is started from this point.

In many large naval vessels and commercial ships the dead reckoning is performed automatically by a device that receives inputs of direction from a gyrocompass and speed from a log and continuously computes dead-reckoning position, which is displayed on dials or traced on a chart or plotting sheet.

The Doppler effect, a frequency shift that is proportional to the speed of relative motion between transmitter and receiver or reflector of radiant energy, either acoustic or electromagnetic, is used in a system to accomplish dead reckoning, automatically. In the ship version, called a Doppler sonar navigator, ultrasonic energy is transmitted obliquely downward (typically 30° from the vertical) and the frequency of the return echo is noted. By using four beams separated 90° laterally, the system provides an indication of vessel speed in both the fore-and-aft and athwartship directions, so that total speed and direction of motion can be determined if the device is properly oriented. When reflections are from the sea bottom (bottom return mode), true ground speed (speed relative to the solid Earth) is measured. When reflections are from suspended particulate matter in the water (volume reverberation mode), the speed is relative to the water. In either mode the speed is integrated to determine distance from a starting point. Doppler sonar navigation has proved particularly useful in survey and geophysical exploration vessels. *See* SONAR.

Similar systems called Doppler navigators, which use electromagnetic energy, have been used in aircraft, but these systems have largely been replaced by inertial navigators. *See* DOPPLER EFFECT; DOPPLER RADAR.

Most aircraft that are used for long overwater flights, and some others, as well as some ships, notably submarines, are equipped with one or more inertial navigators. This device, when properly aligned, provides a continuous indication of speed, position, and heading by means of appropriate inertial sensors. Gyroscopes are used to sense angular motions of the craft and maintain accelerometers in the correct orientation to sense linear accelerations, or changes in speed. Single integration of the accelerations provides a measure of speed, and double integration produces a measure of distance. An inertial navigator is free from effects of wind and current, but like all dead-reckoning systems its output degrades with elapsed time and distance traveled, and must be reset periodically. Its use is particularly attractive in aircraft because of their high speed and hence relatively short time in transit. *See* INERTIAL GUIDANCE SYSTEM.

Knowledge of the real-time present position of a craft is generally considered essential to safe navigation. The Global Positioning System, using NAVSTAR artificial earth satellites, or an integrated system, using a computer and appropriate filter to synthesize outputs of several independent positioning systems, may provide an essentially continuous fix, which would then eliminate the need for dead reckoning. *See* CELESTIAL NAVIGATION; ELECTRONIC NAVIGATION SYSTEMS; PILOTING; SATELLITE NAVIGATION SYSTEMS. [A.B.M.]

Death Cessation of life functions. This can involve the whole organism (somatic death), individual organs (organ death), individual cells (cellular death), and individual parts of cells (organelle death). Although the next smaller level of organization, the macromolecules which make up the cell organelles, may also cease to function, their disintegration is ordinarily not spoken of as death.

Pathogenesis. A normal animal, cell, or organelle exists in a normal state of homeostasis, or a normal "steady state." Following a disturbance of the normal steady state, referred to as an "injury," the living system can be assumed to undergo a change in steady-state level, that is, to exhibit an altered steady state. Such altered steady states can be regarded as having increased, decreased, or unaltered levels of ability to maintain homeostasis. An altered steady state with increased homeostatic ability might include the hypertrophy of a muscle cell resulting from continued exercise; and altered steady state with decreased homeostatic ability is the atrophy or shrinking of cells that occurs following disuse or lack of stimulation by hormones or suitable nutrients. In the case of injuries that do not result in the death of the living system, the system may persist in one of the new or altered steady states for long periods up to many years; that is, although the system differs significantly from the normal steady state, it is able to continue its existence and to maintain homeostasis. On the other hand, certain severe injurious stimuli result in an altered state that ultimately passes a point beyond which recovery of homeostatic ability is impossible even if the injurious stimulus or situation is removed. This point may be considered as a point of no return or the point of death of the living system. Following this point, the system undergoes exponential decay, leading to complete equilibrium with its environment. This period of decay, which is characterized by reactions resulting in the breakdown of structural components of the system, is referred to as necrosis. *See* HOMEOSTASIS.

Somatic death. In the biological sense, somatic death refers to the cessation of characteristic life functions. In higher organisms it can be assumed to result from an interplay between the genetic background of the individual and the effects of the environment. Death is, in a sense, the price of differentiation; in another sense, protoplasm is immortal and all life springs from preexisting life. The undifferentiated amebas need never die, only divide. It would appear that death is inevitable for higher organisms such as mammals and, in a sense, life is a series of little deaths.

Developments in medicine and associated technology involving supportive therapy, resuscitation, hypothermia, extracorporeal circulation, and organ transplantation have reopened serious questions regarding the definition of when an individual is "dead." The vagueness and inconsistency in previous legal and medical definitions have led to serious dilemmas. These are of particular importance in the selection of donors for transplantation of vital organs such as the heart.

Medical techniques have shown that individuals can be sustained for prolonged periods without spontaneous respiratory or cardiac movements as well as without electrical evidence of central nervous system activity. These techniques have also achieved the resuscitation of individuals who would formerly have been considered dead and have clearly shown the survival of transplanted organs from cadavers. Just as organs may survive after the death of the organism, the organism, properly supported by mechanical or other means, can survive the death of organs, including the brain.

The following are changes that occur in the body after somatic death: 1. Cooling (algor mortis) of the body occurs postmortem. 2. Rigidity (rigor mortis) or stiffening of the musculature usually begins within 5–10 h and begins to disappear after 3 or 4 days. 3. Staining (livor mortis) occurs, that is, there is reddish-blue discoloration in the dependent portions of the body resulting from the gradual gravitational flow of unclotted blood. 4. Blood begins to clot shortly after death and sometimes prior to cessation of cardiac function. 5. Autolysis (necrosis) occurs in the cells of the body following somatic death. 6. Putrefaction, bacterial and enzymatic decomposition, begins shortly after death, caused by microorganisms which enter the body.

Organ death. Following somatic death, all organs do not die at the same rate. Length of survival can be prolonged by reducing the temperature of the organs to near 32°F (0°C), which appreciably retards metabolic function and extends survival time. This survival of organs after the death of the host forms the basis for organ transplantation from cadavers.

Cellular death. Death and subsequent necrosis of cells form an important part of many reactions of cells to injury in disease states. The death and disintegration of cells within a living animal incite a vascular reaction called an inflammatory reaction on the part of the host. It is characterized by a series of vascular phenomena which include the migration of leukocytes (white blood cells) from the blood capillaries into the area of tissue damage with subsequent digestion and phagocytosis of the cellular debris resulting from cellular necrosis. [B.F.T.]

Issues. The advancements of modern medicine have brought significant changes in the ways of life and death, and challenge former concepts and definitions of death. As the determination of death becomes increasingly complex in a technological society, the definition of death becomes correspondingly more complex. The meaning of death is a philosophical concept which lies outside the scientific point of view. Although dying is a process which may continue over a considerable period of time, for all practical purposes death occurs at that point where there is an irreversible loss of one's essential human characteristics. Such loss indicates the death of the organism as a whole, the death of a person.

An interdisciplinary committee at the Harvard Medical School examinined possible new criteria for determining death. In 1968 they cited four criteria as determinative of a permanently nonfunctioning brain: unreceptivity and unresponsivity to externally applied stimuli and inner need; absence of spontaneous movements of breathing; absence of reflexes other than spinal column reflexes, and fixed dilated pupils; and a flat electroencephalogram (EEG) to be used as a confirmatory but not mandatory test.

These tests were to be repeated after 24 h, and in the absence of hypothermia or depressant drugs, were to be considered a confirmation of brain death. It has since been conclusively demonstrated that when the flow of blood to the brain has been interrupted for approximately 15 min there is a uniform necrosis and liquefaction of the brain. This definition appears to be a major milestone in determining new criteria for making the determination that death has occurred.

With regard to the issue of organ transplantation, it is contrary to moral intuitions that a dying person might be prematurely defined as dead in order that someone else might harvest the organs. A moral obligation exists to treat the living as such until death occurs. To avoid a conflict in the role of the physician, it has become common practice that the physician for the recipient of an organ donation is not party to the judgment that the donor has died. The needs of a patient for a viable organ must not contaminate the judgment that another person has died.

The ability to define death with more precision is important in cases involving the comatose patient. It is generally accepted as both a moral and legal right that competent persons have the right to refuse medical treatment. Increasingly, dying patients claim a more active role in self-determination regarding medical treatment in the final stage of life.

One of the more radical issues is that of actively ending the life of a suffering person or helping another to die through a positive action. Some ethicists see no moral distinction between removing life-support systems or life-saving medications which allow a patent to die and taking a direct action which causes a patient to die, since the intention and the consequence are the same in both cases. Others disagree, claiming that there is indeed a morally significant difference if a person dies of the underlying disease and is not made to endure still greater suffering by prolonging the dying process than if the person dies because another has caused the death through an intentional and fatal action. [T.R.McC.]

De Broglie wavelength The wavelength $\gamma = h/p$ associated with a beam of particles (or with a single particle) of momentum p; $h = 6.626 \times 10^{34}$ joule-second is Planck's constant. The same formula gives the momentum of an individual photon associated with a light wave of wavelength γ. This formula, along with the profound proposition that all matter has wavelike properties, was first put forth by Louis de Broglie in 1924, and is fundamental to the modern theory of matter and its interaction with electromagnetic radiation. *See* QUANTUM MECHANICS. [E.G.]

Decapoda (Crustacea) One of the more highly specialized orders of the class Crustacea. This order includes the shrimps, lobsters, hermit crabs, and true crabs. The order is so diverse that satisfactory definition is difficult, but a few characters are common to nearly all decapods. The most obvious is a head shield, or carapace, which covers and coalesces with all of the thoracic somites and which overhangs the gills on each side. The first three of the eight pairs of thoracic appendages are specialized as maxillipeds and closely associated with the true mouthparts. The gills are usually well developed and arranged in several series.

Decapods vary in size from less than 1/2 in. (1.25 cm) in length to that of the giant Japanese crab, the largest living arthropod, a spider crab which may span more than 12 ft (3.6 m) between the tips of the outstretched claws. Although most decapods are found in the sea, they are by no means restricted to that habitat. Crayfishes are well-known inhabitants of freshwater streams and ponds, as are several kinds of shrimps and some true crabs. A number of crabs and hermit crabs have become well adapted to a terrestrial existence far from water; they return to the sea only seasonally to hatch their eggs. Many crayfishes burrow in the ground, and one species of crab spends its entire life in the tops of lofty trees.

In a general way, the decapods may be divided into two groups: the long-tailed and the short-tailed forms. The long-tailed species, such as the shrimps and lobsters, have a more or less cylindrical, or laterally compressed, carapace that often bears a head spine or rostrum. The large, muscular abdomen permits the shrimp, or lobster, to dart quickly backward out of danger, but the succulence of this tail makes the animals prey to numerous enemies, including humans. In the short-tailed species, the crabs, the carapace is often broadened and flattened dorsally and usually does not form a rostrum. The much-reduced and feeble abdomen is tucked under the thorax, where it serves the female as a brood pouch for eggs.

Physiology. The nervous system is somewhat variable. Although usually fewer, there may be as many as 11 ganglia, 5 thoracic and 6 abdominal, in the ventral nerve chain posterior to the subesophageal ganglion. The sense organs include eyes, statocysts, olfactory filaments, and tactile setae. The eyes are well developed in most decapods, but they may be reduced or entirely absent in species living in the deep sea, in caves, or in burrows. Luminous organs of various kinds occur in a number of deep-sea decapods, and some shrimps have the ability to eject a luminous fluid.

As in most crustaceans, the alimentary tract is a more or less straight tube divided into three parts: the foregut, the midgut, and the hindgut. The first and last have a chitinous, and sometimes calcified, lining. The foregut, in most decapods, is dilated to form a stomach. Its anterior, or cardiac, portion is at least partially lined with movably articulated, calcified ossicles, controlled by a complex system of muscles called the gastric mill. The posterior, or pyloric, part is provided with hairy ridges which combine to form a straining apparatus. The midgut is variously furnished with blind tubes, and a mass of minutely ramified tubules, known as the hepatopancreas or liver, empties through one or more ducts into the anterior end of the midgut.

The heart is short, polygonal, and situated under the posterior part of the carapace. It has three or more pairs of venous ostia, and two pairs of arteries lead from it, in addition to the median anterior and posterior arteries. The blood collects in a venous sinus in the midventral line, passes to the gills, and then back to the pericardial sinus surrounding the heart.

In practically all decapods, respiration is accomplished by a series of gills, attached to the lateral walls of the thoracic somites and to the basal segments of the thoracic appendages. A continuous current of water is drawn through the branchial chamber and over the gills by the fluttering motion of the outer lobe of the second maxilia. The current usually moves forward, but this direction may be periodically reversed in burrowing species. In those crabs best adapted for life on land, the action of the gills is supplemented by the lining membrane of the branchial chamber. This chamber is covered with minute villi and is unusually well supplied with blood vessels, and thus functions as a lung.

The antennal gland is the chief excretory organ in all decapods. Maxillary glands are often present in the larval stages, but they never persist in the adult. The antennal gland is compact and more complex than in any other crustacean group. It consists of three divisions: the saccule, which is usually partitioned or ramose; the labyrinth, a spongy mass with a complex system of canals; and the bladder with a duct leading to the exterior.

The sexes are separate in most decapods, although protandric hermaphroditism occurs in some shrimps. The testes most often lie partly in the thorax and partly in the abdomen, and they are usually connected across the midline. The ovaries resemble the testes in shape and position.

Development. In only one group of shrimps are all of the presumably primitive larval stages represented. The first stage is a typical crustacean nauplius with an unprotected oval body bearing a median eye and three pairs of appendages. This stage is followed by a metanauplius in which four more appendage rudiments appear. The third pair of the original appendages becomes less of a swimming organ and more like a pair of primitive mandibles. In the third stage, the protozoea, the seven pairs of appendages become more highly developed, a carapace covers the anterior part of the body, the abdomen is clearly formed though unsegmented at first, the rudiments of paired eyes appear, and the heart is formed. In the next stage, the zoea, the eyes become movable and the carapace develops a rostrum. All thoracic appendages are present, at least in rudimentary form, and those of the abdomen appear, especially the uropods. In the last larval stage, the mysis, the well-developed thoracic appendages replace the antennae as the chief swimming organs. The abdomen increases markedly in size and takes on a form similar to that of the adult.

Phylogeny. No true decapod fossils are known with certainty from Paleozoic deposits, but decapod shrimps are not uncommon in Triassic and, especially, Jurassic rocks. Lobsterlike forms related to Recent deep-sea species also appeared in the Triassic; true lobsters are known from the Jurassic, and crayfishes from the Cretaceous. Crabs are well known as fossils, with primitive groups appearing in the Jurassic; several more specialized groups are found in the Cretaceous, and all of the major existing groups were represented in the Tertiary.

The evolution of the decapods has not been satisfactorily worked out and may never be known completely. The presence of a nauplius larva in the development of some shrimps suggests a link with the primitive crustaceans, but it can hardly be doubted that the Decapoda, as a group, are highly specialized. They are certainly closely related to the Euphausiacea, and fusion of the two groups has been suggested by some authors.

Classification. The classification of the 8500 living species of decapods presents a difficult problem that has not yet been entirely solved. The chief disparity seems to lie between the shrimps (Natantia) and all of the other decapods (Reptantia). The classification listing is

- Order Decapoda
  - Suborder Natantia
    - Section Penaeidea
    - Section Caridea
    - Section Stenopodidea
  - Suborder Reptantia
    - Section Macrura
    - Section Anomura
    - Section Brachyura

Penaeidea. The primitive section of the Decapoda, penaeideans, is distinguished by the following characters: The pleura of the first abdominal somite overlap those of the second; the third legs are nearly always chelate, but are no stouter than the first pair; the first pleopods of the male bear a complicated flaplike appendix, the petasma; and the females have a spermatophore receptacle, the thelycum, on the ventral surface of the posterior thoracic somites. The best-known penaeideans, including most of the commercially important shrimps or prawns of the warmer seas (Penaeidae), live on muddy bottoms in shallow or moderate depths. However, they also occur both in the deep sea and as pelagic organisms in the mid-depths. There are more than 300 species of living penaeideans.

Caridea. This is the largest and most diverse group of shrimps and prawns. The pleura of the second abdominal somite overlap those of the first; the third legs are never chelate; there is no petasma or thelycum. The sexes can usually be distinguished by the presence, in the male, of two stylets on the inner edge of the inner branch of the second pleopods. Carideans occur in all parts of the sea, often in association with other marine animals. Members of at least two families, Atyidae and Palaemonidae, are also widespread in fresh water. The edible shrimps and prawns of northern Europe and of northwestern North America, of the genera *Crangon* and *Pandalus*, belong to the Caridea, as do the large fresh-water prawns of the tropical genus *Macrobrachium*. Most shrimps and prawns are favorite foods of fishes. Some carideans maintain "service stations" where they remove parasites from the outer skin, mouths, and gills of the fish. More than 1500 species of Caridea are known.

Stenopodidea. This is a small group of shrimps which superficially resemble the Penaeidea. The third pereiopods are chelate but are much longer and stouter than the first pair; the pleura of the second abdominal somite do not overlap those of the first; and there is no petasma or thelycum. All of the 20 or more living species are marine; some are closely associated with other animals, such as sponges.

Macrura. This long-tailed group of the Reptantia includes the deep-water and fossil eryonids, the spiny lobsters, the true lobsters, and the mud shrimps (Fig. 1). The abdomen is extended and bears a well-developed tail fan. There are about 700 known living species.

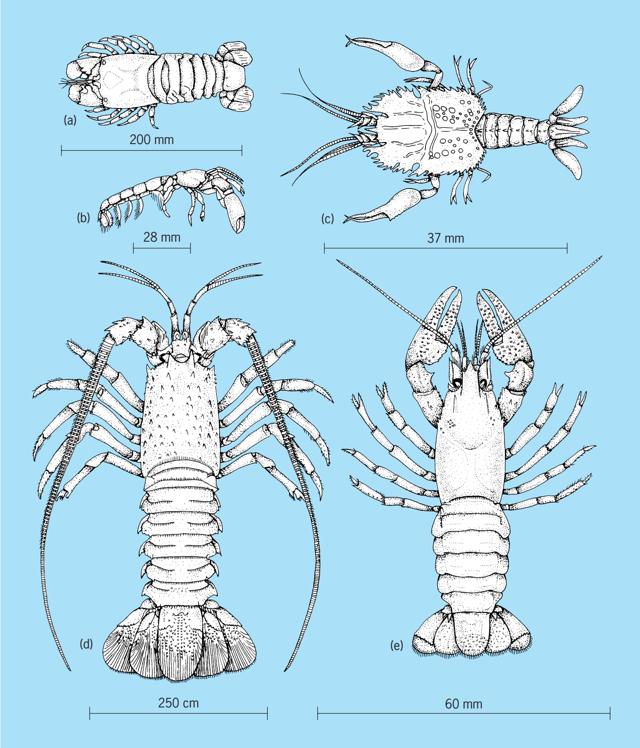


Fig. 1. Reptantian decapods. (*a*) Spanish lobster, *Scyllarides aequinoctialis*. (*b*) Mud shrimp, *Callianidea laevicauda*. (*c*) Eryonid, *Polycheles crucifer*. (*d*) Spiny lobster, *Panulirus interruptus*. (*e*) Crayfish, *Orconectes limosus*. (*Smithsonian institution*)

The Eryonidea are rather thin-shelled, blind inhabitants of the depths of the sea. The carapace is flattened dorsally and considerably expanded laterally. The first four, or all five, pairs of pereiopods are chelate, with the first pair much elongated. There are about 40 living species; the group was probably more numerous in ancient seas.

The Scyllaridea include the spiny lobsters or langoustes (Palinuridae) and the Spanish, or shovel-nosed, lobsters (Scyllaridae). They are heavily armored like the true lobsters but are distinguished by the absence of a rostrum and of chelae, except occasionally on the last pereiopod of the female. They are abundant in shallow and moderate depths of warm and temperate seas, where they are often of considerable commercial importance. There are about 85 Recent species.

The true lobsters and crayfishes, Nephropidea, also have a firm shell but are also characterized by a rostrum and by chelae on the first three pairs of pereiopods, with the first pair being noticeably larger than the others. Most lobsters (*Nephropidae*) are found in cool seas or in the cool, off-shore waters of the tropics. The most familiar lobsters (*Homarus*) are those found along the Atlantic coasts of Europe and North America. The Norway lobster of Europe (*Nephrops*) is also of some commercial importance but is smaller and less meaty. The crayfishes (Cambaridae, Astacidae, Parastacidae) are widespread in fresh waters of the temperate regions of all continents except Africa. They are of commercial importance in southern Europe and Australia. More than 300 living species of lobsters and crayfishes are known, more than half of them being from the fresh waters of the United States.

The mud shrimps, Thalassinidea, are usually thin-shelled, burrowing crustaceans with large, chelate or subchelate first pereiopods, and no chelae on the third pereiopods. More than 250 living species are found in shallow and deep seas throughout the world, especially in tropical and warm temperate regions.

Anomura. This intermediate, and possibly unnatural, group lies between the Macrura and the Brachyura. It includes the galatheids, the porcelain crabs or rock sliders, the hermit crabs, the king crabs, and the mole crabs or hippas. In nearly all of these diverse crustaceans, the first, and sometimes the last, pereiopods are chelate or subchelate. The abdomen is usually bent forward ventrally or is asymmetrical, soft, and twisted. There are about 1300 Recent species.

Brachyura. These are the true crabs (Fig. 2). The abdomen is symmetrical, without a tail fan, and bent under the thorax. The first pereiopods are always chelate or subchelate. The true crabs are as numerous as all other decapods combined, numbering nearly 4500 Recent species. They are divided into four subsections.

The Gymnopleura include about 30 species of primitive burrowing crabs; their carapaces are more or less trapezoidal or elongate, the first pereiopods are subchelate, and some or all of the remaining pereiopods are flattened and expanded for burrowing.

The Dromiacea is a primitive group of about 200 species. The first pereiopods are chelate; the last pair is dorsal in position and modified for holding objects, such as sponges, tunicates, and bivalve mollusk shells, over the crab.

In Oxystomata the first pair of pereiopods are chelate and the last pair are either normal or modified as in the Dromiacea. The oxystomes include the mask crabs (Dorippidae), the box

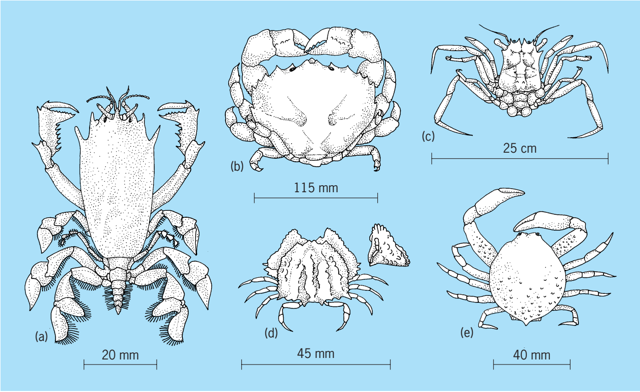

Fig. 2. Common brachyuran crabs. (*a*) Gymnopleuran crab, *Raninoides louisianensis*. (*b*) Dromilid crab, *Dromia erythropus*. (c) Mask crab, *Ethusa mascarone americana*. (*d*) Box crab, *Calappa sulcata*. (*e*) Purse crab, *Persephona punctata*. (*Smithsonian Institution*)

crabs (Calappidae), and the purse crabs (Leucosiidae). There are nearly 500 Recent species.

Most of the crabs, more than 3700 living species, belong to the Brachygnatha, in which the last pereiopods are rarely reduced or dorsal in position. To this group belong the swimming crabs (Portunidae). Also worthy of mention are freshwater crabs (Potamidae, Pseudothelphusidae, and Trichodactylidae), found in tropical and some temperate regions, usually in areas not inhabited by crayfishes. The crabs of the genus *Cancer* are large and abundant enough to be of commercial importance in northern Europe and North America. The rock, or Jonah, crabs of New England and the Dungeness crab of the Pacific Coast are familiar edible crabs of this genus. The ubiquitous little mud crabs (Xanthidae) are well known to every visitor to rocky shores. One of them, the stone crab (*Menippe*), is highly esteemed by connoisseurs of seafood. The pea crabs (Pinnotheridae) are often found in oysters and other bivalve mollusks. The square-backed crabs (Grapsidae) are characteristic of warm, marshy areas but are not restricted to that habitat; they mark the trend toward the true land crabs (Gecarcinidae), the depreciations and intrusions of which are familiar to all who live in the tropics. The ghost crabs (*Ocypode*), which scuttle almost unseen over sandy beaches, and the fiddler crabs (*Uca*) of muddy shores, are closely related. The end of the list is reached with the spider, or decorator, crabs (Majidae), slow-moving animals that often conceal themselves by attaching seaweeds and various sessile animals to their carapaces. One of them (*Macrocheira*) is the largest arthropod now alive. *See* ARTHROPODA; CRAB; CRUSTACEA. [F.A.Ch.]

Decibel

A logarithmic unit used to express the magnitude of a change in level of power, voltage, current, or sound intensity. A decibel (dB) is 1/10 bel.

In acoustics a step of 1 bel is too large for most uses. It is therefore the practice to express sound intensity in decibels. The level of a sound of intensity I in decibels relative to a reference intensity I_R is given by notation (1). Because sound intensity

$$10\ \log_{10} \frac{I}{I_R} \tag{1}$$

is proportional to the square of sound pressure P, the level in decibels is given by Eq. (2). The reference pressure is usually

$$10\ \log_{10} \frac{P^2}{{P_R}^2} = 20\ \log_{10} \frac{P}{P_R} \tag{2}$$

taken as 0.0002 dyne/cm^2 or 0.0002 microbar. (The pressure of the Earth's atmosphere at sea level is approximately 1 bar.) *See* BEL; SOUND PRESSURE.

The neper is similar to the decibel but is based upon natural (napierian) logarithms. One neper is equal to 8.686 dB. *See* NEPER; VOLUME UNIT (VU). [K.D.K.]

Deciduous plants

Plants that regularly lose their leaves at the end of each growing season. Dropping of the leaves occurs at the inception of an unfavorable season characterized by either cold or drought or both. Most woody plants of temperate climates have the deciduous habit, and it may also occur in those of tropical regions having alternating wet and dry seasons. Many deciduous trees and shrubs of regions with cold winters become evergreen when grown in a warm climate. Conversely, such trees as magnolias, evergreen in warm areas, become deciduous when grown in colder climates. *See* LEAF; PLANT PHYSIOLOGY; PLANT TAXONOMY. [N.A.]

Decision analysis

An applied branch of decision theory. Decision analysis offers individuals and organizations a methodology for making decisions; it also offers techniques for modeling decision problems mathematically and finding optimal decisions numerically. Decision models have the capacity for accepting and quantifying human subjective inputs: judgments of experts and preferences of decision-makers. Implementation of models can take the form of simple paper-and-pencil procedures or sophisticated computer programs known as decision aids or decision systems.

The methodology is rooted in postulates of rationality—a set of properties which preferences of rational individuals must satisfy. One such property is transitivity: if an individual prefers action *a* to action *b* and action *b* to action *c*, he or she should prefer *a* to *c*. From the rationality postulates, principles of decision-making are derived mathematically. The principles prescribe how decisions ought to be made, if one wishes to be rational. In that sense, decision analysis is normative.

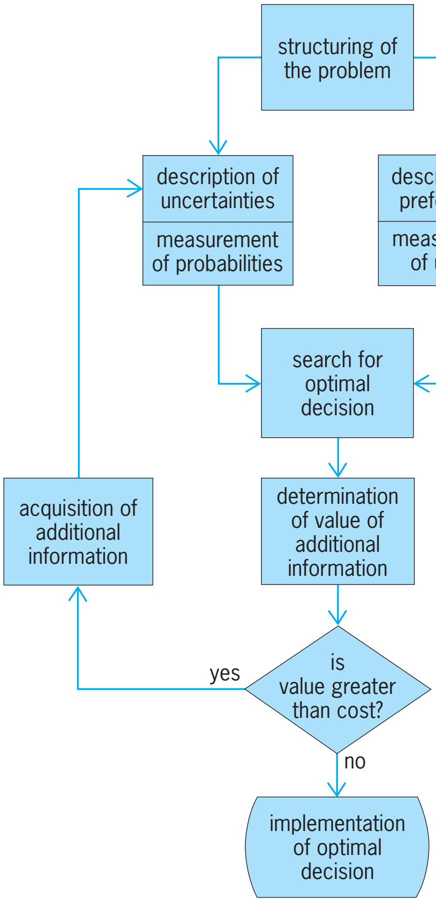
The methodology is broad and must always be adapted to the problem at hand. An illustrative adaptation to a class of problems known as decision-making under uncertainty (or risk) is outlined in the illustration and consists of seven steps:

1. The problem is structured by identifying feasible actions, one of which must be decided upon; possible events, one of which occurs thereafter; and outcomes, each of which results from a combination of decision and event. Problem structuring can be facilitated by displays such as decision trees and decision matrices.

2. At the time of decision-making, the event that will actually occur cannot be predicted perfectly. The degree of certainty about the occurrence of an event, given all information at hand, is quantified in terms of the probability of the event. *See* PROBABILITY.

3. Preferences are personal: the same outcome may elicit different degrees of desirability from different individuals. The subjective value that a decision-maker attaches to an outcome is quantified and termed the utility of outcome.

4. The preceding steps conform to the principle of decomposition: probabilities of events and utilities of outcomes must be measured independently of one another. They are next



A methodology of decision analysis.

combined in a criterion for evaluating decisions. The utility of a decision is defined as the expected utility of the outcome. The optimal, or the most preferred, decision is one with the maximum utility.

5. The probability encodes the current state of information about a possible event. Often, additional information can be acquired in the hope of reducing the uncertainty. The monetary value of such information is computed before purchase and compared with the cost of information. Thus, one can determine whether or not acquiring information is economically rational.

6. The source of information may be a real-world experiment, a laboratory test, a mathematical model, or the knowledge of an expert. The informativeness of the source is described in terms of a probabilistic relation between information and event. This relation, known as the likelihood function, makes it possible to revise the prior probability of the event and to obtain a posterior probability of the event, conditional on additional information. The revision is carried out via Bayes' rule.

7. Given the additional information, prior probabilities can be replaced by posterior probabilities, and the analysis can be repeated from step 4 onward. Steps 4–6 may be cycled many times, until the cost of additional information exceeds its value, at which moment the optimal decision is implemented.

Measurement of probability and utility functions is guided by principles of decision theory, statistical estimation procedures, and empirical laws provided by behavioral decision theory—a branch of cognitive psychology. *See* COGNITION; DECISION THEORY. [R.Krz.]

Decision support system A system that supports technological and managerial decision making by assisting in the organization of knowledge about ill-structured, semistructured, or unstructured issues. A structured issue has a framework comprising elements and relations between them that are known and understood. Structured issues are generally ones about which an individual has considerable experiential familiarity. A decision support system (DSS) is not intended to provide support to humans about structured issues since little cognitively based decision support is generally needed.

Emphasis in the use of a decision support system is upon provision of support to decision makers in terms of increasing the effectiveness of the decision-making effort. This support involves the systems engineering steps of formulation of alternatives, the analysis of their impacts, and interpretation and selection of appropriate options for implementations. *See* SYSTEMS ENGINEERING.

Decisions may be described as structured or unstructured, depending upon whether or not the decision-making process can be explicitly described prior to its execution. Generally, operational performance decisions are more likely than strategic planning decisions to be prestructured. Thus, expert systems are usually more appropriate for operational performance and operational control decisions, while decision support systems are more appropriate for strategic planning and management control. *See* EXPERT SYSTEMS.

The primary components of a decision support system are a database management system (DBMS), a model-base management system (MBMS), and a dialog generation and management system (DGMS). An appropriate database management system must be able to work with both data that are internal to the organization and data that are external to it. Model-base management systems provide sophisticated analysis and interpretation capability. The dialog generation and management system is designed to satisfy knowledge representation, and control and interface requirements. *See* DECISION THEORY. [A.P.Sa.]

Decision theory A broad range of concepts which have been developed to both describe and prescribe the process of decision making, where a choice is made from a finite set of possible alternatives. Normative decision theory describes how decisions should be made in order to accommodate a set of axioms believed to be desirable; descriptive decision theory deals with how people actually make decisions; and prescriptive decision theory formulates how decisions should be made in realistic settings. Thus, this field of study involves people from various disciplines: behavioral and social scientists and psychologists who generally attempt to discover elaborate descriptive models of the decision process of real humans in real settings; mathematicians and economists who are concerned with the axiomatic or normative theory of decisions; and engineers and managers who may be concerned with sophisticated prescriptive decision-making procedures.

Categories of problems. Efforts in decision theory may be divided into five categories:

1. Decision under certainty issues are those in which each alternative action results in one and only one outcome and where that outcome is sure to occur.

2. Decision under probabilistic uncertainty issues are those in which one of several outcomes can result from a given action depending on the state of nature, and these states occur with known probabilities. There are outcome uncertainties, and the probabilities associated with these are known precisely. *See* PROBABILITY.

3. Decision under probabilistic imprecision issues are those in which one of several outcomes can result from a given action depending on the state of nature, and these states occur with unknown or imprecisely specified probabilities. There are outcome uncertainties, and the probabilities associated with the uncertainty parameters are not all known precisely.

4. Decision under information imperfection issues are those in which one of several outcomes can result from a given action depending on the state of nature, and these states occur with imperfectly specified probabilities. There are outcome uncertainties, and the probabilities associated with these are not all known precisely. Imperfections in knowledge of the utility of the various event outcomes may exist as well.

5. Decision under conflict and cooperation issues are those in which there is more than a single decision maker, and where the objectives and activities of one decision maker are not necessarily known to all decision makers. Also, the objectives of the decision makers may differ.

Problems in any of these groupings may be approached from a normative, descriptive, or prescriptive perspective. Problems in category 5 are game theory-based problems. Most decision theory developments are concerned with issues in category 2. *See* GAME THEORY.

Bases of normative decision theory. The general concepts of axiomatic or normative decision theory formalize and rationalize the decision-making process. Normative decision theory depends on the following assumptions:

1. Past preferences are valid indicators of present and future preferences.

2. People correctly perceive the values of the uncertainties that are associated with the outcomes of decision alternatives.

3. People are able to assess decision situations correctly, and the resulting decision situation structural model is well formed and complete.

4. People make decisions that accurately reflect their true preferences over the alternative courses of action, each of which may have uncertain outcomes.

5. People are able to process decision information correctly.

6. Real decision situations provide people with decision alternatives that allow them to express their true preferences.

7. People accept the axioms that are assumed to develop the various normative theories.

8. People make decisions without being so overwhelmed by the complexity of actual decision situations that they would necessarily use suboptimal decision strategies.

Given these necessary assumptions, there will exist departures between normative and descriptive decision theories. A principal task of those aiding others in decision making is to retain those features from the descriptive approach which enable an acceptable transition from normative approaches to prescriptive approaches. The prescriptive features should eliminate potentially undesirable features of descriptive approaches, such as flawed judgment heuristics and information processing biases, while retaining acceptable features of the normative approaches. *See* DECISION ANALYSIS; DECISION SUPPORT SYSTEM.

Determination of utility. When choosing among alternatives, the decision maker must be able to indicate preferences among decisions that may result in diverse outcomes. In simple situations when only money is involved, an expected-value approach might be suggested, in which a larger expected amount of money is preferred to a smaller amount. However, in many situations the utility associated with money is not a linear function of the amount of money involved.

According to expected utility theory, the decision maker should seek to choose the alternative a_i which makes the resulting expected utility the largest possible. The utility u_{ij}, of choosing decision a_i and obtaining outcome event e_j, will also depend upon the particular value of the probabilistically uncertain random variable e_j as conditioned on the decision path that is selected. So, the best that the decision maker can do here is to maximize some function, such as the expected value or utility (EU), as shown below, where the maximization is carried out over all

$$\max_i \mathrm{EU}\{a_i\} = \max_i \sum_{j=1}^{n} u_{ij}\, P(e_j \mid a_i)$$

alternative decisions, and $P(e_j \mid a_i)$ is the probability that the state of nature is e_j given that alternative a_i is implemented. The notation $\mathrm{EU}\{a_i\}$ is often used to mean the expected utility of taking action a_i. Generally, this is also called the subjective expected utility (SEU). "Subjective" denotes the fact that the probabilities may be based on subjective beliefs and the utilities may reflect personal consequences. [A.P.Sa.]

Decomposition potential

The electrode potential at which the electrolysis current begins to increase appreciably. Decomposition potentials are used as an approximate characteristic of industrial electrode processes. *See* ELECTROCHEMICAL PROCESS; ELECTROLYSIS.

Decomposition potentials are obtained by extrapolation of current-potential curves. Extrapolation is not precise because there is a progressive increase of current as the electrode potential is varied. The decomposition potential, for a given element, depends on the range of currents being considered. The cell voltage at which electrolysis becomes appreciable is approximately equal to the algebraic sum of the decomposition potentials of the reactions at the two electrodes and the ohmic drop, or voltage drop, in the electrolytic cell. The ohmic drop term is quite negligible for electrolytes with high conductance. For a discussion of current-potential curves *see* OVERVOLTAGE. *See* ELECTROLYTIC CONDUCTANCE. [P.De.]

Decompression illness

Symptoms in humans which result from a sudden reduction in atmospheric pressure. It is also called dysbarism, caisson disease, the bends, and compressed-air illness. It is most commonly seen in two groups of subjects, (1) those who rapidly ascend in nonpressurized air-planes to altitudes in excess of 18,000 ft (5500 m), and (2) divers, scuba divers, sandhogs, and professional workers in hyperbaric chambers who work under increased ambient pressures and are decompressed. *See* DIVING.

This condition is caused by the formation of nitrogen bubbles in the tissues and blood vessels. These bubbles plug vessels and expand in tissue spaces producing the characteristic symptoms and signs of this illness. Helium, when present in high concentrations utilized by divers or found in some spacecraft, can also produce a similar condition.

The onset of symptoms may occur at any time from a few minutes to several hours after decompression. The most common manifestation is pain in the joints and muscles. However, skin, respiratory, and neurologic symptoms are not uncommon. The skin manifestations are itching, discoloration, and edema (swelling). Respiratory symptoms are coughing and dyspnea (difficulty in breathing). The neurologic symptoms vary from mild paresthesia (sensations of tingling, crawling, or burning of the skin) and weakness to total paralysis; loss of bladder and rectal sphincter control is common. The severe forms of this illness are followed by circulatory failure, paralysis, coma, and death.

Treatment is recompression, followed by gradual decompression to normal atmospheric pressure. Prognosis is generally good except in those subjects who show central nervous system damage. [McC.G.]

Decontamination of radioactive materials

The removal of radioactive contamination which is deposited on surfaces or spread throughout a work area.

Decontamination methods are mechanical or chemical. Commonly used mechanical methods are vacuum cleaning, sand blasting, blasting with solid carbon dioxide, flame cleaning, scraping, ultrasonic cleaning, vibratory finishing, and using lasers to vaporize contaminants.

Chemical methods are used primarily to decontaminate components and tools that are immersed in a tank, either by means of a chemical solvent to dissolve the contaminant, or by using electropolishing techniques to remove the surface layer, including contaminants, from metals. Chemical decontamination methods are also used to remove radioactive deposits from the interior surfaces of piping, pumps, heat exchangers, and boilers. For these applications, the solvent is pumped or flushed through the system, dissolving the radioactive deposits. The solution itself is then radioactive, and the contaminants are typically removed using filters or ion-exchange resins. The use of this approach to clean the coolant systems of nuclear reactors has become common. Dilute chemical reagents, including organic acids, are used to decontaminate the primary coolant systems of operating nuclear power plants to minimize radiation exposure of the workers.

Personnel decontamination methods differ from those used for materials primarily because of the possibilities of injury to the subject. Soap and water (sequestrants and detergents) normally remove more than 99% of the contaminants. If it is necessary to remove the remainder, chemical methods which remove the outer layers of skin can be used. These chemicals, such as citric acid, potassium permanganate, and sodium bisulfite, should be used with caution and preferably under medical supervision because of the risk of injury to the skin surface. It is very difficult to remove radioactive material once it is fixed inside the body, and the safest and most reliable way to prevent radiation exposure from contamination is the application of health physics procedures to prevent entry of radioactive material into the body. [C.J.W.]

Deep inelastic collisions

Either highly energetic collisions of elementary particles, namely, leptons and nucleons, which probe the nucleons' internal structure; or collisions between two heavy ions in which the two nuclei interact strongly while their nuclear surfaces overlap.

Elementary-particle collisions. Deep inelastic collisions of elementary particles are very energetic collisions between leptons such as electrons or neutrinos and nucleons (that is, protons or neutrons, typically in a nucleus) in which the target nucleon breaks up into many particles and the lepton is scattered through a large angle in the center-of-mass frame. These collisions are akin to the Rutherford scattering experiments in which most alpha particles went through a thin gold foil undeflected but some were deflected through large angles. In both cases, the explanation for large deflections is that the incident particle encounters not a uniform sphere of material but a few hard or pointlike objects inside the target. The alpha particles encounter gold nuclei, while leptons strike quarks inside the nucleons. *See* ALPHA PARTICLES; LEPTON; NUCLEON; QUARKS; SCATTERING EXPERIMENTS (NUCLEI).

Deep inelastic scattering experiments are conducted to study the structure of protons and neutrons. In each collision the fraction x of the nucleon's momentum carried by the struck quark is measured, and thus the x distributions of quarks inside a proton are directly measured. These are known as structure functions. Studies of these have shown, among other things, that the momentum of a proton is not carried entirely by quarks. In fact, only about half the momentum can be ascribed to quarks. The other half is believed to be carried by gluons, which are carriers of the strong force which binds the quarks within nucleons and other hadrons. *See* GLUONS.

Modern-day experiments in deep inelastic scattering often use neutrinos or muons as probes. Neutrinos have the advantage that they are not affected by the electric charge of the target nucleus and hence scatter directly off the quarks. Muons are easy to detect and identify. However, the highest-energy deep inelastic collisions are carried out by using an electron-proton collider. These experiments aim to study structure functions at very low values of x where some models predict new behavior. The highest-energy deep inelastic collisions use electrons as probes to search for quark substructure. [M.V.P.]

Heavy-ion collisions. Deep inelastic collisions of heavy ions are characterized by features that are intermediate between those of comparatively simple quasielastic, few-nucleon transfer reactions and those of highly complex compound-nucleus reactions. These deep inelastic or damped collisions often occur for heavy-ion reactions at center-of-mass energies less than 5 MeV per nucleon above the Coulomb barrier. During the brief encounter of the two nuclei, large amounts of kinetic energy of radial and orbital motion can be dissipated. The lifetime of the dinuclear complex (analogous to a chemical molecule) corresponds to the time required for the intermediate system to make a partial rotation (10^{-22} s to 5×10^{-21} s). On separation, the final total kinetic energies of the two reaction fragments can be well below those corresponding to the Coulomb repulsion of spheres, indicating that the fragments are highly deformed in the exit channel, as is known to be the case for fission fragments. *See* NUCLEAR FISSION. [J.R.Hu.]

Deep-marine sediments

The term "deep marine" refers to bathyal sedimentary environments occurring in water deeper than 200 m (656 ft), seaward of the continental shelf break, on the continental slope and the basin (see illustration). The continental rise, which represents that part of the continental margin between continental slope and abyssal plain, is included under the broad term "basin." On the slope and basin environments, sediment-gravity processes (slides, slumps, debris flows, and turbidity currents) and bottom currents are the dominant depositional mechanisms, although pelagic and hemipelagic deposition is also important. *See* BASIN; CONTINENTAL MARGIN; GULF OF MEXICO; MARINE SEDIMENTS.

Types of processes. The mechanics of deep-marine processes is critical in understanding the nature of transport and deposition of sand and mud in the deep sea. In deep-marine environments, gravity plays the most important role in transporting and depositing sediments. Sediment failure under gravity near the shelf edge commonly initiates gravity-driven deep-marine processes, such as slides, slumps, debris flows, and turbidity currents (see illustration). Sedimentary deposits reflect only depositional mechanisms, not transportational mechanisms. *See* SEDIMENTOLOGY.

A slide is a coherent mass of sediment that moves along a planar glide plane and shows no internal deformation. Slides represent translational movement. Submarine slides can travel hundreds of kilometers. For example, the runout distance of Nuuanu Slide in offshore Hawaii is 230 km (143 mi). Long runout distances of 50–100 km (31–62 mi) of slides are common.

A slump is a coherent mass of sediment that moves on a concave-up glide plane and undergoes rotational movements causing internal deformation.

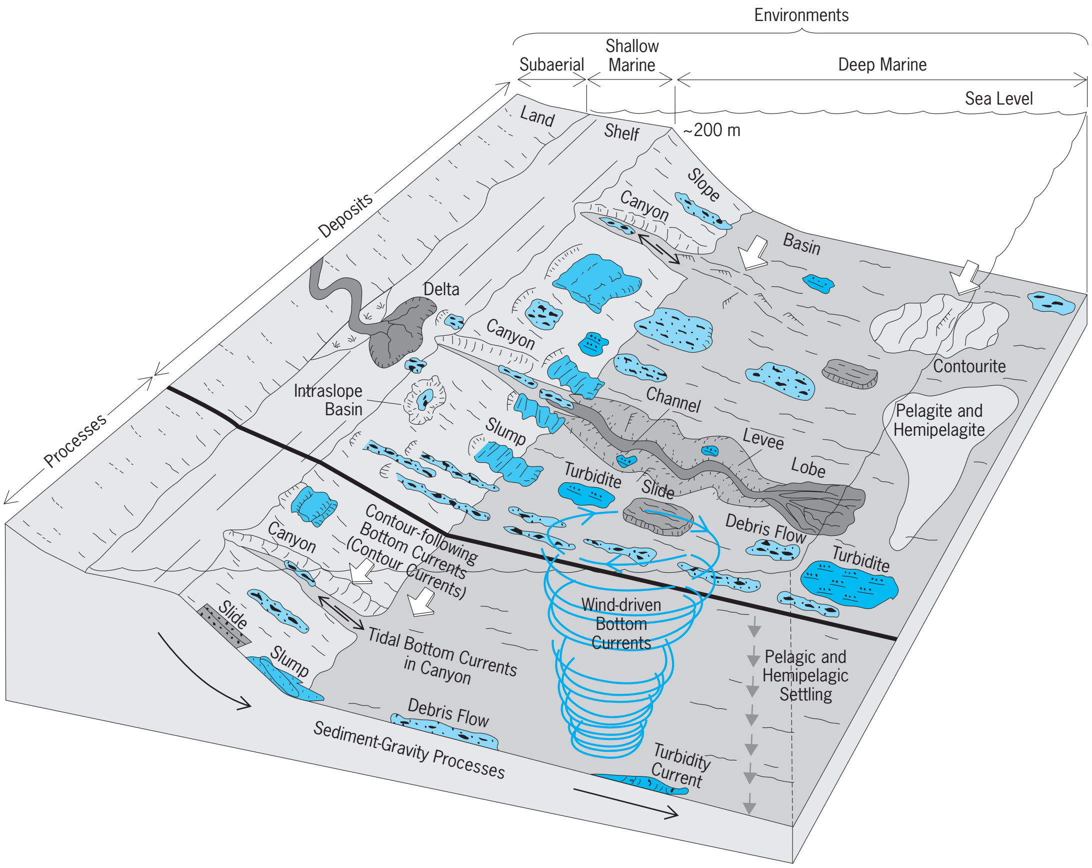
A downslope increase in mass disaggregation results in the transformation of slumps into debris flows. Sediment is now transported as an incoherent viscous mass, as opposed to a coherent mass in slides and slumps. A debris flow is a sediment-gravity flow with plastic rheology (that is, fluids with yield strength) and laminar state. Deposition from debris flows occurs through freezing. The term "debris flow" is used here for both the process and the deposit of that process. The terms "debris flow" and "mass flow" are used interchangeably because each exhibits plastic flow behavior with shear stress distributed throughout the mass. Although only muddy debris flows (debris flows with mud matrix) received attention in the past, recent experimental and field studies show that sandy debris (debris flows with sand matrix) flows are equally important. Rheology is more important than grain-size distribution in controlling sandy debris flows, and the flows can develop in slurries of any grain size (very fine sand to gravel), any sorting (poor to well), any clay content (low to high), and any modality (unimodal and bimodal). *See* RHEOLOGY.

With increasing fluid content, plastic debris flows tend to become turbidity currents. Turbidity currents can occur in any part of the system (proximal and distal), and can also occur above debris flows due to flow transformation in density-stratified flows. A turbidity current is a sediment-gravity flow with newtonian rheology (that is, fluids without yield strength) and turbulent state. Deposition from turbidity currents occurs through suspension settling. Deposits of turbidity currents are called turbidites. Although turbidity currents have received a lot of emphasis in the past, other processes are equally important in the deep sea (see illustration). In terms of transporting coarse-grained sediment into the deep sea, sandy debris flows and other mass flows appear to play a greater role than turbidity currents.

Bottom currents. In large modern ocean basins, such as the Atlantic, thermohaline-induced geostrophic bottom currents within the deep and bottom water masses commonly flow approximately parallel to bathymetric contours (that is, along the slope (see illustration). They are generally referred to as contour currents. However, because not all bottom currents follow regional bathymetric contours, it is preferred that the term "contour current" be applied only to currents flowing parallel to bathymetric contours, and other currents be termed bottom currents. For example, wind-driven surface currents may flow in a circular motion (see illustration) and form eddies that reach the deep-sea floor, such as the Loop Current in the Gulf of Mexico, and the Gulf Stream in the North Atlantic. Local bottom currents that move up- and downslope can be generated by tides and internal waves, especially in submarine canyons. These currents are quite capable of erosion, transportation, and redeposition of fine-to-coarse sand in the deep sea. *See also* GULF STREAM; OCEAN CIRCULATION.

Pelagic and hemipelagic settling. Pelagic and hemipelagic processes generally refer to settling of mud fractions derived from the continents and shells of microfauna down through the water column throughout the entire deep-ocean floor (see illustration). Hemipelagites are deposits of hemipelagic settling of deep-sea mud in which more than 25% of the fraction coarser than 5 micrometers is of terrigenous, volcanogenic, or neritic origin. Although pelagic mud and hemipelagic mud accumulate throughout the entire deep-ocean floor, they are better preserved in parts of abyssal plains (see illustration). Rates of sedmentation vary from millimeters to greater than 50 cm (20 in.) per 1000 years, with the highest rates on the upper continental margin.

Submarine slope environments. Submarine slopes are considered to be of the sea floor between the shelf-slope break



Slope and basinal deep-marine sedimentary environments occurring at water depths greater than 200 m (656 ft). Slides, slumps, debris flows, turbidity currents, and various bottom currents are important processes in transporting and depositing sediment in the deep sea. Note the complex distribution of deep-marine deposits.

and the basin floor (see illustration). Modern continental slopes around the world average 4°, but slopes range from less than 1° to greater than 40°. Slopes of active margins (for example, California and Oregon, about 2°) are relatively steeper than those of passive margins (for example, Louisiana, about 0.5°). On constructive continental margins with high sediment input, gravity tectonics involving salt and shale mobility and diapirism forms intraslope basins of various sizes and shapes (for example, Gulf of Mexico). Erosional features, such as canyons and gullies, characterize intraslope basins. Deposition of sand and mud occurs in intraslope basins. Slope morphology plays a major role in controlling deep-marine deposition through (1) steep versus gentle gradients, (2) presence or absence of canyons and gullies, (3) presence or absence of intraslope basins, and (4) influence of salt tectonics. *See* DIAPIR; EROSION.

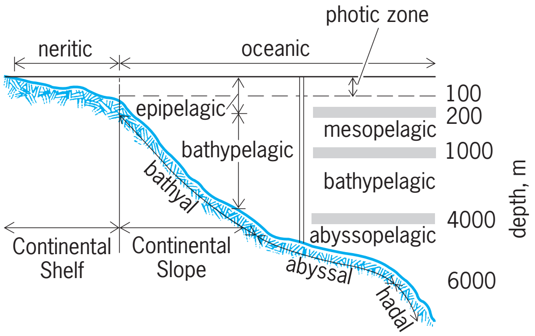
Submarine canyon and gully environments. Submarine canyons and gullies are erosional features that tend to occur on the slope. Although canyons are larger than gullies, there are no standardized size criteria to distinguish between them. Submarine canyons are steep-sided valleys that incise the continental slope and shelf. They serve as major conduits for transporting sediment from land and the continental shelf to the basin floor. Modern canyons are relatively narrow, deeply incised, steeply walled, often sinuous valleys with predominantly V-shaped cross sections. Most canyons originate near the continental shelf break and generally extend to the base of the continental slope. Canyons commonly occur off the mouths of large rivers such as the Hudson and Mississippi, although many others, such as the Bering Canyon in the southern Bering Sea, have developed along structural trends. *See* BERING SEA.

Modern submarine canyons vary considerably in their dimensions. Their average length of canyons has been estimated to be about 55 km (34 mi), although the Bering Canyon, the world's longest, is nearly 1100 km (684 mi). The shortest canyons are those off the Hawaiian Islands, with average lengths of about 10 km (6.2 mi). [G.Sh.]

Deep-sea fauna The deep sea may be regarded as that part of the ocean below the upper limit of the continental slopes (see illustration). Its waters fill the deep ocean basins, cover about two-thirds of the Earth's surface, have an average depth of about 12,000 ft (4000 m), and provide living space for communities of animals that are quite different from those inhabiting the land-fringing waters which overlie the continental shelves (neritic zone). *See* ECOLOGICAL COMMUNITIES.

The deep-sea fauna consists of pelagic animals (swimming and floating forms between the surface and deep-sea floor) and below these the benthos, or bottom dwellers, which live on or near the ocean bottom. Pelagic animals can be divided into the usually smaller forms that tend to drift with the currents (zooplankton) and the larger and more active nekton, such as squids, fishes, and cetaceans. Pelagic, deep-sea animals are frequently termed bathypelagic in contrast to the epipelagic organisms of the surface waters (see illustration). *See* ZOOPLANKTON.

All animal life in the sea, pelagic and benthic, depends on the growth of microscopic plants (phytoplankton). From the surface down to a maximum depth of about 300 ft (100 m) there is sufficient light for photosynthesis and vigorous phytoplanktonic growth. This layer is known as the photic zone. *See* PHYTOPLANKTON.



Classification of marine environments. Right side of diagram illustrates the proposal to divide the bathypelagic zone into mesopelagic, bathypelagic, and abyssopelagic zones. Division of benthic region into bathyal, abyssal, and hadal zones also is shown. 1 m = 3.3 ft.

Bathypelagic fauna. The typical bathypelagic animals begin to appear below depths of about 600 ft (200 m). The bathypelagic fauna is most diverse in the tropical and temperate parts of the ocean. Numerous species are found in all three temperature zones, but many appear to have a more limited distribution. Each species also has a definite vertical occurrence. Findings suggest that there are three main vertical zones, each with a characteristic community. Here the term bathypelagic is used for the fauna between about 3000 and 6000 ft (1000 and 2000 m), that above (between 600 and 3000 ft or 200 and 1000 m) being called mesopelagic and that below 6000 ft (2000 m) abyssopelagic (see illustration). The typical forms of the mesopelagic fauna (stomiatoids and lantern fishes) live in the twilight zone of the deep sea (between the 68 and 50°F or 20 and 10°C isotherms), while the bathypelagic species (ceratioid angler fishes and *Vampyroteuthis*) occur in the dark, cooler parts below the 50°F (10°C) isotherm.

Perhaps the most conspicuous feature of pelagic deep-sea life is the widespread occurrence of luminescent species bearing definite light organs (photophores). Many of the squids and fishes have definite patterns of such lights, as do some of the larger crustaceans (hoplophorid and sergestid prawns and euphausiids). Investigations have shown that flashes from luminescent organisms could be detected down to depths of 12,300 ft (3750 m). *See* Bioluminescence; Photophore gland.

Benthic fauna. There are two main ecological groups of bottom-living animals in the ocean: organisms that attach to the bottom and those that freely move over the bottom. The benthic fauna is most diverse in the temperate and tropical ocean, although the arctic and antarctic areas have their characteristic species. As in the pelagic fauna, certain species occur in all three oceanic zones, while others appear to have a more restricted occurrence. While a number of species—particularly among the polychaete worms, gastropod mollusks, and the brittle stars (Ophiuroidea)—range from littoral to abyssal regions, most forms tend to live within smaller ranges of depth. Data suggest that there are typical communities of animals over the continental slopes (see illustration) extending down to about 9000 ft (3000 m; bathyal zone); others occur below this in the abyssal zone. *See* Marine ecology. [N.B.M.]

Deep-sea trench A long, narrow, very deep, and asymmetrical depression of the sea floor, with relatively steep sides. Oceanic trenches characterize active margins at the ocean-basin–continent or ocean-basin–island-arc boundaries. They contain the greatest oceanic depths and are associated with the most active volcanism, largest negative gravity anomalies, most frequent shallow seismicity, and almost all of the intermediate and deep-focus earthquake activity. As the surface expression of the widely accepted process of subduction by which oceanic crustal material is returned to the upper mantle, they are key elements in current models of plate tectonic evolution on Earth and possibly on Venus. *See* Plate tectonics; Volcanology.

Deep-sea trenches are the signature relief form of the Pacific; in a counterclockwise direction, they occur from southern Chile to just northeast of North Island, New Zealand. A secondary or outer branch trends southward from near Tokyo Bay in a festoon of arcs to south of Palau. The principal gaps in the circum-Pacific chain are from Baja California to south-eastern Alaska, and off the northern coast of New Guinea. From eastern New Guinea to southern Vanuatu the trenches lie southwest, or “inside,” the island chains; otherwise their characteristics are like those facing the Pacific. The Indian Ocean contains only the very long contorted Sunda Trench that appears near the northwestern end of Sumatra and extends southeast and east past Timor, to curve north and west near Aru and end adjacent to Buru. In the Atlantic, the Puerto Rico–Antillean trench system extends outside the island arc from eastern Hispaniola around to Trinidad; but south of 14°N, off Barbados, the trench is filled with sediment. In the far South Atlantic a typical island-arc–trench complex extends from near South Georgia through the South Sandwich Archipelago.

A series of pioneering gravity observations with pendulum instruments on Dutch submarines during the 1920s and 1930s established that the East Indian trenches, and several others, were characterized by a belt of negative gravity anomalies of 150–200+ milligals, that is, values 150–200 parts per million less than normal, interpretable as deficiency of mass near and at their axes.

It was established that oceanic crust is thin, that crust under island arcs is thicker, and its layers display different sound transmission velocities, indicating different composition. Shipboard studies in the Middle America, Tonga, Cedros, Aleutian, Peru-Chile, and Sunda trenches established that the characteristic oceanic crustal layer [that is, 6.8–7.0 km/s (4.1–4.2 mi/s) compressional wave velocity] does not end or thin under the trench; rather, it may thicken slightly but does deepen steeply as it passes beneath the island arc or continental slope by the process of subduction. *See* Earth, gravity field of; Earth, heat flow in; Earth crust; Fault and fault structures; Oceanic islands; Seismology; Subduction zones. [R.L.Fl.]

Deer The name for 41 species of even-toed ungulates (artiodactylids) that comprise the distinct and homogeneous family Cervidae. The males have antlers, which are bony out-growths on their heads that do not contain horn, are generally branched, and are shed yearly. The feet have four toes and, as such, are less developed than those of other ruminants. The third and fourth digits are well developed, while the second and fifth are small and do not touch the ground.

Musk deer occur in the mountains of central Asia at high altitudes in Tibet, Korea, Mongolia, and Siberia. They are solitary animals and are active nocturnally. The male has a scent gland, known as a pod or musk gland, in the skin of the abdomen in front of the navel that secretes musk, used as a fixative in the perfume industry.

A number of species of deer that occur throughout Eurasia are called European deer. The red deer (*Cervus elaphus*), one of the best-known species, is still common throughout Europe and also is found in southwestern Asia and northwestern Africa. These deer are closely related to the wapiti of North America.

One of the best-known species of American deer is the white-tailed deer (*Odocoileus virginianus*), which is also known as the Virginia deer. This animal is found to range in North America and into South America as far as Peru, where it prefers woods and thickets to heavily forested areas. In the western states the mule deer (*O. hemionus*) may be distinguished from the white-tailed deer by the long ears, black-tipped tail, and greater tendency to occur in herds. These animals range from Alaska to New Mexico and prefer more open habitats. The wapiti or North American elk (*Cervus canadensis*) is more common in Canada than in the United States. The Key deer of the Florida Keys (*O. virginianus clavium*) is in danger of extinction because of the destruction of its habitat. *See* ARTIODACTYLA; MOOSE; REINDEER. [C.B.C.]

Definite composition, law of The law that a given chemical compound always contains the same elements in the same fixed proportions by weight. Thus, whatever its source, silver chloride always contains 100 g (3.53 oz) of silver to every 32.85 g (1.159 oz) of chlorine. If a compound is formed by the union of m atoms of one element, each weighing a, with n atoms of another element, each weighing b, the composition by weight of one molecule of the compound is in the ratio $ma{:}nb$. This must be the composition of any mass of the compound, provided that all atoms of the same kind have the same weight. It is now known that this is not usually the case but that the atoms of an element may consist of a number of isotopes, having different masses. However, as long as any sample of the element always contains the same relative proportions of the isotopes, the law still holds. Much more widespread and serious departures from the law of definite composition occur in a large variety of solid compounds (the nonstoichiometric compounds). *See* ISOTOPE; NONSTOICHIOMETRIC COMPOUNDS; STOICHIOMETRY. [T.C.W.]

Defoliant and desiccant Defoliants are chemicals that cause leaves to drop from plants; defoliation facilitates harvesting. Desiccants are chemicals that kill leaves of plants; the leaves may either drop off or remain attached; in the harvesting process the leaves are usually shattered and blown away from the harvested material. Defoliants are desirable for use on cotton plants because dry leaves are difficult to remove from the cotton fibers. Desiccants are used on many seed crops to hasten harvest; the leaves are cleaned from the seed in harvesting. Defoliants and desiccants have also been used during war to destroy vegetation. [A.S.C.]

Degaussing Neutralization of the magnetization of a ship by properly located and oriented current-carrying coils which produce a magnetic field of desired strength and direction. *See* DEMAGNETIZATION.

A steel ship has structural components of many different ferromagnetic characteristics. Many parts become magnetized during the construction, and retain that magnetization for a long time. Other parts are "soft" iron and do not retain a magnetized condition permanently but become magnetized by induction in the magnetic field of the Earth. The ship then has a magnetic field. This magnetization of the ship causes deviation of the magnetic compass and may trigger magnetic mines or other explosive devices when the ship passes near them. *See* MAGNETIZATION.

One method for neutralizing the magnetic field of the ship is to install coils in which currents are maintained to produce components of the field that will neutralize the field due to the magnetization of the ship. These coils are called degaussing coils. [K.V.M.]

Degeneracy (quantum mechanics) A term referring to the fact that two or more stationary states of the same quantum-mechanical system may have the same energy even though their wave functions are not the same. In this case the common energy level of the stationary states is degenerate. The statistical weight of the level is proportional to the order of degeneracy, that is, to the number of states with the same energy; this number is predicted from Schrödinger's equation. In quantum mechanics and in other branches of mathematical physics, the term degeneracy is employed also to characterize the eigenvalues of operators other than the energy operator. *See* EIGENVALUE (QUANTUM MECHANICS). [E.G.]

Degree-day A unit used in estimating energy requirements for building heating and, to a lesser extent, for building cooling. It is applied to all fuels, district heating, and electric heating. Origin of the degree-day was based on studies of residential gas heating systems. These studies indicated that there existed a straight-line relation between gas used and the extent to which the daily mean outside temperature fell below 65°F (18°C).

The number of degree-days to be recorded on any given day is obtained by averaging the daily maximum and minimum outside temperatures to obtain the daily mean temperature. The daily mean so obtained is subtracted from 65°F and tabulated. Monthly and seasonal totals of degree-days obtained in this way are available from local weather bureaus.

A frequent use of degree-days for a specific building is to determine before fuel storage tanks run dry when fuel oil deliveries should be made. Number of Btu which the heating plant must furnish to a building in a given period of time is

$$\text{Btu required} = \text{heat rate of building} \times 24 \times \text{degree-days}$$

where "Btu required" is the heat supplied by the heating system to maintain the desired inside temperature. "Heat rate of building" is the hourly building heat loss divided by the difference between inside and outside design temperatures. When the estimating procedure is applied to buildings with high levels of internal heat gains, as in a well-lighted office building, then degree-day data on other than a 65°F basis are required. *See* AIR CONDITIONING; COMFORT HEATING; PSYCHROMETRICS. [C.G.S.]

Degree of freedom (mechanics) Any one of the number of independent ways in which the space configuration of a mechanical system may change. A material particle confined to a line in space can be displaced only along the line, and therefore has one degree of freedom. A particle confined to a surface can be displaced in two perpendicular directions and accordingly has two degrees of freedom. A particle free in physical space has three degrees of freedom corresponding to three possible perpendicular displacements. A system composed of two free particles has six degrees of freedom, and one composed of N free particles has $3N$ degrees. If a system of two particles is subject to a requirement that the particles remain a constant distance apart, the number of degrees of freedom becomes five. Any requirement which diminishes by one the degrees of freedom of a system is called a holonomic constraint. *See* CONSTRAINT. [R.A.Fi.]

De Haas–van Alphen effect An oscillatory behavior of the magnetic moment of a pure metal crystal with changes in the applied magnetic field B, at very low temperatures. It is named after its discoverers, W. J. de Haas and P. M. van Alphen. This effect has its origin in the Bohr-Sommerfeld quantization of the orbits of conduction electrons under the influence of the magnetic field.

A measurement of the temperature dependence of the oscillation amplitude permits a determination of the cyclotron frequency, or equivalently the electron mass. In a metal, as in a semiconductor, electrons behave with an effective mass m^* rather than the free electron mass, and the de Haas–van Alphen effect thus allows a measurement of m^* in metals. *See* KINETIC THEORY OF MATTER.

Application of the Bohr-Sommerfeld quantization rules shows that the "period" of the de Haas–van Alphen oscillations (it is a period in magnetic field, not time) is given by the equation below. Here a_p is the area of the orbit in momentum space of

$$\Delta\left(\frac{1}{B}\right) = \frac{2\pi\hbar e}{a_p}$$

an electron at the Fermi level, that is, the cross section of the Fermi surface; e is the charge of the electron; and $\hbar$ is Planck's constant divided by 2π. By studying the dependence of a_p on the direction B of the magnetic field, sufficient information can be obtained to construct the detailed shape of the Fermi surfaces of a metal.

Virtually all metals available in sufficient purity have been studied by the de Haas–van Alphen effect. The effect is also the most powerful probe of Fermi surface properties in alloys and intermetallic compounds. *See* BAND THEORY OF SOLIDS; FERMI SURFACE. [J.B.K.]

Dehumidifier Equipment designed to reduce the amount of water vapor in the atmosphere. There are three methods by which water vapor may be removed: (1) the use of sorbent materials, (2) cooling to the required dew point, and (3) compression with aftercooling. *See* DEW POINT.

Sorbents are materials which are hygroscopic to water vapor. Solid sorbents include silica gels, activated alumina, and aluminum bauxite. Liquid sorbents include halogen salts such as lithium chloride, lithium bromide, and calcium chloride, and organic liquids such as ethylene, diethylene, and triethylene glycols and glycol derivatives.

Solid sorbents may be used in static or dynamic dehumidifiers. Bags of solid sorbent materials within packages of machine tools, electronic equipment, and other valuable materials subject to moisture damage constitute static dehumidifiers. A dynamic dehumidifier for solid sorbent consists of a main circulating fan, one or more beds of sorbent material, reactivation air fan, heater, mechanism to change from dehumidifying to reactivation, and aftercooler.

The liquid-sorbent dehumidifier consists of a main circulating fan, sorbent-air contactor, sorbent pump, and reactivator including contactor, fan, heater, and cooler. This unit will control the effluent dew point at a constant level because dehumidification and reactivation are continuous operations with a small part of the sorbent constantly bled off from the main circulating system and reactivated to the concentration required for the desired effluent dew point.

A system employing the use of cooling for dehumidifying consists of a circulating fan and cooling coil. The cooling coil may use cold water obtained from wells or a refrigeration plant, or may be a direct-expansion refrigeration coil. In place of a coil, a spray washer may be used in which the air passes through two or more banks of sprays of cold water or brine, depending upon the dew-point temperature required.

Dehumidifying by compression and aftercooling is used when the reduction of water vapor in a compressed-air system is required. This is particularly important, for example, if the air is used for automatic control instruments or cleaning of delicate machined parts. The power required for compression systems is so high compared to power requirements for dehumidifying by either the sorbent or refrigeration method that the compression system is not an economical one if dehumidifying is the only end result required. [J.E.]

Dehydrogenation A reaction in which hydrogen is detached from a molecule. The reaction is strongly endothermic, and therefore heat must be supplied to maintain the reaction temperature. When the detached hydrogen is immediately oxidized, two benefits accrue: (1) the conversion of reactants to products is increased because the equilibrium concentration is shifted toward the products (law of mass action); and (2) the added exothermic oxidation reaction supplies the needed heat of reaction. This process is called oxidative dehydrogenation. On the other hand, excess hydrogen is sometimes added to a dehydrogenation reaction in order to diminish the complete breakup of the molecule into many fragments.

The primary types of dehydrogenation reactions are vapor-phase conversion of primary alcohols to aldehydes, vapor-phase conversion of secondary alcohols to ketones, dehydrogenation of a side chain, and catalytic reforming of naphthas and naphthenes in the presence of a platinum catalyst. All four of these types of dehydrogenation reactions are of major industrial importance. They account for the production of billions of pounds of organic compounds that enter into the manufacture of lubricants, explosives, plastics, plasticizers, and elastomers. *See* HYDROGENATION; OXIDATION PROCESS. [J.W.Fu.]

Delay line A transmission line (as nearly dissipationless as possible) or an electric network approximation of it which, if terminated in its characteristic impedance, will reproduce at its output a waveform applied to its input terminals with little distortion but at a time delayed by an amount dependent upon the electrical length of the line.

Delay lines are also used for establishing a time sequence for the occurrence of events. A delay line with a total length equal to the greatest time delay required in a system may be used as a basic element. Pulses occurring at intermediate times may be obtained from taps at various points along the line. A specific application is found in the synchronizing signal generator of the television system. Also, the lumped-circuit delay line is an essential element of the wide-band distributed amplifier.

When a signal is digital in nature, or consists of a series of pulses, the series of pulses may be delayed by using a shift register, which might, for example, consist of a chain of cascaded type D flip-flops. If the register has n stages, the pulse series will appear at the output delayed by a time $(n - 1)T$, where T is the interval between consecutive pulses of the system timing clock. The same function can be realized by using switched-capacitor circuits or an array of charge-coupled devices. *See* CHARGE-COUPLED DEVICES; SWITCHED CAPACITOR; TRANSMISSION LINES. [G.M.G.]

Delayed neutron A neutron emitted spontaneously from a nucleus as a consequence of excitation remaining from a preceding radioactive decay event. Analogously, delayed emission of protons and alpha particles is also observed, but the known delayed neutron emitters are more numerous, and some of them have practical implications. In particular, they are of importance in the control of nuclear chain reactors.

In a ^{235}U nuclear reactor, about 0.7% of the neutrons are delayed, the others being prompt. In a conventional, moderated reactor, the prompt neutrons are born, slowed down, and reabsorbed to produce the next fissions in a cycling time of about 1 millisecond. (In a fast-neutron reactor, the time is much shorter.) Consequently, if the reactor were to become overcritical (more neutrons generated per millisecond than are absorbed or leak out), the chain reaction would exponentiate or "run away," and the reactor might overheat itself and possibly cause a dangerous accident unless the control rods could respond within a few milliseconds to correct the situation. The fortunate presence of the delayed neutrons eases the situation, because so long as the reactor operates within the margin of 0.7% ("delayed critical"), the control rods can take as long as several seconds to respond, and thus the chain reaction comes within the range of easy and leisurely control. *See* NEUTRON; NUCLEAR FISSION; REACTOR PHYSICS. [A.H.Sn.]

Deliquescence The absorption of atmospheric water vapor by a crystalline solid until the crystal eventually dissolves into a saturated solution. This behavior is well known for certain salts such as hydrated calcium chloride, $CaCl_2 \cdot 6H_2O$, and zinc chloride, $ZnCl_2$, but it is a property of all soluble salts in air of sufficiently high humidity.

Thermodynamically, the condition for deliquescence is that the partial pressure of the water vapor in the air exceeds the vapor pressure (aqueous tension) of the water in the saturated solution of the salt. The speed at which the process takes place depends upon the rate of diffusion of water vapor into the crystal lattice, crystal size, and other factors. The process will stop when the water vapor in the atmosphere is depleted to the point at which its partial pressure equals that of the saturated solution.

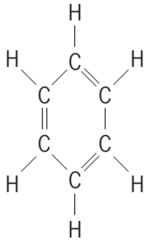
Crystalline solids also may absorb water by increasing their water of hydration if the dissociation pressure of the hydrated species to be formed is less than the partial pressure of the water vapor. It is this process, not deliquescence, which is the opposite of efflorescence.

Deliquescent substances can be used to remove water vapor from air, although they have no special advantage over substances which merely add water of hydration and remain crystalline. *See* Desiccant; Efflorescence; Vapor pressure. [R.L.S.]

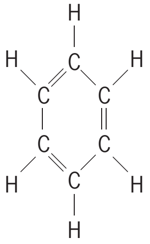
Delocalization A phenomenon in which the most loosely held bonding electrons of some molecules serve to bind not two but several atoms. This contrasts with localization, a characteristic of ordinary single bonds, as in the normal paraffins, for example, methane (CH_4); in ethane, (C_2H_6); or in the molecules water (H_2O) and ammonia (NH_3). *See* Chemical bonding.

The prototype completely delocalized system is the ideal crystalline metal, in which the valence electrons are spaced uniformly over a periodic lattice of positive-ion cores. This confers a special stability to the metal, and it also accounts for its high electrical conductivity and other metallic properties. *See* Metal.

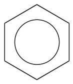
The aromatic and conjugated molecules of organic chemistry contain delocalized electronic systems. The benzene molecule (C_6H_6) is considered the archetypical aromatic molecule. Benzene possesses an underlying single-bonded planar framework $(C_6H_6)^{6+}$ plus six additional electrons. Available for these electrons are six $2p$ orbitals, one on every carbon atom, each perpendicular to the molecular plane. The six electrons, called pi electrons, are ascribable to the six carbon atoms in such a way that neither structure (**1**) nor structure (**2**) is wn accurate representation, but instead a structure that can be described in the valence bond language as a resonance hybrid of the two, schematically written as (**3**), where the circle stands for the delocalized electrons. All molecules containing such rings possess an extra stability associated with the delocalization phenomenon. As a consequence, they also have a low propensity for chemical reactivity. *See* Aromatic; Molecular orbital theory; Resonance (molecular structure). [R.G.P.]



(**1**)



(**2**)

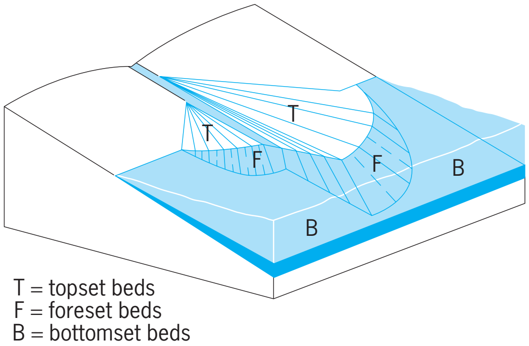


(**3**)

Delta A deposit of sediment at the mouth of a river or tidal inlet. It is also used for storm washovers of barrier islands and for sediment accumulations at the mouths of submarine canyons. *See* Floodplain.

The shape and internal structure of a delta depend on the nature and interaction of two forces: the sediment-carrying stream from a river, tidal inlet, or submarine canyon, and the current and wave action of the water body in which the delta is building. This interaction ranges from complete dominance of the sediment-carrying stream (still-water deltas) to complete dominance of currents and waves, resulting in redistribution of the sediment over a wide area (no deltas). This interaction has a large effect on the shape and structure of the delta body.

Most of the sediment carried into the basin is deposited when the inflowing stream decelerates. If there is little density contrast, this deceleration is sudden and most sediment is deposited near the mouth of the river. If the inflowing water is much lighter than the basin water, for example, fresh water flowing into a colder sea, the outflow spreads at the surface over a large distance away from the outlet. If the inflow is very dense, for instance, cold muddy water in a warm lake, it may form a density flow on or near the bottom, and the principal deposition may occur at great distance from the outlet.



Schematic diagram showing two stages of growth and a Gilbert-type delta. (*After P. H. Kuenen, Marine Geology, John Wiley, 1950*).

Three principal components make up the bodies of most deltas in varying proportions: topset, foreset, and bottomset beds (see illustration). As defined for most deltas, the topset beds comprise the sediments formed on the subaerial delta: channel deposits, natural levees, floodplains, marshes, and swamp and bay sediments. The foreset beds are those formed in shallow water, mostly as a broad platform fronting the delta shore, and the bottomset beds are the deep-water deposits beyond the deltaic bulge. In marine deltas the fluviatile influence decreases and the marine influence increases from the topset to the bottomset beds.

In a different way, deltas can be viewed as being composed of three structural elements: (1) a framework of elongate coarse bodies (channels, river-mouth bars, levee deposits), which radiate from the apex to the distributary mouths (sand fingers); (2) a matrix of fine-grained floodplain, marsh, and bay sediments; and (3) a littoral zone, usually of beach and dune sands which result from sorting and longshore transport of river-mouth deposits by waves, currents, tides, and wind. The relative proportions of these components vary widely. The Mississippi delta consists almost entirely of framework and matrix; its rapid seaward growth is the result of deposition of river-mouth bars and extension of levees, and the areas in between are filled later with matrix. This gives the delta its characteristic bird-foot outline. A different makeup is presented by the Rhone delta, where the supply of coarse material at the distributary mouths is slow, and dispersal by wave action and longshore drift fairly efficient, so that nearly all material is evenly redistributed as a series of coastal bars and dunes across a large part of the delta front. This delta advances as a broad lobate front, while the present Mississippi delta grows at several localized and sharply defined points.

Despite difficult engineering problems, many cities, such as Calcutta, Shanghai, Venice, Alexandria (Egypt), and New Orleans, were constructed on deltas. These problems include shifting and extending shipping channels; lack of firm footing for construction except on levees; steady subsidence; poor drainage; and extensive flood danger. Moreover, in certain deltas the tendency of the main flow to shift away to entirely different areas, with resulting disappearance of the main channels for water traffic, is a constant problem that is difficult and costly to counter. *See* Estuarine oceanography. [T.H.V.A.]

Delta electrons Energetic electrons ejected from atoms in matter by the passage of ionizing particles. In every primary ionizing collision between a charged particle and an atom, one or more electrons are ejected. Delta electrons are, by definition, that small fraction of these emitted electrons having energies which are large compared to the ionization potential. The name is a traditional one—comparable to alpha particles, for energetic helium nuclei, and beta particles, for energetic electrons emitted in radioactive decays. *See* ALPHA PARTICLES; BETA PARTICLES; IONIZATION.

Delta electrons are responsible for the "hairy" appearance of charged particle tracks when they are observed in cloud chambers or in photographic emulsions. In studies of super-high-energy particles in cosmic radiation and from the highest-energy accelerators, observation of the number of delta electrons per centimeter of path length has been shown to lead to a reliable determination of the charge of the energetic particle. [D.A.B.]

Delta resonance A member of a class of subatomic particles called baryons, which exists in four electric charge states and has a total spin of $J = {}^3\!/_2$. In the underlying quark model, the delta resonance (Δ) consists of three quarks whose intrinsic spins of ${}^1\!/_2$ are lined up in the same direction. The Δ is closely related to the more familiar nucleon constituents of atomic nuclei, the neutrons (n) and protons (p). *See* NUCLEON; QUARKS.

The Δ was first observed as a resonant interaction of a beam of pi mesons (π) with a proton target. The probability of a scattering interaction between the π and the proton is strongly dependent on energy, attaining a maximum at the Δ mass of 1236 MeV/c^2 (where c is the speed of light). The formation of the very short-lived Δ (with a lifetime on the order of 10^{-23} s) followed immediately by its decay back into pion and nucleon. *See* MESON; SCATTERING EXPERIMENTS (NUCLEI).

The Δ plays an important role in a wide variety of nuclear phenomena, even under conditions of low energy and momentum transfer. The study of these phenomena reveals much about the presence of pions in nuclei, in addition to neutrons and protons. *See* BARYON; ELEMENTARY PARTICLE; NUCLEAR STRUCTURE. [C.D.]

Demagnetization The reduction or elimination of the magnetic moment in an object; that is, the reverse of magnetization. It is commonly encountered as a procedure for eliminating the inadvertent magnetization of iron (or other ferromagnetic) parts of a sensitive mechanical device that would otherwise result in a malfunction. A suitably intense magnetic field applied in a direction opposite to that of the existing magnetization will serve to reduce or destroy that magnetization. (Alternatively, the material could, if practical, be heated to a temperature above its Curie point, then returned to room temperature, in the absence of any external magnetic field.) The adiabatic (isentropic) demagnetization of paramagnetic materials is a technique used to produce temperatures very near absolute zero. It has been used to cool and study a magnetic substance itself or, through thermal contact, a secondary substance (refrigeration). *See* ADIABATIC DEMAGNETIZATION; FERROMAGNETISM; MAGNETIZATION. [R.P.Hu.]

Demodulator A device used to recover the original modulating signal from a modulated wave. A demodulator is also known as a detector.

In communications systems and in some automatic control systems, the information to be transmitted is first impressed upon a periodic wave called a carrier. The carrier is then said to be modulated. After reception of the modulated carrier, the original modulating signal is recovered by the process of demodulation or detection.

The amplitude, frequency, or phase of a carrier may be changed in the modulation process. Therefore, the process of demodulation and the practical circuits for accomplishing it differ in each case. However, all demodulators require the use of a nonlinear device in order to recover the original modulating frequencies, because these frequencies are not present in the modulated carrier and new frequencies cannot be produced by a linear device. *See* AMPLITUDE MODULATION; FREQUENCY MODULATION; PHASE MODULATION.

A semiconductor diode is frequently used to demodulate an amplitude-modulated (AM) carrier. A simple filter consisting of capacitance and resistance is used to eliminate the carrier and other undesired frequencies from the output of the demodulator. Another common AM detector uses a multiplier circuit, available as a semiconductor chip. A square-law detector is often used to demodulate single-sideband (SSB) signals. A multiplier chip with both inputs tied together serves nicely as a squaring circuit and may be used as a low-distortion demodulator for SSB signals. *See* AMPLITUDE-MODULATION DETECTOR; ELECTRIC FILTER; RECTIFIER; SEMICONDUCTOR DIODE; SINGLE SIDEBAND.

Frequency-modulated (FM) signals and phase-modulated (PM) signals may generally be demodulated by the same type of circuits, the only difference being the filter circuits in their respective outputs.

There are two basic classes of FM or PM demodulators. The first type, known as discriminators, use tuned circuits to change frequency or phase variations into amplitude variations and then use amplitude-demodulating devices such as diodes or a multiplier to recover the modulating frequencies. The second class or type of FM demodulator is the phase-locked loop, which includes a phase detector that may be a multiplier, a low-pass filter, and a voltage-controlled oscillator that produces a frequency proportional to its control voltage. The output of the phase detector is proportional to the phase difference between the incoming FM or PM signal and the voltage-controlled oscillator output. This phase detector output, after filtering, is the desired original modulating signal and also provides the control voltage needed to keep the voltage-controlled oscillator locked to the incoming signal frequency. These phase-locked loops are available as integrated semiconductor circuits, or chips. *See* FREQUENCY-MODULATION DETECTOR; PHASE-MODULATION DETECTOR.

Amplitude modulation and demodulation may be accomplished with the same device. For example, a multiplier performs both of these functions. In addition, phase-locked loops incorporate all the basic circuits needed for the modulation and demodulation of FM, PM, and AM signals. Therefore, circuits have been devised that will either modulate or demodulate FM, PM, and AM signals. These circuits are known as modems and are commonly used in modern communications systems. *See* MODEM.

A carrier wave may be modulated in both amplitude and phase simultaneously when a digital signal is being transmitted. The commonly used system employing this technique uses a 90° phase modulation and a two-level amplitude modulation and is called quadrature amplitude modulation (QAM).

The development of optical demodulators came with the advent of optical-frequency communications systems. *See* MODULATION; MODULATOR; OPTICAL COMMUNICATIONS; OPTICAL DETECTORS. [C.L.A.]

Demospongiae A class of the phylum Porifera, including sponges with a skeleton of one- to four-rayed siliceous spicules or of spongin fibers or both. Several genera lack a skeleton. The Demospongiae constitute the most abundant and widely distributed group of sponges, occurring in the sea from the tidal zone down to abyssal depths (at least to 18,000 ft or 5500 m). One family has invaded fresh water. The species vary in size from thin encrustations several centimeters in diameter to huge cake-shaped forms which may measure up to as much as 6.5 ft (2 m) in diameter. *See* PORIFERA.

Comparative studies of the embryology and early attached stages of sponges of the class Demospongiae suggest at least two evolutionary lines within this group: the subclass Ceractinomorpha and the subclass Tetractinomorpha. [W.D.H.]

Dendritic macromolecule A large molecule having a well-defined three-dimensional structure. Dendritic macromolecules play a crucial role in the chemistry of living systems. In contrast to the high level of structural precision that characterizes many biologically active macromolecules, the sizes and shapes of macromolecules made by polymer chemists are usually far less controlled. Most synthetic polymers are best described as statistical mixtures. However, chemists have sought to develop ways to prepare large molecules with more control over their architecture. If properly designed, such molecules might be capable of performing chemical or physical functions reminiscent of the macromolecules found in living systems.

Dendritic macromolecules are characterized by a highly branched molecular connectivity, whereby each repeat unit forms a branch juncture. The monomers used to prepare dendrimers possess three or more functional groups, and are of the type AB_2, AB_3, and so forth, where A and B represent a functionality (a site of chemical activity) that can combine to form a new covalent bond. Monomer chemistry is thus similar to that used to make condensation polymers except that the functionality is higher (there are more sites of chemical activity). *See* POLYMER.

The architectures of dendritic macromolecules are dramatically different from those of conventional macromolecules. Variations in molecular size, shape, and flexibility are all possible, depending on the monomer's chemical structure and geometry, the branch-point multiplicity, and the number of repetitive cycles carried out. The architecture most typical of dendritic macromolecules is a globular shape where segment density increases in going from the core to the periphery. The unusual structure of dendritic macromolecules, yet to be fully investigated, results in rheological and solubility characteristics that are dramatically different from linear macromolecules. [J.S.Mo.]

Dendroceratida A small order of sponges of the class Demospongiae. Members of this order either have a skeleton of spongin fibers or lack a skeleton. The spongin fibers, when present, are typically dendritic in form, seldom anastomosing to form a network, and arise from a basal plate of spongin adherent to the substratum. The fibers, which in most genera lack foreign inclusions such as sand grains, are made up of concentric layers of spongin, new layers apparently being added throughout the life of the sponge. The flagellated chambers are large and sac-shaped and open directly into the exhalant canals without the intervention of a special channel. Dendroceratid sponges occur chiefly in tidal and shallow coastal regions of all seas. [W.D.H.]

Dendrochronology The science that uses annual tree rings dated to their exact year of formation for dating historical and environmental events and processes. Trees, like most plants, are sensitive to both natural (precipitation and temperature patterns) and human-related (air and water pollution) events that trigger certain responses in the vigor of the tree as seen in its growth rate. In most geographic regions, climate patterns in any year cause a response by trees in the volume of wood the tree produces, and often leave indelible "fingerprints" in certain physical and chemical properties of the wood. These fingerprints can be seen in the varying widths of tree rings. In some years, environmental conditions may be favorable for tree growth, allowing trees to produce greater volumes of wood. In other years, climate conditions may be generally unfavorable for tree growth, causing a reduction in the volume of wood produced. *See* DENDROLOGY; TREE; TREE GROWTH.

Crossdating is the primary guiding principle in dendrochronology, and concerns the matching of patterns of ring widths from one tree with corresponding patterns for the same years from another tree. Crossdating allows scientists to accurately assign calendar dates to tree rings by matching the sequence of tree-ring widths against a known reference chronology. Crossdating is possible because climate is largely a regional phenomenon, affecting trees in a like manner, so that similar patterns of ring widths are produced among many trees. Furthermore, crossdating helps identify false and locally absent rings that may otherwise be recorded as true rings.

Dendrochronology has become a useful tool in many areas of research. Dendroarcheology uses tree rings to date wood material from archeological sites or artifacts, and is most often applied in the southwestern United States and Europe. In dendroclimatology climatic information is mathematically extracted from the tree-ring record and reconstructed back in time for the length of the tree-ring record. Dendroclimatologists also use tree-ring records to quantify the rising levels of atmospheric carbon dioxide to better understand global warming. Dendroecology analyzes changes in ecological processes over time using tree-ring information. Dendropyrochronology reconstructs the history of wildfires from tree rings. Dendrogeomorphology studies earth surface processes using tree-ring data. Dendrohydrology uses tree-ring data to investigate and reconstruct hydrologic properties, such as streamflow and riverflow, runoff, and past lake levels. Dendrochemistry is an important, emerging field of dendrochronology that analyzes the chemical composition of tree rings, especially the mineral elements. *See* ANALYTICAL CHEMISTRY; ARCHEOLOGY; ECOLOGY; GEOMORPHOLOGY; HYDROLOGY. [H.D.G.M.]

Dendrology The division of forestry concerned with taxonomy of trees and other woody plants. Dendrology, called forest botany in some countries, usually is limited to taxonomy of trees but may also include shrubs and woody vines. This basic subject in the training of foresters teaches how trees are named (nomenclature), described (morphology), and grouped (classification); how to find the name of an unknown tree and recognize important forest species (identification); and where trees occur both by geographic ranges of species and by forest types (distribution). Forest stands of similar composition, appearance, and structure are grouped together into areas characterized by major forest types or formation, and are named from the predominant or characteristic species. *See* FOREST AND FORESTRY; PLANT TAXONOMY. [E.L.L.]

Density The mass per unit volume of a material. The term is applicable to mixtures and pure substances and to matter in the solid, liquid, gaseous, or plasma state. Density of all matter depends on temperature; the density of a mixture may depend on its composition, and the density of a gas on its pressure. Common units of density are grams per cubic centimeter, and slugs or pounds per cubic foot. The specific gravity of a material is defined as the ratio of its density to the density of some standard material, such as water at a specified temperature, for example, 60°F (15.6°C), or, for gases the basis may be air at standard temperature and pressure. Another related concept is weight density, which is defined as the weight of a unit volume of the material. *See* DENSITY MEASUREMENT; MASS; WEIGHT. [L.N.]

Density matrix A matrix which is constructed as the most general statistical description of the states of a many-particle quantum-mechanical system. The state of a quantum system is described by a normalized wave function $\psi(x, t)$ [where x stands for all coordinates of the system, and t for the time], which satisfies the Schrödinger equation (1), where H is the hamiltonian

$$H\psi(x,t) = \frac{h}{i}\,\frac{\partial\psi(x,t)}{\partial t} \qquad (1)$$

of the system, and $\hbar$ is Planck's constant divided by 2π. Furthermore, $\psi(x, t)$ may be expanded in terms of a complete orthonormal set $\{\varphi(x)\}$, as in Eq. (2). Then, the density matrix is defined by Eq. (3), and this density matrix describes a pure

$$\psi(x,t) = \sum_n a_n(t)\varphi_n(x) \qquad (2)$$

$$\rho_{mn}(t) = a_n^*(t)a_m(t) \qquad (3)$$

state. Examples of pure states are a beam of polarized electrons and the photons in a coherent beam emitted from a laser. *See* LASER; QUANTUM MECHANICS.

In quantum statistics, one deals with an ensemble of N systems which have the same hamiltonian. If the αth member of the ensemble is in the state ψ^α in Eq. (4), the density matrix is defined as the ensemble average, Eq. (5). In general, this density matrix

$$\psi^\alpha(x,t) = \sum_n a_n{}^\alpha(t)\varphi_n(x) \tag{4}$$

$$\rho_{mn}(t) = \frac{1}{N}\sum_\alpha [a_n{}^\alpha(t)]^*\, a_m{}^\alpha(t) \tag{5}$$

describes a mixed state, for example, a beam of unpolarized electrons or the photons emitted from an incoherent source such as an incandescent lamp. The pure state is a special case of the mixed state when all members of the ensemble are in the same state. *See* STATISTICAL MECHANICS. [S.H.L.]

Density measurement Determination of the mass per unit volume of a substance. The term density is equally applicable to solids (including powders), liquids, and gases. Usually values of density are given in terms of grams per cubic centimeter or pounds per cubic foot. The density of all substances depends on temperature; in the case of gases, on temperature and pressure. The temperature used as a base for determining or reporting values of density is not the same for all substances. For solids 32°F (0°C) is the preferred temperature, although some tables give values at average room temperature because the effect of temperature on density is relatively small for most solids. The effect of temperature on density is more pronounced in liquids, so that the temperature must always be stated along with the density value. For many liquids the reference temperature is 60°F (15.6°C). For gases 32°F and a pressure of 29.921 in. of mercury (or 0°C and 760 mm of mercury or 101.325 kilopascals) are used for most scientific work and for tables of gas data. For fuel gases 60°F (15.6°C) and a pressure of 14.73 lb/in.^{2} absolute (29.99 in. mercury or 101.56 kPa) are the values used in the United States.

In the case of a solid, if the sample is of regular shape, such as a cube or a cylinder, its volume may be determined by linear measurement. The mass of the sample is determined by weighing it on a suitable scale or balance; then this weight divided by the volume gives the density. Ordinarily the weighing is done in air, and the density value is the density in air, or apparent density. By adjusting for the buoyant effect of the air upon the weight of the sample, the real density is obtained.

A second procedure, applicable to irregular as well as regular shaped samples, is to weigh the sample in air and then to suspend it in a liquid of known density. The volume of the sample is equal to its loss of weight in the liquid divided by the density of the liquid. This is the method of hydrostatic weighing.

One method to determine the density of a gas is to completely evacuate a light but strong vessel of suitable size, the interior volume of which is known. The evacuated vessel is weighed, filled with a sample of the gas, and then weighed again. Of course the pressure and temperature of this sample of gas must be obtained.

A densitometer or gravitometer may be used to indicate and record the density of a flowing stream of a liquid or a gas. In a densitometer, a spinning propeller produces a pressure difference between inlet and outlet chambers of the device, which is proportional to the density of the gas flowing through it. [H.S.B.]

Two precision methods, the oscillator or vibrator method and the magnetic method, have emerged which allow more rapid and accurate determinations on liquid systems.

In the oscillator method, the density of a sample is related to the change in resonance frequency of a laterally vibrating tube. This frequency is inversely proportional to the square root of the mass of the tube and its contents. By calibrating the tube with media of known density at a given temperature, the density of unknown solutions may be determined if the volumes are strictly indentical. It is now established, that the accuracy of this method decreases as the viscosity of the medium increases. Hence, accurate viscosity measurements must accompany the density calibrations for a given instrument.

The instruments used in the magnetic method are called magnetic densimeters. This densimeter is a device whereby a tiny ferromagnetic cylinder, encased in a glass or plastic jacket, is held at a precise height within a medium by virtue of a solenoid controlled by a servo system in circuit with a height sensor. The jacket and ferromagnetic material constitute a buoy or float. The solenoid induces a magnetic moment M at the buoy which is proportional to the electric current I to the solenoid. The total magnetic force on the buoy is the product of this moment and the field gradient, dH/dz, where H is the magnetic intensity and z is the vertical distance from the center of the solenoid. The field gradient varies with z and is also proportional to the current. Thus the total magnetic force at a particular distance z in the solution which compensates for the difference in the opposing forces of gravity (downward) and the buoyancy (upward) exerted by the medium, through Archimedes' principle, is $M\ (dH/dz)$. The magnetic force, under proper conditions, is directly proportional to the square of the current, which can be measured very accurately. Thus $M(dH/dz) = kI^2$, where k is a constant. If the buoyant force on the buoy is sufficient to make it float on the liquids of interest, the force generated by the solenoid must be downward to add to the force of gravity. The equation relating these forces is shown below, where, V_B is the volume of the buoy, g is

$$M\left(\frac{dH}{dz}\right) = gV_B\rho - gV_B\rho_B = gV_B(\rho - \rho_B)$$

the acceleration of gravity, and ρ and ρ_B are the densities of the solution and the buoy, respectively. By means of a precision resistor and an accurate differential voltmeter, the measurements consist simply of reading or recording the voltage, which is a parabolic function of the density. [D.W.Ku.]

Dental anthropology The scientific study of people, with their living and extinct primate relatives, using the evidence of teeth. Dental anthropologists include not only those trained in anthropology but also practicing dentists, anatomists, radiologists, forensic scientists, biochemists and geneticists, archeologists, paleontologists, and zoologists.

The deciduous (milk) teeth and permanent (adult) teeth make up the dentition. They have their own distinctive patterns of development, physiology, size and shape, disease, and changes with age, all very different from the bones of the skeleton. In particular, the three tissues of the teeth—enamel, dentine, and cement—do not turn over continuously as do bone and most other tissues of the body. This means that, even in adults, tooth form is more clearly related to the gene-mediated control of development than a structure such as a bone, which is modified throughout life in response to changing physiological factors and mechanical loadings. Another effect of this conservation of original tooth structure is that the layered pattern of growth in dental tissues is preserved throughout life, so that childhood development can be studied even in adults. For archeologists and paleoanthropologists, there is a further advantage in the study of teeth—they are exposed in the mouth. Their adaptation to this harsh, abrasive environment in life ensures that they are the toughest part of the body, and survive relatively unchanged in a wide variety of burial environments. The majority of fossils are teeth and jaws. In addition, teeth bear many traces of the diet and life-style of their owners. Furthermore, teeth are easily studied in living people and animals by direct observation, by taking dental impressions (casts), or by examining teeth extracted in dental surgeries.

For many dental anthropologists, the core of the subject is tooth morphology. Identification of different primate species is most readily done from tooth form in archeological and fossil material. Among the higher primates as a whole, males tend to have larger teeth than females, particularly the canine teeth. Even modern humans show this to a small extent, and it helps to distinguish between the sexes in archeological and forensic remains. The cusps, ridges, and furrows that decorate the crown surface also vary within different species of primates, together with the number and form of tooth roots. The different forms have characteristic frequencies for different populations of living people, and are used to investigate their relationships and history in comparison with archeological groups. *See* DENTISTRY; TOOTH. [S.Hi.]

Dental caries A disease in which the mineralized tissues of the tooth undergo progressive destruction from the surface of the tooth. It is caused by bacteria that colonize the tooth surface and, under certain conditions, produce sufficient acids to demineralize the enamel covering of the tooth crown or the cementum covering the root, and then the underlying dentin. As the destruction of the dentin progresses, along with breakdown of the organic components, the bacteria invade the dead tissue and enter the pulp chamber. The pulpal tissue becomes infected and the typical toothache may ensue. The infection can ultimately destroy the pulpal tissue and extend through the apical openings of the roots and into the surrounding peri-odontal tissues.

The sites of caries development have been correlated with the presence of dental plaque containing one of a number of mutans streptococci—notably in humans. *Streptococcus mutans* and *S. sobrinus.* These microorganisms are cariogenic because of their ability to generate a considerable amount of acid as a result of their metabolism of carbohydrates, and to survive in an acid environment. The acid environment is only slowly neutralized since its dilution is hindered by the fact that the acid is within the dental plaque and thereby shielded from the saliva. Each time a carbohydrate-rich substance is ingested, acid is formed. Therefore, the frequency of ingestion and physical consistency of fermentable carbohydrates are important factors in caries formation. *See* MICROBIOLOGY; TOOTH.

Dental caries can be prevented by making the tooth less susceptible to acid attack, removing cariogenic bacteria from the teeth, and limiting ingestion of cariogenic substrate.

The most effective and least expensive means of rendering the tooth less susceptible to the caries attack is through fluoridation, either by systemic means such as water fluoridation, or by topical application of fluoride to the tooth surfaces. Water fluoridation (approximately 1 part per million) by itself reduces the incidence of caries by 50–60%. Topical fluoridation can be instituted by many means, ranging from professional applications in the dental office to self-applied fluoride in the form of toothpastes, mouth rinses, and gels. The mode of action of fluoridation is not fully understood, but the benefit to the tooth structure is probably a result of a number of actions. It is believed that fluoride, when incorporated into the mineral phase of enamel and the other hard tissues, results in a better crystalline structure that is less susceptible to acid dissolution. Alternatively, the anticaries effect of fluoride may be due to its ability to inhibit demineralization and promote remineralization. Other means of improving the tooth's resistance to dental caries include the application of plastic pit and fissure sealants which eliminate retentive areas on the biting surfaces of the posterior teeth that are more susceptible to carious lesions. [M.R.R.]

Dentistry An autonomous branch of biomedical science that is concerned with the prevention, diagnosis, and treatment of diseases and abnormalities of the teeth, jaws, oral cavity, and adjacent structures.

Dental caries (tooth decay) is one of the most prevalent diseases affecting humans, and the greatest portion of the dentist's time and efforts is expended on treating dental decay and its consequences. In addition to caries, teeth can be damaged by trauma, erosion, and abrasion. Restorative dentistry encompasses efforts to conserve and restore decayed, defective, missing, and traumatically injured teeth.

Significant advances have been made in the practice of restorative dentistry. Development of high-speed, air-driven turbines combined with rotary cutting instruments fashioned from diamonds and ultrahard steel permits the rapid removal of tooth structure with little discomfort to the patient. In addition, many new materials for restorations and impression taking have become available. Especially important is the availability of composite resins which have sufficient strength to withstand biting and chewing pressures.

Seven branches of specialization are recognized by the American Dental Association: oral surgery, orthodontics, pedodontics, periodontics, prosthodontics, oral pathology, and public health dentistry. Other subspecialties such as oral medicine, dental radiology, and periodontal prosthetics exist but are not recognized.

Oral surgery treats diseases and abnormalities of the maxillofacial region by surgical means. Oral surgeons treat a wide variety of problems by removing teeth, reducing bone fractures, removing cysts, tumors, and growths, and correcting congenital anomalies and malformation of the structures of the maxillofacial region.

Orthodontists deal with abnormalities in tooth position and jaw relationships that result in facial disharmony and malfunction. The objective of orthodontic treatment is to establish normal occlusion and facial harmony. The teeth are repositioned and the jaws modified through the use of mechanical force applied with fixed or removable appliances. Successful treatment results in normal shape and expression of the mouth and lips, aids in enunciation and the sounding of words, and permits proper mastication.

Pedodontics is the branch of dentistry concerned with the detection, prevention, and treatment of oral and dental diseases and abnormalities in children. The deciduous or primary teeth are very small and have shapes which differ from those of adult teeth; special procedures and materials are required for their conservation and restoration.

Periodontics is the branch of dentistry devoted to the study, prevention, diagnosis, and treatment of diseases of the tissues supporting the teeth: gingiva (gum tissue), alveolar bone, periodontal ligament, and cementum. Periodontal diseases include gingivitis, periodontitis (sometimes called pyorrhea), primary and secondary occlusal traumatism, gingival hyperplasia, and periodontal atrophy. Several types of anaerobic gram-negative microorganisms are thought to be associated with chronic periodontitis. *See* ANAEROBIC INFECTIONS; PERIODONTAL DISEASE.

Prosthodontics is the branch of dentistry devoted to the construction and replacement of oral structures with artificial substitutes. The replacement of teeth and other oral structures is necessitated by congenital abnormalities, loss of teeth from disease or trauma, and destruction of teeth or jaws or other parts of the mouth by surgical management of neoplasms or trauma.

Oral pathology is concerned with the detection and diagnosis of the diseases of the teeth, oral cavity, and jaws, and also with the oral manifestations of systemic diseases. *See* PATHOLOGY.

Public health dentistry is defined as the science and art of preventing and controlling dental diseases and promoting dental health through organized community efforts. It comprises research, education, prevention, diagnosis, prescription, treatment of problems related to dentistry, and evaluation of community dental care. *See* TOOTH DISORDERS. [R.C.P.]

Dentition The arrangement, type, and number of teeth which are variously located in the oral or in the pharyngeal cavities, or in both. Teeth are found in areas where there is an underlying supporting structure of cartilage or bone and where stomodeal ectoderm is present.

Attachment of teeth is variable among vertebrates. They may be inserted in sockets in the jawbones (thecodont condition), fused to the edge of the bone proper (acrodont condition), or

Dental formulas of some mammals

Animal	Teeth I	Teeth C	Teeth Pm	Teeth M	Total

attached to the inner surface of the jawbone (pleurodont condition). In polyphyodont animals, teeth may be constantly replaced. The polyphyodont condition is characteristic of the fishes and the lower tetrapods in which the teeth are replaced as they are worn out. Most mammals have two sets of teeth during their lifetime, which is the diphyodont condition. These sets are the deciduous, or milk, teeth and the permanent dentition. Monophyodont dentition is the development of only one set of teeth.

Teeth may have a similar form in all regions where they occur (homodont), as distinct from those that are variable in shape (heterodont). The homodont condition is characteristic of nonmammalian vertebrates, although the anterior teeth may differ from those lying in the cheek region of the jaws. A heterodont dentition began to evolve in the reptilian ancestors of mammals, but became fully developed in the mammals. The mammalian heterodont condition is frequently described by a dental formula expressing both the number and kind of teeth in each half jaw, both upper and lower (see table). For humans the formula is I 2/2 C 1/1 Pm 2/2 M 3/3. This can be read for either the right or left side of the jaw; there are 2 upper and 2 lower incisors, 1 upper and 1 lower canine, and 2 premolars and 3 molars in both the upper and lower jaws. According to this formula, humans have a total of 32 teeth, 8 located in each half of the upper jaw and 8 in each half of the lower jaw. *See* TOOTH.

[F.S.S.]

Denudation All the weathering and erosional processes that contribute to the lowering of the land surface. Denudation is, thus, the complement of deposition, which is the accumulation of the products of denudation in sedimentation basins. *See* BASIN; DEPOSITIONAL SYSTEMS AND ENVIRONMENTS; EROSION; WEATHERING PROCESSES.

Contemporary records of sediment and solute flux through river systems, representing the mass removed from the continental surfaces, have been used to estimate rates of denudation since the mid-nineteenth century. These are usually expressed as an average rate of lowering of the land surface, in units of millimeters per thousand years (mm/ka).

In recent decades methods which allow the definition of denudation rates over geologic time scales have been developed. Attempts to invert sedimentary and stratigraphic records, and so define rates of erosion on the contributing continental surface, have greatly benefitted from improved seismic surveys, core extraction, and modeling of sedimentation basin processes. On the land surface itself, estimates of denudation rates based on the dissection of surfaces of known age have improved with the use of digital terrain models and absolute dating techniques. Equivalent estimates show that very rapid rates of bedrock denudation (up to 15 mm/yr) have been maintained in the western Himalaya during the past few million years. *See* DATING METHODS.

Developments in the dating of bedrock surfaces and surficial material in the 1990s represent the greatest improvement in defining rates of denudation during the late Cenozoic era. Potassium-argon (K-Ar) dating of lavas and the magnitude of dissection on volcanic cones had been used earlier to define erosion rates. More recently, exposure dating of bedrock through the accumulation of cosmogenic nuclides produced within them is a development that allows the estimation of average surface lowering rates over long time intervals. Cosmogenic nuclides have also been used to define rates of regolith production and erosion, contributing to denudation, over more recent time periods. Fission track analysis of apatite is another recent development that has had success in defining the long-term tectonic and denudational history of continental margins and mountain systems. *See* APATITE; CENOZOIC; COSMOGENIC NUCLIDE; FISSION TRACK DATING; REGOLITH.

[N.C.]

Deoxyribonucleic acid (DNA) The material that carries genetic information in all organisms, except for some families of viruses that use ribonucleic acid (RNA). The set of DNA molecules that contains all genetic information for an organism is called its genome. DNA is found primarily in the nuclei of eukaryotic cells and in the nucleoid of bacteria. Small amounts of DNA are also found in mitochondria and chloroplasts and in autonomously maintained DNAs called plasmids. *See* NUCLEIC ACID.

DNA is composed of two long polymer strands of the sugar 2-deoxyribose, phosphate, and purine and pyrimidine bases. The backbone of each strand is composed of alternating 2-deoxyribose and phosphate linked together through phosphodiester bonds. A DNA strand has directionality; each phosphate is linked to the 3′ position of the preceding deoxyribose and to the 5′ position of the following deoxyribose (Fig. 1). The four bases found in DNA are adenine, thymine, guanine, and cytosine. Each 2-deoxyribose is linked to one of the four bases via a covalent glycosidic bond, forming a nucleotide. The sequence of these four bases allows DNA to carry genetic information. Bases can form hydrogen bonds with each other. Adenine forms

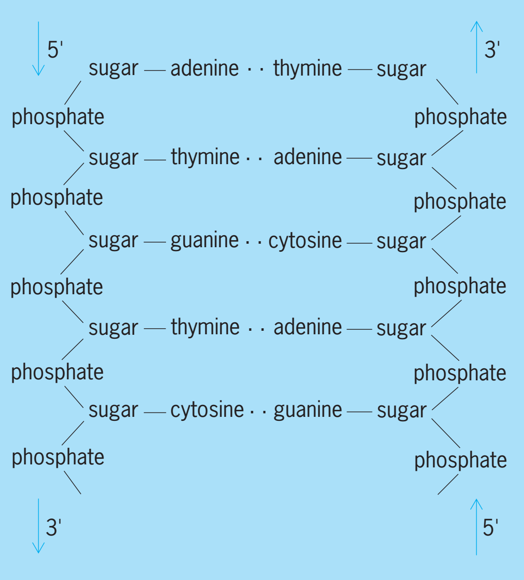

Fig. 1. Diagram of the nucleic acid backbone, a repeating sugar-phosphate polymer chain with base side chains. The two chains are antiparallel, as shown by arrows. The dots between the bases represent hydrogen bonding. Although the chains are drawn flat, they are actually wound around each other in the molecule.

two bonds with thiamine, and cytosine forms three bonds with guanine. These two sets of base pairs have the same geometry, allowing DNA to maintain the same structure regardless of the specific sequence of base pairs. *See* DEOXYRIBOSE; PURINE; PYRIMIDINE.

Structure. DNA is composed of two strands that wrap around each other to form a double helix. The two strands are held together by base pairing and are antiparallel. Thus if one strand is oriented in the $5'$ to $3'$ direction, the other strand will be $3'$ to $5'$. This double-helical structure of DNA was first proposed in 1954 by J. D. Watson and F. H. C. Crick. The most common form of DNA is the B-form, which is a right-handed double helix with 10.4 base pairs per turn. Less common forms of DNA include A-form, which is a right-handed double helix that has 11 base pairs per turn and has wider diameter than B-form, and Z-form, which is a narrow, irregular left-handed double helix.

For cells to live and grow, the genetic information in DNA must be (1) propagated and maintained from generation to generation, and (2) expressed to synthesize the components of a cell. These two functions are carried out by the processes of DNA replication and transcription, respectively. *See* GENETIC CODE.

Replication. Each of the two strands of a DNA double helix contains all of the information necessary to make a new double-stranded molecule (Fig. 2). During replication the two parental strands are separated, and each is used as a template for the synthesis of a new strand of DNA. Synthesis of the nascent DNA strands is carried out by a family of enzymes called DNA polymerases. Base incorporation is directed by the existing DNA strand; nucleotides that base-pair with the template are added to the nascent DNA strand. The product of replication is two complete double-stranded helices, each of which contains all of the genetic information (has the identical base sequence) of the parental DNA. Each progeny double helix is composed of one parental and one nascent strand. DNA replication is very accurate. In bacteria the mutation rate is about 1 error per 1000 bacteria per generation, or about 1 error in 10^9 base pairs replicated. This low error rate is due to a combination of the high accuracy of the replication process and cellular pathways which repair misincorporated bases. *See* MUTATION.

Transcription. In transcription, DNA acts as a template directing the synthesis of RNA. RNA is single-stranded polymer similar to DNA except that it contains the sugar ribose instead of 2-deoxyribose and the base uracil instead of thymidine. The two strands of DNA separate transiently, and one of the two single-stranded regions is used as a template to direct the synthesis of an RNA strand. As in DNA replication, base pairing between the incoming ribonucleotide and the template strand determines the sequence of bases incorporated into the nascent RNA. Thus, genetic information in the form of a specific sequence of bases is directly transferred from DNA to RNA in transcription. After the RNA is synthesized, the DNA reverts to double-stranded form. Transcription is carried out by a family of enzymes called RNA polymerases. Following transcription, newly synthesized RNA is often processed prior to being used to direct protein synthesis by ribosomes in a process called translation. *See* PROTEIN; RIBONUCLEIC ACID (RNA); RIBOSOMES.

Genetic variation. There is a great deal of variation in the DNA content and sequences in different organisms. Because of base pairing, the ratios of adenine to thiamine and cytosine to guanine are always the same. However, the ratio of adenine and thymine to guanine and cytosine in different organisms ranges from 25 to 75%. There is also large variation in the amount of DNA in the genome of various organisms. The simplest viruses have genomes of only a few thousand base pairs, while complex eukaryotic organisms have genomes of billions of base pairs. This variation partially reflects the increasing number of genes necessary to encode more complex organisms, but mainly reflects an increase in the amount of DNA that does not encode proteins (known as introns). A large percentage of the DNA in multicellular eukaryotes is in introns or is repetitive DNA (sequences that are repeated many times). In most eukaryotes the DNA sequences that encode proteins (known as exons) are not continuous but have introns interspersed within them. The initial transcript synthesized by RNA polymerase contains both exons and introns and can be many times the length of the actual coding sequence. The RNA is then processed and the introns are removed through a mechanism called RNA splicing to yield messenger RNA (mRNA), which is translated to make protein.

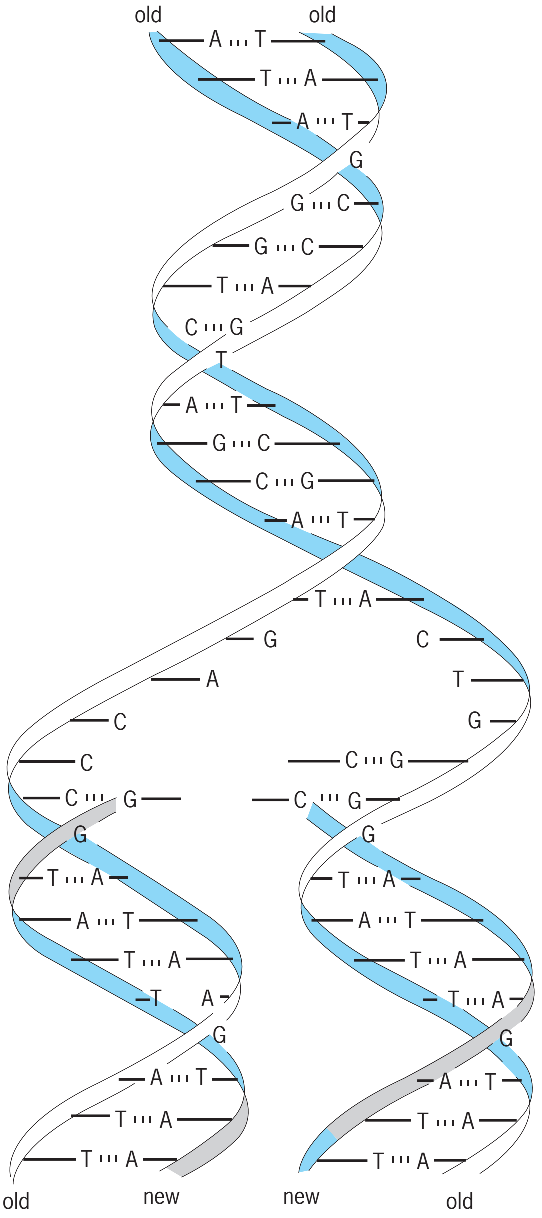

Fig. 2. Replication of DNA: A = adenine, C = cytosine, G = guanine, and T = thymine. (*After J. D. Watson, Molecular Biology of the Gene, W. J. Benjamin, 1965*)

Recombinant technology. Techniques have been developed to allow DNA to be manipulated in the laboratory. These techniques have led to a revolution in biotechnology. This revolution began when methods were developed to cleave DNA at specific sequences and to join pieces of DNA together. Another major component of this technology is the ability to determine the sequence of the bases in DNA. There are two general approaches for determining DNA sequence. Either chemical reactions are carried out which specifically cleave the sugar-phosphate bond at sites which contain a certain base, or

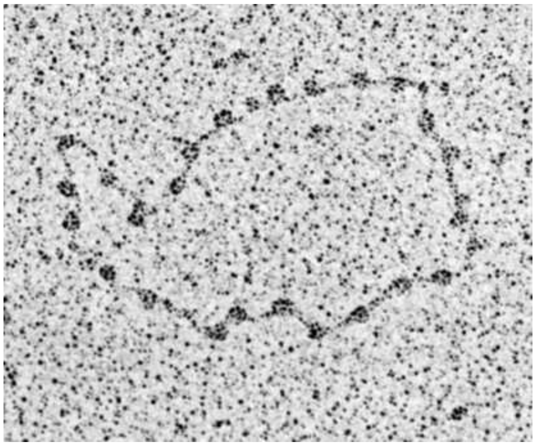

Fig. 3. Electron micrograph of the minichromosome of a virus that infects monkey cells. The circular viral DNA can be seen to be organized in nucleosome "beads." (*From L. Lutter et al., Mol. Cell. Biol., 12:5004–5014, 1992*)

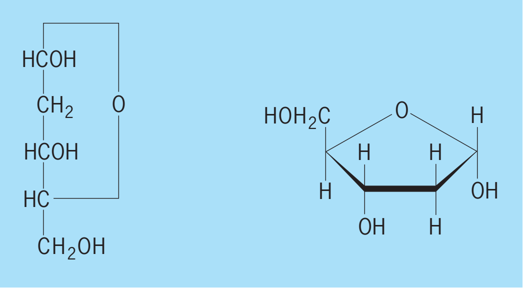
DNA is synthesized in the presence of modified bases that cause termination of synthesis after the incorporation of a certain base. These methods can now be automated so that it is practical to determine the DNA sequences of the entire genome of an organism. Currently, the complete sequences of several bacterial and fungal genomes are known, drafts exist for the complete mouse and rat genomes, and 99% of the gene-containing part of the human sequence has been determined. *See* Human Genome Project. [M.C.Wo.]

In the cell. The full genome of DNA must be substantially compacted to fit into a cell. For example, the full human genome has a total length of about 3 m (10 ft). This DNA must fit into a nucleus with a diameter of 10^{-5} m. This immense reduction in length is accomplished in eukaryotes via multiple levels of compaction in a nucleoprotein structure termed chromatin. The first level involves spooling about 200 base pairs of DNA onto a complex of basic proteins called histones to form a nucleosome. Nucleosomes are connected like beads on a string (Fig. 3) to form a 10-nanometer diameter fiber, and this is further coiled to form a 30-nm fiber. The 30-nm fibers are further coiled and organized into loops formed by periodic attachments to a protein scaffold. This scaffold organizes the complex into the shape of the metaphase chromosome seen at mitosis. *See* Nucleoprotein.

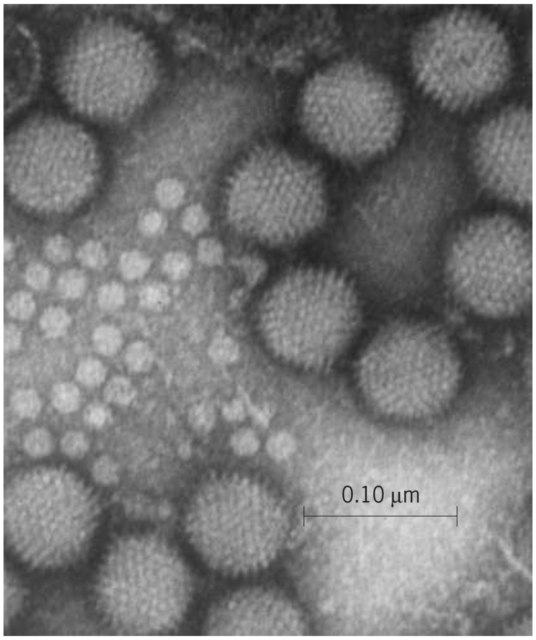
The nucleosome is the fundamental structural unit of DNA in all eukaryotes. Nucleosomes reduce the accessibility of the DNA to DNA-binding proteins such as polymerases and other protein factors essential for transcription and replication. Consequently, nucleosomes tend to act as general repressors of transcription. *See* Nucleosome. [L.C.L.]

Deoxyribose A nucleic acid constituent (see illustration) of all animal, microbial, and plant cells; also known as 2-D-deoxyribose. Deoxyribose is enzymically formed in living cells by reduction of ribonucleoside di- or triphosphate. The four deoxyribose nucleotides, containing adenine, guanine, cytosine, and thymine, are the major constituents of the deoxyribonucleic acids (DNA), which control the hereditary characteristics of every living organism. *See* Deoxyribonucleic acid (DNA); Nucleic acid; Ribose. [W.Z.H.]



Formulas of 2-D-deoxyribose (α-D-2-deoxyribofuranose).

Dependovirus Any of a group (genus) of defective viruses which seem unable to reproduce without help from adenoviruses. They were formerly known as adeno-associated viruses and belong to the family Parvoviridae. These 20-nanometer virus particles were found during electron microscopic studies (see illustration) in several preparations of adenovirus from both human and monkey sources, and have since been observed in many adenovirus stocks. *See* Adenoviridae.



Electron micrograph showing adenovirus particles (70-nm diameter; 0.10 μm = 100 nm) and dependoviruses (20-nm diameter).

Like adenovirus, the dependovirus has a deoxyribonucleic acid (DNA) core. However, the dependovirus, although dependent upon adenovirus for its growth, does not appear to be structurally related to its "helper." Its genetic content, as well as its size, is much smaller than that of adenovirus, and its protein coat is completely different from that of adenovirus. These particles contain single-stranded DNA and a protein coat with icosahedral symmetry. The single-stranded DNA has been shown to be present within the dependovirus virion as either plus or minus complementary strands in separate particles. Upon extraction, the minus and plus strands unite to form a double-stranded helix.

The genetic material of dependovirus not only can persist in cultured cells for long periods without giving evidence of its presence but also can survive within human beings in a latent state, becoming detectable only in specimens taken when the person is concurrently infected with adenovirus. This characteristic permits survival of a defective virus in nature, even though it cannot regularly replicate or be passed in infective form from host to host. *See* Virus classification.

[J.L.Me.; M.E.Re.]

Depositional systems and environments Depositional systems are descriptions of the interrelationships of form and the physical, chemical, or biological processes involved in the development of stratigraphic sequences. Depositional environments are the locations where accumulations of sediment have been deposited by either mechanical or chemical processes.

Depositional systems. Traditional stratigraphic analysis, which emphasized the physically descriptive aspects of strata, has changed; a critical genetic dimension has been added. Where once, for example, a formation may have been described in physical terms as a fine- to medium-grained quartzose sandstone, overlying a thick dark-gray shale sequence and underlying a coal-bearing sequence with discontinuous sands, the same sandstone may now be recognized as a delta-front sandstone, the underlying shale as a prodelta facies, and the overlying coal-bearing formation as the product of deposition on a delta plain. In this interpretation, the three distinct stratigraphic units become part of a genetically related sequence, each a component facies of a prograding delta system. *See* STRATIGRAPHY.

In a modern setting, a particular system of deposition is directly observable and known, whether it is a major delta, an alluvial fan, a meandering river, a barrier bar, a carbonate platform, or the like. Through specific observation, description, and delineation, it may be determined that a variety of depositional processes are active. At the terminus of rivers, sands may be deposited as bars in river mouths, creating the delta front; muds may be carried by suspension into the oceanic waters and deposited through flocculation, creating the prodelta; on the delta plain, a distributary channel may be depositing bed-load sands and, during flooding, may be carrying suspended muds to flanking flood basins or breaching the natural levee to form crevasse splays. Each process or combination of processes gives rise to distinct, specific environments of deposition, with each resulting in a deposit which can be characterized by such features as lithologic composition, texture, sedimentary structures, geometry, size, and relationship to other deposits. *See* DELTA; FLOODPLAIN; RIVER.

Distinct physical, or in some cases biologic or chemical, products of deposition can be related directly to definable, operative processes. Such data permit the development of models of modern deposition in which processes and resulting deposits or facies are linked. By recognizing comparable physical, chemical, and biologic attributes of ancient strata, modern depositional analogs can be applied, and the original processes forming the ancient deposit can be inferred. Such an ancient deposit is called a genetic facies. It contains the sedimentary record and constitutes a three-dimensional stratigraphic (ancient) depositional system. *See* FACIES (GEOLOGY).

An ancient depositional system is a three-dimensional, genetically defined, physical stratigraphic unit that consists of a contiguous set of process-related sedimentary facies. Several corollaries have evolved from the application of this concept. Depositional systems, such as delta, fluvial, and shelf systems, (1) are the stratigraphic equivalents of major physical geographic units; (2) form the principal building blocks of the sedimentary basin fill; and (3) can be applied where principal boundaries of the systems are preserved and where the geometry of the framework facies can be mapped.

The major realms of deposition may be classed broadly as terrigenous clastic depositional systems and biogenic-chemical depositional systems. Each of these major systems is subdivided according to particular systems of deposition, and within each of the subdivisions is an assemblage of genetic facies, which are the fundamental units of depositional systems.

Terrigenous clastic systems, composed chiefly of sands and shales, embrace eight major systems: (1) fluvial or river systems; (2) delta systems; (3) strike coastal systems; (4) fan or clastic wedge systems; (5) lacustrine systems; (6) continental eolian systems; (7) shelf systems; and (8) slope and abyssal systems.

The biogenic-chemical systems consist of three major systems: (1) carbonate systems; (2) glauconitic and authigenic shelf systems; and (3) evaporite systems. [W.L.Fi.]

Depositional environments. Depositional environments may be distinguished from erosional environments, in which erosion of the Earth's surface is taking place. Both depositional and erosional environments are of interest to geomorphologists. However, most attention to depositional environments has come from sedimentologists, particularly in order to understand the origin of sedimentary rocks. *See* EROSION.

Sediment is derived mainly from source areas that are actively undergoing uplift and erosion, and is deposited mainly in areas that are undergoing subsidence. Location of the source and basin of deposition is mainly controlled by large-scale geophysical processes acting within the Earth's mantle, so a major factor affecting the nature and distribution of sedimentary environments is the overall structural development, or tectonics, of the area. *See* PLATE TECTONICS.

Tectonics determines the major geological structure or setting of an environment of deposition, including the location and nature of the main areas undergoing uplift or subsidence. Areas with high relief, such as mountains and volcanoes, suffer rapid erosion and supply much more sediment to basins of deposition than larger areas of low relief. One investigation, for example, found that 82% of the suspended solids (mud) discharged by the Amazon River were supplied by the 12% of the drainage basin located within the Andes Mountains.

A second important major control is climate. This includes the average temperature, the range of temperature variation, the aridity or humidity (ratio of evaporation to precipitation), and the magnitude and frequency of floods and storms. Climate in turn has an important influence on such physical factors as the salinity and energy of the environment (wind and water speeds and degree of turbulence, for example), as well as on the abundance and types of plants and animals.

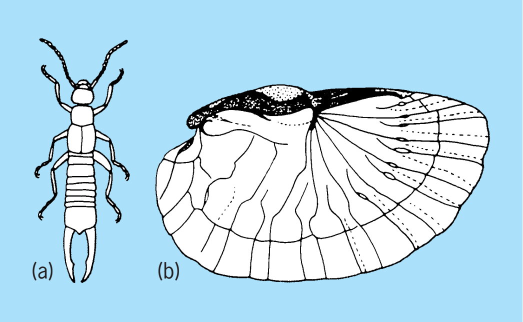
In areas of subsidence and sedimentation, topography results from and controls sedimentary environments. Along a coastline of low relief, for example, spits and barrier islands are produced by waves generated in the open sea. Shallow lagoons on the landward side of barrier islands are protected from wave action by the islands themselves. The distinctive features of the lagoon environment are a result of a topography which has been produced by the accumulation of sediment in another sedimentary environment (the barrier island). *See* BARRIER ISLANDS.

Sedimentary environments can be classified into three categories: terrestrial, including alluvial fans, fluvial plains, sandy deserts, lakes, and glacial regions; mixed (shore-related), including deltas, estuaries, barrier island complexes, and glacial marine environments; and marine, including terrigenous shelves or shallow seas, carbonate shelves or platforms, continental slopes, continental rises, basin plains, ocean ridges, and ocean trenches.

Although the importance of tectonics and climate in controlling sedimentary environments is widely recognized, most classifications are based mainly on topography. Almost all distinguish terrestrial (sub-aerial or fresh-water) from marine environments, and also recognize an important group of mixed or shore-related environments.

A number of major processes operate within environments and determine the types of sediment deposited in the environment, including water depth, energy (waves and current), temperature, and salinity. Biological factors also exert a very strong influence. There would be little or no oxygen in the atmosphere if it were not for the photosynthetic activity of plants. Deposition of calcium carbonate and silica in lakes and the oceans takes place largely through the action of plants and animals, and organic matter deposited along with mineral particles is largely responsible for the development of reducing conditions within sediments after deposition. Vegetable material accumulates in swamps to form peat and coal, and fine organic detritus settles with marine muds and is the ultimate source of oil and gas. Both terrestrial and aquatic plants exert a trapping and binding action that tends to immobilize sedimentary particles, as, for example, when coastal sand dunes or tidal flats become stabilized by the growth of salt-tolerant grasses. Terrestrial vegetation plays an important role in rock weathering. [G.V.M]

Dermaptera An order of insects commonly known as earwigs, in reference to an unfounded superstition that they crawl into the ears of sleeping persons. Earwigs are elongate and flattened, with a pair of forcepslike appendages, or cerci, at the end of the abdomen (see illustration). They are 0.4–1.2 in. (10–30 mm) long, and have chewing mouthparts, gradual metamorphosis, long legs, and shortened, leathery forewings. Some species are flightless, while others are active fliers with well-developed hindwings that fold elaborately under the forewings when the insect is at rest. Most earwigs are brown or black.



Some features of Dermaptera. (*a*) Adult of Labidura. (*b*) Hindwing of *Forficula*. (*After C. P. Brues, A. L. Melander, and F. M. Carpenter, Classification of Insects, Harvard University Press, 1954*)

Earwigs are usually nocturnal and spend the daylight hours under bark or stones, in moist cracks and crevices, or in leaf litter at the soil surface. Most species scavenge on decaying animal or vegetable matter. A few species are predators on smaller insects. The widely introduced European earwig, *Forficula auricularia*, is an occasional pest of buildings, and crop plants, especially seedlings and floral crops.

Worldwide, there are about 1100 species of earwigs, and most of these species are tropical. Fossil earwigs are known from the Jurassic Period. *See* INSECTA. [D.J.Hor.]

Dermatitis Inflammation of the skin with redness and scaling, or if acute, with blisters, edema, and formation of a crust; also known as eczema. Of the several distinct types of dermatitis, each has unique etiology, clinical characteristics, pathology, and treatment.

Atopic dermatitis. Atopic dermatitis usually begins in infancy and may continue into adult life. The eruption is characterized by red patches accompanied by intense itching. The lesions often become secondarily infected, leading to moist discharge and crusting. Although any anatomic site may be affected, the classic locations in infants are the extremities, face, and scalp. In older children and adults, the inside of the elbows, the back of the knees, wrists, eyelids, and neck are most often involved.

Treatment of atopic dermatitis includes oral antihistamines, emollients, topical corticosteroids (particularly ointments), and for more severe cases, systemic corticosteroids. Avoidance of irritants (wool, chemicals, harsh soaps and detergents, perfumes), extremes in temperature and humidity, overbathing, and certain foods is imperative. Mild cleansers are preferred. *See* ANTIHISTAMINE; STEROID.

Contact dermatitis. Contact dermatitis is a reaction that causes acute itching, redness, swelling, large blisters, and in chronic cases, red, scaly papules (raised bumps) and plaques (abnormal flat areas). The two forms are irritant contact dermatitis and allergic contact dermatitis. In irritant contact dermatitis the eruption is caused by a nonallergic reaction resulting from exposure to an irritating substance. Allergic contact dermatitis is an immunologic reaction in persons who have been previously exposed (sensitized) to the allergen. The lesions occur 24–48 h after exposure to an irritant or allergen. The key to treatment is removal of the offending agent. Antihistamines, emollients, and topical and systemic corticosteroids are helpful. *See* ALLERGY.

Seborrheic dermatitis. Seborrheic dermatitis is characterized by reddish to yellow greasy scale that frequently forms on the face (eyebrows, nasolabial folds, forehead), ears, scalp, upper back, central chest, and anogential region. In contrast to atopic and contact dermatitis, itching is uncommon.

Topical corticosteroids are the mainstay of treatment for seborrheic dermatitis. In cases in which *Pityrosporum ovale* is involved, topical antifungal agents (such as ketoconazole cream) are useful. Topical or oral antibiotics are required in cases with secondary bacterial infection. In generalized or recurring cases, systemic corticosteroids may be necessary.

Exfoliative erythroderma. Exfoliative erythroderma is characterized by widespread, warm redness and scaling. Nail degeneration and loss, hair loss, fever, chills, and enlargement of the lymph nodes may also occur. The eruption may be due to an underlying primary skin disorder, such as dermatitis (seborrheic, contact, or atopic) or psoriasis; drug allergy; or leukemia or lymphoma, particularly cutaneous T-cell lymphoma. *See* LEUKEMIA; LYMPHATIC SYSTEM; LYMPHOMA.

Individuals with exfoliative erythroderma are best managed in a hospital setting. Because heat, water, and protein losses occur through damaged skin, careful monitoring of fluid balance, protein losses, and body temperature is imperative. The application of wet dressings or topical corticosteroids and administration of oral antihistamines are important aspects of treatment. *See* INFECTION. [L.M.Co.; K.A.A.]

Flea allergy dermatitis. Flea allergy dermatitis, sometimes called flea-bite dermatitis, affects the skin of small pets (dogs, cats, and ferrets), and results from an allergic reaction to protein substances deposited on (or under) the surface of the skin at the time of flea feeding. It is by far the most common cause of allergic dermatitis in pet animals and a major cause of itchy skin in geographic regions where fleas are found. [J.M.MacD.]

Dermoptera An ancient order of somewhat primate-like herbivorous (plant-eating) and frugivorous (fruit-eating) gliding mammals, now confined to the extreme southeast comer of Asia and parts of the East Indies and the Philippines. Colugos, or flying lemurs, as they are often called, are the only extant members of the group. Modern dermopterans are usually placed in a single genus, though two genera may exist.

The patagium, a flap of skin used in gliding, extends from behind the ears to the hands, then to the feet, and finally to the tip of the tail. The extent of the patagium and the gliding ability, of course, are not known in fossil forms, nor are certain features of the soft anatomy. Skeletal features not related to their gliding adaptations point to distant connections with primitive primate-like insectivores that were no doubt living in southeastern Asia as long ago as the Cretaceous. Colugos probably were restricted to southeastern Asia by the contraction of the tropics that occurred during the Oligocene and later Cenozoic. *See* EUTHERIA; INSECTIVORA; MAMMALIA. [M.C.McK.]

Derrick A hoisting machine consisting usually of a vertical mast, a slanted boom, and associated tackle. Derricks have a wide variety of forms. The mast may be no more than a base for the boom; it may be a tripod, an A-frame, a fixed column, and so on. Fixed stays may guy it in place. The boom may be fixed, it may pivot at the base of the mast, it may swing horizontally from near the top of the mast, or it may be omitted. The derrick may be permanently fixed, temporarily erected, or mobile on a cart or truck.

Derricks are widely used in construction, in cargo handling, and in shops. A manual or powered winch provides the lifting action by coiling in the running tackle, the load swinging free as it rises. *See* HOISTING MACHINES. [D.O.H./F.H.R.]

Derris A genus of tropical shrubs belonging to the legume family (Leguminosae). These plants, with their long branches climbing over other vegetation, occur as members of the jungle undergrowth in Malaysia. Extracts of the roots of *Derris elliptica* long been used by the natives as an arrow poison and to stupefy fish so they can be caught more easily. Derris root is an excellent insecticide, being harmful to both chewing and sucking insects, but not poisonous to human beings. The insecticidal ingredient of derris root is a white, crystalline substance, which is called rotenone. *See* ROSALES. [P.D.St.; E.L.C.]

Descriptive geometry A mathematical-graphical procedure for the visualization of structures and their exact representation in drawings. After analysis of the structure, each element is shown in the drawing in its exact geometrical relation to the other elements. There are two basic methods of descriptive geometry: the projection method and the direct method. The two methods differ as regards the attitude of mind toward the structure and toward the drawing that represents the structure.

Projection method. In the projection method the horizontal projection plane *H* and the vertical projection plane *V* intersect in the line *GL*, which is called the ground line (Fig. 1). These two projection planes divide space into four quadrants, or angles, as numbered in Fig. 1. Point *A*, in the first quadrant, is projected onto the horizontal plane at a_h by means of a projection line perpendicular to the *H* plane, and onto the vertical plane at a_v by means of a projection line perpendicular to the *V* plane. The projections of the points *B, C,* and *D* in the other quadrants are located in a similar manner. Right-angle projection, as described above, is called orthographic projection.

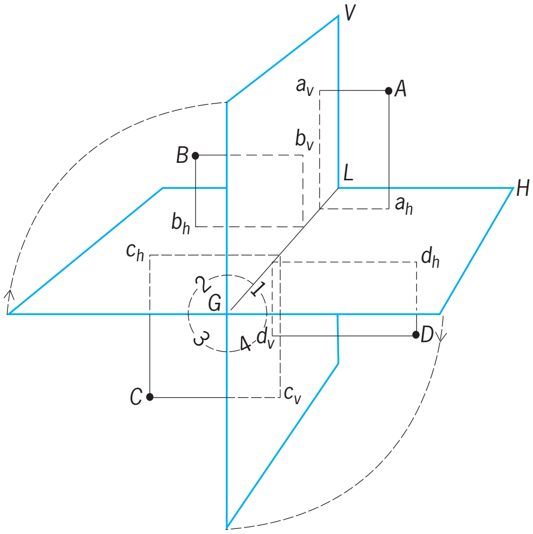


Fig. 1. Planes of projection. (*After G. J. Hood and A. S. Palmerlee, Geometry of Engineering Drawing, 4th ed., McGraw-Hill, 1958*)

To represent horizontal and vertical projections on a flat sheet of paper, the planes are conceived as being hinged along the ground line and brought together by closing the second and fourth quadrants. Projections of *A, B, C,* and *D* then appear in a single plane (Fig. 2). The *H* and *V* projections of a point are always in the same perpendicular to the ground line.

There are two general types of views, perspective and orthographic (Fig. 3). A perspective view of an object is observed from a fixed station point, or point of view, by means of converging rays of light that meet at the eye of the observer. An orthographic view of an object is observed in a chosen direction by means of parallel rays of light.

Direct method. In the direct method the attention is focused on the visualized structure or object. Each view of the object is obtained by looking at the object in a definite direction. The view is orthographic. A view never is considered as two-dimensional or as projected or drawn on a plane. This is the way the engineer who makes and reads the drawings thinks of views.

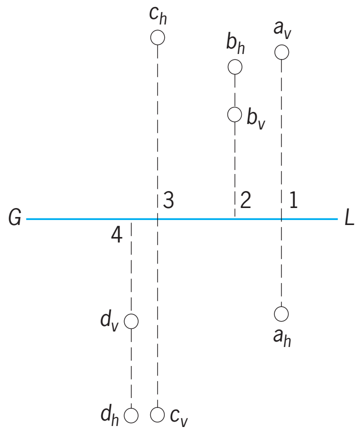

Fig. 2. Projection of points onto projection planes. (*After G. J. Hood and A. S. Palmerlee, Geometry of Engineering Drawing, 4th ed., McGraw-Hill, 1958*)

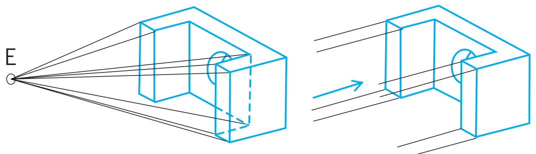

(a) (b)

Fig. 3. Methods of viewing objects. (*a*) **Perspective viewpoint (converging rays).** (*b*) **Orthographic viewpoint (parallel rays).** (*After G. J. Hood and A. S. Palmerlee, Geometry of Engineering Drawing, 4th ed., McGraw-Hill, 1958*)

Orthographic views may be classified into three types: principal views, auxiliary views, and oblique views. The object can be viewed from any direction around three rings—horizontal, frontal, and profile (Fig. 4). The rings represent three mutually perpendicular planes. The intersections of the rings define three mutually perpendicular directions from which six principal views are observed: front and rear, top and bottom, right and left sides.

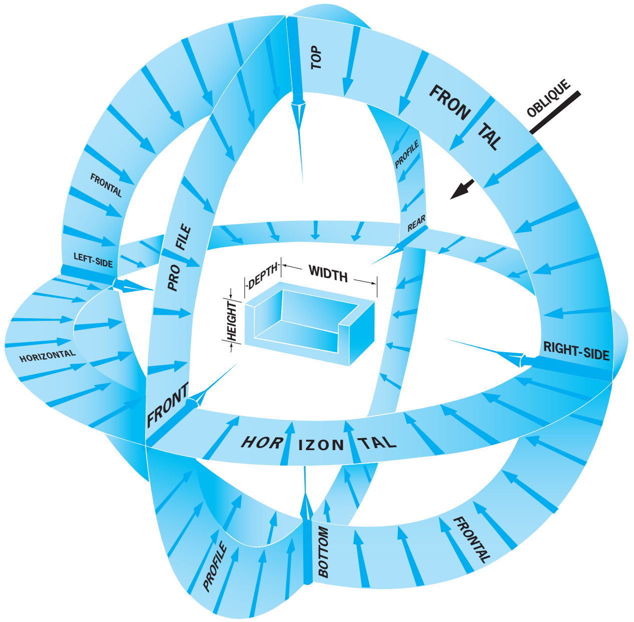

Fig. 4. A series of viewing positions for auxiliary views. (*After G. J. Hood and A. S. Palmerlee, Geometry of Engineering Drawing, 4th ed., McGraw-Hill, 1958*)

An auxiliary view can be observed around any ring in a direction perpendicular to one, and only one, of the directions in which principal views are observed. All views other than principal or auxiliary views are oblique. In Fig. 4 a single arrow, marked oblique, indicates one of the infinite number of directions in which oblique views are observed. *See* DRAFTING; ENGINEERING DRAWING. [A.S.P./C.J.B.]

Desert No precise definition of a desert exists. From an ecological viewpoint the scarcity of rainfall is all important, as it directly affects plant productivity which in turn affects the abundance, diversity, and activity of animals. It has become customary to describe deserts as extremely arid where the mean precipitation is less than 2.5–4 in. (60–100 mm), arid where it is 2.5–4 to 6–10 in. (60–100 to 150–250 mm), and semiarid where it is 6–10 to 10–20 in. (150–250 to 250–500 mm). However, mean figures tend to distort the true state of affairs because precipitation in deserts is unreliable and variable. In some areas, such as the Atacama in Chile and the Arabian Desert, there may be no rainfall for several years. It is the biological effectiveness of rainfall that matters and this may vary with wind and temperature, which affect evaporation rates. The vegetation cover also alters the evaporation rate and increases the effectiveness of rainfall. Rainfall, then, is the chief limiting factor to biological processes, but intense solar radiation, high temperatures, and a paucity of nutrients (especially of nitrogen) may also limit plant productivity, and hence animal abundance. Of the main desert regions of the world, most lie within the tropics and hence are hot as well as arid. The Namib and Atacama coastal deserts are kept coot by the Benguela and Humboldt ocean currents, and many desert areas of central Asia are cool because of high latitude and altitude.

The diversity of species of animals in a desert is generally correlated with the diversity of plant species, which to a considerable degree is correlated with the predictability and amount of rainfall. There is a rather weak latitudinal gradient of diversity with relatively more species nearer the Equator than at higher latitudes. This gradient is much more conspicuous in wetter ecosystems, such as forests, and in deserts appears to be overridden by the manifold effects of rainfall. Animals, too, may affect plant diversity: the burrowing activities of rodents create niches for plants which could not otherwise survive, and mound-building termites tend to concentrate decomposition and hence nutrients, which provide opportunities for plants to colonize.

Each desert has its own community of species, and these communities are repeated in different parts of the world. Very often the organisms that occupy similar niches in different deserts belong to unrelated taxa. The overall structural similarity between American cactus species and African euphorbias is an example of convergent evolution, in which separate and unrelated groups have evolved almost identical adaptations under similar environmental conditions in widely separated parts of the world. Convergent structural modification occurs in many organisms in all environments, but is especially noticeable in deserts where possibly the small number of ecological niches has necessitated greater specialization and restriction of way of life. The face and especially the large ears of desert foxes of the Sahara and of North America are remarkably similar, and there is an extraordinary resemblance between North American sidewinding rattlesnakes and Namib sidewinding adders. *See* ECOLOGY; PHYSIOLOGICAL ECOLOGY (PLANT); PRECIPITATION (METEOROLOGY). [D.F.Ow.]

Desert erosion features A distinctive topography carved by erosion in regions of low rainfall and high evaporation where vegetation is scanty or absent. Although rainfall is low, it is the most important climatic factor in the formation of desert erosion features. Desert rains commonly occur as torrential downpours of short duration with a consequent high percentage of runoff. As a result of the dryness, wind and mechanical weathering also play an important part in desert erosion. *See* SEDIMENTOLOGY; WEATHERING PROCESSES.

When storms of the so-called cloudburst type occur in the desert, sudden rushes of water, or flash floods, sweep down the normally dry washes or the narrow canyons in the mountains bordering the basins. The comparatively large volume of water combined with a high velocity due to the steepness of the slopes give the short-lived streams power to carry large amounts of fine and coarse rock fragments. As a result, the streams have great erosive power.

When intermittent streams leave the canyons and spread out at the foot of a desert mountain, they lose velocity and quickly drop the coarsest of the transported material to build an alluvial fan. Some of the water sinks into the fan, and some evaporates, but whatever remains may follow one of the channels on the fan or spread out in the form of a sheetflood, in either case carrying coarse sand, silt, and clay, and perhaps rolling some larger rock fragments along.

When the water reaches the toe of the fan, it spreads still more, dropping all but the finest silt and clay. Any excess water follows shallow washes to the lowest part of the basin, where it may form a playa lake. This evaporates in a few hours or a few days, depositing the silt and clay, mixed perhaps with soluble salts. The flat-surfaced area resulting from the silt and clay deposition is a playa. *See* PLAYA.

The lack of moisture during most of the year and the scanty vegetation make the wind a more potent agent of erosion in deserts than in humid lands. The finest material is blown high in the air and may be carried entirely out of the area, a process known as deflation. The larger sand grains are rolled along the surface, bouncing into the air when they strike an obstacle, knocking more grains into the air as they hit the ground again, until eventually a sheet of sand is moving along in the 3 or 4 ft (1 or 1.3 m) above the surface. This moving sand abrades rocks and other objects with which it comes in contact; at the same time the grains themselves become rounded and frosted. If movement is impeded by vegetation or other obstacles, sand accumulates to form dunes. *See* DUNE.

Desert landscapes evolve in three stages. In the early, or youthful, stage, alluvial fans are built, washes develop, playas form, and the basins slowly fill with detritus. As this stage progresses, some alluvial fans coalesce to form bajadas or piedmont alluvial plains along the mountain fronts, and individual basins may become deeply filled with waste to form bolsons. Desert flats develop between alluvial fans (or bajadas) and playas, and isolated dunes accumulate on the lee sides of the latter. If the original highlands are flat-topped rather than tilted mountain blocks, mesas develop. As the mountain fronts slowly retreat under the attack of the atmosphere and running water, small bare rock surfaces or pediments form at the canyon mouths, the result of lateral cutting by the intermittent streams. The general tendency during youth is for relief to decrease.

The middle, or mature, stage is initiated by the development of exterior drainage or the capture of higher basins by lower ones as drainage channels erode headward through low divides. The fill deposited during youth undergoes erosion, and pediments become more widely developed. The mountains are worn still lower, and more and more channels extend completely through them, cut by the streams engaged in draining and dissecting the higher basins. Playa deposits or other easily eroded sediments are cut into badlands before being entirely removed, and mesas are reduced to buttes. Undissected remnants of older deposits become covered with desert pavement (flat-lying, interlocking, angular stones left after finer particles are removed by deflation). Where winds are turbulent and large supplies of sand are available, complex dune areas develop. Relief shows some net increase during maturity.

At the late, or old-age, stage of desert evolution, the original mountains are so reduced in elevation that the winds sweep over them with little or no condensation of moisture, and rains become still more infrequent. Great expanses of wind-scoured bare rock, or hammada, are exposed, with here and there a more resistant remnant standing above the general level as an inselberg. Buttes are reduced to smaller bornhardts and finally disappear.Those parts of the flat surface floored by earlier deposits are covered and protected by extensive areas of desert pavement. The rock fragments may be colored brown to black by desert varnish, a coating of manganese and iron oxides. Sand blown from the bare rock surfaces and from the sediments may form large dune areas. If there are no obstacles to obstruct movement or cause wind turbulence, the sand may move as a sheet, forming large expanses of flat or gently undulating sand surfaces. Relief slowly decreases in old age. *See* DESERT. [T.C.]

Desertification Land degradation in low-rainfall and seasonally dry areas of the Earth. It can be viewed as both a process and the resulting condition. Desertification involves the impoverishment of vegetation and soil resources. Key characteristics include the degradation of natural vegetation cover and undesirable changes in the composition of forage species, deterioration in soil quality, decreasing water availability, and increased soil erosion from wind and water. Various stages of desertification can be seen in most of the world's drylands. In rare cases, desertification leads to abandoned, desertlike landscapes.

It is generally agreed that human activities, particularly excessive resource use and abusive land-use practices, are the primary cause of desertification. Specific activities leading to desertification include clearing and cultivation of low-rainfall areas where such cultivation is not sustainable, overgrazing of rangelands, clearing of woody plant species for fuelwood and building materials, and mismanagement of irrigated cropland leading to the buildup of mineral salts in the soil (salinization). Drought is often cited as a basic cause of desertification; however, it merely accelerates or accentuates land degradation processes already under way. *See* DROUGHT.

Consequences of desertification include reduced biological productivity, reduction of biodiversity, a gradual loss of agricultural potential and resource value, loss of food security, reduced carrying capacity for humans and livestock, increased risks from drought and flooding, and in extreme cases, barren lands that are effectively beyond restoration. Paleostudies, supported by model simulations, have shown that the intensity of Northern Hemisphere desert conditions has waxed and waned over the past 9000 years in response to the precession of the Earth's orbit about the Sun. Thus, it may be that the causal factors of desertification, whether climate change or human activities, depend on the time scale being addressed. *See* CLIMATE MODIFICATION; DESERT. [W.Swe.]

Desiccant A substance (adsorbant) used to withdraw moisture from other materials. Although the removal of large quantities of water is done by evaporation, aided by moving air currents and by elevated temperature, the last traces of moisture are often held very tightly and do not evaporate readily. Furthermore, evaporation ceases when the moisture content of the material is reduced to that of the drying-air current. For final drying, a desiccant is used. It may react with water chemically or retain water through capillarity of adsorption. The drying agent is placed directly into the gas or liquid to be dried; solid materials are placed in a desiccator, a closed vessel in which moisture diffuses to the desiccant through the dry desiccator atmosphere. A desiccant loses potency as it takes on water; often it can be renewed by heating. Desiccants which form hydrates can be selected to maintain certain levels of low humidity in a closed vessel. *See* ADSORPTION; DELIQUESCENCE.

Among the more important types of solid desiccants are silica gel, activated alumina, anhydrous calcium sulfate, magnesium perchlorate, oxides (of barium and calcium), and activated carbon. [A.L.H.]

Design standards Specifications of materials, physical measurements, processes, performance of products, and characteristics of services rendered. Design standards may be established by individual manufacturers, trade associations, and national or international standards organizations. The general purpose is to realize operational and manufacturing economies, to increase the interchangeability of products, and to promote uniformity of definitions of product characteristics.

Individual firms often maintain extensive and detailed standards of parts that are available for use in their product designs. Usually the standards have the effect of restricting the variety of parts to certain sizes and materials. In this way the production lots required for inventory purposes are increased, and production economies may thereby be realized through the wider use of mass production. However, even if the larger quantities needed of the relatively few sizes do not in themselves lead to a cheaper manufacturing process, the costs of carrying inventory and setting up for production runs are reduced. A further development of this design approach may lead to the modulization of the entire product line, by reducing it to certain major subassemblies that are common to as many products as possible. Special jobs then typically require only a few added features, and cost savings may be realized.

A possible disadvantage is that the extensive use of generalpurpose parts may jeopardize the space parts business, especially where outside manufacturers can skim off the market for the more commonly used and profitable spare parts once the original patents, if any, have expired, and then leave the more complex and slow-moving spares to the original manufacturer. However, it is precisely this aspect of standardization which is often welcomed by the users of the product.

Standardization also determines the nature of design practice. Especially when the specifications also give data on strength and performance as well as the usual dimensions, it is only necessary to compute loads approximately and then select the nearest standard sizes. Much design effort is thereby saved, especially on detail drawings, bills of material, and so forth. This approach also simplifies programming when computer-aided design is used. *See* COMPUTER-AIDED DESIGN AND MANUFACTURING.

Trade associations are the principal sources of American industrial standards. These involve standardization over an entire product line. In general, their scope is considerably less than that within firms with extensive standardization programs, but the technical and policy considerations in the two levels of standardization are quite similar. Trade standards are primarily concerned with specifying overall dimensions, so that products of different manufacturers may be used interchangeably; with performance, so that customers know what they are buying; and with certain design features, such as major materials, in order to assure proper function. In some cases, dimensional standards particularly must be related to standards in other industries; for instance, an American butter dish must accommodate the standard 4-oz (113.6-g) sticks in which butter is packed. Like national standards to which they are closely related, trade association standards should be established on the basis of as broad a consensus as possible within the industry. If standards were established such that any required burden of retooling and product change would fall in a discriminatory fashion upon only certain members of the industry, legal remedy would certainly be sought under the American antitrust laws.

The principal industrial countries have official agencies that approve, consolidate, and in some cases establish standards. Among them are the British Standards Institution (BSS), German Institute for Norms (DIN), and the American National Standards Institute (ANSI, formerly ASA). The national standardization agencies are members of a wide variety of international groupings and United Nations agencies. The principal ones are the International Organization of Standardization (ISO) and the International Electrotechnical Commission (IEC). These attempt to coordinate national activities and promote cooperation in the area of standardization. Several of the more than 50 organizations deal with weights and measures; others engage in transnational or international activities in the standardization of many products or cover specific regional issues and requirements. Some, like the European Economic Community (EEC), the International Telecommunications Union (ITU), the International Civil Aviation Organization (ICAO), or the administration of the General Agreement on Tariffs and Trade (GATT) mainly have other political, economic, and scientific concerns but must necessarily take note of standardization as part of their work. *See* Engineering design; Physical measurement. [J.E.U.]

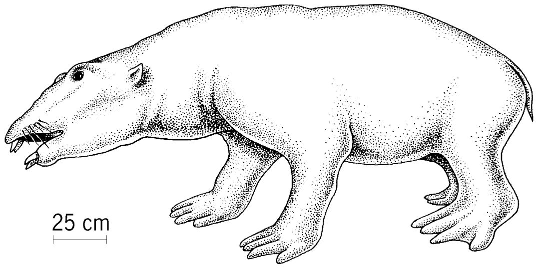
Desmodorida An order of nematodes in which the variable stoma may be armed with a dorsal tooth which may be opposed by subventral denticles. The variable amphids range from reniform-to-elongate loops to simple or multiple spirals. The cephalic sensilla are generally in three whorls; however, the second and third whorls may be combined. Distinguishing the order is the cephalic capsule or helmet and the conspicuous somatic annuli. In some groups, anterior and posterior adhesion tubes are utilized in locomotion.

There are five desmodorid superfamilies: Ceramonematoidea comprise marine forms with distinctive cuticular ornamentation that takes the form of crested annuli; nothing is known of the feeding habits. Most species of Desmodoroidea are found in the marine environment. Draconematoidea are an unusual superfamily of marine forms; when relaxed, the body is dorsally and then ventrally arched into a shallow sigmoid shape. Epsilonematoidea and Monoposthioidea comprise marine forms. *See* Nemata. [A.R.M.]

Desmoscolecida An order of nematodes in which the taxa are readily recognized by their conspicuous body annulation. The annuli may be covered with concretion rings, or the cuticle may be ornamented with scales, warts, or bristles. The cephalic sensilla reportedly are reduced in number. The internal whorl is absent, the second whorl is papilliform, and the four sensilla of the third circlet are setiform. The vesiculate amphids are oval to circular and occupy much of the cephalic region. The somatic setae are tubular, and the open distal ends are often elaborate. The posterior esophagus is only slightly expanded. When pigment spots or ocelli are present, they are just posterior to the esophagus. Females are amphidelphic, and the ovaries are generally outstretched. The male spicules are generally accompanied by a gubernaculum. Both sexes have three caudal glands.

There are two desmoscolecid superfamilies: Most species of Desmoscolecoidea are found in the marine environment, although some species have also been collected from brackish waters. Greeffielloidea are free-living nematodes found primarily in marine or, rarely, estuarine habitats. *See* Nemata. [A.R.M.]

Desmostylia An extinct order of large, hippopotamus-like, amphibious, gravigrade, shellfish-eating mammals that frequented shallow bays and coastal margins during the Oligocene and Miocene (see illustration). Their main distribution was northern trans-Pacific, but discoveries in Florida indicate a much broader distribution. There are two families, the Desmostylidae and the Paleoparadoxidae. These animals probably descended from an ancestral stock that also gave rise to the Proboscidea and Sirenia. *See* Mammalia; Proboscidea; Sirenia. [G.T.J.]



A restoration of *Desmostylus* from the Miocene of California. (*After F. A. Stirton, 1959*)

Desmothoracida An order of Heliozoia. These ameboid organisms live in a stalked perforated organic or inorganic lorica. Stiffened pseudopodia extend from the perforations to capture food which collides with them. The best-known species is *Clathrulina elegans,* found in fresh-water environments. This species has a spherical organic test. Unlike most Heliozoia it has a life cycle which involves motile flagellated cells which arise from the sessile form and then may settle, transforming into amebas with thin pseudopodia. These ameboid forms secrete the stalk and lorica to give rise to the typical sessile (trophic) organism. *See* Heliozoia; Protozoa; Sarcodina. [D.J.Pa.]

Desorption A process in which atomic and molecular species residing on the surface of a solid leave the surface and enter the surrounding gas or vacuum. In stimulated desorption studies, species residing on a surface are made to desorb by incident electrons or photons. Measurements of these species provide insight into the ways that radiation affects matter, and are useful analytical probes of surface physics and chemistry. In thermal desorption studies, adsorbed surface species are caused to desorb as the sample is heated under controlled conditions. These measurements can provide information on surface-bond energies, the species present on the surface and their coverage, the order of the desorption process, and the number of bonding states or sites.

Stimulated desorption. Stimulated desorption from surfaces is initiated by electronic excitation of the surface bond by incident electrons or photons. The classical model of desorption is an adaptation of the theory of gas-phase dissociation, in which desorption results from excitation from a bonding state to an antibonding state.

Another model which is more applicable to the phenomenon of ion desorption was first observed in studies of the desorption of positively ionized oxygen (O^+) from the surface of titanium(IV) oxide (TiO_2). Here it is found that O^+ is desorbed not by valence level excitation, but by ionization of the titanium and oxygen core levels. These levels, of course, have little to do with bonding. Furthermore, the fact that the oxygen is desorbed as an O^+ ion (whereas it is nominally at O^{2-} on the surface) implies a large (three-electron) charge-transfer preceding desorption. This mechanism for desorption can also be effective for covalently bonded surface species.

Stimulated desorption studies are finding wide use. First, they can show the ways in which radiation affects the structure of solids. This will have important applications in the areas of radiation-induced damage and chemistry. Second, as an analytical tool, they offer a unique new way to study the physics and chemistry of atoms on surfaces which, when combined with the many other surface techniques based largely on electron spectroscopy, can provide new insight. Finally, models of the surface bond are put to a much sterner test in attempting to explain desorption phenomena. *See* Radiation damage to materials.

An additional important discovery is that ion angular distributions from stimulated desorption are not isotropic, but show that ions are emitted in relatively narrow cones which project along the nominal ground-state bond directions. Thus this technique provides a direct display of the surface-bonding geometry.

Thermal desorption. Thermal desorption mass spectroscopy is possibly the oldest technique for the study of adsorbates on surfaces. Three primary forms of the thermal desorption experiment involve measurement of (1) the rate of desorption from a surface during controlled heating (temperature-programmed thermal desorption), (2) the rate of desorption at constant temperature (isothermal desorption), and (3) surface lifetimes and diffusion under exposure to a pulsed beam of adsorbates (molecular-beam experiments). Of the three, temperature-programmed thermal desorption is by far the most widely applied. The most straightforward information provided is the nature of the desorbed species from mass analysis, and a determination of the absolute coverage by the adsorbate, which is very difficult to obtain with other techniques. The technique can also provide important kinetic parameters of the desorption process.

While the thermal desorption techniques are among the simplest of surface probes, they remain indispensable because of their directness and the variety of information they convey. Thus while surface science moves to detailed methods involving extremely sophisticated apparatus, the simple thermal desorption methods remain an important part of the overall picture. *See* Surface physics. [M.L.K.]

Destructive distillation The primary chemical processing of materials such as wood, coal, oil shale, and some residual oils from refining of petroleum. It consists in heating material in an inert atmosphere at a temperature high enough for chemical decomposition. The principal products are (1) gases containing carbon monoxide, hydrogen, hydrogen sulfide, and ammonia, (2) oils, and (3) water solutions of organic acids, alcohols, and ammonium salts.

Crude shale oil may be obtained by destructive distillation of carboniferous shales. It may be subjected to a destructive, or coking, distillation to reduce its viscosity and increase its hydrogen content. Residual oils from petroleum refinery operations are subjected to coking distillation to reduce the carbon content. The coke is used for the manufacture of electrode carbon. The main product of the destructive distillation of wood is 40–45% charcoal used in metallurgical processes in which the low content of ash, sulfur, and phosphorus is important. *See* Charcoal; Coal chemicals; Coke; Coking (petroleum); Oil shale; Pyrolysis; Wood chemicals. [H.H.St./H.W.W.]

Detergent A substance used to enhance the cleansing action of water. A detergent is an emulsifier, which penetrates and breaks up the oil film that binds dirt particles, and a wetting agent, which helps them to float off. Emulsifier molecules have an oillike nonpolar portion which is drawn into the oil, and a polar group that is water-soluble; by bridging the oilwater interface, they break the oil into dispersible droplets (emulsion). As a surfactant, a detergent decreases the surface tension of water and helps it penetrate soil.

Soap, the sodium salt of long-chain acids, was the principal detergent until superseded in 1954 by synthetic detergents (syndets) which, unlike soap, do not form insoluble products with the calcium in hard water. Most syndets are of the anionic type, that is, sodium salts of alkyl sulfates or sulfonates. Alkyl benzene sulfonates (ABS) with branched carbon chains were found to persist in wastewater and have been replaced by linear alkyl benzene sulfonates (LAS), which are biodegradable by bacterial action. Anionic detergents are best for water-absorbing fibers such as cotton, wool, and silk. Nonionic detergents are polyethers made by combining ethylene oxide with a 12-carbon lauryl alcohol. They are used for water-repelling "permanent press" fabrics, and their low-foaming property is desirable for automatic washers. Cationic syndets are quarternary base compounds. They are more expensive, but some are germicidal; some are used as fabric softeners and as good metal cleaners.

Detergents must contain alkaline "builders" to bind dissolved metal ions and support emulsification. Sodium pyrophosphate or polyphosphate were preferred because of low cost and high cleansing effectiveness. However, when discharged with laundry wastewater, these compounds supply nutrient to phosphate-deficient lakes and streams and thus lead to eutrophication, and their use is now banned by law. Less harmful, but less effective, builders such as sodium carbonate are now widely used in detergents. *See* Eutrophication.

Many additives are used in detergents to provide scent, brightening (usually through fluorescent action), or bleaching action. Biodegradability is essential for detergents; it ensures that components of detergents will be broken down by bacterial action before undesirable aftereffects can occur. Nonbiodegradable detergents can prevent effective bacterial action in septic tanks and sewage treatment plants, and can cause undesirable persistent foaming in rivers. *See* Soap. [A.L.H.]

Determinant The theory of determinants had its origin in the solution of linear systems of equations. Determinants occur in virtually all branches of mathematics and related fields. *See* Linear systems of equations; Matrix theory; Polynomial systems of equations.

The concept of a determinant can best be explained with reference to a matrix A.

$$\text{Let} \qquad A = \begin{pmatrix} a_{11} & a_{12} & \cdots & a_{1n} \\ a_{21} & a_{22} & \cdots & a_{2n} \\ \cdots & \cdots & \cdots & \cdots \\ a_{n1} & a_{n2} & \cdots & a_{nn} \end{pmatrix}$$

be an n by n square array of numbers. Such an array is called an n by n square matrix, and the numbers a_{ij} in the array are called elements of the matrix. The determinant of the matrix A, as indicated by Eq. (1), is a number which is the value of a certain function of the elements of A.

$$|A| = \begin{vmatrix} a_{11} & a_{12} & \cdots & a_{1n} \\ a_{21} & a_{22} & \cdots & a_{2n} \\ \cdots & \cdots & \cdots & \cdots \\ a_{n1} & a_{n2} & \cdots & a_{nn} \end{vmatrix} \qquad (1)$$

The determinant of Eq. (1) is called a determinant of order n, and it can be defined by induction on n. For explanatory purposes, determinants of orders $n = 1$, 2, and 3 are defined as follows:

For $n = 1$, $|a_{11}| = a_{11}$

For $n = 2$, $\begin{vmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{vmatrix} = a_{11}|a_{22}| - a_{12}|a_{21}| = a_{11}a_{22} - a_{12}a_{21}$

For $n = 3$, $\begin{vmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{vmatrix}$

$$= a_{11}\begin{vmatrix} a_{22} & a_{23} \\ a_{32} & a_{33} \end{vmatrix} - a_{12}\begin{vmatrix} a_{21} & a_{23} \\ a_{31} & a_{33} \end{vmatrix} + a_{13}\begin{vmatrix} a_{21} & a_{22} \\ a_{31} & a_{32} \end{vmatrix}$$

$$= a_{11}(a_{22}a_{33} - a_{23}a_{32}) - a_{12}(a_{21}a_{33} - a_{23}a_{31}) + a_{13}(a_{21}a_{32} - a_{22}a_{31})$$

The determinants of order 2 and 3 are defined in terms of determinants of order 1 and 2, respectively. Suppose now that a determinant of order $n - 1$ has been defined. In Eq. (1), denote by A_{1j}, $j = 1, 2, \ldots, n$, the determinant of order $n - 1$ formed by deleting from Eq. (1) the first row and the jth column. Equation (2) then, by definition, holds.

$$|A| = a_{11}A_{11} - a_{12}A_{12} + a_{13}A_{13} + (-1)^{n-2}a_{1n-1}A_{1n-1} + (-1)^{n-1}a_{1n}A_{1n} \qquad (2)$$

This definition is seen to agree with the definitions for determinants of order 2 and 3 and, by the principle of mathematical induction, defines a determinant of order n for every n. There are many other definitions of a determinant of order n which can be proved to be equivalent to the definition given here. *See* Equations, theory of. [R.A.B.]

Determinism The principle that nature follows exact laws, so that what will happen in the future is a necessary consequence of the state of the world at any given moment in the past. This view, if fully adopted, implies that events which seem to occur by chance would be fully understood if more was known about them, and that apparently free thoughts and choices are explainable and in principle predictable in terms of neuroscience. In a looser sense, determinism refers to claims that mental freedom is much more restricted than people are inclined to suppose.

The question of determinism in physical science cannot be considered apart from the philosophical problem; this gives it added importance and forces its consideration in a very critical spirit.

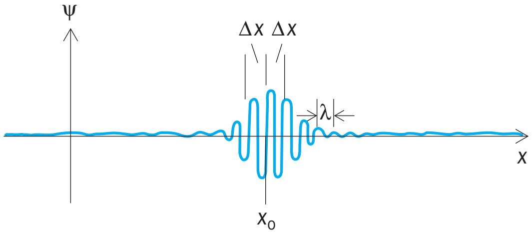
The idea that the world is composed of atoms moving under the influence of certain forces according to certain laws can be traced back to the Greek philosopher Leucippus. Deterministic philosophy was prominent in the work of the seventeenth-century thinker René Descartes, and became widely known through his influence. Isaac Newton carried out a large part of the cartesian program. His theory explained so many natural processes that it began to appear that the universe since the time of Creation might actually have run its course in a deterministic fashion like a machine, without divine intervention. A century after Newton, Pierre Simon de Laplace argued that an Omniscient Calculator, provided with exact knowledge of the state of the universe at present, would be able to predict the entire future. *See* CLASSICAL MECHANICS; NEWTON'S LAWS OF MOTION.

The quantum mechanics of the 1920s introduced the paradox of particles which are, at the same time, waves. A wave of length λ was supposed to accompany, or describe, a particle of momentum $p = h/\lambda$, where h is Planck's constant. The probability of finding a free particle is expressed by a (complex) wave packet (see illustration), and the particle has appreciable probability of being found only where the wave function is large; that is, within a region of size roughly Δx on each side of x_0 in the illustration. A theorem of Fourier analysis shows that Δp, the range of momenta present in the wave packet, is related to Δx as shown below. This means that the more precisely the specification of a

$$\Delta x \ \Delta p \geq h/(2\pi)$$

particle's position x is attempted by means of a localized wave function, the less precisely can its momentum be specified. W. Heisenberg's principle of uncertainty, or indeterminacy, states that it is impossible to measure, and therefore to know, x and p any more accurately than is allowed by this relation, and there are also other pairs of dynamical variables similarly related. *See* FOURIER SERIES.

There remains the question as to whether Heisenberg's principle is merely an unfortunate limitation on an experimenter's ability to know or whether it goes deeper. The general opinion of physicists is that of N. Bohr: the principle expresses a limitation of the precision with which concepts such as position and momentum can be applied at all. Therefore Laplace's Omniscient Calculator cannot predict the future. *See* QUANTUM MECHANICS; UNCERTAINTY PRINCIPLE.



A wave packet—of wavelength approximately λ, and produced perhaps by opening and closing a shutter—traveling through space.

Perceptive mathematicians have warned that determinism is not as obvious a consequence of newtonian physics as it might appear. A series of mathematical results have been proven whose general effect is that for the vast majority of dynamical systems any error in the initial conditions, however small, will be amplified, in general exponentially, and so quickly that the predicted result will soon bear no relation to reality. Thus unless it is assumed that initial conditions are known with perfect accuracy, and perfectly accurate computation takes place thereafter, the Omniscient Calculator will wind up getting everything wrong. *See* CHAOS.

Very few people now think that all events in the natural world are exactly determined. Experiments suggest that some human and animal behavior can reliably be predicted and controlled, but nobody knows the limits within which this can be done. [D.P.]

Deuterium The isotope of the element hydrogen with atomic weight 2.0144 and symbols ^2H or D. The terrestrial natural abundance of deuterium is 1 part in 6700 parts of ordinary hydrogen (protium). Small variations in natural sources are found as a result of fractionation by geological processes.

Deuterium is a gas (D_2) at room temperature. It is prepared from heavy water, D_2O, either by electrolysis or by reaction of D_2O with metals such as zinc, iron, calcium, and uranium. It is also prepared directly by the fractional distillation of liquid hydrogen.

Deuterium is used mainly in the form of heavy water. In the uncombined state it finds uses as a research tool. Liquid deuterium is used in bubble chambers to study the reactions of elementary particles with the deuterium nucleus, the deuteron. Deuterons are frequently accelerated in cyclotrons to study their reactions with other nuclei and also to produce radioactive nuclides. Deuterium gas is used in the direct synthesis of organic compounds for tracer studies. *See* DEUTERON; HEAVY WATER; HYDROGEN; NUCLEAR FUSION; NUCLEAR REACTION; TRITIUM. [J.Big.]

Deuteromycotina A heterogeneous group of anamorphic (asexual or imperfect) fungi in which sporulation may occur on separate hyphae or composite fruit bodies (conidiomata). The diagnostic feature of the group is the lack of a teleomorphic (sexual or perfect) state. There are more than 2500 accepted genera containing 21,000 species.

Traditionally, Deuteromycotina are separated into two classes: Hyphomycetes, which are mycelial forms bearing conidia on separate hyphae or aggregations of hyphae; and Coelomycetes, which are forms that produce conidia in pycnidial, pycnothyrial, acervular, cupulate, or stromatic conidiomata. A third class is sometimes recognized, the Agonomycetes (Mycelia Sterilia); these fail to produce conidia and thus lack conidiomata, although they do form somatic survival propagules. Currently, no ranks are distinguished within the Deuteromycotina, and the subdivisional name itself is no longer in use, the preferred term being Mitotic Fungi or Fungi Anamorphici. *See* AGONOMYCETES; COELOMYCETES; HYPHOMYCETES.

Deuteromycetes are ubiquitous and occupy most conceivable ecological niches. Deuteromycetes such as *Penicillium*, *Aspergillus*, and *Saccharomyces* have been used extensively in manufacturing processes of different kinds. Increasingly important is the use of deuteromycetes in biological control of insects, nematodes, pathogenic fungi, and weeds. *See* DISTILLED SPIRITS; FOOD MANUFACTURING.

Fungal infections (mycoses) are almost always the result of abnormal host immunity. Even before the association of the human immunodeficiency virus (HIV) with acquired immune deficiency syndrome (AIDS), criteria used in defining the syndrome relied heavily on the existence of certain opportunistic infections in the absence of any of the established predisposing conditions. A significant number of these deep-seated infections are caused by deuteromycetes such as *Aspergillus, Candida, Cryptococcus*, and *Histoplasma*. *See* ACQUIRED IMMUNE

DEFICIENCY SYNDROME (AIDS); MEDICAL MYCOLOGY; MYCOTOXIN; OPPORTUNISTIC INFECTIONS. [B.C.S.]

Deuteron The nucleus of the atom of heavy hydrogen, ^{2}H (deuterium). The deuteron *d* is composed of a proton and a neutron; it is the simplest multinucleon nucleus. Its binding energy is 2.227 MeV; that is, this is the amount of energy which must be added to a deuteron for it to dissociate into a proton and a neutron. Deuterons are much used as projectiles in nuclear bombardment experiments. *See* DEUTERIUM; NUCLEAR REACTION. [H.E.D.]

Developmental biology A large field of investigation that includes the study of all changes associated with an organism as it progresses through the life cycle. The life cycles of all multicellular organisms exhibit many similarities. That is, as an organism progresses from one generation to the next there is a series of common processes: for example, gametogenesis, fertilization, embryogenesis, cell differentiation, tissue differentiation, organogenesis, maturation, growth, reproduction, senescence, and death. [D.Ru.]

Analysis of all of the events associated with an organism as it progresses through its life cycle employs a multiplicity of approaches. Tremendous strides have been made in describing at the molecular level the developmental process of cell differentiation. However, the molecular control mechanisms which regulate cell differentiation are not known. Tissue and organ differentiation, as well as morphogenesis, are processes which have been described in detail for many situations, but little is known about the physical and chemical nature of the mechanisms involved. A complete understanding of the development of an organism will require an appreciation and comprehension of the changes which occur at all levels of organization as an organism traverses its life cycle.

The major unifying theme in biology is evolution. Not only has evolution led to the wide variety of organisms now present on Earth, but also evolution has modified the initial processes and patterns of development to the diversity of types currently encountered. This evolution of developmental parameters in multicellular organisms began as single-celled organisms became multicellular. The development of a multicellular organism entails a host of problems not faced by a single-celled organism. For example, cells in one part of the aggregate must coordinate their activities with cells in other parts, nutrients and oxygen must be provided to all cells, and water balance must be maintained.

Developmental biologists have focused on two central areas: the processes and associated mechanisms by which cells become different, that is, cell differentiation; and the processes and associated mechanisms by which patterns are created, that is, morphogenesis.

Current theories state that cells become different by expressing different genes. Thus, a liver cell is different from a muscle cell, not because it contains different genes or genetic information, but because it expresses different sets of genes. This explanation of cell differences is based upon the results of three types of experimental analysis. (1) Some plant cells are totipotent; that is, for tobacco, carrot, and a few other plant species, it has been demonstrated that a single cell (not a gamete) can divide and undergo morphogenesis to form a fertile plant. (2) Nuclei from some differentiated animal cells are totipotent. That is, a nucleus from a differentiated cell can be injected into a mature egg which has had its nucleus removed or destroyed, and the injected nucleus can direct normal development of the organism. (3) The sequences of nucleotides in the DNA of all cells in an organism appear to be the same; that is, DNA-DNA hybridization of DNA from different cell types indicates that the different cell types do not have unique DNA base sequences. Since these results indicate that all cells contain the complete genome for an organism, different cell types appear to arise as a result of the expression of unique sets of genes in each cell type. *See* CELL DIFFERENTIATION; DEVELOPMENTAL GENETICS; GENE ACTION; SOMATIC CELL GENETICS.

Initially the cells of a developing embryo are not restricted in their developmental potential or fate, but as embryogenesis proceeds, a cell's developmental potential becomes restricted or fixed. Restriction of developmental fate is called determination. Two mechanisms have been identified that bring about determination. The first involves the presence of unique factors, called cytoplasmic determinants, which are products of the maternal genome and are located in specific areas of some animal eggs. The cells which come to contain these determinants differentiate along specific pathways. The second mechanism is induction, a process by which two tissues interact so that one or both differentiate along specific pathways. A classic example of induction is the action of mesoderm on the overlaying ectoderm in the frog embryo at the time of gastrulation. The mesoderm acts on the ectoderm, causing it to form the neural plate. Only ectoderm of a certain developmental age is capable of responding to the mesoderm, and this ectoderm is said to be competent. *See* EMBRYONIC INDUCTION.

Developmental biologists have gained substantial insights into the molecular bases for determination in model organisms such as *Drosophila*. At least three sets of cytoplasmic determinants (maternal gene products) are present in the fly egg: determinants for germ-cell formation, determinants controlling dorsal-ventral polarity, and determinants for the anterior-posterior polarity. Some of these determinants are messenger ribonucleic acids (mRNAs) coding for proteins which are transcriptional regulators (that is, proteins that regulate gene activity).

Morphogenesis involves the production of form and structure by integrating the differentiation of many different cells and cell types into specific spatial patterns. This higher level of organization has been difficult to investigate in terms of establishing mechanisms. The processes of determination, competence, and induction are involved. One of the greatest challenges faced by developmental biologists is to bridge the gap between genes and patterns. It is clear that patterns are a result of gene activity, but the relationship between genes and patterns in most organisms is not well understood. *See* ANIMAL MORPHOGENESIS; PLANT MORPHOGENESIS. [C.N.M.]

Developmental genetics The study of how genes control development. Advances in the field have emphasized the degree of conservation of the genes controlling development throughout evolution. Thus, such distant organisms as insects and vertebrates share a number of very homologous genes controlling early development. For example, homeobox genes (*Hox* genes) are used in both insects and mammals to provide information for anterior-posterior positioning. The conservation of the genes is so great that the human version of a *Hox* gene can sometimes substitute for the mutant *Drosophila* gene and correct abnormalities of early development.

Most genes involved in sex determination have not been conserved, but a gene has been cloned in the nematode *Caenorhabditis elegans* which is highly homologous to a gene involved in the *Drosphila* sex determination cascade and to a gene in mammals whose role in sex determination has yet to be fully elucidated. Another organism which is elucidating these genes and has become of great interest is the zebrafish. Its small size and clear embryo allow easy screening of many developmental mutations, and many of the above-mentioned evolutionary conservations have been confirmed in the zebrafish.

Determination is a stage during the developmental process when genes become committed to a particular expression pattern leading to a differentiated state. At the time of this stage, the differentiated state is not yet visible. This aspect can be confirmed by transplantation of determined but not yet differentiated tissues to ectopic sites and observing the transplant's development. Advances have shown that some cell types are not as highly determined as was previously thought. Brain cells have given rise to blood cells, and bone marrow cells have given rise to bone and muscle. This apparent lack of determination in cells previously believed to be determined suggests greater potential for plasticity and the possibility of manipulating cells to new fates to create organs for human transplantation, for example.

Another area of research has involved maternal inheritance. Many of the genes responsible for the determination of cell fate in *C. elegans* larva are laid down in the egg; that is, they are maternal-effect genes. In this case, it is not the genotype of the zygote which influences development but that of the mother. Thus, homozygosity for a recessive mutation in the mother leads to altered development, even though the sperm is from a homozygous wild-type male and the resulting zygote was heterozygous. The percentage of maternal-effect genes is also high in *Drosophila*. *See* GENE ACTION.

Another general phenomenon under genetic control during development is induction—the action of one cell or tissue on other cells in order to determine altered gene expression in them.

Homoeotic mutations change one paired structure to another of a more interior or posterior compartment (for example, a leg to an antenna). The study of their structure and function has provided a paradigm for the role of genes in conveying positional information during development. In *Drosophila*, seven homoeotic genes are grouped in two complexes. Their role in establishing segmental identities is well defined, and the DNA sequence of the genes shows a highly conserved element called the homeobox. This conserved sequence is also found in some pair-rule and polarity genes, and the search for genes homologous to these led to the identification of other genes that are highly conserved in animal evolution. Although *Drosophila* uses one set of homeobox genes (separated into two clusters on two different chromosomes), mammals have amplified the set of genes to a minimum of four clusters of the size of the single cluster in *Drosophila*. These genes maintain the same patterns of expression in both mammals and *Drosophila*. They are expressed 5′ to 3′ in order of transcription, and the 5′-to-3′ order in the cluster is also reflected in the posterior-to-anterior limits of expression of the gene products. Most mutations in homeobox genes are recessive, and embryonic stem-cell knockouts have disclosed that, because there is sufficient redundancy in the mammalian homeobox clusters, the homozygous absence of one homeobox gene does not always result in an apparent phenotype. Paired box genes are another highly conserved family of genes, first identified for their important developmental roles in *Drosophila*. Mutations in these genes frequently cause dominantly inherited birth defects in mammals.

Imprinting, a developmentally important phenomenon that was first discovered in insects, is also important for mammalian development and human disease. In imprinting, genes transmitted through the testis sometimes function differently from those transmitted through the ovary. Many portions of the genome have been found to be imprinted, including the reciprocal imprinting of insulinlike growth factor and its receptor. Some major human diseases occur when both a paternal and a maternal copy of a gene are not present. The Prader-Willi syndrome, a disorder of mental retardation, poor appetite regulation, and mild dysmorphic features, is an example. Advances have strongly implicated gametogenesis-specific methylation of key controlling regions in the imprinting process. Such imprints seem to be erased from the migrating germ cells enroute to the developing gonad, and then are established differentially during ovigenesis and spermatogenesis, presumably by proteins uniquely expressed in the two different gonads and with specificity for the particular DNA sequences. The actual expression of imprinting differences frequently involves (1) competition between cis-linked genetic elements and (2) a nontranslated RNA species. *See* DEVELOPMENTAL BIOLOGY; GENETICS. [R.P.E.]

Developmental psychology The study of age-related changes in behavior from birth to death. Developmental psychologists attempt to determine the causes of such changes. Most research has concentrated on the development of children, but there is increasing interest in the elderly, and to a lesser extent in other age groups. Although most developmental work examines humans, there has been some work on primates and other species that would be considered unethical with human beings. Thus the sensory deprivation of kittens and the separation of monkeys from their mothers have provided information about abnormal perceptual and emotional development, respectively.

Method. Developmental psychologists who study children rely more upon careful observation in natural settings than upon laboratory experiments. Under these circumstances, only partial conclusions can be drawn about the causes of development. The field has been dominated by descriptive research, with increasing attempts to explain developmental phenomena by the use of animal experiments or by statistical methods. In longitudinal research, a group of individuals is studied at regular intervals over a relatively long period of time. This contrasts with cross-sectional research, where individuals of different ages are studied at the same time. Conclusions from the two types of research may differ. Finally, case studies, that is, close and extensive observations of a few subjects, have been relied upon by important developmental theorists such as S. Freud and J. Piaget.

Theories. An explanation of developmental changes requires a judgment as to the relative importance of genetically programmed maturation and environmental influences. Although most developmentalists believe that genetic endowment and environmental experience interact to account for behavior, the degree to which either affects a particular behavior is still often debated. This issue has important implications for the success of environmental intervention in the face of genetic constraints. For example, the influence on children of parental speech versus genetic programming in language acquisition is much debated, as is the origin of gender differences in behavior. *See* BEHAVIOR GENETICS.

Developmental psychology is divided roughly between those who study personal–social (emotional) development and those who study intellectual and linguistic development, although there is a small but growing interest in the overlap between these two aspects of personality, known as social cognition. The study of personal-social development in childhood is dominated by the theory of attachment formulated by J. Bowlby and extended by M. Ainsworth. In adolescence and adulthood, E. Erikson's theory of psychosocial development is prominent. The study of intellectual development at all ages is dominated by Piaget's theory of cognitive constructivism.

Emotional development. Ainsworth defines attachment as "an affectional tie that one person forms to another specific person, binding them together in space, and enduring over time . . . [It] is discriminating and specific." It is not present at birth, but is developed. In a word, attachment means love. Attachment behaviors such as crying, smiling, physical contact, and vocalizing are the means by which attachment is forged but are not to be equated with the more abstract, underlying construct of attachment. Attachment theory is strongly based on ethological notions. Thus, attachment is seen as serving a biological function, that is, the protection of infants by ensuring their proximity to (attached) adults. The common goal of attached individuals is proximity. Bowlby was influenced by Freud's psychoanalytic theory of development, but argues that there is a primary biological need to become attached to at least one adult, whereas Freud argued that love for a mother was secondary to her satisfaction of an infant's hunger.

Intellectual development. For Piaget, intelligence is defined as the ability to adapt to the environment, an ability that depends upon physical and psychological (cognitive) organization. The adaptation process has two complementary components, assimilation and accommodation. Assimilation refers to the tendency to process new information, sometimes with distortion, in terms of existing cognitive structures. Accommodation refers to the opposite process, that is, the modification of existing cognitive structures in response to new information. An individual strives for equilibrium between assimilation and accommodation, with thought being neither unrealistic (excessive assimilation) nor excessively realistic and hence disorganized (excessive accommodation). *See* COGNITION; INTELLIGENCE.

For Piaget, cognition gradually becomes abstracted from perception over the course of 12 years. Infants begin cognitive exploration by actively perceiving and reflexively manipulating objects, giving the name sensorimotor period to the first phase of intellectual development. Perception is a key form of early cognitive activity, especially with newborns. The newborn infant can see, hear, smell, taste, and feel much better than previously thought, though sensitivity in these areas improves throughout the first year of life. Between the ages of 18 and 24 months, infants become capable of symbolic representation, occasionally solving problems just by thinking about them. The major accomplishment of the sensorimotor period is object permanence, the realization that objects continue to exist even when not observable. During the next 5 years, sometimes termed the preoperational period, children work on concrete operations such as classifying objects into categories, arranging things in serial order, figuring out causes and effects, or understanding a one-to-one correspondence of numbers to objects counted. They also eventually manipulate reality enough to overcome perceptual illusions such as that an amount of water changes when it is poured from a short wide glass into a tall narrow glass. From 7 to 11 years, children further consolidate their concrete mental operations. At about 12 years, many adolescents enter the final stage of intellectual development: formal operations. They become capable of abstract, logical thought. They understand reality as a subset of possible worlds, and are able to form multiple, systematic hypotheses, involving all possible combinations of relevant variables, in order to explain things.

Many quarrel with Piaget's age assessments of children, but most people accept his sequence of stages as useful for classifying children.

Moral development. L. Kohlberg's work on moral development spans the chasm between intellectual and emotional development. He studied reasoning about hypothetical moral dilemmas, such as whether a person should steal an unaffordable drug in order to save someone's life. He classified such reasoning in six stages. At birth children are considered to be premoral. By the age of 7, most children are in stage 1, chiefly characterized by the belief that people should act in certain ways in order to avoid physical or other punishment. In 2 or 3 years, children reason primarily in terms of doing things for rewards; this is stage 2. Stage 3 involves reasoning focused less on rewards than on maintaining the approval of others. Stage 4 involves reasoning that unquestioningly accepts conventional rules. Actions are judged by a rigid set of regulations, religious, legal, or both. Most individuals do not develop past this point. A few, however, do reach postconventional moral reasoning, stage 5. These individuals think in terms of moral principles. Rarely, a step higher to stage 6 is reached, governed by original abstract moral principles such as articulaton of the golden rule. Kohlberg argued that moral development is progressive, without regression to earlier stages.

Developmental psychopathology. Traditionally, child clinical psychology (abnormal development) and the study of normal development were separate. However, effort is being made to integrate them. Abnormal development is informative about normal processes. The serious disorders of childhood include autism, attention-deficit disorder with hyperactivity, and depression. Viewed another way, abnormal children are either overcontrolled (obsessive-compulsive) or undercontrolled (impulsive, aggressive). Developmental psychopathologists, however, are interested not just in disordered development in childhood, but in abnormal individuals over their lifetime. Such studies can shed light on the effectiveness of treatments and on the way in which disorders such as hyperactivity may be displayed differently at different ages. [A.McC.]

Devonian The fourth period of the Paleozoic Era, encompassing an interval of geologic time between 418 and 362 million years before present based on radiometric data. The Devonian System encompasses all rocks deposited or formed during the Devonian Period. *See* PALEOZOIC.

The base of the Devonian System has been fixed, by international agreement, at an outcrop of sedimentary rocks at Klonk in the Czech Republic, where it corresponds to the base of the *Monograptus uniformis* graptolite zone. The top of the Devonian System, corresponding to the base of the Carboniferous System, was fixed at LaSerre in southern France, recognized by the base of the *Siphonodella sulcata* conodont zone. The Devonian is customarily divided into Lower, Middle, and Upper series and their corresponding epochs.

Devonian fossils are found to be distributed in three realms. Within each realm there is taxonomic similarity, which indicates that there was reproductive interchange among members of the same phyletic groups, but between each two realms there are various degrees of taxonomic dissimilarity, which indicates that there were various degrees of reproductive isolation among members of the same phylogenetic groups. The largest realm covered Australia, Asia, Europe, western North America, and the Morocco-India fringe of Gondwana, and is termed the Old World Realm. It was unified by relatively free flowage of the warm equatorial currents and their immediate branches among the continental masses throughout this tropical to subtropical region. The Appalachian Realm covered most of eastern North America and the Colombia-Venezuela-Amazon part of northern South American Gondwana, which was adjacent to Appalachian North America during the Devonian. This region was bathed by the temperate southern west-wind current, which crossed a sufficiently broad stretch of ocean so that many Old World larvae could not make the journey, allowing endemic Appalachian forms to develop locally. The Malvinokaffric Realm covered central Gondwana, including southern South America, southern Africa, and Antarctica.

Devonian mountain building was particularly noticeable along the margins of Euramerica. The Acadian orogeny formed mountainous highlands accompanied by a chain of granitic intrusions from Nova Scotia to Pennsylvania during much of Devonian time. These mountains formed a barrier that prevented mixing between organisms of the Appalachian Realm and those of the Old World Realm at the same latitude in central Europe. Erosion from the Acadian mountains produced the thick Catskill deltaic complex of New York and Pennsylvania, which spread its fine-grained sediments far into the interior of eastern North America during later Devonian time. Simultaneously, along the Arctic margin of Canada, the Ellesmerian orogeny was producing folded mountains whose erosional products formed a clastic wedge that was a mirror image of the Catskill deposits. During latest Devonian time, the Roberts Mountains thrust, of the Antler orogeny in Nevada and Idaho, formed at the top of a subduction zone along which continental crust and overlying sediments were descending beneath oceanic sediments. A Late Devonian orogeny also affected eastern Australia. *See* OROGENY; PLATE TECTONICS.

Among the marine invertebrates, trilobites (Arthropoda) were much less abundant than during the Cambrian. The planktic members of the extinct graptolites died out during the Early Devonian, at about the same time as the pelagic ammonoid cephalopods first evolved. The externally two-shelled brachiopods were at their greatest diversity. Lime-secreting corals and stromatoporoids were important and widespread in warm-water environments, and formed reefs during the Middle and Late Devonian. The extinct microfossil group known as conodonts was abundant, widespread, and rapidly evolving during the Devonian, so that conodont fossils are now regarded as the principal tools to be used for international correlation and relative age determination. *See* BRACHIOPODA; CONODONT; GRAPTOLITHINA; MICROPALEONTOLOGY; STROMATOPOROIDEA; TRILOBITA.

The great diversification and radiation of fish in the Devonian has led to the term "Age of Fishes" for the period. Placoderm fish, among the most primitive of the jawed vertebrates, were successful predators in Devonian waters, and some grew to lengths up to 8 m (25 ft) just before their extinction at the end of the Devonian. The sharks, with a cartilaginous skeleton but lacking a swimbladder, may have evolved from an early placoderm. Bony fishes or Osteichthyes, a class that includes all modern fish other than sharks and agnathans, were represented in the Devonian by the primitive acanthodians, but more modern groups of bony fishes appeared in the Early Devonian. Lobe-finned bony fishes, or sarcopterygians, include both the lungfish (Dipnoi) and crossopterygians in the Devonian. The oldest known amphibians, including *Acanthostega* and *Ichthyostega*, occur in strata thought to be high Upper Devonian. *See* CROSSOPTERYGII; DIPNOI; OSTEICHTHYES; PLACODERMI; SARCOPTERYGII.

Land plants began to flourish near the beginning of Devonian time, and were exemplified by the vascular genus *Psilophyton* of the phylum Psilopsida. The latter gave rise in the Devonian to the Lycopsida (scale trees) and Pteropsida (true ferns). *See* LYCOPHYTA; PALEOBOTANY; PSILOTOPHYTA; PTEROPSIDA. [J.G.J.; P.H.H.; D.J.Ov.]

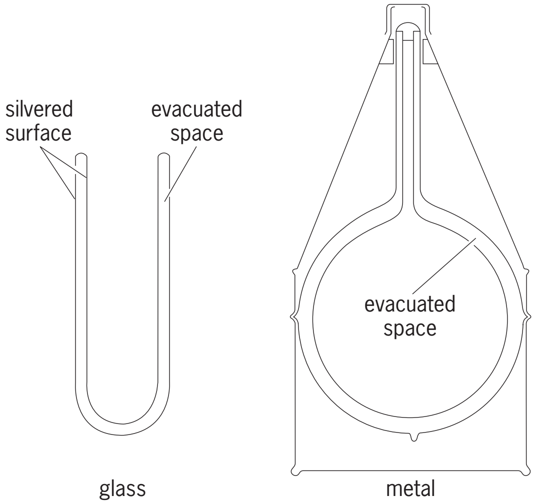
Dew The deposit of liquid water resulting from condensation of atmospheric water vapor to exposed surfaces that cool during the night. Dewfall is noticeable in the early morning after a calm, cool, clear night, usually as beads of liquid water on the outside and upward-facing surfaces of trees, buildings, and so forth. If the ground is moist, some of the condensed water can be evaporated surface moisture. Dew forms when the surface temperature drops sufficiently to saturate air in contact with the surface (that is, when the surface drops to below atmospheric dew-point temperature); when the surface cools to below freezing temperature, frost occurs. *See* DEW POINT; FROST.

Hygroscopic particles on surfaces can act as sites for condensation at temperatures higher than the atmospheric dew-point temperature. Thus, if a surface is not clean, the first deposit of moisture from the air can occur well before the surface cools to dew-point temperature. For some chemicals, such as common salt, condensation can start to occur when the local relative humidity reaches 80%; the humidity must be 100% in the case of a clean surface. Some desert plants exude hygroscopic salts from the interior of leaves which provide preferred sites for condensation and thereby create a supply of water for the plant. *See* HUMIDITY. [B.Hi.]

Dew point The temperature at which air becomes saturated when cooled without addition of moisture or change of pressure. Any further cooling causes condensation; fog and dew are formed in this way.

Frost point is the corresponding temperature of saturation with respect to ice. At temperatures below freezing, both frost point and dew point may be defined because water is often liquid (especially in clouds) at temperatures well below freezing; at freezing (more exactly, at the triple point, $+.01^\circ$C) they are the same, but below freezing the frost point is higher. For example, if the dew point is -9°C, the frost point is -8°C. Both dew point and frost point are single-valued functions of vapor pressure. *See* DEW; EVAPORATION; FOG; HUMIDITY; VAPOR PRESSURE. [J.R.F.]

Dewar flask A vessel having double walls, the space between being evacuated and the surfaces facing the vacuum being heat reflective. It was invented in 1892 by James Dewar as a container for liquid oxygen.



A typical Dewar container.

Dewar's original flasks were made of glass with a coating of mirror silver; this type is still used in the laboratory. But for shipment and storage of liquid gases, metal vacuum vessels are used (see illustration). Thermos Bottle is a trademark for a Dewar vessel for hot and cold foods. [H.W.Ru./G.R.H.]

Dewaxing of petroleum The process of separating hydrocarbons which solidify readily (waxes) from petroleum fractions. Removal of wax is usually necessary to produce lubricating oil which will remain fluid down to the lowest temperature of use. The wax removed may be purified further to produce commercial paraffin or microcrystalline waxes.

Most commercial dewaxing processes utilize solvent dilution, chilling to crystallize the wax, and filtration. Wax crystals are formed by chilling through the walls of scraped surface chillers, and wax is separated from the resultant wax-oil-solvent slurry by using fully enclosed rotary vacuum filters. In a process modification, most of the chilling is accomplished by multistage injection of very cold solvent into the waxy oil with vigorous agitation, resulting in more uniform and compact wax crystals which filter faster.

Complex dewaxing requires no refrigeration, but depends upon the formation of a solid urea–*n*-paraffin complex which is separated by filtration and then decomposed. The catalytic dewaxing process is based on selective hydrocracking of the normal paraffins; it uses a molecular sieve-based catalyst in which the active hydrocracking sites are accessible only to the paraffin molecules. *See* PETROLEUM; PETROLEUM PROCESSING; WAX, PETROLEUM. [S.F.P.]

Dextran A polyglucose biopolymer characterized by preponderance of α-1,6 linkage, and generally produced by enzymes from certain strains of *Leuconostoc* or *Streptococcus*. While formerly its principal utility was as blood plasma substitute, dextran is also employed as packing material in column chromatography and as pharmaceutical agents; its average molecular weight determines usage to a great extent. Dextran's chemical and physical properties depend upon the strain of microorganism employed and the environmental conditions imposed upon the bacterium during growth, or the reaction conditions where an enzymatic method of dextran production is employed. *Leuconostoc* and *Streptococcus* species primarily convert sucrose to dextran and fructose. *Acetobacter* species convert dextrin to dextran. *See* DEXTRIN; POLYMERIZATION; POLYSACCHARIDE. [H.M.Ts.]

Dextrin A polymer of D-glucose which is intermediate in complexity between starch and maltose. The dextrins are usually obtained by hydrolysis of starch with diastase (amylases). The higher dextrins resemble starch, while the lower dextrins more nearly resemble the sugars. Compared with the original starch, the dextrins produce less viscous solutions. They are soluble in water but insoluble in alcohol. Dextrins may be obtained from starch by controlled hydrolysis with acids. They are used commercially as adhesives. Tapioca, waxy maize, and sweet potato starch represent the best material for their manufacture. *See* Glucose. [W.Z.H.]

Diabetes A condition in which excessive amounts of some substances are excreted from the body. The term may refer to either of two unrelated diseases, diabetes mellitus and diabetes insipidus. In common usage, the term diabetes is synonymous with diabetes mellitus.

Diabetes mellitus. This is a disease of abnormal carbohydrate metabolism in which glucose cannot enter the body's cells and be utilized, and therefore remains in the blood in high concentrations. In diabetes mellitus the excess sugar in the blood (hyperglycemia) leads to the excretion of sugar in the urine (glycosuria), a cardinal diagnostic symptom. Glycosuria in turn causes the excretion of large amounts of urine (polyuria), which results in dehydration and intense thirst (polydipsia). Although blood glucose is high, it cannot enter the appetite-regulating cells of the hypothalamus; hunger is therefore great, and the diabetic person tends to eat constantly (polyphagia). But because glucose cannot enter and nourish the cells, body tissues are subjected to the equivalent of starvation; rapid weight loss occurs, part of which is due to the excretion of water in urine. *See* Carbohydrate metabolism.

Diabetes mellitus appears in two varieties, each with its own cause: diabetes mellitus type I (formerly known as juvenile onset diabetes), caused by deficiency of the pancreatic hormone insulin (whose chief function is to promote the entry of glucose into cells); and diabetes mellitus type II (formerly known as maturity onset diabetes), in which insulin is available but cannot be properly utilized. *See* Insulin; Pancreas.

Three factors that are believed to be important in the causation of this disease are heredity, viral infections, and immunological damage to the pancreas. Heredity does operate in determining one's risk of diabetes, but only as a predisposing factor, not as an absolute determinant. The two types of diabetes mellitus have entirely different patterns of inheritance. Virus infection is strongly implicated as one causative factor in the beta-cell destruction that characterizes type I diabetes, but it is not involved in type II diabetes. Some of the viruses that have been implicated are the agents of mumps and rubella (German measles) and coxsackievirus B. Autoimmune reactions, wherein the body's immune defense system attacks its own pancreatic tissue as though it were a foreign substance, are also suggested as a cause for the beta-cell destruction of type I diabetes. *See* Animal virus; Autoimmunity; Human genetics.

Dietary management has been part of diabetic therapy since preinsulin days, when starvation diets were used to prolong the life of type I diabetics. More recently, weight reduction for victims of type II diabetes and complex carbohydrate liberalization for those of both types of diabetes mellitus have been the cornerstone of therapy. Some other dietary measures besides reducing caloric intake are now believed beneficial for type II diabetics. The ingestion of foods high in fiber content, for example, has been shown to reduce hyperglycemia in type II diabetics. For type I diabetics, the traditional diet is high in protein and quite restricted in carbohydrates. Since most type I diabetics are thin, weight reduction is not part of their program.

Diabetes insipidus. Diabetes insipidus is caused by a deficiency of, or resistance to the action of, vasopressin, the antidiuretic hormone produced by the posterior lobe of the pituitary gland. If the pituitary fails to produce vasopressin, the condition is called central diabetes insipidus. If the kidneys do not respond to the vasopressin and fail to concentrate urine, the condition is labeled nephrogenic diabetes insipidus. Symptoms include increased thirst and frequent urination. Permanent damage to the kidneys can result if the condition is not treated.

A low level of vasopressin can be corrected with desmopressin acetate, a synthetic analog of 8-argininevasopressin, which can be administered in the form of a nasal spray. Desmopressin acetate is ineffective in the treatment of nephrogenic diabetes insipidus. *See* Neurohypophysis hormone. [J.Da.; P.E.Br.]

Diadematacea A superorder of Euechinoidea having a rigid or flexible test, perforate tubercles, aulodont lantern, and branchial slits. The group arose in the Late Triassic and differentiated into four stocks, the Diadematoida, Pedinoida, Echinothurioida, and Pygasteroida. *See* Diadematoida; Echinoidea; Echinothurioida; Pedinoida; Pygasteroida. [H.B.F.]

Diadematoida An order of Diadematacea with hollow primary radioles and diademoid ambulacral plates. The tubercles are normally crenulate and the anus remains within the apical system. Three families compose this order: Diadematidae, Micropygidae, and Aspidodiadematidae. *See* Diadematacea. [H.B.F.]

Diagenesis All the chemical, biochemical, and physical changes that sediments undergo from the time of deposition until the stage of metamorphism is reached. Diagenetic changes are gradational, with metamorphism at elevated temperatures or pressures, and with atmospheric weathering effects when sedimentary rocks become exposed at the surface. Sandstones, shales, and carbonate sediments are particularly susceptible to diagenetic modifications. *See* Carbonate minerals; Sandstone; Shale.

Diagenetic processes include purely physical ones that involve rearrangement of the sediments such as compaction, slumping, bioturbation by organisms, infiltration, and soft sediment deformation; biochemical or organic processes such as particle accretion, flocculation, boring, and decomposition; and physiochemical processes such as cementation, authigenesis (formation of new minerals), inversion, recrystallization, grain growth, replacement, and interstratal solution. Most of these processes involve a reduction in porosity and permeability, which are two important sediment properties in considering the migration of subsurface fluids and the accumulation of oil and gas and certain types of mineral deposits in subsurface rock units. However, one diagenetic process, interstratal solution, is of major importance in creating secondary porosity. *See* Authigenic minerals.

There have been attempts to group diagenetic processes into phases (or stages) in order to develop a comprehensive model for diagenetic evolution. The boundary limits of phases are a function of chemical as well as physical conditions and include pH, oxidation potential (Eh), ionic adsorption phenomena, temperature, pressure, depth of burial, and geologic time. In one model, three diagenetic phases are recognized: syndia-genesis, anadiagenesis, and epidiagenesis. Syndiagenesis includes sediment modifications that take place during and immediately following deposition. Anadiagenesis refers to the diagenesis processes that are characterized by expulsion and upward migration of connate water and other fluids, such as petroleum. Epidiagenesis includes those sediment-modifying processes that take place during and after uplift and emergence. *See* Sedimentary rocks. [F.G.Et.]

Dialysis A process of selective diffusion through a membrane by dissolved solutes in liquid solution. As dialysis is usually carried out, the membrane permits the diffusion of low-molecular-weight solutes (crystalloids) but prevents the passage of colloidal and high-molecular-weight solutes (macromolecules). Membranes suitable for this purpose include vegetable parchment, animal parchment, goldbeater's skin (peritoneal membranes of cattle), fish bladders, dialyzing cellophane (Visking sausage casing), and collodion (nitrocellulose deposited from alcohol-ether solution).

The solution is contained within such a membrane. The low-molecular-weight solutes are removed by placing pure solvent outside the membrane. This solvent is changed periodically or continuously until the concentration of diffusible solutes in the solution is reduced to near zero. The technique is used extensively in separating and purifying macro-molecules of biological origin. [Q.V.W.]

Diamagnetism That branch of magnetism which treats of diamagnetic phenomena and of the properties of diamagnetic bodies. Diamagnetism is a property exhibited by substances with a negative magnetic susceptibility, that is, by substances which magnetize in a direction opposite to that of an applied magnetic field. A diamagnetic substance has a magnetic permeability less than 1, and is repelled when placed near a magnet. The magnetization of diamagnetic substances is associated with the currents induced on application of a magnetic field. *See* MAGNETIC SUSCEPTIBILITY.

Although all matter exhibits diamagnetism, only those substances in which paramagnetism is absent are referred to as diamagnetic. This is because paramagnetism, if present, usually predominates, and the gross magnetic response of the material is paramagnetic. Important exceptions are the alkali and alkaline earth metals. The condition for pure diamagnetism is that all electronic spins be paired and all orbital moments either be zero or effectively cancel one another. *See* PARAMAGNETISM.

As stated previously, the diamagnetic response of a substance is small; only a very small fraction of the applied magnetic field is shielded from the interior of the substance by the induced diamagnetic currents. There is one case, however, in which the inducing field is completely shielded (except for small surface effects). This is the perfect diamagnetism exhibited by superconductors, and is known as the Meissner effect. *See* MEISSNER EFFECT; SUPERCONDUCTIVITY. [E.A.; F.Ke.]

Diamond A mineral composed entirely of carbon; the hardest substance known. Diamond is a polymorph of carbon; lonsdaleite, another polymorph, is sometimes referred to as hexagonal diamond. Diamond is found on all continents except Antarctica, which has not yet been explored for it. It occurs in nature as single crystals of gem or industrial quality, and as polycrystalline masses referred to as boart, framesite, or carbonado. It has also been found as minute black grains in some meteorites. Diamond can be synthesized in the laboratory and is produced commercially in large amounts for industrial uses. *See* CARBON; GRAPHITE.

Diamond has a cubic (isometric) crystal structure in which all carbon atoms have covalent (sp^3) bonds. It is this strong bonding that makes diamond hard. Nevertheless, if diamond is struck in specific directions it will readily cleave—a property utilized in the preparation of polished gem diamonds. The combination of refractive index and dispersion gives diamond its brilliance and so-called fire when cut and polished. The thermal conductivity of diamond is the highest of any material (five times that of copper). This property, plus hardness, makes diamond an ideal material for use as a cutting tool in industry and also as a heat sink in electronics. *See* CRYSTAL STRUCTURE.

Although diamond consists of carbon, at least 58 other elements have been found (for example, aluminum, 10 parts per million; hydrogen, 1000 ppm; silicon, 80 ppm) as impurities in natural diamond. However, only two, nitrogen and boron, replace carbon atoms in the diamond lattice. Nitrogen is the major impurity and may substitute for carbon in a number of ways, commonly as either isolated or paired nitrogen atoms, and as discrete platelets of nitrogen within the diamond structure. The presence or absence of nitrogen and the manner of its substitution leads to different physical properties, such as thermal conductivity, electrical restivity, and infrared spectra.

Diamond is resistant to chemical attack, other than by strong oxidizing agents. In vacuum or an inert atmosphere, a clear, colorless gem diamond transforms to a gray-black mass of graphite at about 1500°C (2700°F). In air, diamond oxidizes (burns) to carbon dioxide at and above 800°C (1500°F). At high temperature, some metals (for example, tungsten, titanium, and tantalum) react with diamond to form metal carbides. Metals, such as iron, nickel, cobalt, and platinum, in the molten state are solvents for carbon and dissolve diamond; this phenomenon is used as a basis for the synthesis of diamond.

Most natural diamond, apart from that in meteorites, crystallizes at depths of approximately 110 mi (180 km) in the Earth's upper mantle at temperatures in the range 900–1200°C (1650–2200°F). The host rock in which diamond forms is either a magnesian-rich silica-deficient ultramafic (peridotitic) rock or an ultrabasic eclogitic rock. Minerals that constitute the ultramafic type of diamond-host rock are magnesian rich and include varieties of olivine, pyroxene, and pyrope garnet. The eclogitic rock consists of sodium-bearing pyroxene and an almandine garnet. These various constituent minerals may also occur as inclusions in diamond and result in the host being identified as either an ultramafic (peridotitic) or eclogitic diamond. Diamonds in each group have formed in a distinct and different geochemical environment in the upper mantle. *See* ECLOGITE; LITHOSPHERE; METEORITE; PERIDOTITE.

Diamond is eventually transported to the Earth's surface by unique types of volcanic eruption in which gases play a major role. The eruptions drill narrow (much less than 3000 ft or 1000 m) explosive vents or pipes through the crust of the Earth. Two different rock types, each containing diamond, may result and infill the volcanic neck or pipe. The first type is known as kimberlite, and the second as lamproite. The most productive mine in the world based on the number of diamonds produced per unit of host rock is based on lamproite—the Argyle mine in Western Australia. In general, diamonds are considerably older than the volcanic eruption that transported them to the surface. Thus diamonds that are 3.2 billion years old reached the surface only 85 million years ago. Diamond-dearing kimberlites occur in South Africa, Botswana, Angola, Sierra Leone, Guinea, Tanzania, Brazil, Venezuela, the United States, Canada, Russia, Siberia, China, India, and Australia. Only lamproites in Western Australia and one in Arkansas in the United States are diamond bearing.

The major production of diamond is from the primary sources in South Africa, Botswana, Zaire, Australia, and Siberia, with minor amounts coming from Tanzania and China. The diamond mines in all these countries are based on kimberlite, except for the Argyle mine in Australia, where the source rock is lamproite. Although Botswana and South Africa produce the most gem diamonds, as well as Russia whose production is difficult to assess, the major worldwide production is from the Argyle mine in Australia, albeit mostly industrial diamonds. Diamond production from secondary (alluvial or placer) deposits, apart from the extensive mining of the marine gravels off the west coast of southern Africa, is relatively small compared to the output from mines based on kimberlite and lamproite. Alluvial deposits in Guinea, Ghana, Russia, and Australia are mined by large companies or government agencies. All other alluvial diamond deposits are worked by small local groups or individual miners. *See* PLACER MINING.

Rough diamonds occur in a variety of shapes, including octahedra, dodecahedra, twinned octahedra (macle), and broken or cleavage fragments. The largest diamond found, the Cullinan, was a cleavage fragment. After the rough is sorted into cuttable (gem and near gem) and industrial stones, the decision is made as to how a specific diamond will be shaped and made into a polished gem. The cutting and polishing process can result in the loss of as much as 60% of the original diamond.

Polished diamonds are graded on the basis of the 4 C's—carat, cut, clarity, and color. The carat is the unit of weight in the diamond industry and is standardized as 0.2 gram (0.0071 oz or 200 milligrams) and is divided into 100 points. Thus a 10-point diamond weighs 0.1 ct (0.00071 oz or 20 mg). The largest diamond, the Cullinan, weighed about 3000 ct (4.27 oz or 600 g) and was the size of an average human fist. The grading cut is based on how well the facets and the shape of a polished diamond compare to a standard model. *See* GEM.

Diamonds, although commonly considered to be mostly colorless, actually exist in all the colors of the rainbow. Colored stones are known as fancies, and if of excellent uniform color they are most desirable.

Diamonds were first synthesized in Sweden in 1953. These early experiments used the principle that carbon dissolves in the transition elements of groups 8–10 (such as iron or nickel). At high pressures (50–60 kilobars or 5–6 gigapascals) and temperatures (1500°C or 2700°F), the dissolved carbon nucleates and crystallizes as diamond. Direct conversion of graphite to diamond was achieved in 1961 in shock-wave experiments in which transient high pressures in excess of 300 kb (30 GPa) and temperatures of about 1100°C (2000°F) existed.

Synthetic diamonds generally are not large; most are produced in sizes below 0.004 in. (0.1 mm). These are used extensively as grit for industrial grinding purposes. Colorless gem-quality diamond can also be synthesized, but the cost of synthesis has proved to be greater than the cost of the natural product.

Diamond films can be grown in several ways. For example, diamond crystals up to 0.02 in. (0.5 mm) in size can be formed from a mixture of methane and hydrogen at about 50 torr (6.7 kPa) pressure and 1000°C (1900°F) on a silicon substrate. This method is known as thermally induced chemical vapor deposition, but other techniques may be used, including plasma chemical vapor ion depostion and electron-beam deposition. The diamond films display properties similar to those of natural diamond and have similar hardness and thermal conductivity, both significant properties for the uses of diamond films. *See* VAPOR DEPOSITION.

Diamond, apart from its use as a gem, has numerous applications in industry, and it is designated a strategic mineral. Many of the uses of natural and synthetic diamond are equivalent. Originally, natural diamond, including boart, carbonado, and framesite, was crushed to various sizes of powder and used as grinding and polishing agents for glasses, ceramics, and nonferrous metals. Diamonds, as single crystals or powders, are also bonded in metal drills and bits. Small drills are used in applications such as dental work; large drills are used in drilling for oil and other minerals. Diamond-impregnated wheels are used for cutting many hard materials, including concrete and dimension stone for architectural purposes. Synthetic diamond is sometimes preferred for various uses, as it is grown to the specific grain size rather than crushed as in the case of natural diamond. Diamonds are used in eye surgery, and also as heat sinks and semiconductors in the electronics industry. Diamond films have potential uses as scratchproof coatings on optical lenses, compact discs, and even on nondiamond jewelry; bearings in machines; heat sinks and semiconductors in electronics; and general inert coatings or surfaces in areas of high chemical corrosion. Natural diamond has also been used as optical windows in spacecraft. [H.O.A.M.]

Diapensiales An order of flowering plants, division Magnoliophyta (Angiospermae), in the subclass Dilleniidae of the class Magnoliopsida (dicotyledons). The order has only a single family, the Diapensiaceae, with about 18 species of herbs and dwarf shrubs in temperate and arctic regions of the Northern Hemisphere. Within its subclass the order is marked by sympetalous flowers (flowers with the petals joined to each other by their margins, at least toward the base, forming a basal tube, cup, or saucer), separate pollen grains, and ovules that have a single integument (unitegmic). *Shortia* and *Galax* genera are sometimes cultivated. *See* DILLENIIDAE; FLOWER. [A.Cr.]

Diapir A buoyant mass of ductile rock or sediment that has pierced, or appears to have pierced, overlying rock, known as overburden. The overburden can yield by ductile processes or by brittle faulting. Diapirs form by lateral and vertical intrusion of buoyant or nonbuoyant rock.

Diapirs are composed of salt, gypsum, shale, mud, sand, peat, coal, limestone, ice, serpentinite, granite, gneiss, and migmatite. Salt diapirs are typically several miles wide and high, but sheetlike varieties that have spread or coalesced laterally can be as much as 200 mi (300 km) wide. This type of diapir is economically important. Gneiss and migmatite diapirs are typically 6–13 mi (10–20 km) wide but locally approach 60 mi (100 km) in width. Diapirs doming the sea floor form large islands of salt in the Persian Gulf and islands of shale in the Caspian and Banda seas. *See* GNEISS; GRANITE; MIGMATITE. [M.P.A.J.]

Diapsida A subclass of reptiles characterized by two pairs of temporal openings and a suborbital fenestra, or features derived from this condition. This subclass includes lizards, snakes, tuatara, and crocodiles of the modern fauna, as well as the Mesozoic ancestors of these groups—dinosaurs, flying pterosaurs, aquatic nothosaurs, plesiosaurs, and placodonts—and their ancestors from the late Paleozoic Era. Birds evolved from bipedal theropod dinosaurs and are part of the diapsid radiation, but are placed in a separate class, Aves. *See* AVES; DINOSAUR.

The earliest adequately documented diapsid is *Petrolacosaurus* from the Upper Pennsylvanian Series of Kansas. It is about 8 in. (20 cm) in length, with a relatively long neck and distal limb elements. Aside from these differences in proportions and the presence of the diagnostic temporal openings, the skeleton of Petrolacosaurus strongly resembles that of the most primitive amniotes of the family Protorothyridae.

Fossils from the upper Permian and Lower Triassic are examples of the early stages of a great radiation that has continued to the present. Some Permian and Mesozoic groups, including the coelurosauravids (gliding reptiles from the upper Permian and Lower Triassic series) and the aquatic thalattosaurs, placodonts, and possibly the ichthyosaurs, may have evolved from reptiles at the beginning of the diapsid radiation. All other advanced diapsids can be grouped in two large infraclasses, the Lepidosauria and the Archosauria, represented in the modern fauna by the lizards and snakes on one hand and the crocodiles (and birds) on the other. *See* ARCHOSAURIA; LEPIDOSAURIA. [R.L.C.]

Diarrhea The passage of loose or watery stools, usually at more frequent than normal intervals. Diarrhea is a symptom of many diseases and may be accompanied by nausea, vomiting, griping, tenesmus, and other general or specific indications of a disease.

The more common specific disorders which may produce diarrhea include intestinal infections, such as dysentery, cholera, typhoid fever, food poisonings, and parasitic infestations; food sensitivities; drug and chemical irritation; and vitamin deficiency states.

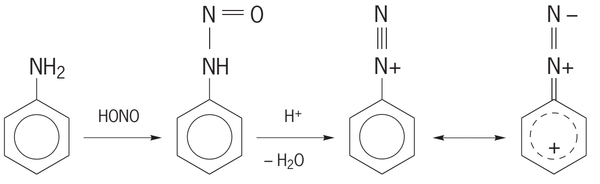
Emotional and psychic disturbances frequently produce diarrhea and other visceral derangements. The poorly understood entities of regional enteritis and ulcerative colitis are perhaps related to these disturbances, as are other psychosomatic disorders.

Diarrhea is a common symptom in gastrointestinal obstruction or in inflammations from local infections or tumor invasion. *See* BACILLARY DYSENTERY; FOOD POISONING; MEDICAL PARASITOLOGY. [E.G.St./N.K.M.]

Diastem A break in the stratigraphic record produced by local erosion or nondeposition and representing a short interval of geologic time. The breaks in deposition are those that would occur within a particular sedimentary environment, rather than those associated with a major change in environment. *See* Stratigraphy; Unconformity.

Nondeposition can result either from excessive turbulence in the environment or from a lack in sediment supply. Discontinuity in sedimentation occurs on many scales. Short breaks, from seconds to days, are associated with migration of bedforms, variation in wave or current energy, and tidal cyclicity. Seasonal deposition occurs due to floods, storms, and plankton blooms. Sedimentation by major floods or hurricanes may occur on a scale of decades to centuries. In the deep ocean, the interval between successive turbidity current flows can be thousands of years. *See* Marine sediments; Sedimentology; Turbidity current. [C.W.By.]

Diazotization The process by which an aromatic primary amine is converted to a diazonium compound. The preparation and reactions of diazonium salts were discovered in 1858 and were the basis of the synthetic dye industry and the development of other industrial chemistry in Europe. In diazotization, sodium nitrite is added to a solution of the amine in aqueous acid solution at 0–5°C (32–41°F). Reaction of the amine with nitrous acid gives a nitrosamine. Tautomerization and loss of water lead to the diazonium ion, which is stabilized by delocalization of the positive charge at the ortho and para carbon atoms of the ring, as in the reaction below.



Nitrosamine Diazonium ion

See Amine; Aromatic hydrocarbon; Delocalization; Tautomerism.

The overall reaction is simple and very general. Substituents of all types—alkyl, halogen, nitro, hydroxyl, sulfonic acid—can be present at any position. Heterocyclic amines such as aminothiazole or aminopyridines can also be diazotized. Aromatic diamines are converted to *bis*-diazonium compounds. Diazonium salts are generally used and handled in aqueous solution; they are explosive if isolated and dried.

The great importance of diazonium compounds in dye technology lies in the coupling reactions that occur with an activated aromatic ring, such as that in phenols or aromatic amines. Coupling, or electrophilic substitution by ArN_2^+, gives compounds with an arylazo group at the position para or ortho to —OH or —NH_2. Reaction with amines occurs in weak acid solution. With phenols the phenoxide ion is the reactive species, and slightly basic solution is used. *See* Chemical equilibrium.

The azo dyes obtained in these coupling reactions are one of the important types of synthetic dyes. The color of the dye can be varied widely by choice of diazonium and coupling components. The coupling reaction lends itself to an important method of applying the dye to fabrics. In this process the coupling reagent, such as a naphtholsulfonic acid, is absorbed onto the fiber, and the coupling reaction is then carried out directly on the fiber by passing the fabric through a bath of the diazonium solution. *See* Dye; Dyeing; Textile chemistry. [J.A.Mo.]

Dichroism In certain anisotropic materials, the property of having different absorption coefficients for light polarized in different directions. There are few natural materials which exhibit strong dichroism. One of the first to be discovered was tourmaline. Light transmitted by thin plates of dark forms of tourmaline is almost completely polarized. *See* Polarized light.

If the absorption in a dichroic material is different for different linear states of polarization, the material is termed linear dichroic. If it is different for right and left circularly polarized light, it is termed circular dichroic. Similarly, there can be elliptically dichroic crystals. [B.H.Bi.]

The study of dichroism allows conclusions as to the submicroscopic fine structure of cells. In visible light only a few cellular components, such as chloroplasts, show absorption. An absorption can, however, be produced by staining. The dichroic staining of plant fibers is especially simple. The elongate stain particles of benzidine dyes, for example, congo red, are deposited in an oriented manner in the spaces between the microfibrils and produce an intrinsic dichroism of the fiber: colored for a vibration plane parallel, colorless for a plane perpendicular to the stain particles and fibrils. Therefore, the direction of strongest absorption indicates the course (parallel or helical) of the microfibrils in the fiber.

Ultraviolet dichroism gives direct information as to the orientation of the absorbing molecules or molecular groups in cell structures. The method has been especially helpful for studies of orientation of deoxyribonucleic acid in nuclei and chromosomes. Lignifed plant cell walls show ultraviolet dichroism. It is pure form dichroism, a fact which eliminates the possibility that lignin is in an anisotropic state in the wall.

By irradiation with ultraviolet light, various compounds of the cell are caused to fluoresce. The fluorescent light is polarized if the object is anisotropic. This phenomenon, called difluorescence, is observable in lignifed cell walls, and leads to the same conclusions as to lignin deposition as emerge from dichroism studies. [F.Ru.]

Dichroism (biology) In absorbing, anisotropic objects, the reference index and the absorption vary with direction. There are two main directions of anisotropy, which are perpendicular to each other. This phenomenon is called dichroism and may be studied in the polarizing microscope with one polarizer. By rotating the microscope stage the object is brought in different directions to the vibration plane of the polarized light, and the change of light absorption is observed. Study of dichroism thus allows conclusions as to the submicroscopic fine structure of cells.

In visible light only a few cellular components, such as chloroplasts, show absorption. An absorption can, however, be produced by staining. The dichroic staining of plant fibers is especially simple. The elongate stain particles of benzidine dyes are deposited in an oriented manner in the spaces between the microfibrils and produce an intrinsic dichroism of the fiber: colored for a vibration plane parallel, colorless for a plane perpendicular to the stain particles and fibrils. Therefore, the direction of strongest absorption indicates the course (parallel or helical) of the microfibrils in the fiber. Dichroic staining may also be carried out with animal tissue. Such studies have been made mainly with fibrous protein structures (collagenous fibers, myofibrils, neurofibrils) and with anisotropic nuclei of certain sperms.

In ultraviolet light many cell components show absorption. Ultraviolet dichroism gives direct information as to the orientation of the absorbing molecules or molecular groups in cell structures. The method has been especially helpful for studies of orientation of deoxyribonucleic acid in nuclei and chromosomes. The maximum absorption here is perpendicular to the molecular direction. Lignified plant cell walls show ultraviolet dichroism. It is pure form dichroism, a fact which eliminates the possibility that lignin is in an anisotropic state in the wall. *See* Cell walls (plant).

By irradiation with ultraviolet light, various compounds of the cell are caused to fluoresce. The fluorescent light is polarized if the object is anisotropic. This phenomenon, called difluorescence, is observable in lignified cell walls, and leads to the same conclusions as to lignin deposition as emerge from dichroism studies. *See* Dichroism. [F.Ru.]

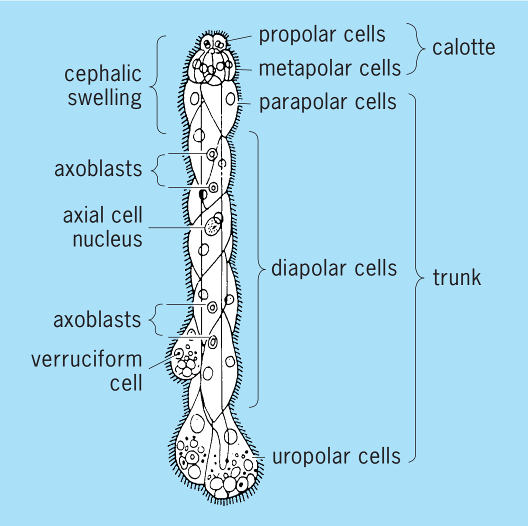
Dicotyledons A large group of flowering plants (angiosperms) that for many years has been considered one of the two main categories of plants, the other being monocotyledons. Dicotyledons have two seedling leaves as opposed to the single one in most monocotyledons. Several deoxyribonucleic acid (DNA) sequence studies subsequently demonstrated that there are two groups of angiosperms, but these correspond not to the number of seed leaves but to the two major pollen types. Thus, the term "dicotyledon" is no longer meaningful because some plants of this type are more closely related to monocotyledons. The group of former dicotyledons, which have pollen with a single aperture, includes magnolia, avocado, black pepper, and pipeworts; they are now termed magnoliids and include monocotyledons. The other category of dicotyledons, those with three (and often more) apertures in their pollen, are called eudicotyledons (true dicotyledons). *See* AVOCADO; EUDICOTYLEDONS; FLOWER; MAGNOLIOPHYTA; MONOCOTYLEDONS; PLANT KINGDOM. [M.W.C.]

Dicranales A large and diverse order of the true mosses (Bryopsida), containing 13 families. Plants in the Dicranales generally have long, narrow leaves, and the peristome (rarely lacking) commonly consists of 16 papillose or vertically pitted-striate teeth. The plants are erect and simple or merely forked and often woolly because of a dense covering of rhizoids among the leaves. *See* BRYIDAE; BRYOPHYTA; BRYOPSIDA. [H.Cr.]

Dictyoceratida An order of sponges of the class Demospongiae which includes the bath sponges of commerce. Dictyoceratida are mostly of considerable size, and form massive, lobate, or branching colonies. Some are leaflike in shape or vase-shaped. A reticulate skeleton of spongin fibers is always present. In many species some or all the fibers enclose foreign bodies, such as sand grains, shell fragments, or spicules of other sponges. There are three families, Spongiidae, Thorectidae, and Dysideidae.

Dictyoceratid sponges are most abundant in tidal and shallow waters of tropical and subtropical regions. Relatively few species occur in Arctic and Antarctic seas, and most occur above the continental slope. A few species are found down to 3300 ft (1000 m). *See* DEMOSPONGIAE. [W.D.H.]

Dicyemida An order of Mesozoa comprising minute, wormlike parasites of the renal organs of cephalopod mollusks. They are composed of a single layer of large, ciliated epithelial cells enclosing one or more elongate axial cells (see illustration).



Morphology of a young dicyemid.

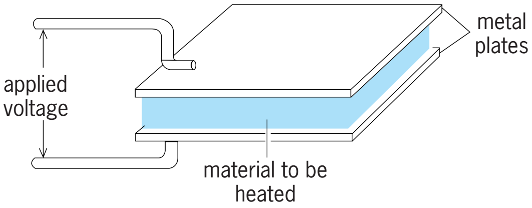
Each axial cell contains, in addition to its own nucleus, reproductive cells and developing larvae. These larvae, when fully developed, escape from the parent organism.

There are two reproductive phases termed the nematogens and rhombogens, respectively. During the nematogen phase vermiform larvae are formed asexually from the germ cells. They increase the infection in the same cephalopod. This is succeeded by the rhombogen phase in which infusoriform, or swarm, larvae are liberated. These are discharged into the sea with their host's urine and their fate is unknown. Zoologists are not in agreement regarding many points in the life cycle, particularly in respect to the interpretation of the infusorigen and its products. *See* MESOZOA. [B.H.McC.]

Didymelales An order of flowering plants, division Magnoliophyta (Angiospermae), in the subclass Hamamelidae of the class Magnoliopsida (dicotyledons). The order contains a single family with but one genus, *Didymeles*, with two species. These dioecious, evergreen trees are restricted to Madagascar. The wood has vessels with scalariform perforations, which is a putatively primitive feature. The leaves are alternate, simple, and entire. The flowers are small; the staminate ones are in open clusters, without perianth, with two stamens, and the pollen grains have three germinal furrows. The pistillate flowers are commonly paired in spikelike clusters; they are hypogynous and sometimes have 1–4 scalelike sepals but no petals. The pistil has but one carpet. This curious genus has often been included in the Hamamelidales; however, the primitive nature of the wood and of the pistil make it anomalous there. *See* HAMAMELIDAE; MAGNOLIOPSIDA; PLANT KINGDOM. [T.M.Ba.]

Dielectric heating The heating of a nominally electrical insulating material due to its own electrical (dielectric) losses, when the material is placed in a varying electrostatic field.

The material to be heated is placed between two electrodes (which act as capacitor plates) and forms the dielectric component of a capacitor (see illustration). The electrodes are connected to a high-voltage source of 2-90-MHz power, produced by a high-frequency vacuum-tube oscillator.



Basic assembly for dielectric heating.

The resultant heat is generated within the material, and in homogeneous materials is uniform throughout. Dielectric heating is a rapid method of heating and is not limited by the relatively slow rate of heat diffusion present in conventional heating by external surface contact or by radiant heating.

This technique is widely employed industrially for preheating in the molding of plastics, for quick heating of thermosetting glues in cabinet and furniture making, for accelerated jelling and drying of foam rubber, in foundry core baking, and for drying of paper and textile products. Its advantages over conventional methods are the speed and uniformity of heating, which offset the higher equipment costs. Because of the absence of high thermal gradients, an improved end-product quality is usually obtained. [G.F.B.]

Dielectric materials Materials which are electrical insulators or in which an electric field can be sustained with a minimal dissipation of power. Dielectrics are employed as insulation for wires, cables, and electrical equipment, as polarizable media for capacitors, in apparatus used for the propagation or reflection of electromagnetic waves, and for a variety of artifacts, such as rectifiers and semiconductor devices, piezoelectric transducers, dielectric amplifiers, and memory elements. The term dielectric, though it may be used for all phases of matter, is usually applied to solids and liquids.

The ideal dielectric material does not exhibit electrical conductivity when an electric field is applied. In practice, all dielectrics do have some conductivity, which generally increases with increase in temperature and applied field. If the applied field is increased to some critical magnitude, the material abruptly becomes conducting, a large current flows (often accompanied by a visible spark), and local destruction occurs to an extent dependent upon the amount of energy which the source supplies to the low-conductivity path. This critical field depends on the geometry of the specimen, the shape and material of the electrodes, the nature of the medium surrounding the dielectric, the time variation of the applied field, and other factors. Temperature instability can occur because of the heat generated through conductivity or dielectric losses, causing thermal breakdown. Breakdown can be brought about by a variety of different causes, sometimes by a number of them acting simultaneously. Nevertheless, under carefully specified and controlled experimental conditions, it is possible to measure a critical field which is dependent only on the inherent insulating properties of the material itself in those conditions. This field is called the intrinsic electric strength of the dielectric. *See* ELECTRICAL BREAKDOWN.

Many of the traditional industrial dielectric materials are still in common use, and they compete well in some applications with newer materials regarding their electrical and mechanical properties, reliability, and cost. For example, oil-impregnated paper is still used for high-voltage cables. Various types of pressboard and mica, often as components of composite materials, are also in use. Elastomers and press-molded resins are also of considerable industrial significance. However, synthetic polymers such as polyethylene, polypropylene, polystyrene, polytetrafluoroethylene, polyvinyl chloride, polymethyl methacrylate, polyamide, and polyimide have become important, as has polycarbonate because it can be fabricated into very thin films. Generally, polymers have crystalline and amorphous regions, increasing crystallinity causing increased density, hardness, and resistance to chemical attack, but often producing brittleness. Many commercial plastics are amorphous copolymers, and often additives are incorporated in polymers to achieve certain characteristics or to improve their workability. [J.H.Ca.]

Dielectric measurements Measurements of the dielectric properties of a material, which are characterized by its complex relative permittivity ϵ_r. For all materials except ferroelectrics, this quantity does not depend on applied field: the general behavior is linear, and so voltage of any convenient magnitude can be used for measurement. *See* FERROELECTRICS; PERMITTIVITY.

Bridge methods. The most commonly used apparatus for measuring ϵ_r is the alternating-current (ac) bridge. These bridges are readily available in the operating range 10–10^6 Hz, and sometimes outside it; ultralow-frequency bridges can go as low as 10^{-3} Hz. Most specimen holders for solids are essentially parallel-plate capacitors with the specimen filling all the space between the plates; for liquids, a test cell with cylindrical electrodes is usually employed. The bridges most commonly used are of the Wheatstone type, the most versatile for dielectric measurements being the Schering bridge.

Resonance methods. Resonance methods, useful for frequencies greater than 1 MHz, involve the injection of voltage or current by one of several methods into an *LC* (inductance-capacitance) resonant circuit. Measurements over a range of frequencies may be made by using coils with different inductance values, but ultimately the inductance required becomes impracticably small, and in the range 10^8–10^9 Hz reentrant cavities are often used. These are hybrid devices in which the plates holding the specimen still form a lumped capacitor, but the inductance and capacitances are distributed along a coaxial line. At higher frequencies, the wavelength is comparable to the dimensions of the apparatus, and transmission methods in coaxial lines and waveguides must be used.

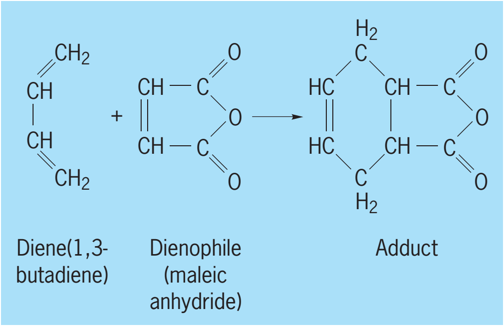
Transmission methods. Coaxial lines are used in the frequency range 300 MHz–3 GHz, and waveguides in the range 3–30 GHz. The transmission characteristics are determined by the complex permittivity of the material filling the line or guide. Many different measurement techniques have been devised, but all derive values of the complex relative permittivity ϵ_r from its relationship to the complex propagation factor γ. *See* TRANSMISSION LINES; WAVEGUIDE.

In practice, traveling waves are rarely used as the basis of measurement, except for high-loss materials. Usually, reflections from terminations set up standing waves, the amplitude of which in the case of a liquid-filled line can be measured by a suitable probe. The ratios of the field magnitudes at adjacent maxima, and the distance between them, give the information required. *See* ATTENUATION (ELECTRICITY); WAVELENGTH.

Submillimeter measurements. Dielectric measurements are difficult to carry out in the frequency range 30–300 GHz, for which λ_0 is in the range 1 cm–1 mm, but for λ_0 less than 1 mm, methods related to infrared spectroscopy are used. Broadband continuous spectra result from Fourier transform spectroscopy, which in its simplest form is equivalent to normal infrared spectroscopy, with the specimen in one of the two passive arms of the interferometer, between the beam divider and either the source or the detector. In the more sophisticated dispersive Fourier transform spectroscopy, the specimen is in one of the active arms, that is, between the beam divider and either mirror. Discrete-point spectra also may be obtained by the use of a Mach-Zehnder interferometer and a laser source. By using interferometric techniques, the frequency range can be extended up to about 5 THz. *See* INFRARED SPECTROSCOPY; INTERFEROMETRY; SPECTROSCOPY.

Time-domain methods. If a constant direct-current (dc) voltage is suddenly applied to a dielectric specimen, in principle the charging current is related through the Fourier integral transformation to the steady-state ac current which would flow if the applied voltage were sinusoidal at any particular frequency. If the dc voltage is suddenly removed, a similar relationship holds between the discharge current and ac current. Thus the variation of complex permittivity with frequency can in principle be derived from a transient signal in the time domain. Because of various limitations, the method is not capable of giving results of an accuracy at all frequencies comparable to those obtainable from a single frequency measurement. Nevertheless, with the aid of computer analysis, the response over a large frequency range can be obtained much more quickly than would be possible by using point-by-point measurement methods. [J.H.Ca.]

Diels-Alder reaction The 1,4-addition of an alkene (the dienophile) to a conjugated diene. The reaction, also known as the diene synthesis, is one of the most valuable and versatile



Example of Diels-Alder reaction.

methods for the preparation of compounds containing a six-membered ring, and proceeds most rapidly when the dienophile is substituted by electron-attracting groups. An example is in the illustration. The Diels-Alder reaction does not require a catalyst, nor is the reaction retarded by the presence of oxidation inhibitors with which dienes are commonly treated to prevent formation of peroxides.

Industrially the diene synthesis is used in the production of the insecticides aldrin and dieldrin. The adduct of butadiene and maleic anhydride is used in the synthesis of the important fungicide captan. [P.E.F.]

Diesel cycle An internal combustion engine cycle in which the heat of compression ignites the fuel. Compression-ignition engines, or diesel engines, are thermodynamically similar to spark-ignition engines. The sequence of processes for both types is intake, compression, addition of heat, expansion, and exhaust. Ignition and power control in the compression-ignition engine are, however, very different from those in the spark-ignition engine. *See* THERMODYNAMIC CYCLE.

Usually, a full-unthrottled charge of air is drawn in during the intake stroke of a diesel engine. A compression ratio between 12 and 20 is used, in contrast to a ratio of 4 to 10 for the Otto spark-ignition engine. This high compression ratio of the diesel raises the temperature of the air during the compression stroke. Just before top center on the compression stroke, fuel is sprayed into the combustion chamber. The high temperature of the air ignites the fuel, which burns almost as soon as it is introduced, adding heat. The combustion products expand to produce power, and exhaust to complete the cycle.

In an actual engine with a given compression ratio, the Otto engine has the higher efficiency. However, fuel requirements limit the Otto engine to a compression ratio of about 10, whereas a diesel engine can operate at a compression ratio of about 15 and consequently at a higher efficiency.

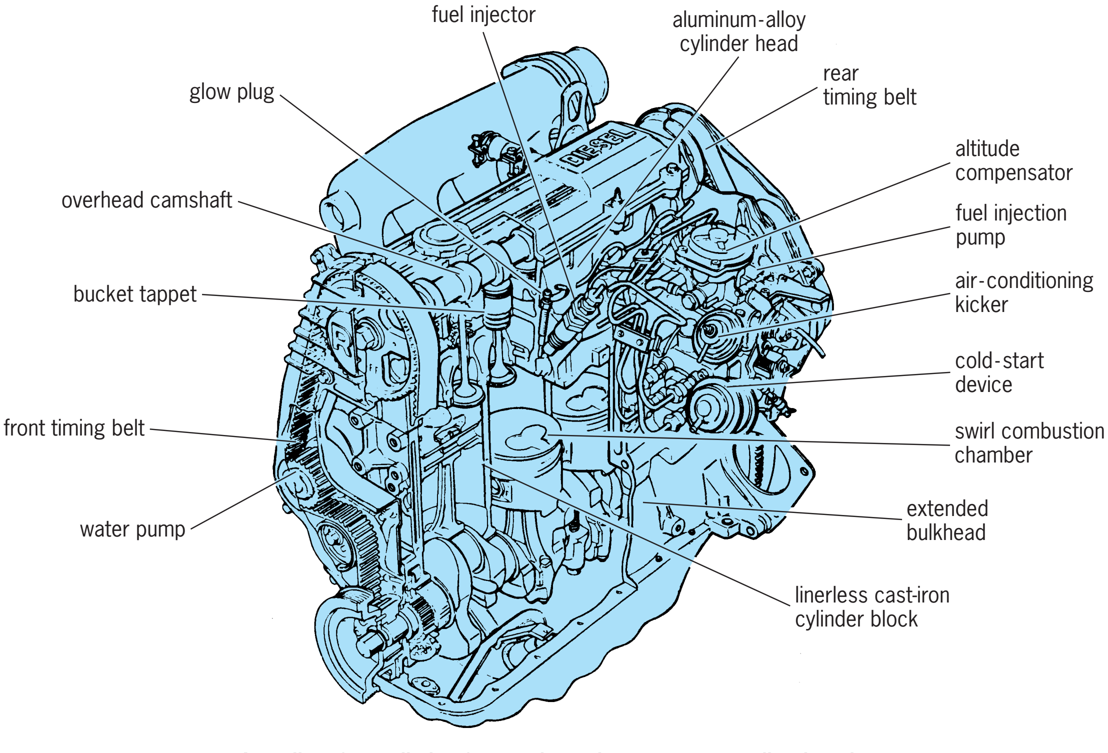
In addition, heat can be added earlier in the cycle by injecting fuel during the latter part of the compression process. This mode of operation is the dual-combustion or semidiesel cycle. With most of the heat added near peak compression, semidiesel efficiency approaches Otto cycle efficiency at a given compression ratio. *See* DIESEL ENGINE. [T.Ba.]

Diesel engine An internal combustion engine operating on a thermodynamic cycle in which the ratio of compression of the air charge is sufficiently high to ignite the fuel subsequently injected into the combustion chamber. Compared to an engine operating on the Otto cycle, the diesel engine utilizes a wider variety of fuels with a higher thermal efficiency and consequent economic advantage under many service applications. *See* DIESEL CYCLE; OTTO CYCLE.

The true diesel engine, as represented in most low-speed engines, uses a fuel-injection system where the injection rate is delayed and controlled to maintain constant pressure during combustion. Adaptation of this injection principle to higher engine speeds has necessitated departure from the constant-pressure specification, because the time available for fuel injection is so short (often 2 ms or less). Nonvolatile (distillate) fuels are burned to advantage in these engines, which cannot be rigorously identified as true diesels but properly should be called commercial diesels. However, all such engines are ordinarily classified as diesels. Diesel engines give high intrinsic and actual thermal efficiency (20–40%).

The diesel engine in the automobile is usually a four-stroke-cycle engine with indirect injection into an auxiliary combustion chamber (see illustration). Most automobile diesel engines use a distributor-type injection pump. The fuel system often includes a fuel-conditioner assembly, which combines a water-in-fuel detector, water-fuel separator, fuel filter, fuel heater, and hand-priming pump in a single unit. *See* COMBUSTION CHAMBER.

Diesel engines in trucks and buses are usually larger and operate at lower speeds than diesel engines in passenger cars. Most truck diesel engines operate on the four-stroke cycle, although many buses and some trucks have two-stroke-cycle engines. These usually have intake ports in the cylinder and exhaust valves in the cylinder head, with scavenging air provided by a crankshaft-driven blower mounted on the crankcase.



A 2.0-liter, four-cylinder, four-stroke-cycle passenger-car diesel engine which has a distributor-type injection pump and indirect injection. (*Ford Motor Co.*)

A unit fuel injector operated by the engine camshaft meters and injects the fuel into the combustion chamber at high pressure at the proper time.

In addition to a noticeable odor, the exhaust gas from the diesel engine contains gaseous and particulate emissions which contribute to air pollution. The particles, or soot, may be removed by a trap oxidizer that consists of a filter and a regeneration system, which burns the trapped particles and cleans the filter. Gaseous emissions of unburned hydrocarbons (HC), carbon monoxide (CO), and oxides of nitrogen (NO_x) may be controlled through the use of electronically controlled fuel injection, exhaust-gas recirculation, and charge-air cooling. Operating the engine on low-sulfur fuel reduces sulfur and particulate emissions. *See* AIR POLLUTION; DIESEL FUEL; FUEL INJECTION. [D.L.An.]

Diesel fuel A broad mixture of hydrocarbons produced as distillates, as residual materials, or as blends of the two during the refining of crude petroleum. Diesel fuel usually has a distillation range of 390–715°F (200–380°C) and a specific gravity range of 0.760–0.935 [equivalent to 61.2–19.8° on the American Petroleum Institute (API) scale]. In addition to these properties, diesel fuel must have <1 wt % sulfur, <0.1 wt % ash, <0.5 vol % water and sediment, and a high flash point (greater than 131°F or 55°C).

Diesel fuel quality is defined by the cetane number, which usually falls into the range 30–60. A high cetane number indicates the potential for easy starting and smooth operation of the engine. The cetane number is the analog of the automobile engine octane number, with cetane (*n*-hexadecane, $C_{16}H_{34}$) having the arbitrarily assigned number of 100. At the other end of the scale, heptamethylnonane, an isomer of cetane, has the assigned cetane number of 0. The cetane number of a diesel fuel is determined by comparison with blends of cetane and heptamethylnonane. It corresponds to the number of parts by volume of cetane in a cetane-heptamethylnonane blend which has the same ignition quality as the fuel. *See* CETANE NUMBER.

The American Society for Testing and Materials (ASTM) has categorized diesel fuels into three general groups. The need to categorize these fuels results from the varied uses of diesel engines, which are designed to operate efficiently on one of the standard diesel fuels. *See* DIESEL ENGINE.

No. 1-D is a light distillate, similar to kerosine, for engines where frequent load changes and speed changes (truck, tractor engines) are essential. This fuel has a flash point greater than 100°F (38°C), with a minimum cetane number of 40. This fuel is believed to be particularly suitable for cold-weather operation. *See* KEROSINE.

No. 2-D is a medium distillate fuel with a lower volatility and higher density than No. 1-D. This fuel finds use in heavier-duty engines, for example, railroad engines, which operate at uniform speeds but with heavier loads than encountered during the use of No. 1-D. The flash point is greater than 125°F (52°C) and the minimum cetane number is 40.

No. 3-D is a heavy distillate fuel with the highest density and lowest volatility of the three diesel fuels. It finds use in low- and medium-speed engines such as marine engines and electric power generation engines, which operate under sustained loads. The flash point is greater than 130°F (54°C) and the minimum cetane rating is 30. [J.G.S.]

Difference equation A relationship between one or more independent variables, one or more dependent variables, and differences of those variables. Difference equations arise in the analysis of discrete systems (for example, a string loaded along its length with small masses), in the solution of differential equations by means of digital computers, in the implementation of digital filters, and in the discrete-time control of systems. An ordinary difference equation expresses a relationship between an independent variable t and one or more dependent variables, $y(t)$, $w(t)$, and so forth, and any successive differences of $y, w \ldots$. The first forward difference of y, relative to the increment h, is defined by Eq. (1). The second forward difference can be obtained by applying the above definition to itself, as in Eq. (2).

$$\Delta y(t) = y(t+h) - y(t) \tag{1}$$

$$\begin{aligned}\Delta^2 y(t) &= \Delta[\Delta y(t)] \\ &= \Delta y(t+h) - \Delta y(t) \\ &= [y(t+2h) - y(t+h)] \\ &\quad -[y(t+h) - y(t)] \\ &= y(t+2h) - 2y(t+h) + y(t)\end{aligned} \tag{2}$$

A difference equation is linear if it is of the first degree with respect to all the quantities $\Delta y(t)$, $\Delta^2 y(t)$, $\Delta^3 y(t), \ldots$. The general solution of difference equations is possible only for the case where they are linear with constant coefficients. However, nonlinear difference equations arise naturally in the solution of nonlinear differential equations. Likewise, the numerical solution of a partial differential equation leads to a partial difference equation. Methods exist for approximating governing equations for linear continuous-time systems by difference equations.

Linear constant-coefficients equations. The independent variable of a difference equation will usually have discrete values. Then the notation can be simplified by making the substitution in Eq. (3). In this case, the arguments of the independent

$$\begin{gathered} t_k = t_0 + kh \\ k = 0, 1, 2, \ldots \end{gathered} \tag{3}$$

variables, if more than one, can be replaced by the subscript k. Then, the forward difference operators given by Eqs. (1) and (2) can be written as Eqs. (4), where the shifting operator E has

$$\begin{aligned} \Delta y_k &= y_{k+1} - y_k = E y_k - y_k \\ \Delta^2 y_k &= E^2 y_k - 2E y_k + y_k \end{aligned} \tag{4}$$

been defined, incrementing the index on the dependent variable by 1 each time it is applied.

The general homogeneous, linear, constant-coefficient difference equation of order n can be written in terms of the shifting operator as Eq. (5). From the solution of linear, constant-

$$\begin{gathered} E^n y_k + A_1 E^{n-1} y_k + \cdots + A_{n-1} E y_k + A_n y_k = 0 \\ k \ge 0 \end{gathered} \tag{5}$$

coefficient differential equations, the solution is assumed to be of the form $e^{rk} = \beta^k$, where r is a suitably chosen constant and $\beta = e^r$. From the definition of the shifting operator, Eqs. (6)

$$\begin{aligned} E\beta^k &= \beta^{k-1} = \beta(\beta^k) \\ E^2\beta^2 &= \beta^{k-2} = \beta^2(\beta^k) \end{aligned} \tag{6}$$

follow, as well as similar equations for higher powers of E. When these equations are substituted into Eq. (5), the result is Eq. (7).

$$\beta^n + A_1 \beta^{n-1} + \cdots + A_{n-1}\beta + A_n = 0 \tag{7}$$

Hence, $y_k = \beta^k$ will satisfy Eq. (5) if β is a root of Eq. (7). If all roots are real and distinct, the most general expression satisfying Eq. (5) is Eq. (8), where $\beta_1, \beta_2, \ldots, \beta_n$ are the roots to Eq. (7) and

$$\begin{gathered} y_k = c_1\beta_1^k + c_2\beta_2^k + \cdots + c_n\beta_n^k \\ k \ge 0 \end{gathered} \tag{8}$$

$c_1, c_2, \ldots, c_n$ are constants to be determined by the initial conditions. *See* ALGEBRA.

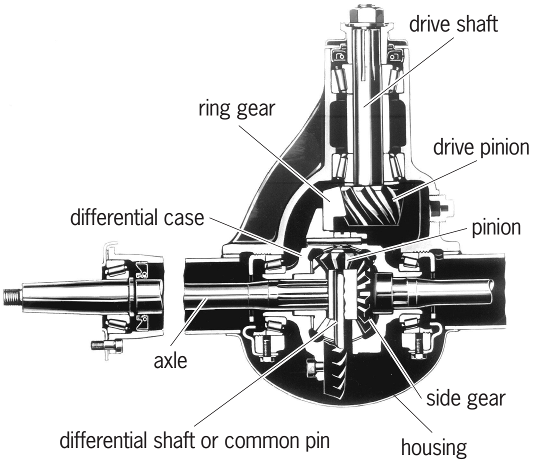
Nonhomogeneous linear equations. The general solution of a nonhomogeneous, linear, constant-coefficient difference equation, given by Eq. (9), is of the form given by Eq. (10),

$$\begin{gathered} E^n y_k + A_1 E^{n-1} y_k + A_{n-1} E y_k + A_n y_k = x_4 \\ k \geq 0 \end{gathered} \tag{9}$$

$$y_k = y_{k,h} + y_{k,p} \tag{10}$$

where $y_{k,h}$ is the solution of the homogeneous equation [$x_k = 0$ in Eq. (9)], and $y_{k,p}$ is the particular solution of Eq. (9). With constant coefficients on Eq. (9), the method of undetermined coefficients can be used to find the particular solution. The solution of constant-coefficient, linear difference equations is facilitated greatly by use of the z transform. *See* DIFFERENTIAL EQUATION; DIGITAL FILTER; INTERPOLATION; LAPLACE'S DIFFERENTIAL EQUATION; LINEAR SYSTEM ANALYSIS; NUMERICAL ANALYSIS. [R.E.Z]

Differential A mechanism which permits a rear axle to turn corners with one wheel rolling faster than the other. An automobile differential is located in the case carrying the rearaxle drive gear (see illustration).



A rear-axle differential. (*Chrysler*)

The differential gears consist of the two side gears carrying the inner ends of the axle shafts, meshing with two pinions mounted on a common pin located in the differential case. The case carries a ring gear driven by a pinion at the end of the drive shaft. This arrangement permits the drive to be carried to both wheels, but at the same time as the outer wheel on a turn overruns the differential case, the inner wheel lags by a like amount.

Special differentials permit one wheel to drive the car by a predetermined amount even though the opposite wheel is on slippery pavement; they have been used on racing cars for years and are now used by a number of car manufacturers. *See* AUTOMOTIVE TRANSMISSION. [H.Fi.]

Differential amplifier An electronic circuit that is designed to amplify the difference between two voltages measured with respect to a common reference, usually designated as ground. By convention, the net difference of two voltages measured with respect to a common reference is called the differential-mode voltage, while the sum of the voltages, usually divided by two to give an average value, is called the common-mode voltage.

An ideal differential amplifier thus has exactly the same gain from each input to its output, and the amplifier produces an output that is directly proportional to its differential-mode voltage. The amplifier delivers zero output in response to common-mode voltages. If these gains are not exactly equal, then equal (common-mode) voltages applied at each input terminal will not be equal at the amplifier output and their difference will not cancel completely. The common-mode gain, the ratio of the output response of a real differential amplifier to the input signal applied equally to each input terminal, is a measure of this gain mismatch.

Differential amplification is very useful when the signal to be amplified exists in an electrically noisy environment, since the noise voltage is usually a common component of both input voltages and, hence, will cancel when the difference of the amplifier inputs is taken. *See* AMPLIFIER.

For a physical differential amplifier to work properly, the electrical paths of each input signal through the amplifier must be nearly identical. Thus, the most important requirement for a differential amplifier is that it be constructed with transistors with closely matched electrical characteristics. Integrated circuits with amplifier transistors physically close to each other meet the required close matching requirement and are ideally suited for the production of differential amplifiers. *See* INTEGRATED CIRCUITS.

Differential-amplifier circuits that are suitable for integrated-circuit fabrication can use either metal oxide semiconductor field-effect transistors (MOSFETs) or bipolar junction transistors (BJTs). The input transistor pair must be matched closely. For best performance, the two load transistors also should be matched. *See* TRANSISTOR. [P.E.A.]

Differential equation A relationship between a function and its derivatives.

If there is one independent variable, the differential equation is called an ordinary differential equation. The general form of such an equation is shown in (1), where t is the independent

$$F(t, u, u', u'', \ldots, u^{(n)}) = 0 \tag{1}$$

variable; u is a function of t; $u' = du/dt$, $u'' = d^2u/dt^2, \ldots, u^{(n)} = d^n u/dt^n$ are the derivatives of u; and $F(t, u_0, u_1, \ldots, u_n)$ is a given function of the $n + 2$ variables $t, u_0, \ldots, u^n$. The positive integer n is called the order of the differential equation; that is, the order of the differential equation is the order of the highest derivative that occurs in the equation. As an example, consider Eq. (2),

$$u'' + u = 0 \tag{2}$$

which is an ordinary differential equation of order 2. A function u is said to be a solution to Eq. (1) if, when u and its derivatives up to order n are substituted into F, the identity expressed in Eq. (1) is valid for t in some interval $a < t < b$. In Eq. (2), $u = \cos t$ and $u = \sin t$ are solutions for $-\infty < t < \infty$, as can be immediately verified.

If there are two or more independent variables, the equation is called a partial differential equation. Again, the order of the equation is the order of the highest partial derivative that occurs in the equation. Thus, the general form of a partial differential equation of order 2, with two independent variables, is given by Eq. (3), where x and y are the independent variables; $u =$

$$F(x, y, u, u_x, u_y, u_{xx}, u_{xy}, u_{yy}) = 0 \tag{3}$$

$u(x, y)$ is a function: $u_x = \partial u/\partial x$, $u_y = \partial u/\partial x$, $u_{xx} = \partial^2 u/\partial x^2$, $u_{xy} = \partial^2 u/\partial x \partial y$, and $u_{yy}, = \partial^2 u/\partial y^2$ are the derivatives of u; and $F(x, y, u, p, q, r, s, t)$ is a given function of eight variables. For example, Eq. (4) is a partial differential equation of order 2. It

$$u_{xy} = 0 \tag{4}$$

is easily verified that $u = h(x) + g(y)$ is a solution of Eq. (4) for any choice of functions h and g.

A differential equation is linear if the function u and its derivatives appear linearly in the equation, and is nonlinear otherwise.

Partial differential equations occur with more than two independent variables. Another possibility is a system of differential equations. This consists of two or more equations involving one or more unknown functions which are to be solved simultaneously. The Cauchy-Riemann equations, Eqs. (5), are a first-order

$$\begin{aligned} u_x - v_y &= 0 \\ u_y + v_x &= 0 \end{aligned} \tag{5}$$

linear system of partial differential equations. *See* COMPLEX NUMBERS. [J.C.P.]

Differential geometry

A branch of mathematics that deals with intrinsic properties of curves and surfaces in three-dimensional euclidean space. The intrinsic properties are those which are independent of the geometrical objects orientation or location in space. The subject is also concerned with nets of curves and families of surfaces, these having wide application in the arts.

The space is referred to a rectangular cartesian coordinate system (x,y,z). A space curve may be defined by a pair of independent equations, $f(x,y,z) = 0$ and $g(x,y,z) = 0$, or, more meaningfully, by parametric equations, $x = x(t)$, $y = y(t)$, $z = z(t)$. In this case the arc length between two points t_0 and t is given by Eq. (1).

$$s = \int_{t_0}^{t} \sqrt{\left(\frac{dx}{dt}\right)^2 + \left(\frac{dy}{dt}\right)^2 + \left(\frac{dz}{dt}\right)^2}\, dt \tag{1}$$

Obviously, if s is chosen as parameter, Eq. (2) holds. In this

$$\left(\frac{dx}{ds}\right)^2 + \left(\frac{dy}{ds}\right)^2 + \left(\frac{dz}{ds}\right)^2 = 1 \tag{2}$$

case dx/ds, dy/ds, dz/ds at a point P are the direction cosines of the tangent to the curve at P.

Consider three nearby points P, P_1, P_2. Through them, in general, one plane may be constructed. The limiting position of this plane as P_1 and P_2 approach P is the osculating plane of the curve at P. The limiting position of the circle through P, P_1, P_2 as P_1 and P_2 approach P is the osculating circle. Its center is the center of curvature and its radius is the radius of curvature p. The reciprocal of the radius of curvature κ is the curvature; its value is shown in expression (3). The perpendicular to the tangent at P in the osculating plane is the principal normal and the perpendicular at P to the osculating plane is the binormal.

$$\sqrt{\left(\frac{d^2x}{ds^2}\right)^2 + \left(\frac{d^2y}{ds^2}\right)^2 + \left(\frac{d^2z}{ds^2}\right)^2} \tag{3}$$

A surface in three-dimensional euclidean space may be given by $f(x,y,z) = 0$ or, more conveniently, by Eqs. (4). For a fixed

$$x = x(u,v) \quad y = y(u,v) \quad z = z(u,v) \tag{4}$$

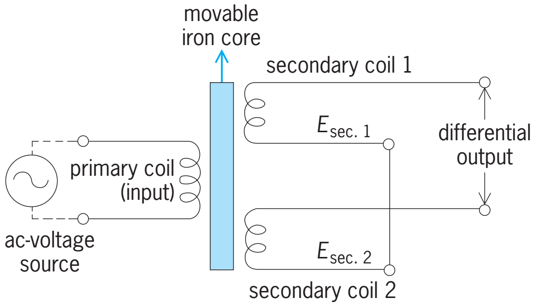
value of v, Eqs. (4) describe a curve in the surface, a u line, and similarly for a fixed value of u. Thus (u,v) are curvilinear coordinates of a point in the surface. The most important quantity in the study of surfaces is the arc length of a curve. This is given by Eq. (5), where E, F, G are functions of partial derivatives of

$$ds^2 = E\,du^2 + 2F\,du\,dv + G\,dv^2 \tag{5}$$

(x,y,z). In the real domain E, G, and $EG - F^2$ are nonnegative and may be zero only at singular points of the surface, or at points where the matrix of the partial derivatives of (x,y,z) is of rank less than two. The right-hand side of Eq. (5) is called the first fundamental form of the surface, where E, F, G are the first fundamental quantities of the surface. All applicable surfaces have the same first fundamental form. Thus any cylinder or cone which is developable (applicable to a plane) has the fundamental form $du^2 + dv^2$, where (u,v) are rectangular cartesian coordinates. Under an arbitrary transformation of the surface coordinates (u,v) the fundamental quantities E, F, G transform linearly so that many problems in the study of surfaces reduce to the question whether a coordinate system exists on the surface in which E, F, G satisfy desired conditions. *See* COORDINATE SYSTEMS; RIEMANNIAN GEOMETRY. [M.S.Kn.]

Differential transformer

An iron-core transformer with movable core. A differential transformer produces an electrical output voltage proportional to the displacement of the core. It is used to measure motion and to sense displacements. It is also used in measuring devices for force, pressure, and acceleration which are based on the conversion of the measured variable to a displacement.



Basic circuit of differential transformer. *E* refers to E pickoff (from E-shaped iron core).

Various available configurations, some translational and others rotational, all employ the basic circuit shown in the illustration: a primary winding, two secondary windings, and a movable core. The primary winding is energized with alternating voltage. The two secondary windings are connected in series opposition, so that the transformer output is the difference of the two secondary voltages. When the core is centered, the two secondary voltages are equal and the transformer output is zero. This is the balance or null position. When the core is displaced from the null point, the two secondary voltages are no longer alike and the transformer produces an output voltage. With proper design, the output voltage varies linearly with core position over a small range. Motion of the core in the opposite direction produces a similar effect with 180° phase reversal of the alternating output voltage. *See* TRANSDUCER; TRANSFORMER. [G.W.]

Differentiation

A mathematical operation performed on a function to determine the effect of a change in the value of the independent variable. Functions of one variable are considered in this article. For differentiation of functions of several variables *see* PARTIAL DIFFERENTIATION.

If f is a function of x, defined on an interval containing x_0, the derivative at x_0 is, by definition, that shown in Eq. (1). For

$$f'(x_0) = \lim_{x \to x_0} \frac{f(x) - f(x_0)}{x - x_0} \tag{1}$$

generalities about derivatives and calculus *see* CALCULUS.

In the quotient on the right, in the definition of $f'(x_0)$, x is restricted to the interval on which f is defined. If $y = f(x)$, $f'(x_0)$ is also denoted by

$$\left(\frac{dy}{dx}\right)_{x=x_0}$$

The limit defining $f'(x_0)$ may not exist. If it does, f is called differentiable at x_0.

The derivative of $f'(x)$, called the second derivative, is denoted by

$$f''(x) \text{ or } \frac{d^2y}{dx^2}$$

A function f is called continuous at x_0 if x_0 is in the domain of f and

$$\lim_{x \to x_0} f(x) = f(x_0)$$

The precise formulation of the limit concept used here is the following: Let g be a function and let A be a number. Then Eq. (2) means that to each positive number ϵ corresponds to

$$\lim_{x \to x_0} g(x) = A \qquad (2)$$

some positive number δ such that $|g(x) - A| < \epsilon$ whenever x is a number in the domain of g such that $x \neq x_0$ and $|x - x_0| < \delta$. It is required of g that its domain shall contain numbers x as close to x_0 as desired, but different from x_0. The domain of g may also contain x_0, but this is irrelevant.

It is a theorem that, if f is differentiable at x_0, then f is continuous at x_0. However, a function can be continuous at x_0, but not differentiable there. An example is $f(x) = |x|$ at $x_0 = 0$. It is even possible for a function to be continuous on an interval and yet not differentiable at any point of this interval.

The chief elementary applications of differentiation are (1) in expressing rates of change (velocity, acceleration), and in solving problems where, through functional relationship, the rate of change of one variable is calculated when the rate of change of another variable is known; (2) in studying graphs of functions and, more generally, in studying curves in the plane or in space of three dimensions: (3) in expressing scientific laws or principles in the form of differential equations; and (4) in the expression of various extensions and applications of the law of the mean, including such topics as l'Hospital's rule and Taylor's formula or series.

The general technique of differentiation is built upon the rules for differentiating combinations of differentiable functions. If $u = f(x)$ and $v = g(x)$ are functions differentiable for the same values of x, then $u + v$ and uv are differentiable and so is u/v if $v \neq 0$. The formulas are shown in Eqs. (3). If u is constant in

$$\begin{aligned} \frac{d}{dx}(u+v) &= \frac{du}{dx} + \frac{dv}{dx} \\ \frac{d}{dx}(uv) &= u\frac{du}{dx} + v\frac{du}{dx} \\ \frac{d}{dx}\left(\frac{u}{v}\right) &= \frac{v\frac{du}{dx} - u\frac{dv}{dx}}{v^2} \end{aligned} \qquad (3)$$

value, then $du/dx = 0$. A very powerful instrument of technique is furnished in the chain rule for composite functions. If y is a differentiable function of u and u is a differentiable function of x, then y is a differentiable function of x, and

$$\frac{dy}{dx} = \frac{dy}{du}\frac{du}{dx}$$

In functional notation, if $y = f(u)$ and $u = h(x)$, then $y = F(x)$, where $F(x) = f[h(x)]$, and then $F'(x) \cdot f'[h(x)]h'(x)$. [A.E.Ta.]

Diffraction The bending of light, or other waves, into the region of the geometrical shadow of an obstacle. More exactly, diffraction refers to any redistribution in space of the intensity of waves that results from the presence of an object that causes variations of either the amplitude or phase of the waves. Most diffraction gratings cause a periodic modulation of the phase across the wavefront rather than a modulation of the amplitude. Although diffraction is an effect exhibited by all types of wave motion, this article will deal only with electromagnetic waves, especially those of visible light. For discussion of the phenomenon as encountered in other types of waves *see* ELECTRON DIFFRACTION; NEUTRON DIFFRACTION; SOUND.

Diffraction is a phenomenon of all electromagnetic radiation, including radio waves; microwaves; infrared, visible, and ultraviolet light; and x-rays. The effects for light are important in connection with the resolving power of optical instruments. *See* RADIO-WAVE PROPAGATION; X-RAY DIFFRACTION.

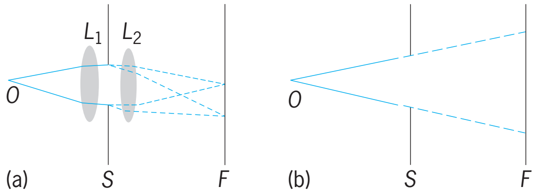


Fig. 1. Observation of the two principal types of diffraction, in the case of a circular aperture. (*a*) Fraunhofer and (*b*) Fresnel diffraction.

There are two main classes of diffraction, which are known as Fraunhofer diffraction and Fresnel diffraction. The former concerns beams of parallel light, and is distinguished by the simplicity of the mathematical treatment required and also by its practical importance. The latter class includes the effects in divergent light, and is the simplest to observe experimentally.

To illustrate the difference between the methods of observation of the two types of diffraction, Fig. 1 shows the experimental arrangements required to observe them for a circular hole in a screen S. The light originates at a very small source O, which can conveniently be a pinhole illuminated by sunlight. In Fraunhofer diffraction, the source lies at the principal focus of a lens L_1 which renders the light parallel as it falls on the aperture. A second lens L_2 focuses parallel diffracted beams on the observing screen F, situated in the principal focal plane of L_2. In Fresnel diffraction, no lenses intervene. The diffraction effects occur chiefly near the borders of the geometrical shadow, indicated by the broken lines. An alternative way of distinguishing the two classes, therefore, is to say that Fraunhofer diffraction concerns the effects near the focal point of a lens or mirror, while Fresnel diffraction concerns those effects near the edges of shadows. Photographs of diffraction patterns are shown in Fig. 2.

Fraunhofer diffraction. This class of diffraction is characterized by a linear variation of the phases of the Huygens secondary waves with distance across the wavefront, as they arrive at a given point on the observing screen. At the instant that the incident plane wave occupies the plane of the diffracting screen, it may be regarded as sending out, from each element of its surface, a multitude of secondary waves, the joint effect of which is to be evaluated in the focal plane of the lens L_2. The analysis of these secondary waves involves taking account of both their amplitudes and their phases. The simplest way to do this is to use a graphical method, the method of the so-called vibration curve, which can readily be extended to cases of Fresnel diffraction. *See* HUYGENS' PRINCIPLE.

The vibration curve results from the addition of a large (really infinite) number of infinitesimal vectors, each representing the

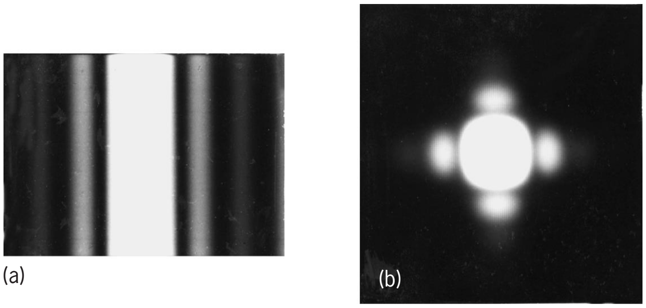

Fig. 2. Diffraction patterns, photographed with visible light. (*a*) Fraunhofer pattern, for a slit; (*b*) Fresnel pattern, circular aperture.

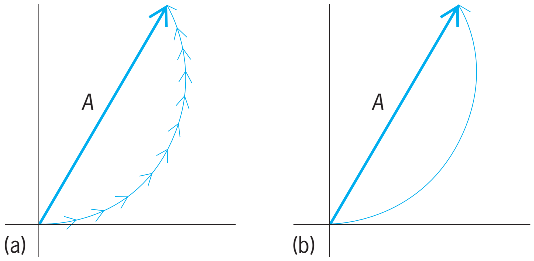

Fig. 3. Vibration curves. *(a)* Addition of many equal amplitudes differing in phase by equal amounts. *(b)* Equivalent curve, when amplitudes and phase differences become infinitesimal.

contribution of the Huygens secondary waves from an element of surface of the wavefront. If these elements are assumed to be of equal area, the magnitudes of the amplitudes to be added will all be equal. They will, however, generally differ in phase, so that if the elements were small but finite each would be drawn at a small angle with the preceding one, as shown in Fig. 3*a*. The resultant of all elements would be the vector *A*. When the individual vectors represent the contributions from infinitesimal surface elements (as they must for the Huygens wavelets), the diagram becomes a smooth curve, the vibration curve, shown in Fig. 3*b*. The intensity on the screen is then proportional to the square of this resultant amplitude. In this way, the distribution of the intensity of light in any Fraunhofer diffraction pattern may be determined.

The intensity distribution for Fraunhofer diffraction by a slit as a function of the angle θ from the center may be simply calculated by the method of the vibration curve. The intensity at any angle is given by Eq. (1), where I_0 is the intensity at the center of the pattern, and β is given by Eq. (2), where b is the width of the slit and λ is the wavelength. The central maximum is twice as wide as the subsidiary ones, and is about 21 times as intense as the strongest of these. A photograph of this pattern is shown in Fig. 2*a*.

$$I = I_0 \frac{\sin^2 \beta}{\beta^2} \tag{1}$$

$$\beta = (\pi b \sin\theta)\lambda \tag{2}$$

Fraunhofer diffraction by a circular aperture determines the resolving power of instruments such as telescopes, cameras, and microscopes, in which the width of the light beam is usually limited by the rim of one of the lenses. The method of the vibration curve may be extended to find the angular width of the central diffraction maximum for this case. An exact construction of the curve or, better, a mathematical calculation shows that the extreme phase differences required are $\pm\, 1.220\pi$, yielding Eq. (3)

$$\sin\theta \approx \theta = \pm \frac{1.220\lambda}{d} \tag{3}$$

for the angle θ at the first zero of intensity. Here d is the diameter of the circular aperture. This pattern has circular symmetry and consists of a diffuse central disk, called the Airy disk, surrounded by faint rings. The angular radius of the disk, given by Eq. (3), may be extremely small for an actual optical instrument, but it sets the ultimate limit to the sharpness of the image, that is, to the resolving power. *See* Resolving power (optics).

Fresnel diffraction. The diffraction effects obtained when the source of light or the observing screen are at a finite distance from the diffracting aperture or obstacle come under the classification of Fresnel diffraction. This type of diffraction requires for its observation only a point source, a diffracting screen of some sort, and an observing screen. The latter is often advantageously replaced by a magnifier or a low-power microscope. The observed diffraction patterns generally differ according to the radius of curvature of the wave and the distance of the point of observation behind the screen. If the diffracting screen has circular symmetry, such as that of an opaque disk or a round hole, a point source of light must be used. If it has straight, parallel edges, it is desirable from the standpoint of brightness to use an illuminated slit parallel to these edges. In the latter case, it is possible to regard the wave emanating from the slit as a cylindrical one. For the purpose of deriving the vibration curve, the appropriate way of dividing the wavefront into infinitesimal elements is to use annular rings in the first case, and strips parallel to the axis of the cylinder in the second case.

The zone plate is a special screen designed to block off the light from every other half-period zone, and represents an interesting application of Fresnel diffraction. The Fresnel half-period zones are drawn, with radii proportional to the square roots of whole numbers, and alternate ones are blackened. The drawing is then photographed on a reduced scale. When light from a point source is sent through the negative, an intense point image is produced, much like that formed by a lens. [F.A.J./W.W.W.]

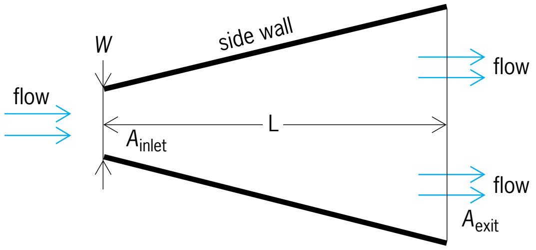
Diffraction grating An optical device consisting of an assembly of narrow slits or grooves, which by diffracting light produces a large number of beams which can interfere in such a way as to produce spectra. Since the angles at which constructive interference patterns are produced by a grating depend on the lengths of the waves being diffracted, the waves of various lengths in a beam of light striking the grating will be separated into a number of spectra, produced in various orders of interference on either side of an undeviated central image. By controlling the shape and size of the diffracting grooves when producing a grating and by illuminating the grating at suitable angles, a beam of light can be thrown into a single spectrum whose purity and brightness may exceed that produced by a prism. Gratings can now be made with much larger apertures than prisms, and in such form that they waste less light and give higher intrinsic dispersion and resolving power. *See* Diffraction.

Transmission gratings consist of a large number of narrow transparent and opaque slits alternating side by side in regular order and with uniform separation, through which a beam of light will appear as a series of spectra in various orders of interference. Reflection gratings, either plane or concave, are used in most spectrographs. Such a grating may consist of an original ruling or of a metal-coated replica from an original. Large grating replicas can now be made which are practically indistinguishable in performance or permanence from an original.

Gratings are engraved by highly precise ruling engines, which use a diamond tool to press into a highly polished mirror surface a series of many thousands of fine shallow burnished grooves. If a grating is to give resolution approaching the theoretical limit, its grooves must be ruled straight, parallel, and equally spaced to within a few tenths of the shortest incident wavelength. Scattered light and false images may arise from local spacing error and groove shape variations of only a few hundredths of the diffracted wavelength.

A grating spectroscope usually consists of a slit, a lens or mirror to collimate the light sent through the slit into a parallel beam, a transmission or reflection grating to disperse the light, a lens or mirror to focus the light into spectrum lines (which are monochromatic images of the slit in the light of each wavelength passing through it), and an eyepiece for viewing the spectrum. If a camera is substituted for the telescope, the instrument becomes a grating spectrograph. If a photoelectric cell, a thermocouple, or other radiation-detecting device is used instead of a camera or telescope, the device becomes a grating spectrometer. *See* Infrared spectroscopy. [G.R.H.]

Diffuser A device in which the kinetic energy of a flow is recovered, thus giving a static pressure rise. A simple example is a diverging passage (see illustration) with flow entering the small end and leaving the large end. For an incompressible flow (density, ρ, is constant) the mass conservation principle,



Standard diffuser geometry.

Eq. (1), indicates that the velocity (V) will decrease through the

$$m = \rho V A$$

diffuser as the area (A) increases, since the mass flow rate (m) is constant. It follows from the Bernoulli principle, Eq. (2), and

$$p_0 = p + {}^1/_2 \rho V^2$$

from the fact that the total pressure (p_0) changes but slightly, that the static pressure (p) rises in the diffuser. All subsonic diffusers, whether incompressible or not, experience stream-tube area increase as kinetic energy is converted to static pressure rise. Supersonic diffusers operate differently since changes in density become very significant. Many different geometries are possible for diffusers. *See* BERNOULLI'S THEOREM; CONSERVATION OF MASS; SUPERSONIC DIFFUSER.

Diffusers serve many vital roles. Many fluid-dynamic processes exhibit excessive kinetic energy at some point in their operating cycle. This kinetic energy can be recovered as a useful static pressure rise by the implementation of a diffuser. For example, hydraulic turbines installed for hydroelectric plant operation invariably use a draft tube, that is, an exhaust diffuser. Likewise, ground-based gas turbines for electric power production or general-purpose expansion turbines for waste-gas expansion generally employ an exhaust diffuser for extra pressure recovery. Compressors and pumps invariably generate excessive kinetic energy as work is done by their rotors, and diffusers are required to recover the kinetic energy as a static pressure rise. The basic elements of fluid transfer include pipes, elbows, valves, and diffusers. *See* COMPRESSOR; GAS TURBINE; HYDRAULIC TURBINE; PUMP. [D.Ja.]

Diffusion The transport of matter from one point to another by random molecular motions. It occurs in gases, liquids, and solids.

Diffusion plays a key role in processes as diverse as permeation through membranes, evaporation of liquids, dyeing textile fibers, drying timber, doping silicon wafers to make semiconductors, and transporting of thermal neutrons in nuclear power reactors. Rates of important chemical reactions are limited by how fast diffusion can bring reactants together or deliver them to reaction sites on enzymes or catalysts. The forces between molecules and molecular sizes and shapes can be studied by making diffusion measurements. *See* CELL PERMEABILITY; EVAPORATION; INTEGRATED CIRCUITS; SEMICONDUCTOR; THERMAL NEUTRONS.

Molecules in fluids (gases and liquids) are constantly moving. Even in still air, for example, nitrogen and oxygen molecules ricochet off each other at bullet speeds. Molecular diffusion is easily demonstrated by pouring a layer of water over a layer of ink in a narrow glass tube. The boundary between the ink and water is sharp at first, but it slowly blurs as the ink diffuses upward into the clear water. Eventually, the ink spreads evenly along the tube without any help from stirring.

Gases. A number of techniques are used to measure diffusion in gases. In a two-bulb experiment, two vessels of gas are connected by a narrow tube through which diffusion occurs. Diffusion is followed by measuring the subsequent changes in the composition of gas in each vessel. Excellent results are also obtained by placing a lighter gas mixture on top of a denser gas mixture in a vertical tube and then measuring the composition along the tube after a timed interval.

Rates of diffusion in gases increase with the temperature (T) approximately as $T^{3/2}$ and are inversely proportional to the pressure. The interdiffusion coefficients of gas mixtures are almost independent of the composition.

Kinetic theory shows that the self-diffusion coefficient of a pure gas is inversely proportional to both the square root of the molecular weight and the square of the molecular diameter. Interdiffusion coefficients for pairs of gases can be estimated by taking averages of the molecular weights and collision diameters. Kinetic-theory predictions are accurate to about 5% at pressures up to 10 atm (1 megapascal). Theories which take into account the forces between molecules are more accurate, especially for dense gases. *See* KINETIC THEORY OF MATTER.

Liquids. The most accurate diffusion measurements on liquids are made by layering a solution over a denser solution and then using optical methods to follow the changes in refractive index along the column of solution. Excellent results are also obtained with cells in which diffusion occurs between two solution compartments through a porous diaphragm. Many other reliable experimental techniques have been devised.

Room-temperature liquids usually have diffusion coefficients in the range 0.5–5 $\times$ 10^{-5} cm^2 s^{-1}. Diffusion in liquids, unlike diffusion in gases, is sensitive to changes in composition but relatively insensitive to changes in pressure. Diffusion of high-viscosity, syrupy liquids and macromolecules is slower. The diffusion coefficient of aqueous serum albumin, a protein of molecular weight 60,000 atomic mass units, is only 0.06 $\times$ 10^{-5} cm^2 s^{-1} at 25°C (77°F).

When solute molecules diffuse through a solution, solvent molecules must be pushed out of the way. For this reason, liquid-phase interdiffusion coefficients are inversely proportional to both the viscosity of the solvent and the effective radius of the solute molecules. Accurate theories of diffusion in liquids are still under development. *See* VISCOSITY. [D.G.L.]

Solids. Diffusion in solids is an important topic of physical metallurgy and materials science since diffusion processes are ubiquitous in solid matter at elevated temperatures. They play a key role in the kinetics of many microstructural changes that occur during the processing of metals, alloys, ceramics, semiconductors, glasses, and polymers. Typical examples of such changes include nucleation of new phases, diffusive phase transformations, precipitation and dissolution of a second phase, recrystallization, high-temperature creep, and thermal oxidation. Direct technological applications concern diffusion doping during the fabrication of microelectronic devices, solid electrolytes for battery and fuel cells, surface hardening of steels through carburization or nitridation, diffusion bonding, and sintering. *See* CREEP (MATERIALS); FUEL CELL; HEAT TREATMENT (METALLURGY); METAL, MECHANICAL PROPERTIES OF; PHASE TRANSITIONS; PLASTIC DEFORMATION OF METAL; SINTERING; SOLID-STATE BATTERY; SURFACE HARDENING OF STEEL.

The atomic mechanisms of diffusion are closely connected with defects in solids. Point defects such as vacancies and interstitials are the simplest defects and often mediate diffusion in an otherwise perfect crystal. Dislocations, grain boundaries, phase boundaries, and free surfaces are other types of defects in a crystalline solid. They can act as diffusion short circuits because the mobility of atoms along such defects is usually much higher than in the lattice. *See* CRYSTAL DEFECTS. [H.Me.]

Digenea A group of parasitic flatworms or flukes constituting a subclass or order of the class Trematoda, in the phylum Platyhelminthes. The name Digenea refers to the two types of generations in the life cycle: (1) the germinal sacs which parasitize the intermediate host (a mollusk or rarely an annelid) and reproduce asexually; and (2) the adult which is primarily endoparasitic in vertebrates and reproduces sexually. The adult usually is hermaphroditic, but many of the blood flukes and a few others are dioecious. Vertebrates of all classes, except the Cyclostomata, serve as definitive hosts. Those feeding on aquatic plants and animals harbor the greatest variety of digenetic trematodes, but several species occur in strictly terrestrial hosts. Effects on the vertebrate vary from no apparent harm to severe and even fatal injury. Control of flukes is by preventive measures, including interruption of their life cycles and treatment with drugs. *See* TREMATODA.

The adult differs from other trematodes in several respects, the most obvious being the absence of a posterior adhesive organ with sclerotized hooks, plates, or multiple suctorial structures. Usually the mouth is anterior and opens into an oral sucker. A second sucker, the ventral one, is at the posterior end of amphistomes, on the ventral surface of distomes, or absent in monostomes. Adult digenetic trematodes occur in any part of the vertebrate that provides egress for their eggs and also in the circulatory system, from which eggs work through the tissues and escape in the feces or urine.

There is no general agreement concerning the classification of the Digenea. The scheme of G. La Rue proposes two superorders, the Anepitheliocystidia and Epitheliocystidia. *See* PLATYHELMINTHES. [R.M.C.]

Digestive system The vertebrate digestive system consists of the digestive tract and ancillary organs that serve for the acquisition of food and assimilation of nutrients required for energy, growth, maintenance, and reproduction. Food is ingested, reduced to particles, mixed with digestive fluids and enzymes, and propelled through the digestive tract. Enzymes produced by the host animal and microbes indigenous to the digestive tract destroy harmful agents and convert food into a limited number of nutrients, which are selectively absorbed. The digestive systems of vertebrates show numerous structural and functional adaptations to their diet, habitat, and other characteristics. Carnivores, which feed exclusively on other animals, and species that feed on plant concentrates (seeds, fruit, nectar, pollen) tend to have the shortest and simplest digestive tract. The digestive tract tends to be more complex in omnivores, which feed on both plants and animals, and most complex in herbivores, which feed principally on the fibrous portions of plants.

Gut structure and function can also vary with the habitat and other physiological characteristics of a species. The digestive tract of fish has adaptations for a marine or fresh-water environment. The basal metabolic rate per gram of body weight increases with a decrease in the body mass. Therefore, small animals must process larger amounts of food per gram of body weight, thus limiting their maximum gut capacity and digesta retention time.

Anatomy. Because of wide species variations, the digestive system of vertebrates is best described in terms of the headgut, foregut, midgut, pancreas, biliary system, and hindgut. The headgut consists of the mouthparts and pharynx, which serve for the procurement and the initial preparation and swallowing of food. The foregut consists of an esophagus for the swallowing of food and, in most species, a stomach that serves for its storage and initial stages of digestion. The esophagus of most vertebrates is lined with a multilayer of cells that are impermeable to absorption. In most birds it contains the crop, an outpocketing of its wall that provides for the temporary storage of food. A stomach is present in all but the cyclostomes and some species of advanced fish and in the larval amphibians. In most vertebrates it consists of a dilated segment of the gut that is separated from the esophagus and midgut by muscular sphincters or valves. This is often referred to as a simple stomach. However, in birds these functions are carried out by the crop (storage), proventriculus (secretion), and gizzard (grinding or mastication). In most vertebrates, a major portion of the stomach is lined with a proper gastric mucosa (epithelium), which secretes mucus, hydrochloric acid (HCl), and pepsinogen. The distal (pyloric) part of the stomach secretes mucus and bicarbonate ions (HCO^{-}_{3}), and its muscular contractions help reduce the size of food particles and transfer partially digested food into the midgut. The stomach of reptiles and most mammals has an additional area of cardiac mucosa near its entrance, which also secretes mucus and bicarbonate ions. *See* ESOPHAGUS; STOMACH.

The midgut or small intestine is the principal site for the digestion of food and the absorption of nutrients. It is lined with a single layer of cells that secrete mucus and fluids, contain enzymes that aid in the final stages of carbohydrate and protein digestion, and absorb nutrients from the lumen into the circulatory system. The surface area of the lumen can be increased by a variety of means, such as folds and pyloric ceca (blind sacs) in fish. In higher vertebrates the lumen surface is increased by the presence of villi, which are macroscopic projections of the epithelial and subepithelial tissue.

The lumen surface is also expanded by a brush border of microvilli on the lumen-facing (apical) surface of the midgut absorptive cells in all vertebrates. The brush border membranes contain enzymes that aid in the final digestion of food and mechanisms that provide for the selective absorption of nutrients. The lumenal surface area of the human small intestine is increased 10-fold by the presence of villi and an additional 20-fold by the microvilli, resulting in a total surface area of 310,000 in.^2 (2,000,000 cm^2).

Digestion in the midgut is aided by secretions of digestive enzymes and fluid by pancreatic tissue, and secretion of bile by the liver. Pancreatic tissue is distributed along the intestinal wall, and even into the liver, of some species of fish. However, the pancreas is a compact organ in sharks, skates, rays, many teleosts, and all other vertebrates. The liver is a compact organ in all vertebrates. One of its many functions is the secretion of bile. In most vertebrates, the bile is stored in the gallbladder and released into the intestine as needed, but a gallbladder is absent in some species of fish and mammals. Bile salts serve to emulsify lipids and increase their surface area available for digestion by the water-soluble lipase. *See* GALLBLADDER; LIVER; PANCREAS.

The hindgut is the final site of digestion and absorption prior to defecation or evacuation of waste products. The hindgut of fish, amphibian larvae, and a few mammals is short and difficult to distinguish from the midgut. However, the hindgut of adult amphibians and reptiles, birds, and most mammals is a distinct segment, which is separated from the midgut by a muscular sphincter or valve. It also tends to be larger in diameter. Thus, the midgut and hindgut of these animals are often referred to as the small intestine and the large intestine. *See* INTESTINE.

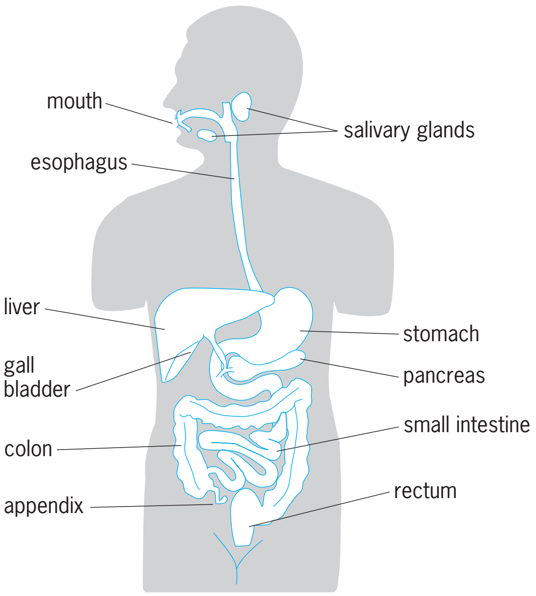
The hindgut of some reptiles and many mammals includes a blind sac or cecum near its junction with the midgut. A pair of ceca are present in the hindgut of many birds and a few mammalian species. The remainder of the hindgut consists of the colon and a short, straight, terminal segment, which is called the rectum in mammals. The digestive and urinary tracts exit separately from the body of most species of fish and mammals. However, in adult amphibians and the reptiles, birds, and some mammals, this segment terminates in a chamber called the cloaca, which also serves as an exit for the urinary and reproductive systems. The hindgut or, where present, the cloaca terminates in the anus. *See* COLON; URINARY SYSTEM.

The hindgut is similarly lined with a single layer of absorptive and mucus-secreting cells. However, it lacks villi, and (with the exception of the cecum of birds) its absorptive cells lack digestive enzymes and the ability to absorb most nutrients. One major function of the hindgut is to reabsorb the fluids secreted into the upper digestive tract and (in animals that have a cloaca) excreted in the urine. It also serves as the principal site for the microbial production of nutrients in the herbivorous reptiles and birds and in most herbivorous mammals. Thus, the hindgut tends to be longest in animals that need to conserve water in an arid environment, and has a larger capacity in most herbivores.

Musculature. The digestion of food, absorption of nutrients, and excretion of waste products require the mixing of ingesta with digestive enzymes and the transit of ingesta and digesta through the digestive tract. In all vertebrates other than the cyclostome the contents are mixed and moved by an inner layer of circular muscle and an outer layer of muscle that runs longitudinally along the tract. The initial act of deglutition (swallowing) and the final act by which waste products are defecated from the digestive tract are effected by striated muscle. This type of muscle is characterized by rapid contraction and is controlled by extrinsic nerves. However, the esophagus of amphibians, reptiles, and birds, and the entire gastrointestinal tract of all vertebrates are enveloped by smooth muscle. This smooth muscle contracts more slowly, and its rate of contraction is partly independent of external stimulation. *See* Muscle.

Nerve and endocrine tissue. The initial act of deglutition and final act of defecation are under the voluntary control of the central nervous system. However, the remainder of the digestive system is subject to the involuntary control of nerves which release a variety of neurotransmitting or neuromodulating agents that either stimulate or inhibit muscular contractions and the secretions of glands and cells. The motor and secretory activities of the digestive system are also under the control of a wide range of other substances produced by endocrine cells that are released either distant from (hormones) or adjacent to (paracrine agents) their site of action. Although there are some major variations in the complement and activities of the neurotransmitters, neuromodulators, hormones, and paracrine agents, their basic patterns of control are similar.

The anatomy of the human digestive system is similar to that of other mammalian omnivores (see illustration). The teeth and salivary glands are those of a mammalian omnivore, and the initial two-thirds of the esophagus is enveloped by striated muscle. A simple stomach is followed by an intestine, whose length consists of approximately two-thirds small bowel and one-third large bowel. The structures of the pancreas and biliary system show no major differences from those of other mammals. During early fetal development, a distinct, conical cecum is present and continues to grow until the sixth month of gestation. However, unlike other primates, the cecum recedes to become little more than a bulge in the proximal colon by the time of birth. The colon continues to lengthen after the birth and is sacculated throughout its length like that of the apes and a few monkeys but few other mammals.



Human digestive system. (*After A. C. Guyton, Textbook of Medical Physiology, 8th ed., Saunders, 1991*)

Physiology. The major physiological activities of the digestive system are motility, secretion, digestion, and absorption. Each activity can be affected by diet and, in the cold-blooded species, is reduced with a decrease in body temperature.

Motility. The mastication of food and the movement of ingesta and digesta through the digestive tract are controlled by the motor activity of muscular contractions. Pressure of food against the palate and back of the mouth stimulates a nerve reflex that passes through a deglutition center in the brain. This reflex closes the entrance into the respiratory system and stops respiration, to prevent the inspiration of food into the lungs, and initiates muscular contractions that pass food into the esophagus. The food (bolus) is then passed down the esophagus and into the stomach by a moving wave of muscular contractions (peristalsis) accompanied by inhibition of the esophageal sphincters. The multicompartmental forestomach of ruminants undergoes a continuous series of complex, repetitive contractions that are controlled by the central nervous system. However, the gastric motility of most species and the intestinal motility of all vertebrates are controlled partially by the intrinsic characteristics of their smooth muscle cells. The result is production of either stationary (mixing) contractions of the stomach and intestine or a series of peristaltic contractions that carry digesta on through the tract.

Digestion. Digestion is accomplished by enzymes produced by the digestive system (endogenous enzymes) or by bacteria that are normal residents of the digestive tract. Plant and animal starches are converted to oligosaccharides (short-chain structures) and disaccharides by amylase, which is secreted by the salivary glands of some species and the pancreas of all vertebrates. The end products of starch digestion, plus the dietary disaccharides, are converted to monosaccharides by enzymes in the brush border of the absorptive epithelial cells lining the small intestine. Vertebrates do not produce enzymes capable of digesting the structural polysaccharides of plants.

Lipids are digested into alcohols, monoglycerides, and fatty acids by lipases and esterases, which are secreted predominantly by the pancreas. However, the lipases are water-soluble enzymes that can attack their substrate only at a lipid-water interface. Therefore, the lipids must be emulsified in order to provide the surface area required for efficient digestion. Emulsification is accomplished by the release of bile salts secreted by the liver and released into the midgut.

Dietary protein is first broken down into long chains of amino acids (polypeptides) by gastric pepsin and pancreatic trypsin. The polypeptides are then attacked by other pancreatic proteases (chymotrypsin, carboxypeptidase, elastase) to form tripeptides, dipeptides, and amino acids. All of these enzymes are secreted in an inactive form to prevent the self-digestion of the secretory cells prior to their release. Pepsin is activated by the acidity resulting from the secretion of hydrochloric acid (HCl) into the stomach, and trypsin is activated by an enzyme (enterokinase) that is secreted by intestinal epithelium. Tri- and dipeptides are digested into amino acids by enzymes in the brush border and contents of midgut absorptive cells. Nucleic acids are digested by pancreatic ribonucleases into pentose sugars, purines, and pyrimidines.

Substantial numbers of bacteria can be found in all segments of the gastrointestinal tract, but the highest numbers are present in those segments in which digesta are retained for prolonged periods of time at a relatively neutral pH. Indigenous bacteria help protect the animal from pathogenic microorganisms by stimulating immunity and competing for substrates. They also convert dietary and endogenous substances that are not digested by endogenous enzymes into absorbable nutrients. Many species of indigenous bacteria can ferment sugars, starches, and structural carbohydrates into short-chain fatty acids. The short-chain fatty acids, which are predominantly acetic, propionic, and butyric acids, are readily absorbed and serve as an additional source of energy. These bacteria also synthesize microbial protein and the B-complex vitamins that may be useful to their host. The contributions of indigenous bacteria to the production and conservation of nutrients are greatest in herbivores. Although it has been estimated that short-chain fatty acid absorption provides 4% of total maintenance energy requirement by dogs and 6–10% of the maintenance energy required by humans, they can account for 30% of the maintenance energy of rabbits and up to 70% of maintenance energy of horses and ruminants. *See* BACTERIAL PHYSIOLOGY AND METABOLISM.

Absorption. The epithelial cells that line the gastrointestinal tract are closely attached to one another at their lumen-facing border by tight junctions, which are relatively impermeable to most substances other than water. Therefore, the major restriction for the absorption of most substances from the lumen into the blood is the apical and basolateral membranes of these cells. Lipid-soluble substances can be transported across the apical cell membranes by passive diffusion down their concentration gradient. The short- and medium-chain fatty acids that result from lipid digestion in the small intestine pass directly into the blood. However, the monoglycerides and long-chain fatty acids are resynthesized into triglycerides by the epithelial cells in the midgut and incorporated into small spheres (chylomicrons), which are transported across the basolateral membrane into the lymphatic system. Fat-soluble vitamins, long-chain alcohols, and other lipids also appear to be incorporated into chylomicrons and to enter the lymphatic system.

The intestinal cell membranes are relatively impermeable to the passive diffusion of water-soluble monosaccharides, amino acids, vitamins, and minerals that constitute a major portion of the required nutrients. These nutrients are selectively transferred across the intestinal cell membranes by carrier-mediated transport. Membrane carriers combine with the nutrient at one membrane surface and pass it across the membrane for release at the opposing surface. Some simply facilitate the diffusion of a substance down its concentration gradient; others are capable of transporting a nutrient against its concentration gradient, which requires either a direct or indirect investment of cellular energy. *See* CELL MEMBRANES.

The metabolic processes of the body require a number of different minerals. Some such as iron, calcium, sodium, and chloride are required in relatively large quantities. Others such as manganese and zinc are labeled trace minerals because they are required in only minute amounts.

The nutrient that is required in largest quantity for digestion, absorption, metabolism, and excretion of waste products is water. Because it readily diffuses across cell membranes down its concentration gradient, the net secretion or absorption of water is determined by the net secretion or absorption of all other substances. Sodium, chloride, and bicarbonate are the principal ions that are present in the extracellular fluids that bathe the body cells of all vertebrates and that are transported across cell membranes. Therefore, the transport of these electrolytes is the major driving force for the secretion or absorption of water. [C.E.St.]

Digital computer A device that processes numerical information; more generally, any device that manipulates symbolic information according to specified computational procedures. The term digital computer—or simply, computer—embraces calculators, computer workstations, control computers (controllers) for applications such as domestic appliances and industrial processes, data-processing systems, microcomputers, microcontrollers, multiprocessors, parallel computers, personal computers, network servers, and supercomputers. *See* CALCULATORS; DIGITAL CONTROL; MICROCOMPUTER; PROGRAMMABLE CONTROLLERS; SUPERCOMPUTER.

A digital computer is an electronic computing machine that uses the binary digits (bits) 0 and 1 to represent all forms of information internally in digital form. Every computer has a set of instructions that define the basic functions it can perform. Sequences of these instructions constitute machine-language programs that can be stored in the computer and used to tailor it to an essentially unlimited number of specialized applications. Calculators are small computers specialized for mathematical computations. General-purpose computers range from pocket-sized personal digital assistants (notepad computers), to medium-sized desktop computers (personal computers and workstations), to large, powerful computers that are shared by many users via a computer network. The vast majority of digital computers now in use are inexpensive, special-purpose microcontrollers that are embedded, often invisibly, in such devices as toys, consumer electronic equipment, and automobiles. *See* BIT; COMPUTER PROGRAMMING; EMBEDDED SYSTEMS.

The main data-processing elements of a computer reside in a small number of electronic integrated circuits (ICs) that form a microprocessor or central processing unit (CPU). Electronic technology allows a basic instruction such as "add two numbers" to be executed many millions of times per second. Other electronic devices are used for program and data storage (memory circuits) and for communication with external devices and human users (input-output circuits). Nonelectronic (magnetic, optical, and mechanical) devices also appear in computers. They are used to construct input-output devices such as keyboards, monitors (video screens), secondary memories, printers, sensors, and mechanical actuators.

Information is stored and processed by computers in fixed-sized units called words. Common word sizes are 8, 16, 32, and 64 bits. Four-bit words can be used to encode the first 16 integers. By increasing the word size, the number of different items that can be represented and their precision can be made as large as desired. A common word size in personal computers is 32 bits, which allows $2^{32} = 4{,}294{,}967{,}296$ distinct numbers to be represented.

Computer words can represent many different forms of information, not just numbers. For example, 8-bit words called characters or bytes are used to encode text symbols (the 10 decimal digits, the 52 upper- and lowercase letters of the English alphabet, and punctuation marks). A widely used code of this type is ASCII (American Standard Code for Information Interchange). Visual information can be reduced to black and white dots (pixels) corresponding to 0's and 1's. Audio information can be digitized by mapping a small element of sound into a binary word; for example, a compact disk (CD) uses several million 16-bit words to store an audio recording. Logical quantities encountered in reasoning or decision making can be captured by associating 1 with true and 0 with false. Hence, most forms of information are readily reduced to a common, numberlike binary format suitable for processing by computer. *See* COMPACT DISK; IMAGE PROCESSING; LOGIC.

Logic components. The operation of a digital computer can be viewed at various levels of abstraction, which are characterized by components of different complexity. These levels range from the low, transistor level seen by an electronic circuit designer to the high, system level seen by a computer user. A useful intermediate level is the logic level, where the basic components process individual bits. By using other basic components called gates, logic circuits can be constructed to perform many useful operations. *See* LOGIC CIRCUITS.

System organization. An accumulator is a digital system that constitutes a simple processor capable of executing a few instructions. By introducing more data-processing circuits and registers, as well as control circuits for a larger set of instructions, a practical, general-purpose processor can be constructed. Such a processor forms the "brain" of every computer, and is referred to as its central processing unit. A CPU implemented on a single integrated-circuit chip is called a microprocessor. *See* MICROPROCESSOR.

A typical computer program is too large to store in the CPU, so another component called the main memory is used to store a program's instructions and associated data while they are being executed (Fig. 1). Main memory consists of high-speed

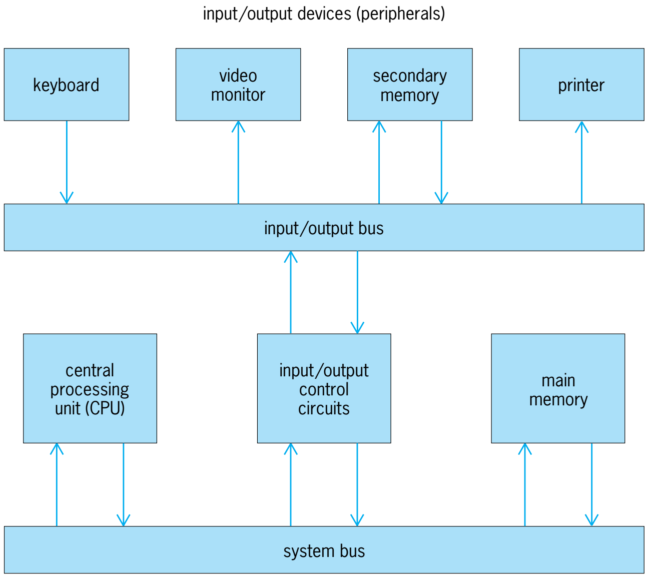


Fig. 1. General organization of a computer.

integrated circuits designed to allow storage and retrieval of information one word at a time. All words in main memory can be accessed with equal ease; hence this is also called a random-access memory (RAM).

A computer program is processed by loading it into main memory and then transferring its instructions and data one word (or a few words) at a time to the CPU for processing. Hence, there is a continual flow of instructions and data words between the CPU and its main memory. As millions of words must be transferred per second, a high-speed communication link is needed between the CPU and main memory. The system bus (Fig. 1) fills this role.

A computer has input-output (I/O) control circuits and buses to connect it to external input-output devices (also called peripherals). Typical input-output devices are a keyboard, which is an input device, and a printer, which is an output device. Because most computers need more storage space than main memory can supply, they also employ secondary memory units which form part of the computer's input-output subsystem. Common secondary memory devices are hard disk drives, flexible (floppy) disk drives, and magnetic tape units. Compared to main memory, secondary memories employ storage media (magnetic disks and tapes) that have higher capacity and lower cost. However, secondary memories are also significantly slower than main memory. *See* COMPUTER PERIPHERAL DEVICES; COMPUTER STORAGE TECHNOLOGY.

No explicit instructions are needed for input-output operations if input-output devices share with main memory the available memory addresses. This is known as memory-mapped input-output, and allows load and store instructions to be used to transfer data between the CPU and input-output devices. In general, a computer's instruction set should include a selection of instructions of the following three types: (1) Data-transfer instructions that move data unchanged between the CPU, main memory, and input-output devices. (2) Data-processing instructions that perform numerical operations such as add, subtract, multiply, and divide, as well as nonnumerical (logical) operations, such as NOT, AND, EXCLUSIVE-OR, and SHIFT. (3) Program-control instructions that can change the order in which instructions are executed, for example branch, branch-on-zero, call procedure, and return from procedure.

The instruction unit (I unit) of a CPU (Fig. 2), also called the program control unit, is responsible for fetching instructions from main memory, using the program counter as the instruction address register. The opcode of a newly fetched instruction *I* is placed in the instruction register. The opcode is then decoded to determine the sequence of actions required to execute *I*. These may include the loading or storing of data assigned to main memory, in which case the I unit computes all needed addresses and issues all needed control signals to the CPU and the system bus. Data are processed in the CPU's execution unit (E unit), also called the datapath, which contains a set of registers used for temporary storage of data operands, and an arithmetic logic unit (ALU), which contains the main data-processing circuits.

Performance measures. A simple indicator of a CPU's performance is the frequency *f* of its central timing signal (clock), measured in millions of clock signals issued per second or megahertz (MHz). The clock frequency depends on the integrated-circuit technology used; frequencies of several hundred megahertz are achievable with current technology. Each clock signal triggers execution of a basic instruction such as a fixed-point addition; hence, the time required to execute such an instruction (the clock cycle time) is $1/f$ microseconds. Complex instructions like multiplication or operations on floating-point numbers require several clock cycles to complete their execution. Another measure of CPU performance is the (average) instruction execution rate, measured in millions of instructions per second (MIPS).

Instruction execution time is strongly affected by the time to move instructions or data between the CPU and main memory. The time required by the CPU to access a word in main memory is typically about five times longer than the CPU's clock cycle time. This disparity in speed has existed since the earliest computers despite efforts to develop memory circuits that would be fast enough to keep up with the fastest CPUs. Maximum performance requires the CPU to be supplied with a steady flow of instructions that need to be executed. This flow is disrupted by branch instructions, which account for 20% or more of the instructions in a typical program.

To deal with the foregoing issues, various performance-enhancing features have been incorporated into the design of computers. The communication bottleneck between the CPU and main memory is reduced by means of a cache, which is a special memory unit inserted between the two units. The cache is smaller than main memory but can be accessed more rapidly, and is often placed on the same integrated-circuit chip as the

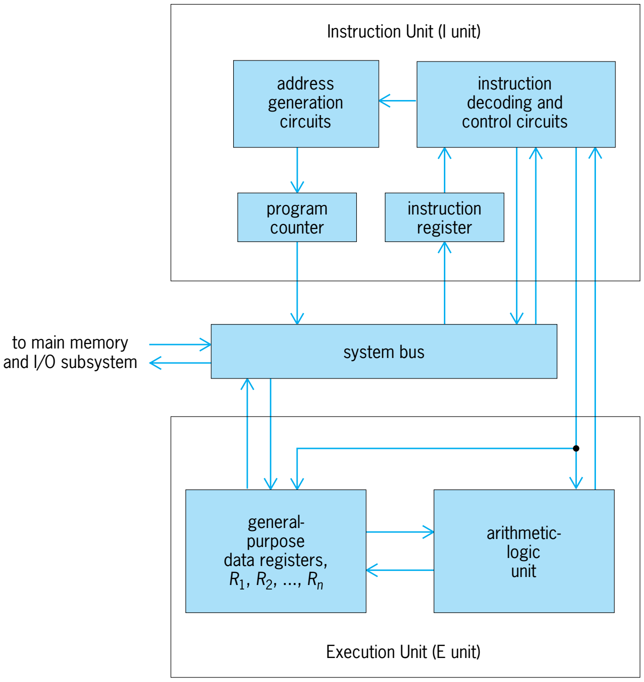

Fig. 2. Internal organization of a CPU.

CPU. Its effect is to reduce the average time required by the CPU to send information to or receive information from the memory subsystem. Special logic circuits support the complex flow of information among main memory, the cache, and the registers of the CPU. However, the cache is largely invisible to the programs being executed.

The instruction execution rate can be increased by executing several instructions concurrently. One approach is to employ several E units that are tailored to different instruction types. Examples are an integer unit designed to execute fixed-point instructions and a floating-point unit designed for floating-point instructions. The CPU can then execute a fixed-point instruction and a floating-point instruction at the same time. Processors that execute several instructions in parallel in this way are called superscalar. *See* CONCURRENT PROCESSING.

Another speedup technique called pipelining allows several instructions to be processed simultaneously in special circuits called pipelines. Execution of an instruction is broken into several consecutive steps, each of which can be assigned to a separate stage of the pipeline. This makes it possible for an n-stage E unit to overlap the execution of up to n different instructions. A pipeline processing circuit resembles an assembly line on which many products are in various stages of manufacture at the same time. The ability of a CPU to execute several instructions at the same time by using multiple or pipelined E units is highly dependent on the availability of instructions of the right type at the right time in the program being executed. A useful measure of the performance of a CPU that employs internal parallelism is the average number of clock cycles per instruction (CPI) needed to execute a representative set of programs.

CISCs and RISCs. A software implementation of a complex operation like multiply is slower than the corresponding hardware implementation. Consequently, as advances in IC technology lowered the cost of hardware circuits, instruction sets tended to increase in size and complexity. By the mid-1980s, many microprocessors had instructions of several hundred different types, characterized by diverse formats, memory addressing modes, and execution times. The heterogeneous instruction sets of these complex instruction set computers (CISCs) have some disadvantages. Complex instructions require more processing circuits, which tend to make CISCs large and expensive. Moreover, the decoding and execution of complex instruction can slow down the processing of simple instructions.

To address the defects of CISCs, a new class of fast computers referred to as reduced instruction set computers (RISCs) was introduced. RISCs are characterized by fast, efficient—but not necessarily small—instruction sets. The following features are common to most RISCs: (1) All instructions are of fixed length and have just a few opcode formats and addressing modes. (2) The only instructions that address memory are load and store instructions; all other instructions require their operands to be placed in CPU registers. (3) The fetching and processing of most instructions is overlapped in pipelined fashion. [J.P.Hay.]

Digital control The use of digital or discrete technology to maintain conditions in operating systems as close as possible to desired values despite changes in the operating environment. Traditionally, control systems have utilized analog components, that is, controllers which generate time-continuous outputs (volts, pressure, and so forth) to manipulate process inputs and which operate on continuous signals from instrumentation measuring process variables (position, temperature, and so forth). In the 1970s, the use of discrete or logical control elements, such as fluidic components, and the use of programmable logic controllers to automate machining, manufacturing, and production facilities became widespread. In parallel with these developments has been the accelerating use of digital computers in industrial and commercial applications areas, both for logic-level control and for replacing analog control systems. The development of inexpensive mini- and microcomputers with arithmetic and logical capability orders of magnitude beyond that obtainable with analog and discrete digital control elements has resulted in the rapid substitution of conventional control systems by digital computer-based ones. With the introduction of microcomputer-based control systems into major consumer products areas (such as automobiles and video and audio electronics), it is clear that the digital computer will be widely used to control objects ranging from small, personal appliances and games up to large, commercial manufacturing and production facilities. *See* MICROCOMPUTER; PROGRAMMABLE CONTROLLERS.

The object that is controlled is usually called a device or, more inclusively, process. A characteristic of any digital control system is the need for a process interface to mate the digital computer and process, to permit them to pass information back and forth.

Measurements of the state of the process often are obtained naturally as one of two switch states; for example, a part to be machined is in position (or not), or a temperature is above (or below) the desired temperature. Control signals sent to the process often are expressed as one of two states as well; for example, a motor is turned on (or off), or a valve is opened (or closed). Such binary information can be communicated naturally to and from the computer, where it is manipulated in binary form. For this reason the binary or digital computer/process interface usually is quite simple.

Process information also must be dealt with in analog form; for example, a variable such as temperature can take on any value within its measured range, or, looked at conceptually, it can be measured to any number of significant figures by a suitable instrument. Furthermore, analog variables generally change continuously in time. Digital computers are not suited to handle arbitrarily precise or continuously changing information; hence, analog process signals must be reduced to a digital representation (discretized), both in terms of magnitude and in time, to put them into a useful digital form.

The magnitude discretization problem most often is handled by transducing and scaling each measured variable to a common range, then using a single conversion device—the analog-to-digital converter (ADC)—to put the measured value into digital form. *See* ANALOG-TO-DIGITAL CONVERTER.

Discretization in time requires the computer to sample the signal periodically, storing the results in memory. This sequence of discrete values yields a “staircase” approximation to the original signal, on which control of the process must be based. Obviously, the accuracy of the representation can be improved by sampling more often, and many digital systems simply have incorporated traditional analog control algorithms along with rapid sampling. However, newer control techniques make fundamental use of the discrete nature of computer input and output signals. Analog outputs from a computer most often are obtained from a digital-to-analog converter (DAC), a device which accepts a digital output from the computer, converts it to a voltage in several microseconds, and latches (holds) the value until the next output is converted. Usually a single DAC is used for each output signal. *See* DIGITAL-TO-ANALOG CONVERTER.

In order to be used as the heart of a control system, a digital computer must be capable of operating in real time. Except for very simple microcomputer applications, this feature implies that the machine must be capable of handling interrupts, that is, inputs to the computer’s internal control unit which, on change of state, cause the computer to stop executing some section of program code and begin executing some other section. The ability to initiate operations on schedule and to respond to process interrupts in a timely fashion is the very basis of real-time computing; this feature must be available in any digital control system.

Computer control systems for large or complex processes may involve complicated programs with many thousands of computer instructions. Several routes have been taken to mitigate the difficulty of programming control computers. One approach is to develop a single program which utilizes data supplied by the user to specify both the actions to be performed on the individual process elements and the schedule to be followed. Another approach is to develop a rather sophisticated operating system to supervise the execution of user programs, scheduling individual program elements for execution as specified by the user or needed by the process. *See* DIGITAL COMPUTER.

Many applications, particularly machining, manufacturing, and batch processing, involve large or complex operating schedules. Invariably, these can be broken down into simple logical sequences. Some applications—in the chemical process industries, in power generation, and in aerospace areas—require the use of traditional automatic control algorithms.

Attempts to expand the digital control medium through development of strictly digital control algorithms is an important and continuing trend. Such algorithms typically attempt to exploit the sampled nature of process inputs and outputs, significantly decreasing the sampling requirements of the algorithm. *See* CONTROL SYSTEMS. [D.A.Me.]

Digital counter An instrument which, in its simplest form, provides an output that corresponds to the number of pulses applied to its input. Counters may be categorized into two types: the Moore machine or the Mealy machine. The simpler counter type, the Moore machine, has a single count input (also called the clock input or pulse input), while the Mealy machine has additional inputs that alter the count sequence. Digital counters take many forms, including geared mechanisms (tape counters and odometers are examples), relays (old pinball machines and old telephone switching systems), vacuum tubes (old test equipment), and solid-state semiconductor circuits (most modern electronic counters).

Most digital counters operate in the binary number system, since binary is easily implemented with electronic circuitry. Binary allows any integer (whole number) to be represented as a series of binary digits, or bits, where each bit is either a 0 or 1 (off or on, low or high, and so forth).

Digital counters are found in much modern electronic equipment, especially equipment that is digitally controlled or has digital numeric displays. A frequency counter, as a test instrument or a channel frequency display on a radio tuner, consists simply of a string of decade counters that count the pulses of an input signal for a known period of time, and display that count on a seven-segment display. A digital voltmeter operates by using nearly the same idea, except that the counter counts a known frequency for a period of time proportional to the input voltage. *See* ANALOG-TO-DIGITAL CONVERTER.

A digital watch contains numerous counter/dividers in its large-scale integration (LSI) chip, usually implemented with complementary metal oxide semiconductor (CMOS) technology.

Digital computers may contain counters in the form of programmable interval timers that count an integral number of clock pulses of known period, and then generate an output at the end of the count to signal that the time period has expired. Most of the counters in a microprocessor consist of arithmetic logic units that add one many-bit number to another, storing the results in a memory location. The program and data counters are examples of this kind of counter. *See* DIGITAL COMPUTER; MICROPROCESSOR.

Counters have progressed from relays to light-wavelength-geometry very-large-scale-integrated circuits. There are several technologies for building individual digital counters. Single counters are available as integrated circuit chips in emitter-coupled logic, transistor-transistor logic, and CMOS. [M.E.W.]

Digital filter Any digital computing means that accepts as its input a set of one or more digital signals from which it generates as its output a second set of digital signals. While being strictly correct, this definition is too broad to be of any practical use, but it does demonstrate the possible extent of application of digital-filter concepts and terminology.

Capabilities. Digital filters can be used in any signal-manipulating application where analog or continuous filters can be used. Because of their utterly predictable performance, they can be used in exacting applications where analog filters fail because of time- or other parameter-dependent coefficient drift in continuous systems. Because of the ease and precision of setting the filter coefficients, adaptive and learning digital filters are comparatively simple and particularly effective to implement. As digital technology becomes more ubiquitous, digital filters are increasingly acknowledged as the most versatile and cost-effective solutions to filtering problems.

The number of functions that can be performed by a digital filter far exceeds that which can be performed by an analog, or continuous, filter. By controlling the accuracy of the calculations within the filter (that is, the arithmetic word length), it is possible to produce filters whose performance comes arbitrarily close to the performance expected of the perfect models. For example, theoretical designs that require perfect cancellation can be implemented with great fidelity by digital filters.

Linear difference equation. The digital filter accepts as its input signals numerical values called input samples and produces as its output signal numerical values called output samples. Each output sample at any particular sampling instant is a weighted sum of present and past input samples, and past output samples. If the sequence of input samples is x_n, x_{n+1}, x_{n+2}, . . . , then the corresponding sequence of output samples would be y_n, y_{n+1}, y_{n+2}, ... *See* DIFFERENCE EQUATION.

From this simple time-domain expression, a considerable number of definitions can be constructed. If the filter coefficients (the a's and the *b*'s) are independent of the *x*'s and *y*'s, this digital filter is a linear filter. If the a's and *b*'s are fixed, this is a linear time-invariant (LTI) filter. The order of the filter is given by the largest of the subscripts among the *a*'s and *b*'s, that is, the larger of *M* and *N*. If the *b*'s are all zero (that is, if the output is the weighted sum of present and past input samples only), the digital filter is referred to as a nonrecursive (having no feedback) or finite impulse response (FIR) filter because the response of the filter to an impulse (actually a unit pulse) input is simply the sequence of the "*a*" coefficients. If any value of *b* is nonzero, the filter is recursive (having feedback) and is generally an infinite impulse response (IIR) filter.

If the digital filter under consideration is not a linear, time-invariant filter, the transfer function cannot be used.

Transfer functions. Although the time-domain difference equation is a useful description of a filter, as in the continuous-domain filter case, a powerful alternative form is the transfer function. The information content of the transfer function is the same as that of the difference equation as long as a linear, time-invariant system is under consideration. A difference equation is converted to transfer-function form by use of the *z* transform. The *z* transform is simply the Laplace transform adapted for sampled systems with some shorthand notation introduced. *See* LAPLACE TRANSFORM; Z TRANSFORM.

Adaptive filters. So far only LTI filters have been discussed. An important class of variable-parameter filter change their coefficients to minimize an error criterion. These filters are called adaptive because they adapt their parameters in response to changes in the operating environment. An example is an FIR digital filter whose coefficients are continually adjusted so that the output will track a reference signal with minimum error. The performance criterion will be the minimization of some function of the error. *See* ELECTRIC FILTER. [S.A.Wh.]

Digital-to-analog converter A device for converting information in the form of combinations of discrete (usually binary) states or a signal to information in the form of the value or magnitude of some characteristics of a signal, in relation to a standard or reference. Most often, it is a device which has electrical inputs representing a parallel binary number, and an output in the form of voltage or current.

Digital-to-analog (D/A) converters (sometimes called DACs) are used to present the results of digital computation, storage, or transmission, typically for graphical display or for the control of devices that operate with continuously varying quantities. D/A converter circuits are also used in the design of analog-to-digital converters that employ feedback techniques, such as successive-approximation and counter-comparator types. In such applications, the D/A converter may not necessarily appear as a separately identifiable entity.

The fundamental circuit of most D/A converters involves a voltage or current reference; a resistive "ladder network" that derives weighted currents or voltages, usually as discrete fractions of the reference; and a set of switches, operated by the digital input, that determines which currents or voltages will be summed to constitute the output.

The output of the D/A converter is proportional to the product of the digital input value and the reference. In many applications, the reference is fixed, and the output bears a fixed proportion to the digital input. In other applications, the reference, as well as the digital input, can vary; a D/A converter that is used in these applications is thus called a multiplying D/A converter. It is principally used for imparting a digitally controlled scale factor, or "gain," to an analog input signal applied at the reference terminal. *See* AMPLIFIER; ANALOG COMPUTER.

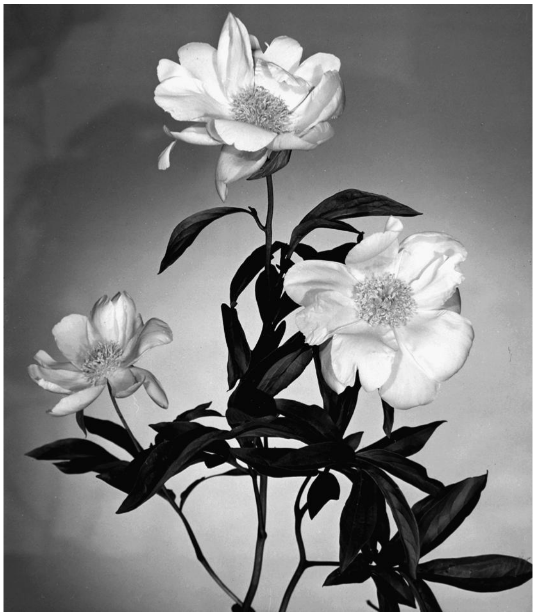
Except for the highest resolutions (beyond 18 bits), commercially available D/A converters are generally manufactured in the form of integrated circuits, using bipolar, MOS, and hybrid technologies. A single chip may include just the resistor network and switches; it may also include a reference circuit, output amplifier, and one or more sets of registers (with control logic suitable for direct microprocessor interfacing). *See* INTEGRATED CIRCUITS. [D.H.S.]

Digitalis A genus of the figwort family (Scrophulariaceae) ranging from the Canary Islands to central Asia. Foxglove (*Digitalis purpurea*), a native of western Europe, is the source of the important drug digitalis, much used in the treatment of heart disorders. The active ingredient, digitalin, slows and regulates the heartbeat, improving the tone and rhythm, and making the contractions more effective. *See* SCROPHULARIALES. [P.D.St./E.L.C.]

Dill An annual culinary herb of the carrot family, Apiaceae (Umbelliferae). It supplies four products: dill seed oil, dill leaf oil, dill seed, and dill leaf. Although all of the dill grown in the United States is one species, *Anethum graveolens,* a slightly different species, *A. sowa,* is grown in Asia. In the United States, two cultivars are grown, Mammoth and Bouquet. Other varieties exist, such as those developed in India and Russia, but are not extensively grown here. Dill can be grown in most soil types in all areas of the United States, but most of the production is centered in Oregon, Washington, Florida, and California.

Most of the production of dill seed oil is for use in the pickle industry for flavoring dill pickles. Dill leaf oil is little used, and relatively little dill is grown for this purpose. Dill seed is used as a spice, and large quantities of it are imported into the United States. India is the primary producer of dill seed for culinary use. *See* APIALES; FAT AND OIL (FOOD). [S.Kir.]

Dilleniales An order of flowering plants, division Magnoliophyta (Angiospermae), subclass Dilleniidae, class Magnoliopsida (dicotyledons). It consists of two families: the Dilleniaceae, with about 350 species; and the Paeoniaceae, with a single genus of some 30 species. Within its subclass the order is marked by separate carpels; numerous stamens; bitegmic (having two integuments), crassinucellate (having a nucellus that is more than one cell thick) ovules; and seeds that have a well-developed endosperm and are provided with an aril (a partial or complete covering or appendage, usually derived from the funiculus of the ovule). The garden peony (*Paeonia lactiflora*) is a familiar member of the order (see illustration). *See* DILLENIIDAE; MAGNOLIOPHYTA. [A.Cr.; T.M.Ba.]



The garden peony (*Paeonia lactiflora*), of the family Paeoniaceae. (*F. E. Westlake, National Audubon Society*)

Dilleniidae A large subclass of the class Magnoliopsida (dicotyledons) of the division Magnoliophyta (Angiospermae), the flowering plants, consisting of 13 orders, 78 families, and nearly 25,000 species. The subclass is morphologically ill-defined, but most of the orders and species have the carpels united to form a compound pistil. The petals are either separate or joined into a sympetalous corolla. The stamens, when numerous, are initiated in centrifugal sequence. Many of the species have numerous ovules on parietal placentas; that is, the placentas are borne along the walls of an ovary which is usually with a single chamber.

The largest orders included in the subclass are the Violales, Capparales, Malvales, Theales, and Ericales. Other orders include the Dilleniales, Lecythidales, Nepenthales, Salicales, Diapensiales, Ebenales, Primulales, and Batales. See separate articles on each order. *See* MAGNOLIOPHYTA. [A.Cr.; T.M.Ba.]

Dimensional analysis A technique that involves the study of dimensions of physical quantities. Dimensional analysis is used primarily as a tool for obtaining information about physical systems too complicated for full mathematical solutions to be feasible. It enables one to predict the behavior of large systems from a study of small-scale models. It affords a convenient means of checking mathematical equations. Finally, dimensional formulas provide a useful cataloging system for physical quantities.

All the commonly used systems of units in physical science have the property that the number representing the magnitude of any quantity (other than purely numerical ratios) varies inversely with the size of the unit chosen. Thus, if the length of a given piece of land is 300 ft, its length in yards is 100. The ratio of the magnitude of 1 yd to the magnitude of 1 ft is the same as that of any length in feet to the same length in yards, that is, 3. The ratio of two different lengths measured in yards is the same as the ratio of the same two lengths measured in feet, inches, miles, or any other length units. This universal property of unit systems, often known as the absolute significance of relative magnitude, determines the structure of all dimensional formulas. *See* Units of measurement.

In defining a system of units for a branch of science such as mechanics or electricity, certain quantities are chosen as fundamental and others as secondary, or derived. The choice of the fundamental units is always arbitrary and is usually made on the basis of convenience in maintaining standards. In mechanics the fundamental units most often chosen are mass, length, and time.

It can be proved that every secondary quantity which satisfies the condition of the absolute significance of relative magnitude is expressible as a product of powers of the primary quantities. Such an expression is known as the dimensional formula of the secondary quantity. There is no requirement that the exponents be integral.

The technique of dimensional analysis has several important applications. It is intuitively obvious that only terms whose dimensions are the same can be equated. The equation 10 kg = 10 m/s, for example, makes no sense. A necessary condition for the correctness of any equation is that the two sides have the same dimensions. This is often a help in the verification of complicated analytic expressions. Of course, an equation can be correct dimensionally and still be wrong by a purely numerical factor.

The application of dimensional analysis to the derivation of unknown relations depends upon the concept of completeness of equations. An expression which remains formally true no matter how the sizes of the fundamental units are changed is said to be complete. Assume a group of n physical quantities $x_1, x_2, \ldots, x_n$, for which there exists one and only one complete mathematical expression connecting them, namely, $\phi(x_1, x_2, \ldots, x_n) = 0$. Some of the quantities $x_1, x_2, \ldots, x_n$ may be dimensional constants. Assume further that the dimensional formulas of the n quantities are expressed in terms of m fundamental quantities $\alpha, \beta, \gamma, \ldots$. Then it will always be found that this single relation ϕ can be expressed in terms of some arbitrary function F of $n - m$ independent dimensionless products $\pi_1, \pi_2, \ldots, \pi_{n-m}$, made up from among the n variables, as in the equation below.

$$F(\pi_1, \pi_2, \ldots, \pi_{n-m}) = 0$$

This is known as the π theorem. It was first rigorously proved by E. Buckingham. The main usefulness of the π theorem is in the deduction of the form of unknown relations. The procedure is particularly useful in hydraulics and aeronautical engineering, where detailed solutions are often extremely complicated.

A further application of dimensional analysis is in model design. Often the behavior of large complex systems can be deduced from studies of small-scale models at a great saving in cost. In the model each parameter is reduced in the same proportion relative to its value in the original system. *See* Model theory.

Dimensional formulas also provide a convenient shorthand notation for representing the definitions of secondary quantities and are helpful in changing units from one system to another. [J.W.St.]

Dimensionless groups A dimensionless group is any combination of dimensional or dimensionless quantities possessing zero overall dimensions. Dimensionless groups are frequently encountered in engineering studies of complicated processes or as similarity criteria in model studies. A typical dimensionless group is the Reynolds number (a dynamic similarity criterion), $N_{Re} = VD\rho/\mu$. Since the dimensions of the quantities involved are velocity V: $[L/\theta]$; characteristic dimension D: $[L]$; density ρ: $[M/L^3]$; and viscosity μ: $[M/L\theta]$ (with M, L, and θ as the fundamental units of mass, length, and time), the Reynolds number reduces to a dimensionless group and can be represented by a pure number in any coherent system of units. *See* Dynamic similarity.

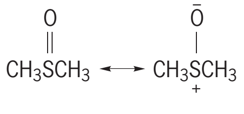
Many important problems in applied science and engineering are too complicated to permit completely theoretical solutions to be found. However, the number of interrelated variables involved can be reduced by carrying out a dimensional analysis to group the variables as dimensionless groups. *See* Dimensional analysis.

The advantages of using dimensionless groups in studying complicated phenomena include:

1. A significant reduction in the number of "variables" to be investigated; that is, each dimensionless group, containing several physical variables, may be treated as a single compound "variable," thereby reducing the number of experiments needed as well as the time required to correlate and interpret the experimental data.
2. Predicting the effect of changing one of the individual variables in a process (which it may be impossible to vary much in available equipment) by determining the effect of varying the dimensionless group containing this parameter (this must be done with some caution, however).
3. Making the results independent of the scale of the system and of the system of units being used.
4. Simplifying the scaling-up or scaling-down of results obtained with models of systems by generalizing the conditions which must exist for similarity between a system and its model.
5. Deducing variation in importance of mechanisms in a process from the numerical values of the dimensionless groups involved; for instance, an increase in the Reynolds number in a flow process indicates that molecular (viscous) transfer mechanisms will be less important relative to transfer by bulk flow ("inertia" effects), since the Reynolds number is known to represent a measure of the ratio of inertia forces to viscous forces. *See* Froude number; Knudsen number; Mach number; Reynolds number. [J.Ca.; G.D.F.]

Dimensions (mechanics) Length, mass, time, or combinations of these quantities serving as an indication of the nature of a physical quantity. Quantities with the same dimensions can be expressed in the same units. For example, although speed can be expressed in various units such as miles/hour, feet/second, and meters/second, all these speed units involve the ratio of a length unit to a time unit; hence, the dimensions of speed are the ratio of length L to time T, usually stated as LT^{-1}. The dimensions of all mechanical quantities can be expressed in terms of L, T, and mass M. The validity of algebraic equations involving physical quantities can be tested by a process called dimensional analysis; the terms on the two sides of any valid equation must have the same dimensions. *See* Dimensional analysis; Units of measurement. [D.Wi.]

Dimethyl sulfoxide A versatile solvent (formula C_2H_6OS) abbreviated DMSO, used industrially and in chemical laboratories as a medium for carrying out chemical reactions. Its uses have been extended to that of a chemical reagent where DMSO itself is involved in a chemical change. It is the simplest member of a class of organic compounds which are typified by the polar sulfur-oxygen bond represented in the resonance hybrid shown below. The molecule is pyramidal in shape with the oxygen and the carbons at the corners.



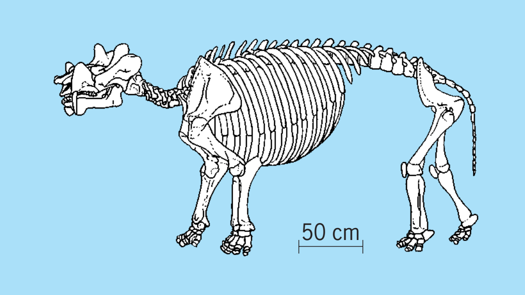
$$CH_3\overset{\overset{O}{\|}}{S}CH_3 \longleftrightarrow CH_3\underset{+}{\overset{\overset{\bar{O}}{|}}{S}}CH_3$$

DMSO is a colorless, odorless (when pure), and very hygroscopic stable liquid (bp 189°C, mp 19.5°C). It is manufactured commercially by reacting the black liquor from digestion in the kraft pulp process, with molten sulfur to form dimethyl sulfide which is then oxidized with nitrogen tetroxide. This highly polar aprotic solvent is water- and alcohol-miscible and will dissolve most polar organic compounds and many inorganic salts.

As an aprotic solvent, DMSO strongly solvates cations, leaving a highly reactive anion. Thus in DMSO, basicity and nucleophilicity is enhanced, and it is a superior solvent for many elimination, nucleophilic substitution, and solvolysis reactions in which nucleophile and base strength are important. Nucleophilic substitution reactions in which halogens or sulfonate esters are displaced by anions such as cyanide, alkoxide, thiocyanate, azide, and others are accelerated 1000 to 10,000 times in DMSO over the reaction in aqueous alcohol. Dimethyl sulfoxide is also superior to protic solvents as a media for elimination reactions. Its high dielectric constant makes DMSO a useful solvent for dissolving resins, polymers, and carbohydrates. It is employed commercially as a spinning solvent in the manufacture of synthetic fibers.

The apparent low toxicity and high skin permeability have led to extensive studies in numerous biological systems, including humans. Inorganic salts or small-molecular-weight organic compounds dissolved in DMSO can be transported across skin membrane, indicating a potential hazard in commercial use. [W.W.E./F.W.Sw.]

Dinocerata An extinct order of large herbivorous mammals, often called uintatheres, from early Cenozoic deposits of North America and northern Asia. Members of this group have semigraviportal limbs, that is, adapted to bearing considerable weights, with hoofed, five-toed feet (see illustration). A saber-like canine tooth and protective lower jaw flange are present in all forms except the aberrant *Gobiatherium*. Horns are absent or very small on the most primitive forms. Middle and late Eocene uintatheres in North America developed an imposing array of six horns. One pair was on the tips of the nasal bones, another was above the root of the saberlike canine tooth, and a third pair above the ear region.



Skeleton of *Uintatherium*, a middle Eocene member of the Dinocerata.

The order Dinocerata consists of one family, the Uintatheriidae, which is divided into three subfamilies: Prodinoceratinae, Uintatheriinae, and Gobiatheriinae. The Dinocerata left no descendants. They are believed to have arisen from the arctocyonid condylarths but from a different subfamily than that which gave rise to the order Pantodonta. *See* MAMMALIA; PANTODONTA. [M.C.McK.]

Dinoflagellida An order of the class Phytamastigophorea; also known as the Dinoflagellata. Although primarily marine, some dinoflagellates occur in fresh water. Some possess brown chromatophores, some are variously colored, and others are colorless. All types of nutrition exist, and some species are parasitic. Two flagella emerge laterally from a longitudinal depression or sulcus. An encircling flagellum in a groove or girdle divides the body into epicone and hypocone; the other, extending backward, propels the organism forward. The nucleus is very large.

Ceratium hirundinella blooms in fresh water, causing tastes and odors. Marine blooms of *Gymnodinium breve* produce the fish-killing red tides along the Gulf Coast of the southern United States. *See* PHYTAMASTIGOPHOREA. [J.B.L.]

Dinophyceae A large and extremely diverse class of biflagellate algae (dinoflagellates) in the chlorophyll *a–c* phyletic line (Chromophycota). In protozoological classification, these organisms constitute an order, Dinoflagellida, of the class Phytomastigophora. Many taxonomists emphasize the distinctness of dinoflagellates by placing them in a separate division (Pyrrophyta or Pyrrhophyta) or even in a separate kingdom (Mesokaryota). More than 1200 species are known, classified into 18 orders and 54 families. Most are microscopic, but a few reach a diameter of 2 mm (0.08 in.). Cell shape is highly variable, with many planktonic species having elaborately modified surfaces. Dinoflagellates occur in marine, brackish, and fresh waters, frequently producing algal blooms. They may be benthic as well as planktonic, and a few are colonial. Ameboid, palmelloid, coccoid (with or without a gelatinous sheath), and filamentous forms are also known. *See* DINOFLAGELLIDA.

Dinoflagellates span the spectrum of nutritional diversity. About half of the species are photosynthetic, and some of these are facultatively osmotrophic (absorbing nutrients) or phagotrophic (engulfing food). Symbiosis involving dinoflagellates is a common occurrence in marine environments. The phenomenon is most important in coral reefs, where up to half of the carbonate in calcified structures is derived by way of photosynthesis carried out by endosymbiotic dinoflagellates.

Several dinoflagellates contain substances that are toxic to other organisms. Blooms of some of these dinoflagellates cause "red tides" that are lethal to fishes or invertebrates. *See* ALGAE. [P.C.Si.; R.L.Moe]

Dinosaur The term Dinosauria (Greek, "terrible lizards") was coined by the British comparative anatomist Richard Owen in 1842 to represent three partly known, impressively large fossil reptiles from the English countryside: the carnivore *Megalosaurus*, the duckbilled *Iguanodon*, and the armored *Hylaeosaurus*.

As dinosaurs became better known, their taxonomy and classification developed, as well as their diversity. In 1888 H. G. Seeley recognized two quite different hip structures in dinosaurs and grouped them accordingly. Saurischia, including the carnivorous Theropoda and the giant, long-necked Sauropoda, retained the generalized reptilian hip structure in which the pubis points down and forward and the ischium points down and backward. The remaining dinosaurs have a pubis that also points down and backward, and lies parallel to the ischium; this reminded Seeley of the configuration in birds, and so he named this group Ornithischia. However, the ornithischian pubis is only superficially similar to that of birds, which are descended from, and are thus formally grouped in, Saurischia. Seeley's discovery, in fact, only recognized the distinctness of Ornithischia, but he concluded that Saurischia and Ornithischia were not particularly closely related. Even within Saurischia, there were general doubts that Sauropoda and Theropoda had any close relationship. In 1974 it was argued that there were a great many unique features, including warm-bloodedness, that diagnosed the dinosaurs as a natural group, including their descendants the birds. A 1986 analysis listed nine uniquely derived features of the skull, shoulder, hand, hip, and hindlimb that unite Dinosauria as a natural group; this analysis has been since modified and improved, and today Dinosauria is universally accepted as a natural group, divided into Ornithischia and Saurischia. *See* ORNITHISCHIA; SAURISCHIA.

Dinosaurs are archosaurs, a group that includes crocodiles, birds, and all the descendants of their most recent common ancestor. The closest relatives of dinosaurs, which evolved with them in the Middle and Late Triassic (about 225 million years ago), include the flying pterosaurs and agile, rabbit-sized forms such as *Lagosuchus* and *Lagerpeton*. The common ancestor of all these forms was small, lightly built, bipedal, and probably an active carnivore or omnivore. Somewhat larger, with skulls ranging 15–30 cm (6–12 in.) in length, were *Eoraptor* and *Herrerasaurus* from the Late Triassic of Argentina, and *Staurikosaurus* from the early Late Triassic of Brazil. They were thought to be primitive saurischian dinosaurs, but it was later determined that they were outside the group formed by Saurischia plus Ornithischia, a view generally followed. In reconsidering these genera plus the more recently discovered *Eoraptor*, it has been argued that all three are both saurischians and theropods. However, they lack some features of both groups, so their position remains controversial. This testifies to a burst of evolutionary change at this very interesting time in vertebrate history, and it shows that there are a variety of taxa that are very close to the origin of dinosaurs. The first definite ornithischians and saurischians appear at almost the same time as these taxa, though dinosaurs remained generally rare and not very diverse components of terrestrial faunas until the beginning of the Jurassic Period (about 200 million years ago). *See* Jurassic; Triassic.

An area of great interest is how the dinosaurs and their closest relatives differ from their contemporaries. Their posture and gait hold some important clues. Like pterosaurs, *Lagosuchus, Lagerpeton*, and their other close relatives, the first dinosaurs stood upright on their back legs. The head of the thigh bone angled sharply inward to the hip socket, which was slightly perforated. The femur moved like a bird's, in a nearly horizontal plane; the shin bone (tibia) swung back and forth in a wide arc, and the fibula (the normally straplike bone alongside the tibia) was reduced because the lower leg did not rotate about the knee, like a crocodile's or lizard's does. The ankle, too, had limited mobility: it formed a hinge joint connecting the leg to long metatarsals (sole bones), which were raised off the ground. All these features can be seen today in birds, the living descendants of Mesozoic dinosaurs. Because the first dinosaurs were bipedal, their hands were free for grasping prey and other items, and the long fingers bore sharp, curved claws. The neck was long and S-shaped, the eyes large, and the bones lightly built and relatively thin-walled. And all dinosaurs, even the Jurassic giants, walked on their toes.

Ornithischia. Ornithischians (Fig. 1) are a well-defined group diagnosed by several unique evolutionary features; the entire group was analyzed cladistically in 1986, and a phylogeny was described that has been the basis of all later work. Ornithischians have a predentary bone, a toothless, beaklike addition to the front of the lower jaw that, like the front of the upper jaw, probably had a horny covering in life. This appears to have been an adaptation for plant eating. Even the earliest ornithischians lacked at least a pair of their front teeth, and some later members lost all of them. The jaw joint was set below the occlusal plane, nutcrackerlike, an arrangement interpreted as serving for increased leverage and for crushing plant material. The teeth were set in from the side of the jaw, suggesting the presence of fleshy cheeks to help sustain chewing. The cheek teeth were broad, closely set, and leaf-shaped, and were often ground down to a shearing surface. In the hip, the pubis pointed backward. In all but the most generalized ornithischians, a new prong on the pubis was developed from the hip socket, upward, forward, and outward. This may have provided a framework to support the guts or to anchor the hindlimb muscles.

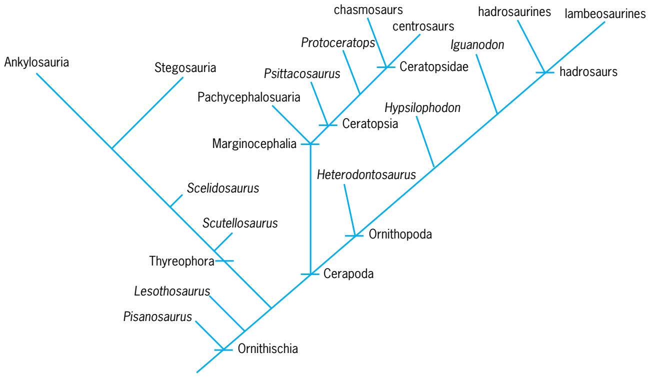


Fig. 1. Relationships of the ornithischian dinosaurs. (*After P. C. Sereno, Phylogeny of the bird-hipped dinosaurs (Order Ornithischia), Nat. Georg. Soc. Res., 2:234–256, 1986*)

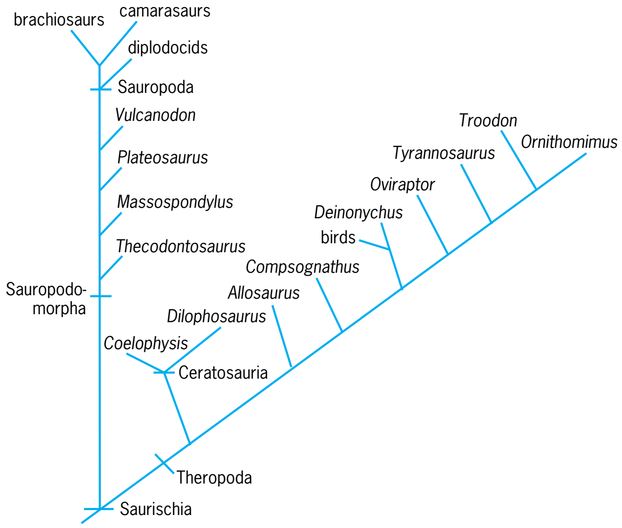

Fig. 2. Relationships of the saurischian dinosaurs. (*After J. A. Gauthier, Saurischian monophyly and a new class of vertebrates, Mem. Calif. Acad. Sci., 8:1–55, 1986; and T. R. Holtz, Jr., The phylogenetic position of the Tyrannojaundae, J. Paleont., 78:1100–1117, 1994*)

The most generalized ornithischians known are the fragmentary *Pisanosaurus* from the Late Triassic of Argentina and the small *Lesothosaurus* from the Early Jurassic of South Africa. In the major ornithischian radiation, Thyreophora branch off first, and Cerapoda are divided into Ornithopoda and Marginocephalia. All known ornithischians are herbivores.

Saurischia. Saurischia (Fig. 2) includes Sauropodomorpha and Theropoda. For many years it was doubted that Saurischia formed a natural group because its two subgroups are so different, but in 1986 Jacques Gauthier demonstrated its validity cladistically. Uniquely derived features of Saurischia include the long neck vertebrae; the long asymmetrical hand in which the second digit is the longest; the slightly offset thumb with its short basal metacarpal, robust form, and large claw; and several other features of the skull and vertebrae. Unlike ornithischians, saurischians are fairly well represented in Late Triassic faunas as well as in the later Mesozoic. *See* Mesozoic.

Paleobiology. Dinosaurs laid eggs, and many nests have been found, but matching nests and eggs to their makers is difficult unless embryos are preserved. It appears that the young stayed around the nest and were fed by the parents until their bones fully calcified and they could fend for themselves. It is not clear how widespread either of these behaviors (or others) was among dinosaurs, but birds (living dinosaurs) are known for their extended parental care, and crocodiles, their closest living relatives, also care for their young, so it may be a general behavior among archosaurs.

If their bones are any indication, dinosaurs grew rapidly. Microscopic studies of their long bones show that the tissue was as well vascularized as in birds and mammals and that it was rapidly replaced. The texture of the bone is predominantly fibrolamellar, as in birds and mammals, and juvenile bone also shows a highly woven pattern reflecting rapid growth.

Footprints provide strong evidence that many kinds of dinosaurs traveled in groups, at least occasionally, and this is supported by records of mass burials. Whether traveling in family groups or (at least occasionally) in large herds, all dinosaurs of any appreciable size would have had to migrate to exploit food sources successfully, if only in a local area. Annual migrations may have followed seasonal patterns of weather and vegetation.

A general picture of dinosaurian social behavior—no doubt highly variable among groups—is drawn from inferences about mass remains of trackways and bones, parental care, and the great variety of skeletal features conspicuously related to intraspecific interactions. The diversity of horns, crests, domes, knobs, and frills in many dinosaur groups contrasts starkly with the relative uniformity of their postcranial skeletons. Communicating, recognizing members of the same species, attracting mates, and repelling rivals, as well as delivering similar signals to members of different species, are all behavioral functions of such structures in living animals.

Dinosaurs evolved from within Reptilia, but they are as unlike living reptiles as bats and whales are unlike horses among living mammals (and they may have been just as diverse metabolically). The physiology of extinct animals can be assessed only indirectly. The evolution of thermal strategies in dinosaurs was probably mosaic, depending on the adaptations of individual groups, and should not be considered an all-or-nothing proposition of hot-bloodedness. Many lines of evidence suggest that Mesozoic dinosaurs were similar in behavior and activity to mammals and birds; no evidence seems to ally them physiologically to crocodiles and lizards. But dinosaurs should be taken on their own terms, not shoehorned into models of reptile or mammal physiology based on available living analogs.

For 160 million years during the Mesozoic Era, dinosaurs are represented by some 550 named genera and 800 named species, of which perhaps around 300 are valid, and nearly half of which are based on single (often partial) specimens. Through time, dinosaurian diversity increased, but the difference between preserved diversity and some estimates of projected diversity is traced in part to varying availability of the rock record, plus differential exploration. Known diversity ranged from about five genera in the Norian (Late Triassic) to over 75 in the Maastrichtian (latest Cretaceous). Evolution in dinosaurs was rapid: few dinosaurian genera survive more than the temporal span of a typical geologic formation (a few million years), and close relatives are often observed in succeeding formations. At the beginning of the Age of Dinosaurs, the continents were just beginning to drift apart. Dinosaurs are known from every continent and are often used to establish land connections, such as between North America and Asia in the Late Cretaceous, or the isolation of South America during much of the Cretaceous.

Many causes have been proposed for dinosaur extinction at the end of the Mesozoic Era, but most (for example, reproductive sterility, plant toxin poisoning, cataracts, supernova explosion, glaciation) have no supporting evidence. The apparent sudden decline of dinosaurs is surprising in view of their long dominance. In the last few million years of the Cretaceous, known dinosaur diversity, based mainly on excellent exposures from the United States Western Interior, declined precipitously until, in the meters of sediment just below the Cretaceous-Tertiary boundary, only *Triceratops* and *Tyrannosaurus* survive. An explanation is needed for this drop in diversity. In 1980, it was proposed that a giant asteroid had struck the Earth at the end of the Cretaceous, causing widespread marine and terrestrial extinctions. As valid as the proposal of a giant asteroid impact now appears, some of the proposed biotic effects are clearly overdrawn. Dinosaurs were all but extinct by that time. Apparently the birds survived the impact's effects, and so did most groups of fishes, sharks, amphibians, lizards, snakes, crocodiles, and mammals. Many of these groups are notoriously sensitive to environmental disturbances. Hence any catastrophic scenarios for the terrestrial biota at the end of the Mesozoic must account both for the latest Cretaceous decline in dinosaurian diversity and the survival of any proposed environmental catastrophes by other terrestrial animals and plants. *See* AVES; EXTINCTION (BIOLOGY); REPTILIA. [K.P.]

Diode A two-terminal electron device exhibiting a nonlinear current-voltage characteristic. Although diodes are usually classified with respect to the physical phenomena that give rise to their useful properties, in this article they are more conveniently classified according to the functions of the circuits in which they are used. This classification includes rectifier diodes, negative-resistance diodes, constant-voltage diodes, light-sensitive diodes, light-emitting diodes, and capacitor diodes.

A circuit element is said to rectify if voltage increments of equal magnitude but opposite sign applied to the element produce unequal current increments. An ideal rectifier diode is one that conducts fully in one direction (forward) and not at all in the opposite direction (reverse). This property is approximated in junction and thermionic diodes. Processes that make use of rectifier diodes include power rectification, detection, modulation, and switching. *See* RECTIFIER.

Negative-resistance diodes, which include tunnel and Gunn diodes, are used as the basis of pulse generators, bistable counting and storage circuits, and oscillators. *See* NEGATIVE-RESISTANCE CIRCUITS; OSCILLATOR; TUNNEL DIODE.

Breakdown-diode current increases very rapidly with voltage above the breakdown voltage; that is, the voltage is nearly independent of the current. In series with resistance to limit the current to a nondestructive value, breakdown diodes can therefore be used as a means of obtaining a nearly constant reference voltage or of maintaining a constant potential difference between two circuit points, such as the emitter and the base of a transistor. Breakdown diodes (or reverse-biased ordinary junction diodes) can be used between two circuit points in order to limit alternating-voltage amplitude or to clip voltage peaks. *See* LIMITER CIRCUIT.

Light-sensitive diodes, which include phototubes, photovoltaic cells, photodiodes, and photoconductive cells, are used in the measurement of illumination, in the control of lights or other electrical devices by incident light, and in the conversion of radiant energy into electrical energy. Light-emitting diodes (LEDs) are used in the display of letters, numbers, and other symbols in calculators, watches, clocks, and other electronic units. *See* LIGHT-EMITTING DIODE; PHOTOCONDUCTIVE CELL; PHOTODIODE; PHOTOELECTRIC DEVICES; PHOTOTUBE; PHOTOVOLTAIC EFFECT.

Semiconductor diodes designed to have strongly voltage-dependent shunt capacitance between the terminals are called varactors. The applications of varactors include the tuning and the frequency stabilization of radio-frequency oscillators. *See* JUNCTION DIODE; MICROWAVE SOLID-STATE DEVICES; SEMICONDUCTOR DIODE; VARACTOR. [H.J.R.]

Diopside The monoclinic pyroxene mineral which in pure form has the formula $CaMgSi_2O_6$. Pure diopside melts congruently at 1391°C (2536°F) at atmospheric pressure. Diopside has no known polymorphs. Its structure consist of chains of SiO_4 tetrahedrons in which each silicon ion shares an oxygen with each of its two nearest silicon neighbors. These chains are linked together by Ca and Mg ions in octahedral coordination.

Diopside forms gray to white, short, stubby, prismatic, often equidimensional, crystals. Small amounts of iron impart a greenish color to the mineral. Pure diopside is common and occurs as a metamorphic alteration of impure dolomites in medium and high grades of metamorphism.

Natural diopsidic pyroxenes which show extensive solid solution with jadeite and to a lesser extent with acmite are called omphacite. Omphacite is a principal constituent of eclogites, rocks of basaltic composition which have formed at high pressure. *See* DOLOMITE; ECLOGITE; PYROXENE. [F.R.B.]

Diopter A measure of the power of a lens or a prism. The diopter (also called dioptrie) is usually abbreviated D. Its dimension is a reciprocal length, and its unit is the reciprocal of 1 m (3.28 ft). *See* FOCAL LENGTH; LENS (OPTICS).

The dioptric power of a prism is defined as the measure of the deviation of a ray going through a prism measured at the distance of 1 m. A prism that deviates a ray by 1 cm in a distance of 1 m is said to have a power of one prism diopter. *See* OPTICAL PRISM.

Spectacle lenses in general consist of thin lenses, which are either spherical, to correct the focus of the eye for near and far distances, or cylindrical or toric, to correct the astigmatism of the eye. An added prism corrects a deviation of the visual axis. The diopter thus gives a simple method for prescribing the necessary spectacle for the human eye. [M.J.H.]

Diorite A phaneritic (visibly crystallized) plutonic rock having intermediate SiO_2 content (53–66%), composed mainly of plagioclase (oligoclase or andesine) and one or more ferromagnesian minerals (hornblende, biotite, or pyroxene), and having a granular texture. Diorite is the plutonic equivalent of andesite (a volcanic rock). This dark gray rock is used occasionally as a building stone and is known commercially as black granite. *See* IGNEOUS ROCKS.

Gray or white plagioclase feldspar is the dominant mineral. Rocks with more calcic plagioclases and more abundant ferromagnesian minerals are gabbros. Rocks with greater proportions of alkali feldspar are called monzonite. Those with more quartz are called quartz-diorite or tonalite.

The texture of diorites is notably variable. Most often diorites are equigranular, with coarse, partly or mostly anhedral plagioclase and hornblende crystals, subordinate biotite, and interstitial quartz and orthoclase.

Diorite is found as isolated small bodies such as dikes, sills, and stocks, but it is also found in association with other plutonic rocks in batholithic bodies. It is closely associated with convergent plate boundaries where calc-alkalic magmatism and mountain building are taking place. *See* MAGMA. [W.I.R.]

Dioscoreales A widespread order of lilioid monocotyledons composed of four or five families, the most important of which is Dioscoreaceae (650 species). These families contain some of the most peculiar plants among the monocots. Two families, Thismiaceae and Burmanniaceae (with 35 and 140 species, respectively), are largely composed of nonphotosynthetic herbaceous species that parasitize fungi, whereas other members, such as the bat plant (*Tacca*, Taccaceae) and the yams (*Dioscorea*) have net-veined leaves similar to dicots. Most of the 600 species of *Dioscorea* are vines, and all contain diosgenin, a precursor of progesterone and cortisone, leading to their being commercially collected in some parts of the world. *See* MAGNOLIOPHYTA. [M.W.C.]

Diphtheria An acute infectious disease of humans caused by *Corynebacterium diphtheriae*. Classically, the disease is characterized by low-grade fever, sore throat, and a pseudomembrane covering the tonsils and pharynx. Complications such as inflammation of the heart, paralysis, and even death may occur due to exotoxins elaborated by toxigenic strains of the bacteria. The upper respiratory tract is the most common portal of entry for *C. diphtheriae*. It can also invade the skin and, more rarely, the genitalia, eye, or middle ear. The disease has an insidious onset after a usual incubation period of 2–5 days.

The only specific therapy is diphtheria antitoxin, administered in doses proportional to the severity of the disease. Antitoxin is produced by hyperimmunizing horses with diphtheria toxoid and toxin. It is effective only if administered prior to the binding of circulating toxin to target cells. Antibiotics do not alter the course, the incidence of complications, or the outcome of diphtheria, but are used to eliminate the organism from the patient.

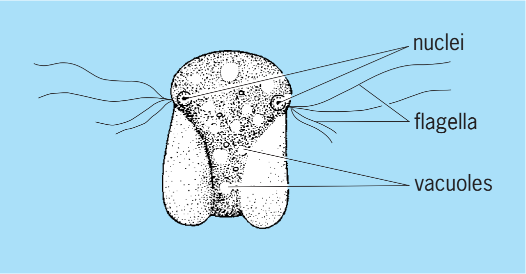
Persons with protective antitoxin titers may become infected with diphtheria but do not develop severe disease. Since the 1920s, active immunization with diphtheria toxoid has proved safe and effective in preventing diphtheria in many countries. Diphtheria toxoid is produced by incubating the toxin with formalin. Active immunization requires a primary series of four doses, usually at 2, 4, 6, and 18 months of age, followed by a booster at school entry. *See* IMMUNITY; MEDICAL BACTERIOLOGY; TOXIN; VACCINATION. [R.Ch.; C.V.]

Diphyllidea An order of tapeworms of the subclass Cestoda. Species of this order belong to a single genus and live in the intestine of elasmobranch fishes. The scolex has a large muscular rostellum armed with hooks and two fused pairs of suckers; the neck is armed with T-shaped hooks. Larval stages have been found parasitizing marine mollusks and crustaceans, but the life history is not known. *See* CESTODA. [C.P.R.]

Diplogasterida An order of nematodes in which the labia are seldom well developed; however, a hexaradiate symmetry is distinct. The external circle of labial sensilla may appear setose, but they are always short, never long or hair-like. The stoma may be slender and elongate, or spacious, or any gradation between. The stoma may be armed or unarmed; the armature may be movable teeth, fossores, or a pseudostylet. The corpus is always muscled and distinct from the postcorpus, which is divisible into an isthmus and glandular posterior bulb. The metacorpus is almost always valved. The female reproductive system may have one or two ovaries, and males may or may not have caudal alae; however, a gubernaculum is always present. The male tail commonly has nine pairs of caudal papillae; three are preanal and six are caudal.

There are two superfamilies: The members of Diplogasteroidea are predators, bacterial feeders, and omnivores; they are often found in association with insects or the fecal matter of herbivores. Cylindrocorporoidea include both free-living forms and intestinal parasites of amphibians, reptiles, and certain mammals. *See* NEMATA. [A.R.M.]

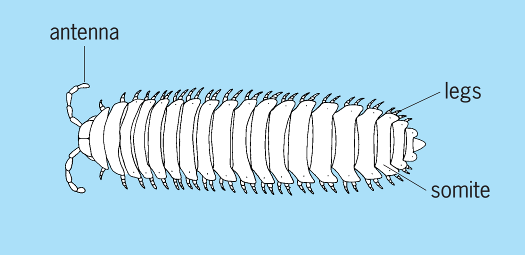
Diplomonadida An order of the class Zoomastigophorea, phylum Protozoa. These are small, colorless flagellates, some of which are free-living, some parasitic. The body is bilaterally symmetrical, composed of two mirror halves, each with a nucleus and a full set of kinetic organelles. There are four flagella to a side, not all of the same length.



A diplomonad, *Trepomonas rotans*. (*After McCracken*)

Trepomonas rotans is probably the most common of the free-living species (see illustration), and usually occurs in water of high organic, low (or no) oxygen content, such as sewage. It occurs in ocean water also. This genus also is found as a parasite or symbiont in other animals, such as amphibians. *Hexamita* is another genus containing both free-living and parasitic representatives; *Spironucleus* is parasitic; and *Giardia* has several species which parasitize vertebrates. In humans giardiasis results in severe dysentery; however, adequate medication is available. *See* ZOOMASTIGOPHOREA. [J.B.L.]

Diplopoda A class of terrestrial, tracheate, oviparous arthropods. Diplopods (millipeds) are largely cryptic in habits, are saprophytic feeders, and are characterized by the development of a compact head with a pair of short, simple, eight-jointed antennae, and powerful mandibles. The body is not differentiated into thorax and abdomen, but is composed of a variable number of similar, cylindrical diplosomites, each of which (except the first two or three) bears two pairs of walking legs (see illustration). The body wall is chitinous, with a thick impregnation of calcium carbonate in the majority of species. Most millipeds are variously adapted for rolling into a closed spiral or nearly perfect sphere when threatened.



A diplopod. (*After R. E. Snodgrass, A Texbook of Arthropod Anatomy, Cornell University Press, 1952*)

The sexes are separate and fertilization is internal, following prolonged clasping behavior. Eggs may be laid in a cluster and "brooded" by the mother, scattered singly in the humus environment, or enclosed in an igloo-shaped mud nest built by the mother. Postembryonic development is gradual, without major changes in appearance, and may require a year or more for completion.

More than 8000 species have been described, although so far only the fauna of Europe is well known. In general, about 11 orders and more than 111 families are recognized. Probably as many as 25,000 species will eventually be recognized. Classification is based to a large extent upon shape of the male gonopods, which are quite constant and characteristic for each species.

Most species are local in distribution, because millipeds generally remain close to the parental habitat, and some may be restricted to a few square miles. Even genera are limited in distribution, and only a few occur on more than one continent.

The diplopods have a long geological history; they arose in the Early Devonian and were well developed by the Late Pennsylvanian. *See* ARTHROPODA. [R.L.Ho.]

Diplura An order of ancestrally wingless Hexapoda comprising about 800 species and variously considered as apterygotan insects or as their independent sister group. These insects are equipped with three pairs of thoracic legs and a pair of antennae on the head. They are slender and white, but unlike typical insects they have intrinsic muscles in the antennal segments beyond the basal one. All diplurans lack eyes, and have paired mandibles and maxillae largely enclosed by fused folds of the head so that only the tips are exposed for retrieving food. The dipluran body size is usually small, under 0.4 in. (1 cm) long, but some Australian *Heterojapyx* species reach 2 in. (5 cm).

Their habitat is normally cryptic in soil, under stones, and in rotten wood, where Campodeidae feed on vegetable matter, while other families apparently are predaceous. Campodeidae are found worldwide and are common in temperate and tropical regions, while the other eight families are mainly restricted to warmer climates and are often discontinuous or local in distribution. *See* APTERYGOTA. [W.L.Bro.]

Dipnoi The lungfishes, one of the three subclasses of Osteichthyes. In comparison with Devonian lungfishes, extant species have reduced the number of median fins, changed the shape of the tail, and decreased ossification of the braincase and other endochondral bones.

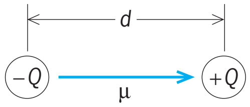
The recent family Lepidosirenidae includes five species from Africa and South America. Lepidosirenids have eellike bodies, filamentous paired fins, two lungs, tooth plates with three cutting blades, a greatly reduced skull roof, and an elongated ceratohyal important in suction feeding and respiration. Lepidosirenids are obligate air breathers, and the heart, arterial tree, and gills are highly specialized. To breathe air, the fish protrudes its snout from the water surface, gulps air into the mouth, and then forces it into the lung by closing the mouth and raising the floor of the oral cavity.

The family Ceratodontidae is represented by the single species *Neoceratodus forsteri* from Australia. They are stout-bodied with large scales, leaf-shaped paired fins, and tooth plates with flattened crushing surfaces. Adults reach more than 3 ft (1 m) in length. The diet includes plants, crustaceans, and soft-bodied invertebrates. [W.Be.]

Early dipnoans were marine; fresh-water adaptations occur in Paleozoic and most post-Paleozoic dipnoans. Burrowing habits developed independently in late Paleozoic gnathorhizids and extant lepidosirenids. Dipnoans were common worldwide from the Early Devonian to the end of the Triassic, but are rare since. They are restricted to the southern continents in the Cenozoic. *See* OSTEICHTHYES. [H.P.S.]

Dipole Any object or system that is oppositely charged at two points or poles, such as a magnet, a polar molecule, or an antenna element. The properties of a dipole are determined by its dipole moment, that is, the product of one of the charges by their separation directed along an axis through the centers of charge. *See* DIPOLE MOMENT.

An electric dipole consists of two electric charges of equal magnitude but opposite polarity, separated by a short distance (see illustration); or more generally, a localized distribution of positive and negative electricity without net charge whose mean positions of positive and negative charge do not coincide.



Electric dipole with moment $\mu = Qd$.

Molecular dipoles which exist in the absence of an applied field are called permanent dipoles, while those produced by the action of a field are called induced dipoles. *See* POLAR MOLECULE.

The term magnetic dipole originally referred to the fact that a magnet has two poles and, because of these two poles, experiences a torque in a magnetic field if its axis is not along a magnetic flux line of the field. It is now generalized to include electric circuits which, because of the current, also experience torques in magnetic fields. *See* MAGNET.

An electric dipole whose moment oscillates sinusoidally radiates electromagnetic waves and is known as a hertzian dipole; it is of interest in developing the theory of electromagnetic radiation. For practical purposes, a half-wave dipole, consisting of two collinear conducting rods, fed at the center, whose combined length equals half the wavelength of the radiation to be transmitted or received, is often used as an antenna element, either by itself or in an array, or as a feed for a reflector. *See* ANTENNA (ELECTROMAGNETISM); ELECTROMAGNETIC RADIATION; ELECTROMAGNETIC WAVE TRANSMISSION. [A.E.Ba.]

Dipole-dipole interaction The interaction of two atoms, molecules, or nuclei by means of their electric or magnetic dipole moments. This is the first term of the multipole-multipole series of invariants. More precisely, the interaction occurs when one dipole is placed in the field of another dipole. The interaction energy depends on the strength and relative orientation of the two dipoles, as well as on the distance between the centers and the orientation of the radius vector connecting the centers with respect to the dipole vectors. The electric dipole-dipole interaction and magnetic dipole-dipole interaction must be distinguished.

The center of the negative charge distribution of a molecule may fail to coincide with its center of gravity, thus creating a dipole moment. An example is the water molecule. If such molecules are close together, there will be a (electric) dipole-dipole interaction between them. Atoms do not have permanent dipole moments, but a dipole moment may be induced by the presence of another atom nearby; this is called the induced dipole-dipole interaction. Induced dipole-dipole forces between atoms and molecules are known by many different names: van der Waals forces, London forces, or dispersion forces. These induced dipole-dipole forces are responsible for cohesion and surface tension in liquids. They also act between unlike molecules, resulting in the adsorption of atoms on macroscopic objects. *See* ADSORPTION; COHESION (PHYSICS); INTERMOLECULAR FORCES; SURFACE TENSION; VAN DER.

The magnetic dipole-dipole interaction is found both on a macroscopic and on a microscopic scale. Two compass needles within reasonable proximity of each other illustrate clearly the influence of the dipole-dipole interaction. In quantum mechanics, the magnetic moment is partially due to a current arising from the motion of the electrons in their orbits, and partially due to the intrinsic moment of the spin. The same interaction exists between nuclear spins. Magnetic dipole-dipole forces are particularly important in low-temperature solid-state physics, the interaction between the spins of the ions in paramagnetic salts being a crucial element in the use of such salts as thermometers and as cooling substances. *See* ADIABATIC DEMAGNETIZATION; DIPOLE; ELECTRON; LOW-TEMPERATURE THERMOMETRY; MAGNET; MAGNETIC THERMOMETER; NUCLEAR MOMENTS. [P.H.E.M.]

Dipole moment A mathematical quantity characteristic of a dipole unit equal to the product of one of its charges times the vector distance separating the charges. The dipole moment μ associated with a distribution of electric charges q_i is given by

$$\mu = \sum_i q_i \mathbf{r}_i$$

where $\mathbf{r}_i$ is the vector to the charge q_i. For systems with a net charge (for example, positive), the origin is taken at the mean position of the positive charges (and vice versa). Dipole moments have the dimensions coulomb-meters. Molecular dipole moments were previously expressed in debye units, where 1 debye = 3.336×10^{-30} C · m. *See* DIPOLE. [R.D.W.]

Dipsacales An order of flowering plants (angiosperms) in the asterid I group of the eudicotyledons consisting of around 6 families and almost 1000 species. Like many asterids of the asterid II group, Dipsacales have an inferior ovary and opposite leaves. They also have fewer stamens than petals (or petal lobes), and the flowers are often bilaterally symmetric or of irregular symmetry. Family limits have changed recently as a result of deoxyribonucleic acid (DNA) sequence studies, but the species content of the order is still similar to previous systems of classification. The flowers are typically arranged in heads, similar to those of their close relatives in Asterales and Apiales, but the ovary often contains more than one seed (reduced to a single seed in Dipsacaceae and Valerianaceae). Familiar members of Dipsacales include elderberry (*Sambucus*, Adoxaceae), honeysuckle (*Lonicera*, Caprifoliaceae), and teasel (*Dipsacus*, Dipsacaceae). *Viburnum* (Adoxaceae) and *Abelia* (Linnaeaceae) are commonly planted ornamental shrubs. *See* ASTERALES; MAGNOLIOPHYTA; PLANT KINGDOM. [M.W.C.]

Diptera An order of the class Insecta known as the true flies and so named because they possess only two wings. This characteristic, together with a pair of balancers or halteres, distinguishes flies from all other orders of the Insecta. The three names for members of the order, known commonly as flies, gnats, or midges, form a part of the common names of most families, genera, and species of the order. The term fly also forms a part of the compound names of the insects in many other orders, such as butterfly, mayfly, and chalcid fly, but when used alone it is correctly applied only to the members of the Diptera. The forms most commonly known as maggots are actually dipterous larvae, and keds (Hippoboscidae) are parasitic forms of flies that have lost their wings. The Diptera are the most important group of insects considered in medical entomology. Many, especially the mosquitoes, are the vectors for numerous parasites and diseases.

In number of species, it is the third largest order; only the Coleoptera and Lepidoptera are larger. There are approximately 100,000 kinds of flies in the world, of which over 18,500 inhabit America north of Mexico.

The order is ubiquitous and is more widespread than any other of the insects. Diptera are found on every continent and most islands of the world, except for the coldest parts of the Arctic and Antarctic, and at the tops of extremely high mountain ranges. They occur in almost all available ecological niches. Specimens have been taken at altitudes of many thousands of feet by specially constructed traps attached to airplanes.

Taxonomy. For convenience, the families of Diptera may be divided into the Nematocera and the Brachycera, and the latter group further divided into the Orthorrhapha and the Cyclorrhapha. Adults of the Nematocera are characterized by their slow flight and long antennae. These are the more primitive Diptera, and the major groups are represented in fossil deposits as old as Jurassic and Cretaceous age.

The Brachycera are generally swift fliers, and their antennae are no longer than the head. In the Orthorrhapha, the adult fly emerges from the pupa through a T-shaped anterior opening, while in the Cyclorrhapha it emerges from a circular opening at the anterior end of the puparium.

Following is a list of scientific and vernacular names of the more common families of flies.

- Nematocera
  - Trichoceridae (winter crane flies)
  - Ptychopteridae (phantom crane flies)
  - Tipulidae (crane flies)
  - Psychodidae (moth flies and sand flies)
  - Blepharoceridae (net-winged midges)
  - Chironomidae (midges)
  - Ceratopogonidae (biting midges)
  - Simuliidae (black flies)
  - Chaoboridae (phantom midges)
  - Culicidae (mosquitoes)
  - Dixidae (dixid midges)
  - Anisopodidae (wood gnats)
  - Bibionidae (march flies)
  - Scatopidae (scatopsid flies)
  - Mycetophilidae (fungus gnats)
  - Sciaridae (black fungus gnats)
  - Cecidomyiidae (gall midges)
- Brachycera—Orthorrhapha
  - Stratiomyidae (soldier flies)
  - Rhagionidae (snipe flies)
  - Tabanidae (horse flies and deer flies)
  - Bombyliidae (bee flies)
  - Asilidae (robber flies)
  - Empididae (dance flies)
  - Dolichopodidae (long-legged flies)
- Brachycera—Cyclorrhapha
  - Lonchopteridae (spear-winged flies)

Phoridae (hump-backed flies)
Platypezidae (flat-footed flies)
Syrphidae (syrphid flies)
Pipunculidae (big-headed flies)
Lonchaeidae (lonchaeid flies)
Lauxaniidae (lauxaniid flies)
Drosophilidae (pomace or fruit flies)
Ephydridae (shore flies)
Anthomyiidae (anthomyiid flies)
Muscidae (house flies)
Calliphoridae (blow flies)
Sarcophagidae (flesh flies)
Oestridae (bot flies)
Tachinidae (tachinid flies)
Hippoboscidae (louse flies)
Micropezidae (stilt-legged flies)
Diopsidae (stalk-eyed flies)
Sciomyzidae (marsh or snail-killing flies)
Sepsidae (black scavenger flies)
Heleomyzidae (heleomyzid flies)
Sphaeoceridae (small dung flies)
Agromyzidae (leaf-miner flies)
Tethinidae (tethinid flies)
Chloropidae (frit flies)
Conopidae (thick-headed flies)
Tephritidae (fruit flies)
Piophilidae (skipper flies)

Morphology. Adult flies vary from somewhat less than 1 mm (0.04 in.) to over 25 mm (1 in.) in body length. The head is vertical, usually with three ocelli at the dorsal vertex and the mouthparts ventral. In some cases, however, the head is distinctly longer than high when viewed laterally. The compound eyes are usually large and prominent.

The mouthparts are modified for either lapping or piercing, but never with the mandibles apposable and capable of chewing. The structure of the mouthparts varies greatly throughout the order so that their homologies are often rather difficult to determine. Throughout the Orthorrhapha there tends to be a retention of mandibles for piercing, especially in those flies that require blood meals. In the Cyclorrhapha, on the other hand, mandibles tend to be reduced or lost entirely, and with few exceptions the work of the mouthparts is largely sucking, with the maxillae and labium taking over the large share of work. Since all adult flies imbibe fluids only, the presence of a pharyngeal "pump" to transfer fluids from the external substrate to the gut is characteristic.

Each antenna typically has two basal segments and one or more additional segments called the flagellum. In the Nematocera the flagellum consists of a variable number of quite similar segments. In all remaining flies that are three distinct antennal segments. The third segment, representing the flagellum, is usually longer than the two basal ones and sometimes complex.

The prothorax and metathorax are small and closely united with the large mesothorax which contains the musculature for the single pair of wings. The legs are usually alike, except in species in which the prothoracic pair are raptorial and species in which the fore, mid, or hind legs of the males are modified by secondary sexual characters.

Only the first pair of wings, the mesothoracic pair, is developed. The second pair is reduced to a pair of club-shaped organs, or halteres, which serve as balancing organs in flight. They are present in most species, even when the mesothoracic wings are absent. In many species, especially those of the Nematocera, abundant scalelike setae clothe the veins and sometimes the margins of the wings. The wings of some of the higher Diptera bear yellow, brown, or black markings that aid in species identification.

In certain families of Diptera, some of the setae covering the head and body are greatly enlarged and are used for identification. The location and relative size of these bristles are often characteristic of species, genera, or families.

Life cycle. The adult stage in the life history may be regarded as a reproductive and dispersal phase, during which these insects increase both in number and often in geographic range. Females select suitable oviposition sites and lay a variable number of eggs, after which they usually die. The eggs, after a period of incubation of varying length, give rise to larvae, which represent a growth phase. During this period, the insect does almost nothing but nourish itself, thus providing the tissues necessary for a later transformation into an adult. This growth period is divided into stages, or instars, each of which terminates with the molting of the larval skin to allow increase in size for the stage that follows. In the Diptera there are four larval instars. In most of the Orthorrhapha, especially those with aquatic immature forms, all four instars are active; but in the Cyclorrhapha, at the third larval molt, a hard puparium is formed inside which a quiescent fourth larval stage occurs. At the conclusion of the final larval instar, there is a dramatic reorganization in tissue structure initiated by the action of appropriate hormones on the so-called "imaginal buds," a process that eventually results in the formation of an adult insect. During this time, the insect is called a pupa because its external form is now altered and any external activity virtually ceases.

When the adult tissues are almost fully formed, the fly emerges from its pupal case and spends some time in drying, hardening, and expanding its wings, attaining color, and reaching sexual maturity. It is then ready to start its cycle once again.

Economic importance. Diptera have probably more economic importance than any other insect order. This importance comes from the relatively few species that affect domestic animals and plants. The vast majority of forms have no direct importance although a number are beneficial in one way or another.

Only a relatively few dipteran species cause severe economic loss to humans. Perhaps of most concern is the role played by them in disease transmission. About 70 species of *Anopheles* mosquitoes transmit an estimated 500,000 cases of malaria each year. Yellow fever is transmitted principally by a single mosquito, *Aedes aegypti*. Dengue, or breakbone fever, a usually nonfatal disease of worldwide distribution that leaves its victims debilitated for several weeks, is transmitted by *Aedes aegypti* and *A. albopictus*. Filariasis, primarily a disease of peoples of Africa, the Orient, and the Pacific islands, is caused by a minute roundworm whose larvae are transmitted by a few species of *Anopheles, Mansonia, Culex*, and *Aedes*, With modern methods used by bacteriologists and virologists, a large number of virus diseases known to be transmitted by mosquitoes have been found in humans. Many of these, such as Sindbis virus of Egypt, may not produce clinical symptoms of disease, but others, such as the equine encephalitides, which include western, eastern, St. Louis, Japanese, and others, may be quickly fatal in humans. With the exception of the viruses, none of the diseases mentioned above are transmitted by any insects other than members of the order Diptera.

A few less well-known diseases are transmitted by other flies. Black flies transmit *Onchocerca volvulus*, the causative agent of onchocerciasis, a disease affecting the eyes of natives of Central and parts of South America. Sandflies of the genus *Phlebotomus* transmit organisms that cause kala azar, Oriental sore, pappataci fever, and Oroya fever. Even today large parts of Africa remain underdeveloped because of the presence of sleeping sickness, a fatal disease transmitted by tsetse flies. Species of the genus *Chrysops* (Tabanidae) are instrumental in carrying tularemia, primarily a disease of rodents.

Domestic animals, hides, meat, and dairy products are affected by disease transmission or by direct attack by flies. Anthrax, tularemia, botulism, many virus diseases, and nagana, a form of sleeping sickness, are some of the diseases transmitted by members of the Diptera that take an annual toll amounting to millions of dollars. Some flies wreak their damage by direct attack. The primary screwworm fly deposits eggs on hides of animals, and the larvae, upon hatching, burrow through the skin and into the flesh. The secondary screwworm gains entrance through holes, often infected, already present on the skin surface. *Hypoderma lineata* and *H. bovis* are botflies of special importance. Eggs of both species are laid on hairs of cattle, and the hatching larvae bore through the skin into the connective tissue. During their development they wander through the tissues of the animal, and when mature they escape through holes which they make along the spine of their host and drop to the ground to pupate. Horses are afflicted by a species of *Gasterophilus*. They lick the eggs from their bodies, and the larvae settle and dwell in their stomachs, often in large numbers. Sheep are victims of the sheep botfly, whose larvae live in their nasal passages and sinuses. All of these insects affect the meat, milk, and wool production of animals through debilitation and irritation, and hides may be rendered completely useless by their entrance and exit holes. An interesting dipteran is the bee louse, which is a wingless, ectoparasite of the honeybee.

Economic losses as a result of damage by flies to crops are perhaps not as great as those caused by other insects, yet their presence has necessitated the expenditure of large sums of money for control. Among these, perhaps the most important are members of the family Tephritidae, the larvae of which feed upon and ruin the succulent flesh and seeds of their hosts. The most important of these are the European and American cherry fruit flies; their relatives in the genus *Rhagoletis* that attack walnuts in North America; six or seven species of the genus *Anastrepha* which attack many kinds of fruit in the New World; the Mediterranean fruit fly which is a limiting factor in the production of many fruits, especially citrus; and several species of the genus *Dacus*, which attack olives, citrus fruits, many kinds of vegetables, and other edible plants and plant parts in Europe, the Orient, and Pacific islands.

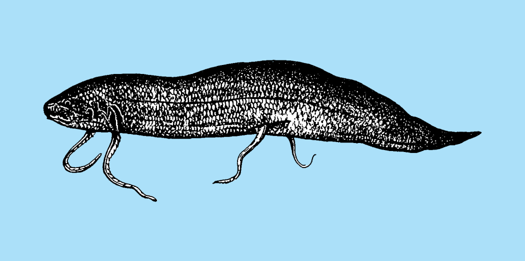
Larvae of some flies mine the leaves of ornamentals thereby defacing them, reducing their growth potentials, and affecting their production and sale by nurseries. The larvae of some species of Muscidae are known as root maggots and burrow into the underground parts of plants with considerable loss to growers of truck crops over the world. *See* ARTHROPODA; INSECTA.

[R.J.G.]

Dipteriformes The single order of the subclass Dipnoi, the lungfishes. Some authorities divide the lungfishes into a series of orders. *See* DIPNOI.

Dipteriformes are classified in some nine families, of which two very dissimilar types have living representatives. The Ceratodontidae, well known as Mesozoic fossils from all continents, differ but little from the Recent Australian species, *Neoceratodus forsteri*. This is a heavy-bodied lungfish with large scales and paddlelike paired fins; it reaches a length of 6 ft (2 m). It has a single dorsal lung with a ventral connection to the gut and can survive in deoxygenated waters by breathing air, but does not estivate. The Lepidorsirenidae, with a fossil history going back to the Permian, survive today in South America (*Lepidosiren paradoxa*) and Africa (four species of *Protopterus*). These are slender, eellike fishes with small, thin scales and slender, ribbonlike paired fins (see illustration). They have paired ventral lungs like tetrapods and are obligate air breathers. They can survive desiccation by encasing themselves in a protective capsule of mud as swamps dry, and they breathe atmospheric air until freed by seasonal rains. The young of the Lepidosirenidae have external gills which disappear with age. *See* HIBERNATION AND ESTIVATION.

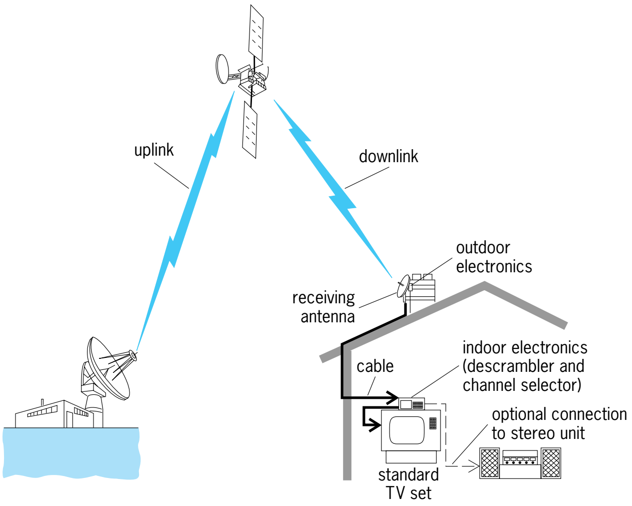
[R.M.B.]



African lungfish (*Protopterus annectens*), length to 32 in. (80 cm). (*After G. A. Boulenger, Catalogue of the Fresh Water Fishes of Africa in the British Museum, vol. 1, 1909*)

Direct broadcasting satellite systems Systems for transmitting television and other program material via satellite directly to individual homes and businesses. Direct broadcasting satellite (DBS) systems operate at microwave frequencies, in a portion of the Ku band; in North and South America these systems operate in the frequency range 12.2–12.7 GHz. *See* RADIO SPECTRUM ALLOCATIONS.

Although direct broadcasting satellites had been operating in Europe and Japan for a number of years, the first United States direct broadcasting satellite was launched on December 17, 1993, and the second in July 1994, followed by additional satellites in subsequent years.



Direct broadcasting satellite system.

DBS systems use a satellite in geostationary orbit to receive television signals sent up from the Earth's surface, amplify them, and transmit them back down to the surface. The satellite also shifts the signal frequency, so that a signal sent up to the satellite in the 17.3–17.8-GHz uplink band is transmitted back down in the 12.2–12.7-GHz downlink band. The downlink signal is picked up by a receive antenna located atop an individual home or office; these antennas are usually in the form of a parabolic dish, but flat square phased-array antennas are sometimes used, and may eventually become commonplace. The receive antenna may be permanently pointed at the satellite, which is at a fixed point in the sky, in a geostationary orbit. *See* ANTENNA (ELECTROMAGNETISM).

It is difficult to build receivers to operate at the microwave downlink frequencies, so the signal from the dish antenna is first passed to a downconverter, usually mounted outdoors on the antenna, that shifts it to (typically) the 0.95–1.45-GHz band. This signal is then conducted by cable to the receiver atop the television set. The receiver contains the channel selector, as well as a decoder to permit the user to view authorized channels. The receiver is connected by an additional cable to the television set (see illustration).

A typical direct broadcasting satellite contains 16 transponders, or amplifiers, the maximum permitted under present regulations, each with a radio-frequency power output in the range 120–240 W. Two or more direct broadcasting satellites may be located at any of the orbital locations assigned to the United States, for a maximum of 32 transponders.

DBS satellites in the United States typically use digital signals; a single 24-MHz satellite transponder can carry an error-corrected digital signal of 30 megabits per second or greater. A wide variety of communications services can be converted to digital form and carried as part of this digital signal, including television, high-definition television (HDTV), stereo audio, one-way videoconference, information services (such as news retrieval services), and digital data.

Modern digital signal compression technology greatly increases the capacity of a satellite transponder. It is possible to compress up to perhaps 10 television signals into the bandwidth of a DBS transponder, depending on the amount of motion in the picture and the amount of screen resolution required. Since some common programming (for example, sports) contains a good deal of motion, the average compression factor for a DBS system will typically be lower than 10. *See* DATA COMPRESSION.

DBS systems, like all satellite systems operating in the K_u band, are subject to attenuation of their signals by rain. The combination of satellite power and receive-dish antenna size is chosen to enable reception for all but the heaviest rainfall periods of the year, corresponding to an outage period of perhaps 7 h per year at any particular location. The DBS customer can further reduce this expected outage period by purchasing a slightly larger dish antenna. *See* COMMUNICATIONS SATELLITE; TELEVISION. [H.W.Ra.]

Direct-coupled amplifier A device for amplifying signals with direct-current components. There are many different situations where it is necessary to amplify signals having a frequency spectrum which extends to zero. Some typical examples are amplifiers in electronic differential analyzers (analog computers), certain types of feedback control systems, medical instruments such as the electrocardiograph, and instrumentation amplifiers. Amplifiers which have capacitor coupling between stages are not usable in these cases, because the gain at zero frequency is zero. Therefore, a special form of amplifier, called a dc (direct-current) or direct-coupled amplifier, is necessary. These amplifiers will also amplify alternating-current (ac) signals. *See* AMPLIFIER; ANALOG COMPUTER; BIOMEDICAL ENGINEERING; CONTROL SYSTEMS; INSTRUMENTATION AMPLIFIER.

Some type of coupling circuit must be used between successive amplifier stages to prevent the relatively large supply voltage of one stage from appearing at the input of the following stage. These circuits must pass dc signals with the least possible amount of attenuation.

Interstage direct-coupling in transistor dc amplifiers must be implemented with special care. The use of both *npn* and *pnp* transistors is a possible solution. However, the *pnp* transistors available in monolithic form have relatively poor current-gain and frequency-response characteristics. If a dc amplifier is formed by a cascade of *npn* stages, there is a positive dc level buildup toward the positive supply voltage. This voltage buildup limits the linearity and amplitude of the available output swing. The problem can be overcome by using a level-shift stage between each stage to shift the output dc level toward the negative supply with minimum attenuation of the amplified signal. Practical dc level-shift stages suitable for monolithic circuit applications can use Zener diodes, a series of diodes, or a V_{BE} multiplier circuit.

It is generally recognized that the differential amplifier is the most stable dc amplifier circuit available. This is true because in this circuit the performance depends on the difference of the device parameters, and transistors can be manufactured using the planar epitaxial technique with very close matching of their parameters.

A method of amplifying dc (or slowly varying) signals by means of ac amplifiers is to modulate a carrier signal by the signal to be amplified, amplifying the modulated signal, and demodulating at the output.

The offset voltage of matched transistor pairs of differential amplifiers can be a source of serious problems in precision analog dc amplifier applications. Typically the offset voltage of matched metal oxide semiconductor (MOS) transistor pairs can be reduced to within ±20 mV by careful processing. However, even this low offset voltage in many applications is unacceptable. It is possible to reduce the effective input offset voltage to below ±1 mV by using chopper-stabilized amplifiers employing offset-nulling or auto-zero techniques. These techniques are essentially sampled-data methods and are based on the concept of measuring periodically the offset voltage and subsequently storing it as a voltage across a holding capacitor and then subtracting it from the signal plus the offset. [C.C.H.]

Direct current Electric current which flows in one direction only through a circuit or equipment. The associated direct voltages, in contrast to alternating voltages, are of unchanging polarity. Direct current corresponds to a drift or displacement of electric charge in one unvarying direction around the closed loop or loops of an electric circuit. Direct currents and voltages may be of constant magnitude or may vary with time.

Direct current is used extensively to power adjustable-speed motor drives in industry and in transportation. Very large amounts of power are used in electrochemical processes for the refining and plating of metals and for the production of numerous basic chemicals.

Direct current ordinarily is not widely distributed for general use by electric utility customers. Instead, direct-current (dc) power is obtained at the site where it is needed by the rectification of commercially available alternating-current (ac) power to dc power. *See* DIRECT-CURRENT TRANSMISSION; ELECTRIC POWER SYSTEMS. [D.D.R.]

Direct-current generator A rotating electric machine which delivers a unidirectional voltage and current. An armature winding mounted on the rotor supplies the electric power output. One or more field windings mounted on the stator establish the magnetic flux in the air gap. A voltage is induced in the armature coils as a result of the relative motion between the coils and the air gap flux. Faraday's law states that the voltage induced is determined by the time rate of change of flux linkages with the winding. Since these induced voltages are alternating, a means of rectification is necessary to deliver direct current at the generator terminals. Rectification is accomplished by a commutator mounted on the rotor shaft. Carbon brushes, insulated from the machine frame and secured in brush holders, transfer the armature current from the rotating commutator to the external circuit. *See* COMMUTATION; ELECTRIC ROTATING MACHINERY; GENERATOR; WINDINGS IN ELECTRIC MACHINERY.

The field windings of dc generators require a direct current to produce a magnetomotive force (mmf) and establish a magnetic flux path across the air gap and through the armature. Generators are classified as series, shunt, compound, or separately excited, according to the manner of supplying the field excitation current.

In the separately excited generator, the field winding is connected to an independent external source. Separately excited generators are among the most common of dc generators, for they permit stable operation over a very wide range of output voltages.

Using the armature as a source of supply for the field current, dc generators are also capable of self-excitation. Residual magnetism in the field poles is necessary for self-excitation. Series, shunt, and compound-wound generators are self-excited, and each produces different voltage characteristics. The armature winding and field winding of a series generator are connected in series. The field winding of a shunt generator is connected in parallel with the armature winding. A compound generator has both a series field winding and a shunt field winding. Both windings are on the main poles with the series winding on the outside. The shunt winding furnishes the major part of the mmf. The series winding produces a variable mmf, dependent upon the load current, and offers a means of compensating for voltage drop. [R.T.W.]

Direct-current motor An electric rotating machine energized by direct current and used to convert electric energy to mechanical energy. It is characterized by its relative ease of speed control and, in the case of the series-connected motor, by an ability to produce large torque under load without taking excessive current. *See* ELECTRIC ROTATING MACHINERY.

The principal parts of a dc motor are the frame, the armature, the field poles and windings, and the commutator and brush assemblies. The frame consists of a steel yoke of open cylindrical shape mounted on a base. Salient field poles of sheet-steel laminations are fastened to the inside of the yoke. Field windings placed on the field poles are interconnected to form the complete field winding circuit. The armature consists of a cylindrical core of sheet-steel disks punched with peripheral slots, air ducts, and shaft hole. These punchings are aligned on a steel shaft on which is also mounted the commutator. The commutator, made of hard-drawn copper segments, is insulated from the shaft. Segments are insulated from each other by mica. Stationary carbon brushes in brush holders make contact with commutator segments. Copper conductors placed in the insulated armature slots are interconnected to form a reentrant lap or wave style of winding. *See* COMMUTATION; WINDINGS IN ELECTRIC MACHINERY.

Rotation of a dc motor is produced by an electromagnetic force exerted upon current-carrying conductors in a magnetic field. For basic principles of motor action *see* MOTOR.

Direct-current motors may be categorized as shunt, series, compound, or separately excited.

The field circuit and the armature circuit of a dc shunt motor are connected in parallel. The field windings consist of many turns of fine wire. The entire field resistance, including a series-connected field rheostat, is relatively large. The field current and pole flux are essentially constant and independent of the armature requirements. The torque is therefore essentially proportional to the armature current. Typical applications are for load conditions of fairly constant speed, such as machine tools, blowers, centrifugal pumps, fans, conveyors, wood- and metal-working machines, steel, paper, and cement mills, and coal or coke plant drives.

The field circuit and the armature circuit of a dc series motor are connected in series. The field winding has relatively few turns per pole. The wire must be large enough to carry the armature current. The flux of a series motor is nearly proportional to the armature current which produces it. Therefore, the torque of a series motor is proportional to the square of the armature current, neglecting the effects of core saturation and armature reaction. An increase in torque may be produced by a relatively small increase in armature current. Typical applications of this motor are to loads requiring high starting torques and variable speeds, for example, cranes, hoists, gates, bridges, car dumpers, traction drives, and automobile starters.

A compound motor has two separate field windings. One, generally the predominant field, is connected in parallel with the armature circuit; the other is connected in series with the armature circuit. The field windings may be connected in long or short shunt without radically changing the operation of the motor. They may also be cumulative or differential in compounding action. With both field windings, this motor combines the effects of the shunt and series types to an extent dependent upon the degree of compounding. Applications of this motor are to loads requiring high starting torques and somewhat variable speeds, such as pulsating loads, shears, bending rolls, plunger pumps, conveyors, elevators, and crushers. *See* DIRECT-CURRENT GENERATOR.

The field winding of a separately excited motor is energized from a source different from that of the armature winding. The field winding may be of either the shunt or series type, and adjustment of the applied voltage sources produces a wide range of speed and torque characteristics. Small dc motors may have permanent-magnet fields with armature excitation only. Such motors are used with fans, blowers, rapid-transfer switches, electromechanical activators, and programming devices. [L.F.C.]

Direct-current transmission The conveyance of electric power by conductors carrying unidirectional currents. *See* DIRECT CURRENT.

A dc line with two conductors is cheaper to construct and often has lower power losses than a three-phase ac line rated for the same power. Moreover, the same dc line is often considered as equal in reliability of service to a double-circuit three-phase line. The economic advantages are proportional to the line length but are offset by the substantial cost of the converting equipment. However, several other factors influence the selection of dc.

If the ac frequencies at the converting stations are nominally the same but controlled separately, their frequency independence is maintained by the dc link. In other words, the dc system is an asynchronous link. This is the justification of many back-to-back schemes such as the ties between regions in the United States and between European countries.

Although North America operates at 60 Hz and most other parts of the world operate at 50 Hz, on occasion there is a need to interconnect ac systems having different nominal frequencies. The asynchronous nature of dc serves as a frequency changer with the control action of each converter synchronized to its local ac frequency. The Sakuma frequency changer in Japan is a back-to-back scheme, connecting two regions which, for historical reasons, have frequency standards of 50 and 60 Hz.

The electrical shunt capacitance of cables is charged and discharged at the frequency of the voltage. Since the capacitance is proportional to distance, an ac cable longer than a few tens of miles is loaded to its thermal rating by a capacitor charging current, with no power being conveyed to the remote termination. Unless the cable can be sectioned for intermediate compensating measures, dc is obligatory for many cable applications. This is especially the case for submarine links where overhead lines are not an option.

All parts of an ac system function at the same nominal frequency. A system is designed to ensure that the generators do not lose synchronism despite load variations and large fault disturbances. The system is then considered to be dynamically stable. This becomes more of a challenge when the generating stations are geographically dispersed and remote from load centers, as opposed to the relatively tightly knit systems found in Europe. Should an ac connection to another system be contemplated, the combined system is intended to operate in synchronism, although the dynamic stability in either system may deteriorate below acceptable security. In comparison, a dc interconnection maintains the dynamic independence of each system. For example, remote hydroelectric generation at Churchill Falls in Labrador and on rivers entering James Bay prevents Hydro-Quebec from establishing synchronous connections with neighboring power companies for reasons of potential instability. Mutual interties and export contracts for electric power to the New York power pool and New England utilities have been implemented by several dc links.

The automatic control circuits at the converting stations permit the dc power to be accurately set at a value determined by the system control center. Furthermore, the dc power is maintained during dynamic ac frequency disturbances and can be rapidly changed (modulated) in as little as a few milliseconds, on demand. The same control permits the direction of dc power to be reversed equally quickly. This ability to ride through disturbances and to permit precise power scheduling and modulation responsive to dynamic needs has become of increasing value in the operation of power systems. The power flow in an individual ac line cannot be independently controlled to the degree offered by dc transmission.

A typical dc converter station contains conventional ac equipment in its ac switchyard supplemented by equipment specific to the ac-dc conversion. Solid-state converters are connected on the dc side with a center neutral point which is usually connected to a remote ground electrode. Balanced dc currents are circulated on each pole at plus and minus dc voltages with respect to ground. *See* Converter; Electric power substation. [J.Re.]

Direction-finding equipment Equipment used for determining the direction from which a received signal is being radiated. Direction finders serve a variety of applications. In navigation, a direction finder on a moving vehicle, such as an aircraft or a ship can be used to provide either a transmitter's bearing to yield relative positioning information if the transmitter's location and range are known, or the vehicle's heading for guidance along a desired route toward a given destination. A direction finder may also be a ground station used to obtain bearing information on a moving source. This information, when passed on, can be useful for the moving source in navigating. Surveillance uses of direction finders include uncovering covert transmitters in espionage, locating the emitter in search-and-rescue missions, and tracking crewless objects in scientific missions.

Most direction-finding systems are based on two principles, one exploiting antenna gain characteristics and the other using phase-frequency relationships observed by a moving or a multiple-element antenna.

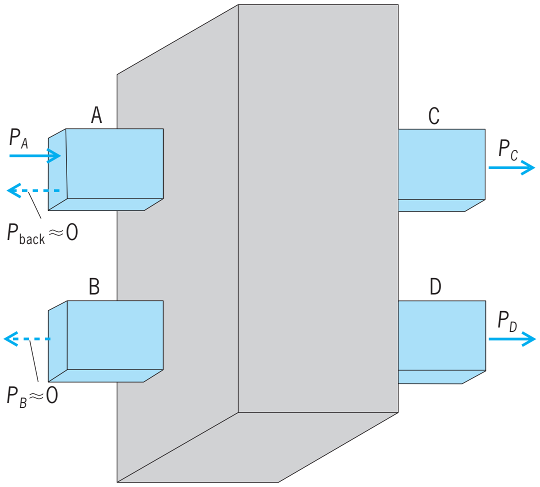
Direction-finding systems based on antenna gain sometimes take advantage of variations where the received signal amplitude is either a maximum or a minimum. Signal-minimum systems exploit the distinct null found in an antenna's gain pattern. Some of the earliest direction-finding equipment using loop antennas was conceived on this principle. The advent of higher-frequency systems and highly directive antennas, such as phased arrays and parabolic dishes, provided the basis for signal-maximum systems, which can pinpoint the direction in which the signal is strongest. *See* Antenna (electromagnetism).

The principle of induced Doppler frequency modulation requires movement of the antenna to cause additional Doppler shift to the original signal. The frequency of the signal received by the moving antenna will vary in relation to that received by a fixed antenna. The antenna motion most suited for omnidirectional purposes is circular. For this, the induced Doppler is zero at the instant when the antenna motion is perpendicular to the bearing of the received signal. *See* Doppler effect.

Airborne automatic direction finders (ADFs) are constrained by size and weight. For their simplicity, signal-minimum systems with loop antennas are widely used. *See* Air navigation; Electronic navigation systems. [P.Hw.]

Directional coupler A four-port waveguide device (see illustration) in which an incoming wave at any one port (for example, A) appears at two others (C and D) but not at the fourth (B). This device finds numerous applications in waveguide networks such as microwave waveguides, integrated optics, and optical fibers. It is the equivalent of the hybrid induction coil used in conventional wire circuit telephony to provide side-tone balance. *See* Telephone.

Directional couplers are usually made by introducing some form of lumped or continuous coupling among several guides so that the coupled waves interfere constructively in some directions while canceling one another in other directions. A simple two-hole coupler consists of two identical microwave waveguides running adjacent to each other with two small holes of the same size and shape coupling between them. It is limited by a narrow-frequency band over which the directivity is high, and a small coupling factor which is on the order of 10–30 dB. To alleviate these problems, multipath couplers are used, where the backward cancellation is obtained through destructive interference among waves excited by three or more coupling elements (such as holes), usually spaced a quarter-wavelength apart. The coupling holes are not necessarily equal. A natural extension to the multipath coupler is the slot coupler, where the coupling element is a continuous slot that is several wavelengths long and often tapered, and the coupling is continuously distributed along the length of the interaction.



Four-port directional waveguide coupler. P_A is the input power, and P_B, P_C, and P_D are the powers of the output waves at ports B, C, and D respectively.

Holes and slots are appropriate coupling elements for closed metallic waveguides, where the propagating field is completely enclosed within the walls of the guide. Other design alternatives exist for open waveguides such as microwave striplines, diffused dielectric optical guides used in integrated optics, and optical fibers. In these guides, the propagating field extends beyond the physical dimensions of the guiding structure (for example, the metallic plates of the stripline or the core of the fiber), and proximity coupling becomes possible. For example, the electromagnetic field of a single-mode optical fiber has an exponentially decreasing, evanescent, nonradiating tail in the first few micrometers of the cladding. Fusion, etching, and mechanical polishing techniques may be used to bring two fiber cores close enough to each other to make possible the transfer of power from one core to the other through the interaction of the corresponding evanescent fields.

Weak directional couplers can selectively monitor either the forward or backward power flow in waveguides, and medium-to-strong couplers serve as amplitude combiners and splitters in various resonators and sensors. All of these applications require high directivity, low insertion loss, and negligible back reflections. Many other useful junctions are also based on the same physical principles. *See* Integrated optics; Microwave measurements; Microwave power measurement; Optical communications; Optical fibers; Waveguide. [M.Tu.]

Directivity The general property of directional discrimination displayed by systems that receive or emit waves. Thus, loudspeakers, microphones, radio antennas, underwater sound projectors, hydrophones, and even telescopes all have the common property that their effectiveness depends upon the direction from which the wave is either emitted or received. The manner in which a sender or receiver is directional depends largely upon its geometrical shape and, in particular, upon its dimensions compared to those of the wavelength involved.

Directivity is a desirable property of a receiver because it permits the identification of the direction from which a signal comes and because noise from other directions is eliminated. It is desirable in a sender because the available energy can be concentrated in a given direction. A simple example of directivity is furnished by the megaphone, which effectively increases the size of the emitting area, thus increasing directivity. [W.S.Cr.]

Disasteroida A paraphyletic grouping of extinct irregular echinoids, members of which gave rise to the Holasteroida and Spatangoida in the Lower Cretaceous. Disasteroids have a split apical disc; the posterior two ocular plates and their associated ambulacra are separated from the remainder of the apical disc (and the anterior three ambulacra) by intercalated interambulacral plates. Disasteroids have a strong bilateral symmetry. Larger pore pairs, arranged in phyllodes around the mouth, suggest that disasteroids were deposit feeders with penicillate feeding tube feet. Most species probably lived infaunally, though not burrowing deeply.

Five families are included: Acrolusiidae, Collyritidae, Disasteridae, Pygorhytidae, and Tithoniidae, separated principally on apical disc plating. Approximately 75 species have been named, arranged in 17 genera. The oldest species is late Bajocian (Middle Jurassic) and the youngest Albian (Lower Cretaceous). The group achieved its greatest diversity during the Upper Jurassic. *See* ATELOSTOMATA; ECHINODERMATA. [A.B.S.]

Discomycetes A class in the phylum Ascomycota, commonly known as cup fungi. They form a well-developed mycelium which bears the sexual (ascus) and asexual (conidium) states. The ascocarp (apothecium) is generally cup or saucer shaped. In general, the asci are exposed when they mature, except in one group (truffles) that forms the ascocarps underground (hypogeous ascocarps). The ascocarp arises as coiled or intertwined initials that can be distinguished as male (antheridium) and female (ascogonium) in some species. Layers of hyphae develop around these initials to form the tissue of the ascocarp. As this development occurs, the initial coil forms a system of ascogenous hyphae that transform into asci. The asci form in a broad layer (hymenium) on the apothecium. They have a single rigid wall (unitunicate), with two basic types of apex, operculate and inoperculate. Operculate asci have a hinged cap (operculum) at the tip that opens to allow discharge of ascospores. In inoperculate asci, the apex has a pore or a small slit through which the spores are discharged. In most species, ascospores are forcibly discharged. Their shape is variable, but they are usually one celled and hyaline.

The Discomycetes occur on soil and on living and dead plants, either as saprobes or as parasites. The operculate discomycetes includes the largest of all ascomycetes: the edible morels (*Morchella*), prized for their flavor; those with large, showy red or orange apothecia (*Cookeina, Sarcoscypha, Scutellinia*); and truffles (*Tuber*). Among the inoperculate Discomycetes are numerous plant pathogens, such as *Monilinia fructicola* (brown rot of peach), which forms small, brown, cup-shaped ascocarps with long stalks, and the needle cast fungus (*Lophodermium pinastri*), which forms narrow, elongate ascocarps that open by a slit on pine needles. *See* ASCOMYCOTA; EUMYCOTA; FUNGI. [R.T.H.]

Discriminant For a polynomial $f(x) = a_nx^n + a_{n-1}x^{n-1} + \cdots + a_1x + a_0$, the discriminant is given by the expression

$$D = a_n^{2n-1}(x_1 - x_2)^2(x_1 - x_3)^2 \cdots (x_1 - x_n)^2(x_2 - x_3)^2 \cdots$$

$$(x_2 - x_n)^2 \cdots (x_{n-1} - x_n)^2$$

where $x_1, x_2, \ldots, x_n$ are the roots of the equation $f(x) = 0$.

The importance of the discriminant D lies in the fact that D vanishes if, and only if, the equation $f(x) = 0$ has equal roots. Since the value of the discriminant is unchanged if any two letters x_i and x_j are interchanged, it is a symmetric function of the roots, and can be expressed in terms of the coefficients of $f(x)$. The discriminant of a quadratic polynomial $f(x) = a_2x^2 + a_1x + a_0$ is $D = {a_1}^2 - 4a_2a_0$. The discriminant of a cubic polynomial $f(x) = a_3x^3 + a_2x^2 + a_1x + a_0$ is

$$D = 18a_3a_2a_1a_0 - 4{a_2}^3a_0 + {a_2}^2{a_1}^2 - 4a_3{a_1}^2 - 27{a_3}^2{a_0}^2$$

See EQUATIONS, THEORY OF; POLYNOMIAL SYSTEMS OF EQUATIONS. [R.A.B.]

Disease A deleterious set of responses which occurs at the subcellular level, stimulated by some injury, and which is often manifested in altered structure or functioning of the affected organism. With advances in understanding and the development of sensitive probes, it has become clear that the fundamental causes of diseases are based on biochemical and biophysical responses within the cell. These responses are now being categorized and, slowly, the mechanisms are being understood.

The term homeostasis refers to functional equilibrium in an organism and to the processes that maintain it. There is a range of responses that is considered normal. If cells are pushed to respond beyond these limits, there may be an increase, a decrease, or a loss of normal structure or function. These changes may be reversible or irreversible. If irreversible, the cells may die. Thus, subcellular changes may be reflected in altered tissues, organs, and consequently organisms, and result in a condition described as diseased. *See* HOMEOSTASIS.

Lesions are the chemical and structural manifestations of disease. Subjective manifestations of a disease process such as weakness, pain, and fatigue are called symptoms. The objective measurable manifestations such as temperature, blood pressure, and respiratory rate changes are called signs or physical findings. Changes in the chemical or cellular makeup of an organ, tissue, or fluid of the body or its excretory products are called laboratory findings. To make a diagnosis is to determine the nature of the pathologic process by synthesizing information from these sources evaluated in the light of the patient's history and compared with known patterns of signs and symptoms. In common usage, the term disease indicates a constellation of specific signs and symptoms attributable to altered reactions in the individual which are produced by agents that affect the body or its parts.

Etiology is the study of the cause or causes of a disease process. Although a disease may have one principal etiologic agent, it is becoming increasingly apparent that there are several factors involved in the initiation of a disease process. Susceptibility of the individual is an ever present variable. The etiologic factors can conveniently be divided into two categories (see table). One group consists of endogenous (internal; within the body) factors, and may originate from errors in the genetic material. The other category of etiologic factors is exogenous (environmental). These account for the majority of disease reactions. Exogenous factors include physical, chemical, and biotic agents.

Pathogenesis refers to the mechanisms by which the cell, and consequently the body, responds to an etiologic agent. It involves biochemical and physiological responses which are reflected in ultrastructural, microscopic, or gross anatomic lesions. There are a limited number of ways in which cells respond to injury. The nature of the response is modified by the nature of the agent, dose, portal of entry, and duration of exposure, as well as many host factors such as age, sex, nutritional state, and species and individual susceptibility.

The diseases which are important in causing human death have changed in the last 80 years. In 1900 six of the ten leading causes of death in the United States were infectious (biotic) agents. At present, only one of the ten leading causes of death in the United States, influenza and pneumonia, is due to biotic agents. While most of the biotic causes of diseases were being brought under control, continued population growth (in large part, a consequence of the control of infectious disease) and the remarkable growth of industrialization have been associated with an increased prevalence of diseases caused by physical and chemical agents. These include cancer, cirrhosis, and cardiovascular disease.

General principles of the organism's response to toxic substances, some of which occur naturally in the environment, have evolved from a great number of investigations of agent-host interaction. They are: (1) All substances entering the organism are toxic; none is harmless. Dose rate of exposure and route of entry into the body determine whether a toxic response will occur or not. (2) All agents evoke multiple responses. (3) Most of the biological responses are undesirable, leading to the development of pathological changes. (4) A given dose of an agent does not produce the same degree of response in all individuals. Thus, when disease is viewed as interaction between the environment and the individual, the control of disease is largely the management of the environmental causes of disease. [N.K.M.; C.Qu]

Common exogenous and endogenous causes of disease

Causative agent	Disease
EXOGENOUS FACTOR	
Physical	
Mechanical injury	Abrasion, laceration, fracture
Nonionizing energy	Thermal bums, electric shock, frostbite, sunburn
Ionizing radiation	Radiation syndrome
Chemical	
Metallic poisons	Intoxication from methanol, ethanol, glycol
Nonmetallic inorganic poisons	Intoxication, from phosphorous, borate, nitrogen dioxide
Alcohols	Intoxication from methanol, ethanol, glycol
Asphyxiants	Intoxication from carbon monoxide, cyanide
Corrosives	Burns from acids, alkalies, phenols
Pesticides	Poisoning
Medicinals	Barbiturism, salicylism
Warfare agents	Burns from phosgene, mustard gas
Hydrocarbons (some)	Cancer
Nutritional deficiency	
Metals (iron, copper, zinc)	Some anemias
Nonmetals (iodine, fluorine)	Goiter, dental caries
Protein	Kwashiorkor
Vitamins:	
A	Epithelial metaplasia
D	Rickets, osteomalacia
K	Hemorrhage
Thiamine	Beriberi
Niacin	Pellagra
Folic acid	Macrocytic anemia
B_{12}	Pemicious anemia
Ascorbic acid	Scurvy
Biological	
Plants (mushroom, fava beans, marijuana, poison ivy, tobacco, opium)	Contact dermatitis, systemic toxins, cancer, hemorrhage
Bacteria	Abscess, scarlet fever, pneumonia, meningitis, typhoid, gonorrhea, food poisoning, cholera, whooping cough, undulant fever, plague, tuberculosis, leprosy, diphtheria, gas gangrene, botulism, anthrax
Spirochetes	Syphilis, yaws, relapsing fever, rat bite fever
Virus	Warts, measles, German measles, smallpox, chickenpox, herpes, roseola, influenza, psittacosis, mumps, viral hepatitis, poliomyelitis, rabies, encephalitis, trachoma
Rickettsia	Rocky Mountain spotted fever, typhus
Fungus	Ringworm, thrush, actinomycosis, histoplasmosis, coccidiomycosis
Parasites (animal)	
Protozoa	Amebic dysentery, malaria, toxoplasmosis, trichomonas vaginitis
Helminths (worms)	Hookworm, trichinosis, tapeworm, filariasis, ascariasis
ENDOGENOUS FACTOR	
Hereditary	Phenylketonuria, alcaptonuria, glycogen storage disease, Down's syndrome (trisomy 21), Turner's syndrome, Klinefelter's syndrome, diabetes, familial polyposis
Hypersensitivity	Asthma, serum sickness, eczema drug idiosyncrasy

Disease ecology

Disease ecology The interaction of the behavior and ecology of hosts with the biology of pathogens, as it relates to the impact of diseases on populations.

Threshold theorem. For a disease to spread, on average it must be successfully transmitted to a new host before its current host dies or recovers. This observation lies at the core of the most important idea in epidemiology: the threshold theorem. The threshold theorem states that if the density of susceptible hosts is below some critical value, then on average the transmission of a disease will not occur rapidly enough to cause the number of infected individuals to increase. In other words, the reproductive rate of a disease must be greater than 1 for there to be an epidemic, with the reproductive rate being defined as the average number of new infections created per infected individual. Human immunization programs are based on applying the threshold theorem of epidemiology to public health; specifically, if enough individuals in a population can be vaccinated, then the density of susceptible individuals will be sufficiently lowered that epidemics are prevented. *See* EPIDEMIOLOGY; VACCINATION.

In general, the rate of reproduction for diseases is proportional to their transmissibility and to the length of time that an individual is infectious. For this reason, extremely deadly diseases that kill their hosts too rapidly may require extremely high densities of hosts before they can spread. All diseases do not behave as simply as hypothesized by the threshold theorem, the most notable exceptions being sexually transmitted diseases. Because organisms actively seek reproduction, the rate at which a sexually transmitted disease is passed among hosts is generally much less dependent on host density.

Population effects. Cycles in many animal populations are thought to be driven by diseases. For example, the fluctuations of larch bud moths in Europe are hypothesized to be driven by a virus that infects and kills the caterpillars of this species. Cycles of red grouse in northern England are also thought to be driven by disease, in this case by parasitic nematodes. It is only when grouse are laden with heavy worm burdens that effects are seen, and those effects take the form of reduced breeding success or higher mortality during the winter. This example highlights a common feature of diseases: their effects may be obvious only when their hosts are assaulted by other stresses as well (such as harsh winters and starvation).

The introduction of novel diseases to wild populations has created massive disruptions of natural ecosystems. For example, the introduction of rinderpest virus into African buffalo and wildebeest populations decimated them in the Serengeti. African wild ungulates have recovered in recent years only because a massive vaccination program eliminated rinderpest from the primary reservoir for the disease, domestic cattle. But the consequences of the rinderpest epidemic among wild ungulates extended well beyond the ungulate populations. For example, human sleeping sickness increased following the rinderpest epidemic because the tsetse flies that transmit sleeping sickness suffered a shortage of game animals (the normal hosts for tsetse flies) and increasingly switched to humans to obtain meals.

It is widely appreciated that crop plants are attacked by a tremendous diversity of diseases, some of which may ruin an entire year's production. Diseases are equally prevalent among wild populations of plants, but their toll seems to be reduced because natural plant populations are so genetically variable that it is unlikely that any given pathogen strain can sweep through and kill all of the plants—there are always some resistant genotypes. But when agronomists have bred plants for uniformity, they have often depleted genetic diversity and created a situation in which a plant pathogen that evolves to attack the crop encounters plants with no resistance (all the plants are the same). For example, when leaf blight devastated the United States corn crop, 70% of that crop shared genetically identical cytoplasm, and the genetic uniformity of the host exacerbated the severity of the epidemic. *See* PLANT PATHOLOGY.

Disease emergence. Humans are dramatically altering habitats and ecosystems. Sometimes these changes can influence disease interactions in surprising ways. Lyme disease in the eastern United States provides a good example of the interplay of human habitat modifications and diseases. Lyme disease involves a spirochete bacterium transmitted to humans by ticks. However, humans are not the normal hosts for this disease; instead, both the ticks and the bacterium are maintained primarily on deer and mouse populations. Human activities influence both deer and mice populations, and in turn tick populations, affecting potential exposure of humans to the disease. Much less certain are the impacts of anticipated global warming on diseases. There is some cause for concern about the expansion of tropical diseases into what are now temperate regions in those cases where temperature sets limits to the activity or distribution of major disease vectors. *See* LYME DISEASE; POPULATION ECOLOGY. [P.Ka.]

Dispersion (radiation)

The separation, by refraction, interference, scattering, or diffraction, of acoustic and electromagnetic radiation or energy into its constituent wavelengths or frequencies. For a refracting, transparent substance, such as a prism of glass, the dispersion is characterized by the variation of refractive index with change in wavelength of the radiation. Refractive index (n) is defined as the ratio of the velocity of the radiation in free space (air at standard temperature and pressure for sound, and a vacuum for electromagnetic radiation) to the velocity in the substance in question. I. Newton used a small hole in a window shade and a glass prism to disperse sunlight into a visible spectrum, from violet through red. Using a second prism, he showed that no further decomposition of any of the spectral colors could be achieved. *See* OPTICAL PRISM; REFRACTION OF WAVES.

The condition where the refractive index decreases as wavelength increases is termed normal dispersion. The opposite condition is termed anomalous dispersion, and almost always occurs in regions outside the range of visible wavelengths. [R.A.Buc.]

Dispersion relations

Relations between the real and imaginary parts of a response function. A response function relates a cause and its effect through an integral equation. The term dispersion refers to the fact that the index of refraction of a medium is a function of frequency. In 1926 H. A. Kramers and R. Kronig showed that the imaginary part of an index of refraction (that is, the absorptivity) determines the real part (that is, the refractivity); this is called the Kramers-Kronig relation. The term dispersion relation is now used for the analogous relation between the real and imaginary parts of the values of any response function. *See* COMPLEX NUMBERS. [C.J.G.]

Displacement current

The name given by J. C. Maxwell to the term $\partial \mathbf{D}/\partial t$ which must be added to the current density $\mathbf{i}$ to extend to time-varying fields the magnetostatic result of A. M. Ampère that $\mathbf{i}$ equals the curl of the magnetic intensity $\mathbf{H}$. In integral form this result is given by the equation below, where the unit vector $\mathbf{n}$ is perpendicular to the surface

$$\oint \mathbf{H} \cdot d\mathbf{s} = \int_S \left(\mathbf{i} + \frac{\partial \mathbf{D}}{\partial t} \right) \cdot \mathbf{n}\, dS$$

dS. The concept of displacement current has important consequences for insulators and for free space where $\mathbf{i}$ vanishes. For conductors, however, the difference between the above equation and Ampère's result is negligible. *See* AMPERE'S LAW; MAXWELL'S EQUATIONS.

If one defines current as a transport of charge, the term displacement current is certainly a misnomer when applied to a vacuum where no charges exist. If, however, current is defined in terms of the magnetic fields it produces, the expression is legitimate. [W.R.Sm.]

Displacement pump

A pump that develops its action through the alternate filling and emptying of an enclosed volume. There are five basic types: reciprocating, direct-acting steam, rotary, vacuum, and air-lift.

Positive-displacement reciprocating pumps have cylinders and plungers or pistons with an inlet valve, which opens the cylinder to the inlet pipe during the suction stroke, and an outlet valve, which opens to the discharge pipe during the discharge stroke. Reciprocating pumps may be power-driven through a crank and connecting rod or equivalent mechanism, or direct-acting, driven by steam or compressed air or gas. Power-driven reciprocating pumps are highly efficient over a wide range of discharge pressures. Except for some special designs with continuously variable stroke, reciprocating power pumps deliver essentially constant capacity over their entire pressure range when driven at constant speed.

A reciprocating pump is readily driven by a reciprocating engine; a steam or power piston at one end connects directly to a fluid piston or plunger at the other end. Steam pumps can be built for a wide range of pressure and capacity by varying the relative size of the steam piston and the liquid piston or plunger. The delivery of a steam pump may be varied at will from zero to maximum simply by throttling the motive steam, either manually or by automatic control. Reciprocating pumps are used for low to medium capacities and medium to highest pressures. They are useful for low- to medium-viscosity fluids, or high-viscosity fluids at materially reduced speeds. Specially fitted reciprocating pumps are used to pump fluids containing the more abrasive solids.

Another form of displacement pump consists of a fixed casing containing gears, cams, screws, vanes, plungers, or similar elements actuated by rotation of the drive shaft. Most forms of rotary pumps are valveless and develop an almost steady flow rather than the pulsating flow of a reciprocating pump.

Although vacuum pumps actually function as compressors, displacement pumps are used for certain vacuum pump applications. Simplex steam pumps with submerged piston pattern fluid ends are used as wet vacuum pumps in steam heating and condensing systems. Sufficient liquid remains in the cylinder to fill the clearance volume and drive the air or gas out ahead of the liquid. *See* VACUUM PUMP.

In handling abrasive or corrosive waters or sludges, where low efficiency is of secondary importance, air-lift pumps are used. The pump consists of a drop pipe in a well with its lower end submerged and a second pipe which introduces compressed air near the bottom of the drop pipe. The mixture of air and water in the drop pipe is lighter than the water surrounding the pipe. As a result, the mixture of air and water is forced to the surface by the pressure of submergence. *See* COMPRESSOR; PUMP. [E.F.W.]

Distance-measuring equipment An internationally standardized navigation system which allows an aircraft to measure its distance from a selected ground-based beacon. Such beacons are used throughout the world by all airliners, most of the military aircraft of the West, and a large number of general-aviation aircraft. The range of service is line-of-sight up to 300 mi (480 km) and system accuracy is usually 0.1 mi (0.16 km) but precision equipment, intended for use during landing, has accuracy of 100 ft (30 m).

The airborne equipment, called an interrrogator, transmits pulses of 1 kW peak power on 1 of 126 frequencies. These are in the 1025–1150-MHz band and are spaced 1 MHz apart. Each pulse is of 3.5 microseconds duration and is paired with another, spaced 12 or 36 microseconds later. The combination of frequencies and pulse spacings therefore provides 252 operating channels.

The beacon on the ground, called a transponder, receives these pulses, delays them by 50 μs, and then retransmits them, usually with a power of 1 kW, on 252 frequencies lying between 962 and 1213 MHz. The pulse-pair spacing is 12 μs on those frequencies not used by the interrogator, and 30 μs on those frequencies shared with the interrogator. The transponder transmission is called the reply. The frequency difference between interrogation and reply is always 63 MHz. This arrangement allows each transmitter frequency to act as the local oscillator for its associated superheterodyne receiver, the intermediate frequency of which is 63 MHz. For landing purposes, some transponders have powers as low as 100 W.

In the aircraft the replies to its own interrogations are recognized by their phase coherence with their own transmissions, and by the elapsed time measured between transmissions and reception (minus the 50-μs transponder delay), usually by means of a crystal clock. This elapsed time is about 12 μs for each nautical mile (7 μs for each kilometer), and is displayed in the cockpit on a digital meter, which is usually calibrated in miles and tenths of miles. *See* ELECTRONIC NAVIGATION SYSTEMS; INSTRUMENT LANDING SYSTEM (ILS); RHO-THETA SYSTEMS; TACAN. [S.H.D.]

Distillation A method for separating homogeneous mixtures based upon equilibration of liquid and vapor phases. Substances that differ in volatility appear in different proportions in vapor and liquid phases at equilibrium with one another. Thus, vaporizing part of a volatile liquid produces vapor and liquid products that differ in composition. This outcome constitutes a separation among the components in the original liquid. Through appropriate configurations of repeated vapor-liquid contactings, the degree of separation among components differing in volatility can be increased many fold. *See* PHASE EQUILIBRIUM.

Distillation is by far the most common method of separation in the petroleum, natural gas, and petrochemical industries. Its many applications in other industries include air fractionation, solvent recovery and recycling, separation of light isotopes such as hydrogen and deuterium, and production of alcoholic beverages, flavors, fatty acids, and food oils.

Simple distillations. The two most elementary forms of distillation are a continuous equilibrium distillation and a simple batch distillation.

In a continuous equilibrium distillation, a continuously flowing liquid feed is heated or reduced in pressure (flashed) so as to cause partial vaporization. The vapor and liquid disengage while flowing through an open drum, and the products emerge as vapor and liquid streams. The vapor product can be condensed to form a liquid distillate. It is also possible to use a vapor feed, subjected to cooling and thereby partial condensation, again followed by disengagement of the resultant vapor and liquid in an open drum. *See* VAPOR CONDENSER.

In a simple batch distillation, an entire batch of liquid is initially charged to a vessel and is then heated, typically by condensation of steam inside a metal coil within the vessel. Vapor is thereby continuously generated, and may be condensed to form a liquid distillate, which is collected. In the batch distillation, increments of vapor are formed in equilibrium with all liquid compositions ranging from the original to the final, whereas the continuous equilibrium distillation gives vapor in equilibrium with only the final liquid composition. Since the distillate consists primarily of the more volatile components and the feed liquid contains more of these substances than does the final liquid, the simple batch distillation gives a more enriched distillate than does the continuous equilibrium distillation.

Fractional distillation. Unless the vapor pressures of the species being separated are very dissimilar, a simple distillation does not produce highly purified products. Product purities can be increased by repeated partial vaporizations and condensations. The liquid from an initial continuous equilibrium distillation can be partially vaporized by additional heating. The remaining liquid can again be heated and partially vaporized, forming another liquid and so forth. Each liquid is progressively enriched in the less volatile substances. Similarly, successive partial condensations of the vapor fraction from the initial continuous equilibrium distillation produce vapor products successively enriched in the more volatile components. *See* VAPOR PRESSURE.

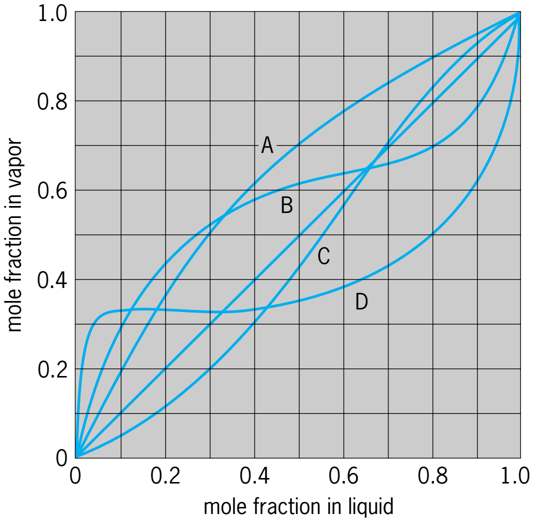
The process involved in successive partial vaporizations and condensations would lead to only very small amounts of the most enriched products, along with numerous streams having intermediate compositions. A logical step is to recycle each of these intermediate streams to the prior vessel in the sequence of contactors. Recycling of the intermediate vapors and liquids has another highly beneficial effect in that it negates the need for intermediate heaters and coolers. The resultant process is known as continuous fractional distillation. It is usually carried out in a distillation column, which is a simpler, more compact form of equipment than the cascade of vessels used in the process of recycling intermediate vapors and liquids. *See* DISTILLATION COLUMN.

Vapor-liquid equilibria. The separation accomplished in a distillation relates to the difference in composition of vapor and liquid phases at equilibrium. These relationships are the subject matter of phase-equilibrium thermodynamics. *See* CHEMICAL THERMODYNAMICS; GAS; LIQUID.

The dependence of liquid-phase activity coefficients upon liquid composition is complex; consequently vapor-liquid equilibrium relationships can have quite different characteristics. For example, the two-component benzene-toluene system (curve A in the illustration) is a relatively ideal system, for which the activity coefficients are close to 1.0 over the liquid composition range. The mole fraction of benzene in the vapor is therefore always greater than that in the liquid, and the relative volatility has a nearly constant value of 2.4. Such a system can be separated readily into products of high purity by continuous fractional distillation.

In the acetone-carbon disulfide system (curve B), there are positive deviations from ideality, meaning that the activity coefficients are greater than 1.0 and increase for either component as that component becomes more dilute in the mixture. The result is that the relative volatility is greatest at low concentrations of the more volatile component (acetone) and decreases at higher concentrations. Because of hydrogen bonding between the two components, the acetone-chloroform system (curve C) exhibits negative deviations from ideality, meaning that the activity coefficients are less than 1.0. The isobutanol-water system (curve D) exhibits sufficiently extreme positive deviations from ideality so that two immiscible liquid phases form over much of the composition range. Continuous fractional distillation cannot produce two products of high purity for such a system.

Distillation pressure. The pressure under which a distillation is performed is a matter of choice, although operation at pressures more removed from atmospheric becomes more costly.



Types of binary vapor-liquid equilibrium relationship; equilibrium vapor mole fraction of the more volatile (first named) component as a function of the liquid mole fraction of the more volatile component. The pressure is constant at 1 atm (101 kilopascals) for all systems. Curve A, benzene-toluene; B, acetone-carbon disulfide; C, acetone-chloroform; D, isobutyl alcohol-water.

Altering the pressure of a distillation can serve to alter the vapor-liquid equilibrium relationship, a feature that can be used to advantage.

Because of the relationship between vapor pressure and temperature, the temperatures within a distillation column are lower for lower pressures. Vacuum distillation is an effective means of maintaining lower temperatures for separations involving heat-sensitive materials.

Steam distillation is an alternative to vacuum distillation for separations of organic substances. In this process, steam is fed directly to the bottom of a column and passes upward, composing a substantial fraction of the vapor phase. The combined partial pressures of the organic substances being distilled are thereby lessened, giving the lower temperatures characteristic of a vacuum distillation. [C.J.Ke.]

Distillation column An apparatus used widely for countercurrent contacting of vapor and liquid to effect separations by distillation or absorption. In general, the apparatus consists of a cylindrical vessel with internals designed to obtain multiple contacting of ascending vapor and descending liquid, together with means for introducing or generating liquid at the top and vapor at the bottom.

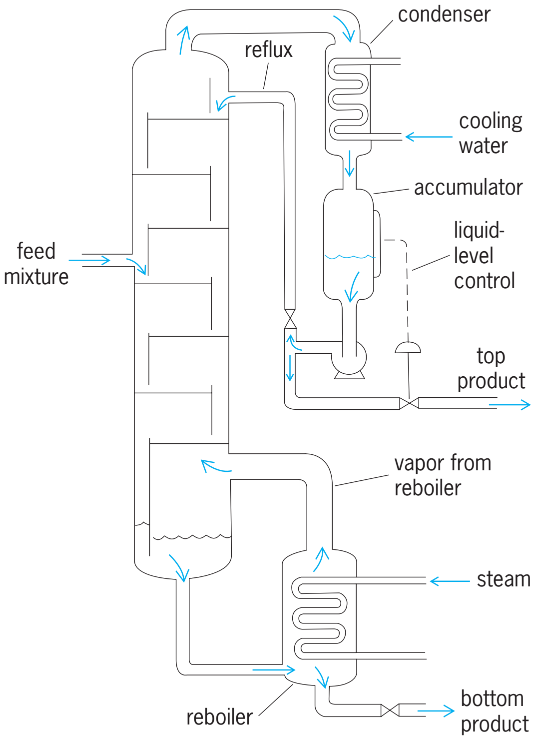
In a column that can be applied to distillation (see illustration), a vapor condenser is used to produce liquid (reflux) which is returned to the top, and a liquid heater (reboiler) is used to generate vapor for introduction at the bottom. In a simple absorber, the absorption oil is the top liquid and the feed gas is the bottom vapor. In all cases, changes in composition produce heat effects and volume changes, so that there is a temperature gradient and a variation in vapor, and liquid flows from top to bottom of the column. These changes affect the internal flow rates from point to point throughout the column and must be considered in its design.

Distillation columns used in industrial plants range in diameter from a few inches to 40 ft (12 m) and in height from 10 to 200 ft (3 to 60 m). They operate at pressures as low as a few millimeters of mercury and as high as 3000 lb/in.^{2} (2 megapascals) at temperatures from −300 to 700°F (−180 to 370°C). They are made of steel and other metals, of ceramics and glass, and even of such materials as bonded carbon and plastics.

A variety of internal devices have been used to obtain more efficient contacting of vapor and liquid. The most widely used devices are the bubble-cap plate, the perforated or sieve plate, and the packed column.

The bubble-cap plate is a horizontal deck with a large number of chimneys over which circular or rectangular caps are mounted to channel and distribute the vapor through the liquid. Liquid flows by gravity downward from plate to plate through separate passages known as downcomers.

The perforated or sieve plate is a horizontal deck with a multiplicity of round holes or rectangular slots for distribution of vapor through the liquid. The sieve plate can be designed with downcomers similar to those used for bubble-cap trays, or it can be made without downcomers so that both liquid and vapor flow through the perforations in the deck.



Elements of a distillation column.

The packed column is a bed or succession of beds made up of small solid shapes over which liquid and vapor flow in tortuous countercurrent paths. Expanded metal or woven mats are also used as packing. The packed column is used without downcomers, but in larger sizes usually has horizontal redistribution decks to collect and redistribute the liquid over the bed at successive intervals of height. The packed column is widely used in laboratories. It is often used in small industrial plants, especially where corrosion is severe and ceramic or glass materials must be chosen. *See* DISTILLATION; GAS ABSORPTION OPERATIONS. [M.Sou.]

Distortion (electronic circuits) The behavior of an electrical device or communications system whose output is not identical in form to the input signal. In a distortionless communications system, freedom from distortion implies that the output must be proportional to a delayed version of the input, requiring a constant-amplitude response and a phase characteristic that is a linear function of frequency. *See* RESPONSE.

In practice, all electrical systems will produce some degree of distortion. The art of design is to see that such distortion is maintained within acceptable bounds, while the signal is otherwise modified in the desired fashion. In general, distortion can be grouped into four forms: amplitude (nonlinear), frequency, phase, and cross modulation.

Amplitude distortion. All electronic systems are inherently nonlinear unless the input signal is maintained at an incrementally small level. Once the signal level is increased, the effects of device nonlinearities become apparent as distorted output waveforms. Such distortion reduces the output voltage capability of operational amplifiers and limits the power available from power amplifiers. Amplitude distortion may be reduced in amplifier stages by the application of negative feedback. *See* AMPLIFIER; FEEDBACK CIRCUIT; OPERATIONAL AMPLIFIER.

Frequency distortion. No practical device or system is capable of providing constant gain over an infinite frequency band. Hence, any nonsinusoidal input signal will encounter distortion since its various sinusoidal components will undergo unequal degrees of amplification. The effects of such distortion can be minimized by designing transmission systems with a limited region of constant gain. Thus, in high-fidelity systems, the amplifier response is made wide enough to capture all the harmonic components to which the human ear is sensitive.

Phase distortion. Since the time of propagation through a system varies with frequency, the output may differ in form from the input signal, even though the same frequency components exist. This can easily be demonstrated by noting the difference between the addition of two in-phase sine waves and two whose phase relationship differs by several degrees. In digital systems, such changes can be significant enough to cause timing problems. Hence, the phase-frequency response must be made linear to obtain distortionless transmission. *See* EQUALIZER.

Cross modulation. Sometimes referred to as intermodulation, this occurs because of the nonlinear nature of device characteristics. Thus, if two or more sinusoidal inputs are applied to a transistor, the output will contain not only the fundamentals but also signal harmonics, sums and differences of harmonics, and various sum or difference components of fundamental and harmonic components. While these effects are generally undesirable, they may be utilized to advantage in amplitude modulation and diode detection (demodulation). *See* AMPLITUDE-MODULATION DETECTOR; AMPLITUDE MODULATOR. [F.W.S.]

Distributed systems (computers)

A distributed system consists of a collection of autonomous computers linked by a computer network and equipped with distributed system software. This software enables computers to coordinate their activities and to share the resources of the system hardware, software, and data. Users of a distributed system should perceive a single, integrated computing facility even though it may be implemented by many computers in different locations. This is in contrast to a network, where the user is aware that there are several machines whose locations, storage replications, load balancing, and functionality are not transparent. Benefits of distributed systems include bridging geographic distances, improving performance and availability, maintaining autonomy, reducing cost, and allowing for interaction. *See* LOCAL-AREA NETWORKS; WIDE-AREA NETWORKS.

The object-oriented model for a distributed system is based on the model supported by object-oriented programming languages. Distributed object systems generally provide remote method invocation (RMI) in an object-oriented programming language together with operating systems support for object sharing and persistence. Remote procedure calls, which are used in client-server communication, are replaced by remote method invocation in distributed object systems. *See* OBJECT-ORIENTED PROGRAMMING.

The state of an object consists of the values of its instance variables. In the object-oriented paradigm, the state of a program is partitioned into separate parts, each of which is associated with an object. Since object-based programs are logically partitioned, the physical distribution of objects into different processes or computers in a distributed system is a natural extension. The Object Management Group's Common Object Request Broker (CORBA) is a widely used standard for distributed object systems. Other object management systems include the Open Software Foundation's Distributed Computing Environment (DCE) and Microsoft's Distributed Common Object Manager (DCOM).

CORBA specifies a system that provides interoperability among objects in a heterogeneous, distributed environment in a way that is transparent to the programmer. Its design is based on the Object Management Group's object model.

This model defines common object semantics for specifying the externally visible characteristics of objects in a standard and implementation-independent way. In this model, clients request services from objects (which will also be called servers) through a well-defined interface. This interface is specified in Object Management Group Interface Definition Language (IDL). The request is an event, and it carries information including an operation, the object reference of the service provider, and actual parameters (if any). The object reference is a name that defines an object reliably.

The central component of CORBA is the object request broker (ORB). It encompasses the entire communication infrastructure necessary to identify and locate objects, handle connection management, and deliver data. In general, the object request broker is not required to be a single component; it is simply defined by its interfaces. The core is the most crucial part of the object request broker; it is responsible for communication of requests.

The basic functionality provided by the object request broker consists of passing the requests from clients to the object implementations on which they are invoked. In order to make a request, the client can communicate with the ORB core through the Interface Definition Language stub or through the dynamic invocation interface (DII). The stub represents the mapping between the language of implementation of the client and the ORB core. Thus the client can be written in any language as long as the implementation of the object request broker supports this mapping. The ORB core then transfers the request to the object implementation which receives the request as an up-call through either an Interface Definition Language (IDL) skeleton (which represents the object interface at the server side and works with the client stub) or a dynamic skeleton (a skeleton with multiple interfaces).

Many different ORB products are currently available; this diversity is very wholesome since it allows the vendors to gear their products toward the specific needs of their operational environment. It also creates the need for different object request brokers to interoperate. Furthermore, there are distributed and client-server systems that are not CORBA-compliant, and there is a growing need to provide interoperability between those systems and CORBA. In order to answer these needs, the Object Management Group has formulated the ORB interoperability architecture.

The interoperability approaches can be divided into mediated and immediate bridging. With mediated bridging, interacting elements of one domain are transformed at the boundary of each domain between the internal form specific to this domain and some other form mutually agreed on by the domains. This common form could be either standard (specified by the Object Management Group, for example, Internet Inter-ORB Protocol or IIOP), or a private agreement between the two parties. With immediate bridging, elements of interaction are transformed directly between the internal form of one domain and the other. The second solution has the potential to be much faster, but is the less general one; it therefore should be possible to use both. Furthermore, if the mediation is internal to one execution environment (for example, TCP/IP), it is known as a full bridge; otherwise, if the execution environment of one object request broker is different from the common protocol, each object request broker is said to be a half bridge. [M.Y.E.]

Distributed systems (control systems)

Collections of modules, each with its own specific function, interconnected to carry out integrated data acquisition and control.

Industrial control systems have evolved from totally analog systems through centralized digital computer-based systems to multilevel, distributed systems. Originally, industrial control systems were entirely analog, with each individual process variable controlled by a single feedback controller. Although analog control systems were simple and reliable, they lacked integrated information displays for the process operator.

In supervisory control, the analog portion of the system is implemented in a traditional manner (including analog display in the central operating room), but a digital computer is added which periodically scans, digitizes, and inputs process variables to the computer. The computer is used to filter the data, compute trends, generate specialized displays, plot curves, and compute unmeasurable quantities of interest such as efficiency or quality measures. Once such data are available, optimal operation of the process may be computed and implemented by using the computer to output set-point values to the analog controllers. This mode of control is called supervisory control because the computer itself is not directly involved in the dynamic feedback. *See* DIGITAL COMPUTER.

Direct digital control replaces the analog control with a periodically executed equivalent digital control algorithm carried out in the central digital computer. A direct digital control system periodically scans and digitizes process variables and calculates the change required in the manipulated variable to reduce the difference between the set point and the process variable to zero. *See* ALGORITHM.

The advantages of direct digital control are the ease with which complex dynamic control functions can be carried out and the elimination of the cost of the analog controllers themselves. To maintain the attractive display associated with analog control systems, the display portion of the analog controller is usually provided. Thus operation of the process is identical to operation of digital supervisory control systems with analog controllers, except that "tuning" of the controllers (setting of gains) can be done through operator consoles.

The cost reduction which resulted from the introduction of direct digital control was offset by a number of disadvantages. The most notable of these were the decrease in reliability and the total loss of graceful degradation. Failure of a sensor or transmitter had the same effect as before, but failure of the computer itself threw the entire control system into manual operation. Hence it was necessary to provide analog controllers to back up certain critical loops which had to function even when the computer was down.

Increasing demand for ever-higher levels of supervisory control highlighted two disadvantages of centralized digital computer control of processes. First, process signals were still being transmitted from the process sensor to the central control room in analog form, meaning that separate wires had to be installed for every signal going to or from the computer. Second, the digital computer system itself evolved into a very complex unit because of the number of devices attached to the computer and because of the variety of different programs needed to carry out the myriad control and management functions. The latter resulted in the need for an elaborate real-time operating system for the computer which could handle resources, achieve desired response time for each task, and be responsible for error detection and error recovery in a highly dynamic real-time environment. Design coding, installation, and checkout of centralized digital control systems was so costly and time-consuming that application of centralized digital control was limited.

Low-cost electronic hardware utilizing large-scale integrated circuits provided the technology to solve both of these problems while retaining the advantages of centralized direct digital and supervisory control. The solution, distributed control, involved distributing control functions among hardware modules to eliminate the critical central computer. *See* INTEGRATED CIRCUITS.

The combination of reliable, responsive distributed control and general-purpose communication networks leads to a system which can be adapted to critical control applications in a very flexible manner, with potential for increased productivity in plants, increased safety, and decreased energy consumption. Technology for higher-speed computation, data communication, and object-oriented software organization allows the integration of distributed control systems into plant-wide and enterprise-wise systems. *See* CONTROL SYSTEMS; DIGITAL CONTROL; MULTILEVEL CONTROL THEORY; OBJECT-ORIENTED PROGRAMMING. [J.D.S.]

Distribution (probability) The results of a series of independent trials, random variables, or errors often occur in fairly regular and predictable patterns that can be expressed mathematically. The most important of them are called the binomial, normal, and Poisson distributions.

Consider n independent trials, each of which results in success S or failure F, with corresponding probabilities p and $q = 1 - p$. Denote by S_n the number of successes. Because there are $\binom{n}{k}$ possible ways to select k places for S and $n - k$ places for F, the probability distribution of the random variable S_n is given by

$$P\{S_n = k\} = \binom{n}{k} p^k q^{n-k}$$

where $k = 0, 1, \ldots, n$. This is the binomial distribution. Its expectation is np, its variance npq. *See* PROBABILITY.

The standard normal density is defined for $-\infty < x < \infty$ by

$$\phi(x) = (2\pi)^{-1/2} e^{-x^2/2}$$

The standard normal distribution function or error function $\Phi(x)$ is its integral from $-\infty$ to x. The normal distribution function with mean m and variance s^2 is $\Phi[(x - m)/s]$; its density is $2\pi^{-1/2} s^{-1} e^{-(x-m)^2/(2s^2)}$. As x goes from $-\infty$ to ∞, the function increases from 0 to 1. It plays an important role in many fields. In particular, $u(t,x;\xi) = 2\pi^{-1/2} t^{-1/2} e^{-(x-\xi)^2/(4t)}$ is the fundamental solution of the heat (or diffusion) equation $u_t = u_{xx}$ and represents the heat distribution on the x axis at time t caused by a unit heat source initially concentrated at $x = \xi$. Probabilistically, this represents the transition probabilities in the Wiener process. A random variable whose distribution is normal is called normal or Gaussian. Many empirical quantities (for example, the amount of water in a reservoir, certain inherited characteristics such as height, and the experimental error of physical measurements) represent the cumulative effect of many small components, and the statistical fluctuations of such quantities may be expected to follow the normal distribution

The Poisson distribution with parameter λ is the probability distribution of a random variable assuming the values 0, 1, 2,. . . with probabilities $p_k(\lambda) = e^{-\lambda}\lambda^{k/}K!$ Both its expectation and variance equal λ. This is one of the most important distributions; it plays a basic role in the theory of stochastic processes and in many applications.

Consider a large number n of independent trials, each of which results in success or failure with probabilities p and $q = 1 - p$. Ordinarily, interest is restricted to the case where p is very small, but the expected number of successes $np = \lambda$ is of moderate size. Typical examples may be obtained by considering centenarians, color-blind people, or triplets in a large population. The number of successes in the n trials is a random variable with the binomial distribution, but under the present circumstances the binomial is close to the Poisson distribution and may be replaced by it. In fact, the probability of no success is $q^n = (1 - \lambda/n)^n$, which is close to $e - \lambda$, the first term of the Poisson distribution.

In other circumstances the Poisson distribution appears, not as an approximation, but as the exact expression of a law of nature. This is true in particular of processes where certain events, such as radioactive disintegrations, mutations, power failures, and accidents, occur in time in such a way that (1) the probability that an event occurs during any given time interval of length dt is, asymptotically, λdt and (2) there is no interaction or aftereffect between nonoverlapping time intervals. A similar argument applies to random distributions of points in space, with t interpreted as volume; typical examples are stars, flaws of material, raisins in a cake, and animal litters in a field. *See* ANALYSIS OF VARIANCE; STATISTICS. [W.F.]

District heating The supply of heat, either in the form of steam or hot water, from a central source to a group of buildings. Most district heating systems in the United States rely on separate steam generation facilities close to load centers. In some cities, notably New York, high-pressure district steam is used extensively to feed turbines that drive pumps and refrigerant compressors. Although some district heating plants serve detached residences, the cost of underground piping and the small quantities of heating service required makes this service generally unfeasible. District heating, apart from utility-supplied systems in downtown areas of cities, is accepted as efficient practice in many colleges, universities, and government complexes.

In Europe, a substantial part of the heat distribution is by hot water from plants combining power and heat generation. Hot water distribution systems have the advantage of high thermal mass (hence, storage for peak periods) and freedom from problems of condensate return. On the other hand, pumping costs are high and two mains are required, supply and return. *See* COMFORT HEATING. [R.L.K.]

Diving Skin diving, scuba diving, saturation diving, and "hard hat" diving are techniques used by scientists to investigate the underwater environment. Skin diving is usually without breathing apparatus and is done with fins and faceplate. The diver's underwater observation is limited to the time that breath can be held (1–2 min). Diving with scuba (self-contained underwater breathing apparatus) and "hard hat" provide the diver with a breathable gas, thus expanding the submerged time and the depth range of underwater observations. This type of diving is limited by human physiology and the diver's reaction to the pressure and nature of the breathing gas. Saturation diving permits almost unlimited time down to depths of 100 ft (30 m).

Scuba diving. Scuba is used by trained personnel as a tool for direct observation in marine research and underwater engineering. This equipment is designed to deliver through a demand-type regulator a breathable gas mixture at the same pressure as that exerted on the diver by the overlying water column. The gas which is breathed is carried in high-pressure cylinders (at starting pressures of 2000–3000 psi or 14–20 megapascals) worn on the back.

Scuba can be divided into three types: closed-circuit, semiclosed-circuit, and open-circuit. In the first two, which use pure oxygen or various combinations of oxygen, helium, and nitrogen, exhaled gas is retained and passed through a canister containing a carbon dioxide absorbent for purification and then recirculated to a bag worn by the diver. During inhalation additional gas is supplied to the bag by various automatic devices from the high-pressure cylinders. These two types of equipment are much more efficient than the open-circuit system, in which the exhaled gas is discharged directly into the water after breathing. Most open-circuit systems use compressed air because it is relatively inexpensive and easy to obtain. Although open-circuit scuba is not as efficient as the other types, it is preferred because of its safety, the ease in learning its use, and its relatively low cost.

For physiological reasons scuba diving is limited to about 165 ft (50 m) of water depth. Below this depth when using compressed air as a breathing gas, the diver is limited, not by equipment, but by the complex temporary changes which take place in the body chemistry while breathing gas (air) under high pressure.

Saturation diving. This type of diving permits long periods of submergence (1–2 weeks). It allows the diver to take advantage of the fact that at a given depth the body will become fully saturated with the breathing gas and then, no matter how long the submergence period, the decompression time needed to return to the surface will not be increased. Using this method, the diver can live on the bottom and make detailed measurements and observations, and work with no ill effects. This type of diving requires longer periods of decompression in specially designed chambers to free the diver's body of the high concentration of breathing gas. Decompression times of days or weeks (the time increases with depth) are common on deep dives of over 200 ft (60 m). [R.F.Di.]

Physiology. Environmental effects on the submerged diver are quite different from those experienced at sea level. Two elements are very evident during the dive. As the depth of surrounding water increases, pressure on the air the diver breathes also increases. In addition, as the pressure increases, the solubility of the gases in the diver's tissues increases. The tissues, therefore, accumulate certain gases which are not metabolized. The increased presence of certain gases causes specific and often dangerous physiological effects.

The total pressure of the atmosphere at sea level is approximately 760 mmHg or 30.4 in. Hg. Pressure increases underwater at the rate of 1 atm (10 kilopascals) for each 33 ft (10 m) that the diver descends. The total pressure applied to the body and to the breathing gas increases proportionately with depth. As pressure of the gas increases, the amount of gas that is absorbed by the body increases. This is particularly evident if the diver is breathing air within a caisson since the percentage of nitrogen in the breathing gas increases proportionately to the amount of oxygen that is removed. Likewise, the amount of carbon dioxide in the body increases during the dive, particularly if the exhaled air is not separated from the inhaled air.

One of the more obvious effects of gases on divers is caused by nitrogen. This gas makes up about 78% of the air that is normally breathed, and its solubility in the tissues increases as atmospheric pressure increases. When nitrogen is dissolved in the body, more than 50% is contained in the fatty tissues; this includes the myelin sheaths which surround many nerve cells. When divers undergo increased pressure, amounts of nitrogen in nerve tissue increase and lead to nitrogen narcosis or "rapture of the deep." Nitrogen narcosis can occur at 415 ft (130 m) or 5 atm (500 kPa), and increases in severity as the diver descends below this depth. The irrational behavior and euphoria often seen in nitrogen narcosis can result in serious, even deadly mistakes during a dive. The maximum time that divers can remain underwater without showing symptoms decreases with increasing depth.

One of the earlier recognized problems associated with human diving is known as decompression sickness, the bends, or caisson disease. If a diver is allowed to stay beneath the surface for long periods of time, the volume of dissolved gases in the tissues will increase. This is particularly true of nitrogen in the case of air breathing. When nitrogen accumulates in the tissues, it remains in solution as long as the pressure remains constant. However, when pressure decreases during the ascent, bubbles form in the tissues. Nitrogen bubbles can occur in nerves or muscles and cause pain, or they can occur in the spinal cord or brain and result in paralysis, dizziness, blindness, or even unconsciousness. Bubbles forming in the circulatory system result in air embolism. If the embolism occurs in the circulation of the lungs, a condition known as the chokes occurs. *See* DECOMPRESSION ILLNESS.

A method of prevention of decompression sickness was suggested by J. S. Haldane in 1907. Haldane introduced the method of stage decompression, in which the diver is allowed to ascend a few feet and then remain at this level until the gases in the tissues have been allowed to reequilibrate at the new pressure. This stepwise ascent is continued until the diver finally reaches the surface. A modern variation of this method consists of placing the diver in a decompression chamber after the surface is reached, to allow for periods of decompression which simulate ocean depths. [J.H.F.]

Diving animals Truly aquatic animals have no need for a specialized diving response, because they are able to obtain oxygen directly from the water and thus sustain themselves indefinitely in the aquatic medium. Terrestrial or land animals, on the other hand, have in many cases gone back to the aquatic mode of living in varying degrees. In all of these has arisen the problem of obtaining the necessary gas exchange in an aquatic environment with only the physical attributes of a terrestrial animal. Many of these terrestrial animals have adapted so well as to achieve almost perfect freedom in the water.

All classes of terrestrial vertebrates (birds, mammals, and reptiles) have species which spend part of their lives under water or seek food or shelter by becoming submerged for a period of time. One example, a fresh-water mammalian species, is the North American beaver. One of the first changes noted in these and other animals that normally dive beneath the surface of the water is a reduction in heart rate, called bradycardia. However, those animals which traditionally utilize an aquatic habitat show a more pronounced reduction in heart rate in a much shorter time. In the other two classes of animals which contain divers, the reptiles and birds, some excellent examples reflect reductions in heart rate similar to the rates seen in mammals.

Warm-blooded animals show a more rapid response to submergence than do reptilian species. Those mammals, such as seals, which are traditionally found in open-ocean environments show the most dramatic responses of all. The reptiles in general utilize less oxygen than do warm-blooded animals and have slower resting heart rates, so that their response would be expected to be less spectacular. Also, reptilian reaction times are generally slower than those seen in mammals, and are usually modified by the temperature of the water in which they dive, so that a slower response to the diving stimulus is expected.

Specifically, the diving response enables the animal to remain underwater for longer periods of time. Not only does the heart rate slow down, but blood flow to specific muscles is decreased or stopped altogether. Lactic acid produced as a result of anaerobic glycolysis in muscles thus isolated is less likely to enter the systemic circulation and alter the functions of vital organs such as the brain and heart. This response also reduces the likelihood that hydrogen ions will build up in the blood and stimulate chemoreceptors (receptors which respond to changes in blood carbon dioxide levels and hydrogen ion concentration) which control breathing. Blood flow thus remains constant and unrestricted to the most essential organs, such as brain, heart, and lungs, during the dive, and arterial pressure to these organs remains at the normal level, so that perfusion of the capillaries with blood is not altered.

Other changes in the bodies of divers are also apparent, but are seen as changes in total body chemistry. For instance, glycogen and adenosinetriphosphate, which are the principal energy sources of muscles, are in more than ample supply in divers, and appear to have been stored for that time when they are most needed. Oxygen stores are essential to the length of time that a diver may stay submerged, and diving animals have concentrations of myoglobin in their muscles which gives them a remarkable ability to store oxygen. *See* DIVING. [J.H.F.]

Division In arithmetic and algebra, the process of finding one of two factors of a number (or polynomial) when their product and one of the factors are given. The symbol ÷ is used in elementary English and American arithmetics to denote division. Division is more often symbolized by the double dot :, the bar —, or the solidus /; thus $x ; y$, $\frac{x}{y}$, or x/y indicates division of a number x by a number y. Considered as an operation inverse to multiplication, x/y is a symbol denoting a number whose product with y is x. Another way to base division upon multiplication is provided by the concept of the reciprocal of a number. If y is any number (real or complex) other than 0, there is a number, denoted by $1/y$ and called the reciprocal of y, whose product with y is 1. Then x/y is the symbol for the product of x and $1/y$. This view of division furnishes a means of extending the concept to objects other than real or complex numbers. *See* ALGEBRA; MULTIPLICATION. [L.M.Bl]

Docodonta One of the most primitive mammalian orders known, found in the Jurassic of North America and England and possibly in Rhaetic deposits. In docodonts the main jaw articulation was formed by the dentary and squamosal bones, but the articular and quadrate bones formed a secondary jaw articulation. Early members of other Mesozoic orders possessed the same double articulation, but by Late Jurassic time only the docodonts still retained this transitional reptile-mammal condition. *See* MAMMALIA. [M.C.McK.]

Dogs All breeds of domestic dogs, the wild dogs, and related species belong to the family Canidae. Despite the various breeds of domestic dogs which are known, the scientific name for all is *Canis familiaris*. The origin of domestic dogs is obscure, but they seem to be most closely related to the wolf. In many respects the dog is structurally primitive and shows a genetic plasticity which accounts for the many varieties.

Domestic breeds. There are more than 100 breeds of domestic dogs, and their classification is based principally on their uses. The domestic breeds are the sporting breeds, hounds, terriers, working breeds, and the toy breeds.

The sporting breeds are trained and employed for retrieving or finding game. The largest group in this class is the spaniels, of which there are about 10 types. The spaniels have been trained to retrieve and to flush game, and they hunt both birds and fur-bearing animals. Retrievers are specially trained to locate and return game to hunters and are used most commonly in hunting waterfowl. There are four varieties: the curly, the Chesapeake Bay, the golden retriever, and the Labrador. Pointers and setters, used for hunting upland game birds, range ahead of the hunter, point the game until the hunter arrives, and retrieve the fowl after it has been flushed and shot. Among the varieties that are used in these pursuits are the Weimeraner, the English and Irish setters, and the German short-haired pointer.

The hound group includes the basset, the bloodhound, the whippet, the dachshund, the wolfhound, and the beagle. The greyhound, one of the oldest breeds, is built for speed with its thin body and long legs. The bloodhounds and foxhounds (smaller, stockier dogs) are used for hunting, mostly by scent. The beagle, now more a pet than a hunter, can also follow a scent and is easier to follow on foot.

The terriers originally were bred for hunting burrowing animals, such as the badger and fox. The Boston terrier is the only breed to have originated in the United States. The fox terrier, typical of the group, may have been derived from the foxhound. It was originally bred for fox hunting but is an excellent ratter. Other terriers are the Airedale, largest of the group, and the Scottish and Skye terriers.

Most of the working breeds are large animals used as draught animals, for police work, for herding, and as guide dogs for the blind. Other draught breeds are the Alaskan malamute, the Eskimo, and the Samoyed. Among the animals used as guard dogs and for police work are the Doberman, the German shepherd, and the Great Dane. The collies, Belgian sheep dogs, and English sheep dogs are outstanding sheep herders. The bulldog is now more of a pet and house dog than a guard dog, but it is pugnacious if set on an intruder and will not release the person. The poodle, said to be the most intelligent dog, can be trained as a gun dog and was originally used for duck shooting.

Some of the toy breeds have been known for centuries and are principally household pets which may develop an instinct for protecting the premises of the owner. They are all quite small, some being miniatures of the larger breeds. The chihuahua is the smallest. Some of the more popular varieties are the Pomeranian, Pekingese, and pug.

Wild species. The wild species of the family, numbering about 36 and having a wide distribution, include several wild dogs, wolves, coyotes, foxes, and jackals. There are a number of wild dogs which have never been domesticated, unlike the dingo of Australia (*Canis dingo*) that is believed to have been a domestic dog introduced into Australia during prehistoric times and then reverted to its wild state. The Asiatic wild dog occurs throughout Asia, Java, and Sumatra and is considered to be three distinct species by some authorities while others regard it as two subspecies of *Cuon alpinus*, which is also known as the Siberian wild dog. The Cape hunting dog (*Lycaon pictus*) ranges throughout the grasslands of eastern and southern Africa but has become reduced in numbers.

The common European wolf (*Canis lupus*) is the species that once ranged throughout the temperate forested regions of Europe, Asia, and North America. This species has been exterminated in the British Isles and almost so in France, but they do occur in other European countries such as Italy, Spain, and the Balkans and are still plentiful in the Scandinavian countries. The gray wolf or timber wolf, originally extremely common in North America, is now restricted to Alaska and the subarctic regions of Canada.

The coyote (*Canis latrans*) is sometimes called the prairie wolf and is a close relative of the true wolf, although it is smaller than the wolves. They inhabit the prairies, open plains, and desert areas of North America.

Jackals are scavengers as well as menaces to domestic poultry. Both the oriental jackal (*Canis aureus*), the most widely distributed jackal, and the black-backed jackal (*C. mesomelas*) can be easily tamed. *Canis aureus* has spread from southeastern Europe and northern Africa through Asia as far south as Burma. It prefers higher elevations in contrast to *C. mesomelas*, which is found in the grasslands of eastern and southern Africa.

Foxes have relatively short legs and long bodies, big erect ears, pointed snouts, and long bushy tails. The Old World red fox (*Vulpes vulpes*) is closely related to, but is smaller than, the American red fox (*V. fulva*), which is found throughout North America. The American species has undergone many color phases and mutations and includes other varieties such as the silver fox and the cross fox. Scent glands are present in the anal region, which account for the characteristic odor of these animals. *See* CARNIVORA; MAMMALIA; SCENT GLAND. [C.B.C.]

Dogwood A tree, *Cornus florida*, also known as flowering dogwood, which may reach a height of 40 ft (12 m) and is found in the eastern half of the United States and in southern Ontario, Canada. It has opposite, simple, deciduous leaves with entire margins. When this tree is in full flower, the four large, white, notched bracts or petallike growths surrounding the small head of flowers give an ornamental effect. Pink, rose, and cream-colored varieties are commonly planted. The wood is very hard and is used for roller skates, carpenters' planes, and other articles in which hardness is desired. The Pacific dogwood (*C. nuttalli*), which grows in Idaho and from southwestern British Columbia to southern California, is similar to the eastern dogwood, but has rounded bracts. The Japanese dogwood (*C. kousa*) is a similar small tree with pointed bracts and blooms in June. Other shrubby species of dogwood are used as ornamentals. *See* CORNALES; FOREST AND FORESTRY; TREE. [A.H.G.; K.P.D.]

Dolerite A fine-textured, dark-gray to black igneous rock composed mostly of plagioclase feldspar (labradorite) and pyroxene and exhibiting ophitic texture. It is commonly used for crushed stone. Its resistance to weathering and its general appearance make it a first-class material for monuments. *See* STONE AND STONE PRODUCTS.

The most diagnostic feature is the ophitic texture, in which small rectangular plagioclase crystals are enclosed or partially wrapped by large crystals of pyroxene. As the quantity of pyroxene decreases, the mineral becomes more interstitial to feldspar. The rock is closely allied chemically and mineralogically with basalt and gabbro. As grain size increases, the rock passes into gabbro; as it decreases, diabase passes into basalt. *See* BASALT; GABBRO.

Diabase forms by relatively rapid crystallization of basaltic magma (rock melt). It is a common and extremely widespread rock type. It forms dikes, sills, sheets, and other small intrusive bodies. The Palisades of the Hudson, near New York City, are formed of a thick horizontal sheet of diabase. In the lower part of this sheet is a layer rich in the mineral olivine. This concentration is attributed by some investigators to settling of heavy olivine crystals through the molten diabase and by others to movement of early crystals away from the walls of the passageway along which the melt flowed upward from depth, before it spread horizontally to form the sill. *See* MAGMA.

As defined, diabase is equivalent to the British term dolerite. The British term diabase is an altered diabase in the sense defined here. *See* BASALT; GABBRO; IGNEOUS ROCKS. [C.A.C.]

Dolomite The carbonate mineral $CaMg(CO_3)_2$. Often small amounts of iron, manganese, or excess calcium replace some of the magnesium; cobalt, zinc, lead, and barium are more rarely found. Dolomite is normally white or colorless with a specific gravity of 2.9 and a hardness of 3.5–4 on Mohs scale. It can be distinguished from calcite by its extremely slow reaction with cold dilute acid. Dolomite is a very common mineral, occurring in a variety of geologic settings. It is often found in ultrabasic igneous rocks, notably in carbonatites and serpentinites, in metamorphosed carbonate sediments, where it may recrystallize to form dolomite marbles, and in hydrothermal veins. The primary occurrence of dolomite is in sedimentary deposits, where it constitutes the major component of dolomite rock and is often present in limestones. *See* DOLOMITE ROCK; LIMESTONE; SEDIMENTARY ROCKS. [A.M.G.]

Dolomite rock Sedimentary rock containing more than 50% by weight of the mineral dolomite [$CaMg(CO_3)_2$]. The term dolostone is used synonymously. Since dolomites usually form by replacement of preexisting limestones, it is often possible to see relict grains, fossils, and sedimentary structures preserved in dolomite rocks. More often, however, original textures are obliterated. *See* DOLOMITE; LIMESTONE.

Field differentiation of dolomite from calcite ($CaCO_3$) is most easily accomplished by application of dilute hydrochloric acid. Calcite is strongly effervescent in acid, whereas dolomite is usually very weakly effervescent unless scratched or ground into a fine powder. Dolomite also often weathers to a brown color on outcrop because of the common substitution of iron for magnesium in the dolomite structure. X-ray diffraction analysis is the most reliable method for the differentiation of dolomite from calcite, and also the best method for characterization of the degree of ordering of a particular dolomite sample. *See* X-RAY DIFFRACTION.

Dolomite rocks are predominantly monomineralic. The most common noncarbonate minerals are quartz (either authigenic or detrital), clay minerals, pyrite, and glauconite. Evaporite minerals or their replacements are also common.

Geologists have been unable to decipher the exact conditions of dolomite formation. This so-called dolomite problem revolves around several questions relating to the stoichiometry of the reaction in which dolomite is formed, the fact that dolomite is not common in young marine sediments, and the type of geological setting in which ancient dolomites formed.

The relative proportions of dolomite and calcite have changed through geologic time. Dolomitic rocks are dominant in the Precambrian and early Paleozoic, whereas calcitic rocks become dominant in the late Mesozoic and continue to dominate through the present. Several alternative hypotheses have been offered to explain this.

In a few geological settings, dolomite is forming within the sediments at the present time. One general setting includes a wide variety of supratidal ponds, lagoons, tidal flats, and sabkhas such as the Solar Lake in Israel, the Coorong Lagoon in Australia, the bank tops of Andros Island in the Bahamas, and the Sabkha of Abu Dhabi. Each of these environments is hot, more saline than seawater, and rich in organic matter. A second general setting of modern dolomite formation is in continental margin sediments underlying productive coastal oceanic upwelling zones. Examples include the Peru-Chile margin, the southern California borderlands, the Gulf of California, and the Walvis Ridge west of Namibia (southwestern Africa). This second set of geological environments is characterized by lower water temperature and normal marine salinity. Like the first set, these environments are rich in organic matter. The association of dolomite formation with abundant organic carbon seems to be the one common thread linking each dolomite occurrence and possibly controlling dolomite precipitation.

Dolomites are extremely important oil reservoir rocks. This is partly a result of the high porosity of many dolomite rocks and partly the result of the association between dolomite formation and the presence of sedimentary organic matter.

Dolomites are also the main host rocks for lead and zinc ore deposits. Rocks of this type are known as Mississippi Valley ore deposits. Neither the origin of the ore-forming solutions nor the association between the lead-zinc ores and the dolomite rocks has been satisfactorily explained. *See* PETROLEUM GEOLOGY; SEDIMENTARY ROCKS. [P.A.B.]

Domain (electricity and magnetism) A region in a solid within which elementary atomic or molecular magnetic or electric moments are uniformly aligned.

Ferromagnetic domains are regions of parallel-aligned magnetic moments. Each domain may be thought of as a tiny magnet pointing in a certain direction. The relatively thin boundary region between two domains is called a domain wall. Within a wall the magnetic moments rotate from the direction of one of the domains to the direction in the adjacent domain.

A ferromagnet generally consists of a large number of domains. For example, a sample of pure iron at room temperature contains many domains whose directions are distributed randomly, making the sample appear to be unmagnetized as a whole. Iron is called magnetically soft since the domain walls move easily if a magnetic field is applied. In a magnetically hard or permanent magnet material a net macroscopic magnetization is introduced by exposure to a large external magnetic field, but thereafter domain walls are difficult to either form or move, and the material retains its overall magnetization.

Antiferromagnetic domains are regions of antiparallel-aligned magnetic moments. They are associated with the presence of grain boundaries, twinning, and other crystal inhomogeneities.

Ferroelectric domains are electrical analogs of ferromagnetic domains. *See* ANTIFERROMAGNETISM; FERROELECTRICS; FERROMAGNETISM; MAGNETIC MATERIALS; MAGNETIZATION; TWINNING (CRYSTALLOGRAPHY). [J.F.He.]

Dominance The expression of a trait in both the homozygous and the heterozygous condition. In experiments with the garden pea, the Austrian botanist Gregor Mendel crossed plants from true-breeding strains containing contrasting sets of characters. For seed shape, round and wrinkled strains were used. When plants with round seeds were crossed to plants with wrinkled seeds (P_1 generation), all offspring had round seeds. When the offspring (F_1 generation) were self-crossed, 5474 of the resulting F_2 offspring were round and 1850 were wrinkled. Thus, the round trait is expressed in both the F_1 and F_2 generations, while the wrinkled trait is not expressed in the F_1 but is reexpressed in the F_2 in about one-fourth of the offspring. In reporting these results in a paper published in 1866, Mendel called the trait which is expressed in the F_1 generation a dominant trait, while the trait which is unexpressed in the F_1 but reappears in the F_2 generation was called a recessive trait. *See* MENDELISM.

Traits such as round or wrinkled are visible expressions of genes. This visible expression of a gene is known as the phenotype, while the genetic constitution of an individual is known as its genotype. The alternate forms of a single gene such as round or wrinkled seed shape are known as alleles. In the P_1 round plants, both alleles are identical (since the plant is true-breeding), and the individual is said to be homozygous for this trait. The F_1 round plants are not true-breeding, since they give rise to both round and wrinkled offspring, and are said to be heterozygous. In this case, then, the round allele is dominant to the wrinkled, since it is expressed in both the homozygous and heterozygous condition. Dominance is not an inherent property of a gene or an allele, but instead is a term used to describe the relationship between phenotype and genotype. *See* ALLELE; GENE ACTION.

The production of phenotypes which are intermediate between those of the parents is an example of partial or incomplete dominance. The phenomenon of incomplete dominance which results in a clear-cut intermediate phenotype is relatively rare. However, even in cases where dominance appears to be complete, there is often evidence for intermediate gene expression.

The separate and distinct expression of both alleles of a gene is an example of codominance. This is a situation unlike that of incomplete dominance or complete dominance. In humans, the MN blood group is characterized by the presence of molecules called glycoproteins on the surface of red blood cells. These molecules or antigens contribute to the immunological identity of an individual. In the MN blood system, persons belong to blood groups M, MN, or N. These phenotypes are produced by two alleles, M and N, each of which controls the synthesis of a variant glycoprotein. In the heterozygote MN, there is separate and complete expression of each allele. This is in contrast to incomplete dominance, where there is an intermediate or blending effect in heterozygotes. Codominance usually results in the production of gene products of both alleles. *See* BLOOD GROUPS.

Individuals in which the phenotype of the heterozygote is more extreme than in either of the parents are said to exhibit overdominance. The concept of overdominance is important in understanding the genetic structure of populations and is usually related to characteristics associated with fitness, such as size and viability.

The production of superior hybrid offspring by crossing two different strains of an organism is known as heterosis. The hybrid superiority may take the form of increased resistance to disease or greater yield in grain production. The mechanism which results in heterosis has been widely debated but is still unknown. *See* BREEDING (PLANT); HETEROSIS.

A physiological explanation of dominance was put forward by S. Wright in 1934. He argued that variations in metabolic activity brought about by the heterozygous condition are likely to have little effect on the phenotype because enzymes are linked together in pathways so that the substrate of one enzyme is the product of another. Recessive mutations, when homozygous, may halt the activity of one enzyme and thus bring the entire pathway to a halt, producing a mutant phenotype. Heterozygotes, on the other hand, are likely to have only a reduction in activity of one enzyme which will be averaged out over the entire metabolic pathway, producing little phenotypic effect. Molecular studies of dominance have extended Wright's ideas by exploring the kinetic structure of metabolic pathways and enzyme systems. The results obtained thus far tend to support the thrust of his hypothesis, and have established that the dominant phenotype seen in heterozygotes for a recessive allele can be explained without the need to invoke the existence of modifiers. *See* GENETICS; MOLECULAR BIOLOGY; MUTATION. [M.R.C.]

Donkeys and allies Donkeys, asses, and mules are included in the family Equidae along with the horses and zebras. These are odd-toed ungulates and therefore belong to the mammalian order Perissodactyla.

Donkeys (*Equus asinus*) originated in Africa, and their only relatives in the wild state are found in Ethiopia and Somaliland. They have been domesticated and are used principally as pack animals throughout Asia and Europe. They are hardy animals but better suited to hot climates since they are sensitive to cold.

The wild ass of Asia (*E. hemionus*) is known by a variety of common names, and because of its extensive distribution it has been divided into a number of races or subspecies. In the central regions of Mongolia is the kulan (*E. h. hemionus*), the onager (*E. h. onager*) occurs in Persia and India, while the kiang (*E. h. kiang*), largest of all the races, is restricted to Tibet and the Sikkim. The Syrian wild ass (*E. h. hemippus*) is extremely rare and possibly extinct. The Asian wild asses are the most abundant of the wild Equidae after the zebras. The African wild ass (*E. asinus*) is also becoming rare in its natural habitat, being found only between the Sudan and Somaliland.

The mule is a hybrid resulting from the cross of the male ass (*E. asinus*) and the mare or female horse (*E. caballus*). When the female ass is bred to a stallion, the cross is called a hinny. These crosses do not occur naturally and both mule and hinny are usually sterile. *See* Perissodactyla. [C.B.C.]

Donnan equilibrium The distribution of diffusible ions on either side of a semipermeable membrane in the presence of macro-ions that are too large to pass through the membrane. The Donnan equilibrium thus is the result of (1) external constraints (boundary conditions) that enforce an unequal distribution of mobile ions and (2) a corresponding electrical potential on the membrane as a balance. This equilibrium is named for F. G. Donnan, the first to describe it and formulate the theory.

Typically, within a solution system that consists of two communicating compartments (for example, an inner and outer compartment), the polyions of a macromolecular polyelectrolyte (a colloidal electrolyte) are confined to one compartment (for example, the inner one) by the semipermeable membrane, which allows the exchange of solvent and low-molecular-weight electrolytes by diffusion between the compartments. Since electrical neutrality must obtain in either compartment, and since the macro-ions are confined to one side, the concentration of the diffusible ions in the two compartments cannot be the same. At thermodynamic equilibrium—assuming for simplicity an electrolyte of which both ions are small, carry a charge of 1, and diffuse readily throughout the system in which they are dissolved—the chemical potential (activities) for the outer ionic pair must equal that of the diffusible ion pair on the inside. This condition is fulfilled when the products of the activities are equal, as shown in Eq. (1), where m_o and m_i are the molalities and γ_o and γ_i are

$$m_o^+ m_o^- \gamma_o^\pm = m_i^+ m_i^- \gamma_i^\pm \tag{1}$$

the activity coefficients within the outer and inner compartments, respectively. In dilute solution, the molalities are approximately equal to the molarities, and the activity coefficients are practically equal to 1. The equilibrium of the solvent (whether the nondiffusible species is ionized or not) follows upon flux of the solvent into the (closed) cell that holds the macromolecular solute, until osmotic pressure equalizes the activities of the solvent in both cells. *See* Activity (thermodynamics).

The inequality of the individual ionic concentrations on either side of the membrane means that, at equilibrium, the membrane must carry a charge whose free energy is equal in magnitude and opposite in sign to the free energy that results from the unequal individual activities of the diffusible ions. This is shown in Eq. (2) for a negatively charged nondiffusible polyelectrolyte,

$$\begin{aligned} E &= \frac{RT}{F} \ln \frac{[\mathrm{Na}_i^+]}{[\mathrm{Na}_o^-]} \\ &= \frac{RT}{F} \ln \frac{[\mathrm{Cl}_o^-]}{[\mathrm{Cl}_i^-]} \end{aligned} \tag{2}$$

where E is the potential difference. In other words, the presence of the nondiffusing species on one side of the membrane and the resulting differences in salt concentration enforce a polarization of the membrane (which is independent of the nature of the diffusible ions).

Equation (1) permits the determination of the concentration (activity) of the ions of the same charge as the macro-ions within the inside cell, which is equal to the activity of the ions that have diffused in from the outer cell. It can also be seen that the osmotic pressure of a closed inner cell must be larger than the osmotic pressure that would be caused by the macro-ions alone, by an amount that corresponds to the number of ions that compensate the charges on the macro-ions, plus that of the ions that diffused in; that is, the osmotic pressure depends on the average molecular weight of the nonsolvent components of the inner cell. Therefore, if the salt concentration of the outer cell, and along with it the concentration in the inner cell, is raised, the contribution to the osmotic pressure by the macro-ions becomes relatively smaller and eventually becomes constant, amounting to the osmotic pressure of the macro-ions in their uncharged state. At the same time, the concentrations of the diffusible ions inside and outside approach one another. The same situation obtains in the absence of a membrane, when microscopic gel particles possess covalently bound ionized groups in their interior. Suspended microscopic gel particles, or dense polyelectrolyte coils, may thus carry a charge due to the effect of the Donnan equilibrium. *See* Osmosis.

The Donnan equilibrium is a frequent contributor to membrane potentials, but differential adsorption or, as in living systems, differences in the rates of passive or active ion transport through biological membranes are usually the main sources of membrane potentials of living cells. *See* Colloid; Ion-selective membranes and electrodes. [F.R.E.]

Donor atom An impurity atom in a semiconductor which can contribute or donate one or more conduction electrons to the crystal by becoming ionized and positively charged. For example, an atom of column 5 of the periodic table substituting for a regular atom of a germanium or silicon crystal is a donor because it has one or more valence electrons which can be detached and added to the conduction band of the crystal. Donor atoms thus tend to increase the number of conduction electrons in the semiconductor. The ionization energy of a donor atom is the energy required to dissociate the electron from the atom and put it in the conduction band of the crystal. *See* Acceptor atom; Semiconductor. [H.Y.F.]

Dopamine A catecholamine neurotransmitter that is synthesized by certain neurons in the brain and interacts with specific receptor sites on target neurons.

Dopamine is manufactured inside dopamine neurons in a controlled manner from the amino acid precursor L-tyrosine, which mammals obtain through the normal diet. Dopamine is then stored in vesicles within the nerve terminals, which may fuse with the cell membrane to release dopamine into the synapse.

The release of neurotransmitter is controlled by a variety of factors, including the firing rate of the dopamine nerve cell (termed impulse-dependent release) and the release- and synthesis-modulating presynaptic dopamine receptors located on the dopamine nerve terminals. Since presynaptic dopamine receptors are sensitive to the cell's own neurotransmitter, they are called dopamine autoreceptors. Once released, dopamine also acts at postsynaptic receptors to influence behavior. The actions of dopamine in the synapse are terminated primarily by the reuptake of neurotransmitter into the presynaptic terminal by means of an active dopamine transporter. Dopamine may then be either repackaged into synaptic vesicles for rerelease or degraded by the enzyme monoamine oxidase. The dopamine transporter is an important site of action of the drugs cocaine and amphetamine. *See* SYNAPTIC TRANSMISSION.

Although it was first thought that dopamine occurred only as an intermediate product formed in the biosynthesis of two other catecholamine neurotransmitters, norepinephrine and epinephrine, dopamine is now recognized as a neurotransmitter in its own right. Several distinct dopamine neuronal systems have been identified in the brain. These include systems within the hypothalamus and the pituitary gland; systems within the midbrain that project to a variety of cortical and limbic regions and basal ganglia; the retinal system; and the olfactory system. *See* BRAIN; EPINEPHRINE; NORADRENERGIC SYSTEM.

The midbrain dopamine neurons which project to a variety of forebrain structures are critically involved in normal behavioral attention and arousal; abnormalities in the normal functioning of these systems have been implicated in a variety of disorders. For example, Parkinson's disease involves a degeneration of the midbrain dopamine neurons. This condition is often successfully treated by providing affected individuals with L-dopa, which is readily converted to dopamine in the brain. Attention deficit disorder, which is usually first diagnosed in childhood, is thought to involve dopamine systems, because the treatment of choice, methylphenidate, binds to the dopamine transporter and alters dopamine levels in the synapse. *See* PARKINSON'S DISEASE.

Drugs used to treat the major symptoms of schizophrenia are potent dopamine receptor antagonists. It is possible that certain schizophrenias are the result of increased activity in dopamine neuronal systems, but this has not as yet been conclusively demonstrated. A similar involvement of midbrain dopamine systems has been implicated in the multiple tic disorder Tourette's syndrome, which is treated, often successfully, with dopamine receptor antagonists. *See* NEUROBIOLOGY; SCHIZOPHRENIA. [L.A.C.]

Doppler effect The change in the frequency of a wave observed at a receiver whenever the source or the receiver of the wave is moving relative to the other or to the carrier of the wave (the medium). The effect was predicted in 1842 by C. Doppler, and first verified for sound waves in 1845 from experiments conducted on a moving train.

The Doppler effect for sound waves is now a commonplace experience: If one is passed by a fast car or a plane, the pitch of its noise is considerably higher in approaching than in parting. The same phenomenon is observed if the source is at rest and the receiver is passing it. The linear optical Doppler effect was first observed in 1905 from a shift of spectral lines emitted by a beam of fast ions (canal rays) emerging from a hole in the cathode of a gas discharge tube run at high voltage. Still, their velocity was several orders of magnitude below that of light in vacuum. The precise interferometric experiments of A. A. Michelson and E. W. Morley (1887) showed clearly that the velocity of light is not bound to any ether, but is measured to be the same in any moving system. This result was a crucial check for A. Einstein's theory of special relativity (1905), which also makes a clear prediction for the optical Doppler effect.

The Doppler effect has important applications in remote-sensing, high-energy physics, astrophysics, and spectroscopy.

Let a wave from a sound source or radar source, or from a laser, be reflected from a moving object back to the source, which may itself move as well. Then a frequency shift is observed by a receiver connected to the source. The measurement provides an excellent means for the remote sensing of velocities of any kind of object, including cars, ships, planes, satellites, flows of fluids, or winds. *See* DOPPLER RADAR; REMOTE SENSING.

The light from distant stars and galaxies shows a strong Doppler shift to the red, indicating that the universe is rapidly expanding. However, this effect can be mixed up with the gravitational redshift that results from the energy loss which a light quantum suffers when it emerges from a strong gravitational field.

The Doppler width and Doppler shift of spectral lines in sunlight (Fraunhofer lines) are important diagnostic tools for the dynamics of the Sun's atmosphere, indicating its temperature and turbulence. *See* ASTRONOMICAL SPECTROSCOPY; COSMOLOGY; GRAVITATIONAL REDSHIFT; REDSHIFT; SUN. [E.W.O.]

Doppler radar A radar system used to measure the relative velocity of the system and the radar target. The operation of these systems is based on the fact that the Doppler frequency shift in the target echo is proportional to the radial component of target velocity. *See* DOPPLER EFFECT.

Airborne systems are used to determine the velocity of the vehicle relative to the Earth for such purposes as navigation, bombing, and aerial mapping, or relative to another vehicle for fire control or other purposes. Ground or ship equipment is used to determine the velocity of vehicular targets for fire control, remote guidance, intercept control, traffic control, and other uses.

Doppler navigation radar is a type of airborne Doppler radar system for determining aircraft velocity relative to the Earth's surface. It is generally used with a navigation computer. The signal from a single beam can provide only the velocity component in the direction of that beam. Complete velocity determination requires, therefore, the use of at least three beams. Most systems use four beams for symmetry.

A preferred technique for obtaining coherent detection is to employ sinusoidal frequency modulation. A sideband of the detected beat between echo and transmitter signal is used. Modulation index and rate and the sideband order are chosen such that echoes from nearby objects are rejected, while those from distant objects are accepted. Leakage noise is reduced at the expense of lowered efficiency. [F.B.B.]

Pulse Doppler radars are useful tools for the observation of the movements of precipitation particles. The Doppler frequency shift associated with the velocity of atmospheric targets, such as precipitation particles or artificial chaff, is always a very small fraction (10^{-6} to 10^{-8}) of the radar operating frequency. The observation and measurement of such small frequency shifts require excellent radar system frequency-stability characteristics that are not usually found in conventional radars but can be added without a drastic increase in equipment cost. *See* RADAR. [R.Lh.]

Doppler VOR A vhf omnidirectional radio range (VOR) employing the Doppler principle. If VOR beacons are installed in the vicinity of obstructions, or when aircraft using VOR signals fly over mountainous terrain, the bearing accuracy is deteriorated by reflections (site and enroute errors). The Doppler VOR solves this problem by two fundamental principles maintaining full compatibility of the radiated information with existing airborne receivers. It uses (1) a wide-base antenna array for suppressing the effects of multipath propagation and (2) the Doppler principle for determination of bearing. *See* DOPPLER EFFECT.

Disturbances by multipath propagation can be reduced by wide-aperture systems because of integration or averaging between the information transferred over the direct and the reflected propagation path. Wide-base systems, however, have the drawback that their directional information becomes ambiguous as soon as the aperture is larger than half a wavelength, approximately.

By applying the Doppler principle, one can overcome these limitations. A dipole rotating eccentrically on an orbit periodically changes the distance between transmitter and receiver, thus modulating the frequency of the radiated carrier by a deviation

f_D according to the equation below. Here D is the diameter of

$$f_D = \frac{\text{velocity}}{\text{wavelength}} = \frac{\pi D f_{rot.}}{\lambda}$$

the array and $f_{\text{rot.}}$ is the number of rotations, or revolutions, per second. The resulting Doppler effect produces a sinusoidal frequency modulation of the carrier frequency; the phase of this FM contains the bearing information (variable phase).

The Doppler VOR presents two essential advantages over conventional VOR: the improvement of absolute accuracy in good and poor terrain, and the spectacular radial stability and smoothness even over mountains. [E.Kr.]

Dormancy In the broadest sense, the state in which a living plant organ (seed, bud, tuber, bulb) fails to exhibit growth, even when environmental conditions are considered favorable. In a stricter context, dormancy pertains to a condition where the inhibition of growth is internally controlled by factors restricting water and nutrient absorption, gas exchange, cell division, and other metabolic processes necessary for growth. By utilizing the latter definition, dormancy can be distinguished from other terms such as rest and quiescence which reflect states of inhibited development due to an unfavorable environment.

Physically induced dormancy can be separated into two distinct classes, based on external conditions imposed by the environment (light, temperature, photoperiod) and restraints induced by structural morphology (seed-coat composition and embryo development).

The physical environment plays a key role in dormancy induction, maintenance, and release in several plant species.

1. *Temperature*. The onset of dormancy in many temperate-zone woody species coincides with decreasing temperature in the fall. However, it is the chilling temperature of the oncoming winter which is more crucial, particularly in regard to spring budbreak.

2. *Light duration and quality*. Possibly the single most important environmental variable affecting dormancy is day length or photoperiod. *See* PHOTOPERIODISM.

3. *Water and nutrient status*. Dormancy is affected by the availability of water and nutrients as demonstrated by many grasses, desert species, and subtropical fruits which go into dormancy when confronted by drought or lack of soil fertility. *See* FERTILIZER; PLANT MINERAL NUTRITION; PLANT-WATER RELATIONS.

4. *Environmental interactions*. Several of the factors previously discussed do not simply act independently, but combine to influence dormancy.

Examples of dormancy imposed by physical restrictions are most evident in the structural morphology of dormant seeds. These restrictions specifically pertain to the physical properties of the seed coat and developmental status of the embryo.

1. *Seed-coat factors*. The seed-coat material surrounding embryos of many plants consists of several layers of tissue, termed integuments, which are infiltrated with waxes and oils. In effect these waterproofing agents enable the seed coat to inhibit water absorption by the embryo. This results in a type of seed dormancy very characteristic of legume crops (clover and alfalfa). The environment itself can break this type of seed-coat dormancy through alternating temperature extremes of freezing and thawing. The extreme heat induced by forest fires is especially effective.

Seed-coat-induced dormancy can also result from mechanical resistance due to extremely hard, rigid integuments commonly found in conifer seeds and other tree species with hard nuts.

2. *Embryonic factors*. The morphological state of the embryo is yet another physical factor affecting dormancy. Often the embryo is in a rudimentary stage when the seed is shed from the maternal plant; dormancy will usually cease in these plants as the embryos reach an adequate state of maturation.

Studies dealing with dormancy have resulted in searches for endogenous plant hormones which regulate the process. Studies involving dormant buds of ash (*Fraxinus americana*) and birch (*Betula pubescens*) revealed the presence of high concentrations of a growth inhibitor or dormancy-inducing and -maintaining compound. This compound was later identified as abscisic acid. As buds of these trees began to grow and elongate, the levels of abscisic acid fell appreciably, supporting the role for abscisic acid in the regulation of dormancy. Abscisic acid is also important in the regulation of seed dormancy, as exemplified by seeds of ash in which abscisic acid levels are high during the phase of growth inhibition, but then decline rapidly during stratification, resulting in germination. *See* ABSCISIC ACID.

In conjunction with decreased levels of abscisic acid, the endogenous supply of many growth promoters, such as gibberellins, cytokinins, and auxins, have been reported to rise during budbreak in sycamore (*Acer pseudoplatanus*) as well as in Douglas fir (*Pseudotsuga menziesii*). Levels of these dormancy-releasing compounds also correlate well with the breaking of seed dormancy. The hormonal regulation of dormancy can best be perceived as a balance between dormancy inducers or maintainers and dormancy-releasing agents. *See* AUXIN; CYTOKININS; GIBBERELLIN; PLANT HORMONES.

In addition to endogenous hormones, there are a variety of compounds that can break dormancy in plant species when they are applied exogenously. Many of these substances are synthetic derivatives or analogs of naturally occurring, dormancy-releasing agents.

The physical environment exerts a marked influence on dormancy. The plant, however, needs a receptor system to perceive changes in the environment so it can translate them into physiological responses which in most cases are under hormonal control. In the case of changing day length or photoperiod, phytochrome may serve as a receptor pigment. Phytochrome essentially favors the production of either abscisic acid (short days) or gibberellic acid (long days). Stress conditions, such as limited water or nutrient availability, favor the production of abscisic acid, whereas a period of chilling often promotes synthesis of gibberellic acid and other compounds generally considered as growth promoters. *See* PHYTOCHROME.

The mode of action of endogenous growth regulators can only be postulated at this time. Whatever the specific mechanism, it probably involves the regulation of gene action at the level of deoxyribonucleic acid (DNA) and ribonucleic acid (RNA), which subsequently controls protein synthesis. In this framework, abscisic acid is believed to repress the functioning of nucleic acids responsible for triggering enzyme and protein synthesis needed for growth. Gibberellic acid, on the other hand, promotes synthesis of enzymes essential for germination as in the case of α-amylase production that is crucial for barley seed growth. *See* BUD; NUCLEIC ACID; PLANT GROWTH; SEED. [C.S.M.]

Dormouse The name applied to the 31 species of Old World rodents of the family Gliridae. These animals are

The fat dormouse *Glis glis*.

intermediate between squirrels and rats; they are vegetarians and arboreal like the former, but most have a general appearance like the latter.

The fat dormouse (*Glis glis*; see illustration), the largest member of the family, is found throughout Europe and western Asia. The only species of dormouse native to Britain is the common dormouse (*Muscardinus avellanarius*), which is about the size of a house mouse. Another species, found in central and southern Europe, is the garden dormouse (*Eliomys quercinus*), which is smaller than the fat dormouse but has similar habits. *See* RODENTIA. [C.B.C.]

Dorylaimida An order of nematodes in which the labia are generally well developed; however, many taxa exhibit a smoothly rounded anterior. The labial region is often set off from the general body contour by a constriction. The cephalic sensilla are all located on the labial region. When there is no constriction, the labial region is defined as that region anterior to the amphids. The amphidial pouch is shaped like an inverted stirrup, and the aperture is ellipsoidal or a transverse slit. The stoma is armed with a movable mural tooth or a hollow axial spear. The anterior portion of the tooth or spear is produced by a special cell in the anterior esophagus. The esophagus is divided into a slender, muscular anterior region and an elongated or pyriform glandular/muscular posterior region. There are generally five esophageal glands with orifices posterior to the nerve ring. In some taxa there are three glands, and in others seven have been reported. The esophagointestinal valve is well developed. The mesenteron is often clearly divided into an anterior intestine and a prerectum. Females have one or two reflexed ovaries; when there is only one, the vulva may shift anteriorly. Males have paired equal spicules that are rarely accompanied by a gubernaculum. The males often have the ventromedial preanal supplements preceded by paired adanal supplements.

There are seven dorylaimid superfamilies: Actinolaimoidea, Belondiroidea, Diphtherophoroidea, Dorylaimoidea, Encholaimoidea, Nygolaimoidea, and Trichodoroidea. *See* NEMATA. [A.R.M.]

Dosimeter A device used to measure the dose of ionizing radiation received by an individual. There are many types of dosimeters with varying characteristics and capabilities appropriate for different applications. They differ in sensitivity, energy range, and species of radiation to which they respond. Some can be read out directly by the wearer, while others must be sent to a specially equipped facility to determine the dose.

The air ionization chamber dosimeter is usually about the size and shape of a fountain pen with a clip suitable for carrying in a pocket, and is sometimes referred to as a pen meter or pocket dosimeter. The outside housing is usually made of plastic. Inside, a conductive cylinder and an insulated central electrode form an air-filled capacitor which is charged by connecting to a charging voltage supply. X-rays or gamma rays absorbed in the air space ionize the air, discharging the capacitor in proportion to the dose received. The dose is read by connecting the dosimeter to a quartz fiber or other type of electrometer which reads the charge remaining on the capacitor. *See* CAPACITOR; ELECTROMETER; GAMMA-RAY DETECTORS; IONIZATION CHAMBER; X-RAYS.

The housing of the film badge dosimeter is of plastic or metal, typically 50 mm square (2 in.) by 12 mm (0.5 in.) thick and equipped with a clip for attaching to clothing. It contains one or more film packets, usually standard dental x-ray film packets. The film is developed in a standardized procedure, and the optical density is measured and correlated to exposure, greater exposure being darker. The side of the badge housing is equipped with one or more filters of lead, aluminum, copper, silver, or cadmium which cover different parts of the film and leave part uncovered. These filters modify the response of different areas of the film and thereby provide more information to correct the response to approximate that of tissue. *See* RADIOGRAPHY.

The physical packaging of a thermoluminescent dosimeter can be similar to a film badge with filters incorporated, but the film is replaced by pieces of thermolumiscent materials. Absorbed radiation energy excites electrons of the thermoluminescent material, creating excited metastable states. These states remain excited until the material is subsequently heated to a sufficient temperature, when they deexcite, emitting visible light. The intensity of the emitted light is proportional to the absorbed radiation energy. The exposed material is placed in an automated instrument which heats it in a controlled manner, and the light is measured with a photomultiplier tube and the resulting signal is converted to a dose. If the exposed material is heated sufficiently to anneal all excited states, the dosimeter can be reused. Lithium fluoride is extensively used for thermoluminescent dosimeters, activated with manganese and titanium. *See* PHOTOMULTIPLIER; THERMOLUMINESCENCE.

Usually rectangular in shape, the electronic dosimeter ranges in size from a transistor radio to a pocket pager, though some devices resemble a fountain pen. It contains as sensing element a Geiger-Müller tube along with high-voltage supply, counting and control electronics, and a digital display, all powered by a battery. A wide variety of features are available. For example, a dose alarm can sound when a preset accumulated dose is reached, or a dose-rate alarm can sound when a preset dose rate is exceeded. An electrical connection can be made with a computer for dose recordkeeping. *See* GEIGER-MÜLLER COUNTER.

The active element of a track etch dosimeter is a piece of CR-39 plastic (from Columbia resin 39), made by polymerization of allyl diglycol carbonate. When a high-energy charged particle, such as a proton recoiling from a fast neutron, traverses the material, it gives up energy and leaves a trail of chemical damage. The material is subsequently exposed to a suitable etchant such as sodium hydroxide (NaOH), and damage sites are preferentially etched, leaving pits which can be observed and counted under a microscope. This dosimeter is sensitive only to high-energy neutrons, so it is usually used in conjunction with other dosimeters. *See* PARTICLE TRACK ETCHING.

The operation of the bubble detector dosimeter is based on the change to gas bubbles of superheated liquid (at a temperature above its boiling point) triggered by fast neutron interactions. A commercial bubble detector personal neutron dosimeter consists of a clear plastic tube with an aluminum fitting at one end, about the size of a large pen. It holds about 8 cm^3 (0.5 $in.^3$) of clear, solid elastic polymer containing about 10,000 superheated liquid droplets. On exposure to fast neutrons, small uniform-sized bubbles form. The bubbles are counted visually and a fast neutron dose calculated using a calibration factor determined for that dosimeter. *See* HEALTH PHYSICS. [P.Ry.]

Double diffusion A type of convective transport in fluids that depends on the difference in diffusion rates of at least two density-affecting components. This phenomenon was discovered in 1960 in an oceanographic context, where the two components are heat and dissolved salts. Besides different diffusivities, it is necessary to have an unstable or top-heavy distribution of one component.

In the oceanographic context, if the unstable component is the slower-diffusing one (salt), with the overall gravitational stability maintained by the faster-diffusing component (heat), then “salt fingers” will form. Since warm, salty tropical waters generally overlie colder, fresher waters from polar regions, this is a very common stratification in the mid- to low-latitude ocean. Salt fingers arise spontaneously when small parcels of warm, salty water are displaced into the underlying cold, fresh water. Thermal conduction then removes the temperature difference much quicker than salt diffusion can take effect. The resulting cold, salty water parcel continues to sink because of its greater density. Conversely, a parcel of cold, fresh water displaced upward gains heat but not salt, becoming buoyant and continuing to rise. The fully developed flow has intermingled columns of up- and downgoing fluid, with lateral exchange of heat but not salt, carrying advective vertical fluxes of salt and to a lesser extent heat.

Another form of double-diffusive convection occurs when the faster-diffusing component has an unstable distribution. In the ocean, this happens when cold, fresh water sits above warmer, saltier and denser water. Such stratifications are common in polar regions and in local areas above hot springs at the bottom of the deep sea. *See* OCEAN CIRCULATION; OCEANOGRAPHY; SEAWATER.

The importance of double diffusion lies in its ability to affect water mass structure with its differential transport rates for heat and salt. This is believed to play a significant role in producing certain oceanic water types with well-defined relationships between temperature and salinity. *See* OCEAN CIRCULATION; SEAWATER. [R.W.Sc.]

Douglas-fir A large coniferous tree, *Pseudotsuga menziesii* (formerly *P. taxifolia*), known also as red fir, belonging to the pine family (Pinaceae). It is one of the most widespread and most valuable tree species of western North America and ranks among the world's most important. In the United States, this species is first in total stand volume, lumber production, and veneer for plywood. It is the most common Christmas tree in the West and is the state tree of Oregon. *See* PINALES.

Douglas-fir is a large to very large evergreen tree with narrow pointed crown of slightly drooping branches; at maturity it reaches a height of 80–200 ft (24–60 m) and a trunk diameter of 2–5 ft (0.6–1.5 m). The bark is dark or reddish brown, very thick, deeply furrowed, and often corky. The needlelike leaves spreading mostly in two rows are flat, and flexible, with a very short leafstalk. Buds are distinctive, conical pointed, scaly, and dark red. The cones are elliptical and light brown, with many thin rounded cone-scales, each above a longer distinctive three-pointed bract.

The natural distribution of Douglas-fir extends from southwestern Canada (British Columbia and Alberta) south through the western United States (Washington, Oregon, the Sierra Nevada, and the Rocky Mountains), and south to central Mexico. This species has been introduced into the eastern United States, Europe, and elsewhere.

Two varieties are distinguished: coast Douglas-fir of the Pacific region and Rocky Mountain or inland Douglas-fir. The latter has shorter cones with bracts bent backward. Though not so large, it is hardier and grows better in the East. *See* FOREST AND FORESTRY; TREE. [E.L.L.]

Down syndrome A developmental disability due to abnormal chromosome number or structure. It is characterized by physical and behavioral features and has been considered the most common form of genetic aberration. Incidence among the newborn is estimated at 3 in 1000, in the general population approximately 1 in 1000. The difference reflects the early mortality.

The most common type (trisomy 21) is due to a nondisjunction of chromosome 21 during the original cell division, resulting in an extra chromosome 21. These children have a total of 47 chromosomes instead of the usual 46. However, the extra material from chromosome 21 can also be attached to another chromosome through translocation; such children have Down syndrome but only 46 chromosomes. More rarely, the trisomy 21 breaks up, giving some cells with 47 chromosomes and some with 46 (mosaicism).

The characteristic physical features include almond-shaped eyes; a rounded, brachycephalic skull with flattened occipital region; a broad, flattened bridge of the nose; an enlarged fissured tongue; broad hands with stubby fingers; often a single "simian" palmar crease; hypotonic muscle development; thick, everted, and cracked lips; dry, rough skin; subnormal height; and infantile genitalia. Not all of these physical signs are present in every case, and some may be observed in individuals without Down syndrome. However, Down syndrome is diagnosed when most of the anomalies are present.

The degree of mental defect is not directly related to the number or gravity of the physical signs, but rather to a combination of those anomalies and the specific chromosomal defect. Few children with Down syndrome are classified today as severely retarded. Most are moderately to mildly retarded and are often educable and highly trainable. They tend to be curious, observant, skillful at mimicry, and usually, very affectionate. Aggression and hostility are rare; however, they are often stubborn and compulsive and are not easily frustrated. They are excellent candidates for vocational training.

Pathological research suggests nonspecific, generalized defective brain development. There is a tendency toward thyroid dysfunction and congenital heart defects. There may also be vision problems, but below-average dental caries. Medication has little effect on the physical condition or on the mental retardation. *See* ALZHEIMER'S DISEASE; CONGENITAL ANOMALIES.

Although there are some reports of more than one child with Down syndrome in a single family, it is not a classical hereditary disease. Incidence is increased if the mother is under 16 or over 35 years old or the father is of advanced age. Furthermore, the Down syndrome child may result from a late or problem pregnancy or the last of numerous pregnancies. Thyroid deficiency, hypopituitarism, and pathology of the ovary have been observed in the mothers, and the probability of upset in their endocrine balance may increase with age. However, the basic etiology is still very much in doubt.

Prenatal identification of Down syndrome in the fetus is possible through amniocentesis. *See* HUMAN GENETICS; MENTAL RETARDATION. [H.Le.]

Drafting The making of drawings of objects, structures, or systems that have been visualized by engineers, scientists, or others. Such drawings may be executed in the following ways: manually with drawing instruments and other aids such as templates and appliqués, freehand with pencil on paper, or with automated devices.

Engineers often draft their own designs to determine whether they are workable, structurally sound, and economical. However, much routine drafting is done under the supervision of engineers by technicians specifically trained as drafters. *See* COMPUTER GRAPHICS; DESCRIPTIVE GEOMETRY; ENGINEERING DRAWING.

Graphic symbols have replaced pictorial representations leading to the introduction of templates that carry frequently used symbols, from which the draftsman quickly traces the symbols in the required positions on the drawing. [C.J.B.]

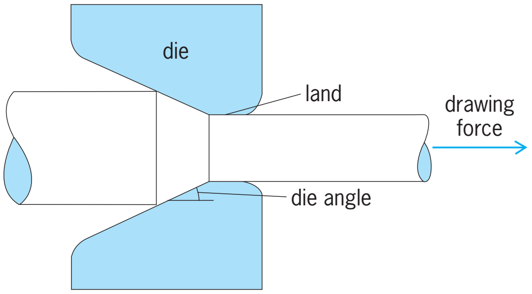
Where the design procedures from which drawings are developed are repetitive, computers can be programmed to perform the design and to produce their outputs as instructions to automatic drafting equipment. Essentially, automated drafting is a method for creating an engineering drawing or similar document consisting of line delineation either in combination with, or expressed entirely by, alphanumeric characters.

The computer receives as input a comparatively simplified definition of the product design in a form that establishes a mathematical or digital definition of the object to be described graphically. The computer then applies programmed computations, standards, and formatting to direct the graphics-producing device. This method provides for close-tolerance accuracy of delineation and produces at speeds much greater than possible by manual drafting. In addition, the computer can be programmed to check the design information for accuracy, completeness, and continuity during the processing cycle. [T.C.P.]

Dragonfly A member of the suborder Anisoptera of the order Odonata of the class Insecta. The adults are large, attractive insects characterized by four similar-appearing elongate, membranous wings with numerous characteristic veins; very large compound eyes; tiny antennae; chewing mouthparts; and a long, slender abdomen terminating in a short pair of cerci. Adults are strong, agile fliers and are all predacious. In flight, their legs are held to form a "basket" which entraps small insects. Dragonflies are considered very beneficial since they consume large numbers of mosquitoes, flies, gnats, and similar pests. Dragonflies are most commonly found near permanent water. Eggs are laid in the water or on the banks. The nymphs are all aquatic and predacious. *See* ODONATA. [F.R.V.]

Drawing of metal An operation wherein the work-piece is pulled through a die, resulting in a reduction in outside dimensions. This article deals only with bar and wire drawing and tube drawing. *See* SHEET-METAL FORMING.

Among the variables involved in the drawing of wires and bars are properties of the original material, percent reduction of cross-sectional area, die angle and geometry, speed of drawing, and lubrication. The operation usually consists of swaging the end of a round rod to reduce the cross-sectional area so that it can be fed into the die; the material is then pulled through the die at high speeds. Most wire drawing involves several dies in tandem to reduce the diameter to the desired dimension. Die materials are usually alloy steels, carbides, and diamond. Diamond dies are used for drawing fine wires. The purpose of the die land is to maintain dimensional accuracy (see illustration).



Cross section of drawing die.

Tubes are also drawn through dies to reduce the outside diameter and to control the wall thickness. The thickness can be reduced and the inside surface finish can be controlled by using an internal mandrel (plug). Various arrangements and techniques have been developed in drawing tubes of many materials and a variety of cross sections. Dies for tube drawing are made of essentially the same materials as those used in rod drawing. [S.Ka.]

Drier (paint) A material added to paint formulations to facilitate the oxidation of oils. Driers are salts of metals. Acids used to render metals soluble in oil, and therefore useful as driers, may be fatty acids, rosin, or naphthenic or octoic acids derived from petroleum. Cobalt, the most reactive of drier metals, is generally regarded as a surface drier, and it is widely used as the only additive in thin-film paint formulations. Lead, while less reactive than cobalt, may have increasing restrictions in its applications because of ecological requirements. Numerous other metals, including cerium and vanadium, have been used occasionally, and are effective driers. Certain organic compounds also catalyze the drying of oils and have been used for this purpose when freedom from all metallic contamination is required.

In general, small amounts of drier are essential to the formation of a satisfactory paint film within a reasonable time. Addition of large amounts of drier, however, can lead to premature embrittlement and failure of the paint film. *See* DRYING OIL; PAINT. [C.R.Ma.; C.W.Si.]

Drilling, geotechnical The drilling of holes for gathering and evaluating earth materials in order to design and monitor construction projects. Geotechnical data are required for the accurate, safe, and efficient design and construction of buildings, bridges, highways, dams, and mining sites. The data are derived from analysis of soil and rock samples obtained by drilling. Soil sampling usually is done with a split-spoon sampler, a tube that opens lengthwise to remove the sample. Rock cores are obtained by diamond drilling, using a hollow, diamond-embedded drill bit to cut an intact rock sample. The samples are tested in laboratories for compressive and shear strength, grain size, weathering properties, moisture content, and consolidation projections. The results are used to determine the materials' supporting characteristics, ability to resist transmission of fluids as with dams, and ability to stand without lateral support as in highway cuts or quarries. In addition, tunneling and mining are accomplished safely only with an understanding of the properties of the soil and rock above and below the projected opening. In-hole or in-situ testing through boreholes drilled in a formation is done to determine the material's permeability, water yield, movement (with inclinometers), and settlement over time (with settlement indicators). *See* ENGINEERING GEOLOGY; ROCK MECHANICS; SOIL MECHANICS. [T.B.St.]

Drone A pilotless aircraft capable of performing a nondestructive mission; when used destructively it is properly termed a missile. *See* GUIDED MISSILE; MISSILE.

There are three basic types of drones: the preprogrammed, the smart, and the remotely piloted drone.

A preprogrammed drone responds to an on-board timer or scheduler and has no sensor contact with the ground. The drone follows a set routine of maneuvers, altitude changes, speed changes, and course changes that are programmed through an autopilot to the drone's control surfaces and engine throttle. The drone is usually recovered by a parachute at the end of the mission.

A smart drone carries various sensors and is equipped with an on-board computer. The ability of a smart drone to make decisions governing course and altitude changes is limited only by its computer and sensor capacity. For example, a smart drone could probably take off on its own from a given airport, navigate a circuitous route, make decisions en route based on weather or enemy radar action, fly to a second airport, and make a safe landing. *See* GUIDANCE SYSTEMS; NAVIGATION.

The remotely piloted vehicle (RPV), probably the most common type of drone, is under the constant control of an operator or pilot through radio links. The pilot or pilots can be located on the ground, in other aircraft, or on ships. Typical missions for remotely piloted vehicles include reconnaissance or surveillance of enemy activities, target acquisition, relay of friendly communications, and jamming of enemy communications.

Advanced remotely piloted vehicles are equipped with low-light-level television and infrared sensors that allow over-the-horizon reconnaissance imagery to be transmitted to ground commanders as it is being acquired. *See* INFRARED IMAGING DEVICES. [R.Stro.]

Drought A general term implying a deficiency of precipitation of sufficient magnitude to interfere with some phase of the economy. Agricultural drought, occurring when crops are threatened by lack of rain, is the most common. Hydrologic drought, when reservoirs are depleted, is another common form. The Palmer index is used by agriculturalists to express the intensity of drought as a function of rainfall and hydrologic variables.

The meteorological causes of drought are usually associated with slow, prevailing, subsiding motions of air masses from continental source regions. These descending air motions, of the order of 660–1000 ft (200 or 300 m) per day, result in compressional warming of the air and therefore reduction in the relative humidity. Since the air usually starts out dry, and the relative humidity declines as the air descends, cloud formation is inhibited—or if clouds are formed, they are soon dissipated. [J.N.]

Drug delivery systems

The engineering of physical, chemical, and biological components into systems for delivering controlled amounts of a therapeutic agent over a prolonged period, thereby maintaining plasma or tissue drug levels at a constant level. Controlled drug delivery systems can take a variety of forms, such as mechanical pumps, polymer matrices or microparticulates, and externally applied transdermal patches.

The most obvious approach for controlled drug delivery involves miniaturization of the familiar infusion system. Mechanical pumps, either totally implantable or requiring percutaneous catheters, have been used to deliver insulin, anticoagulants, analgesics, and cancer chemotherapy. Drugs are maintained in a liquid reservoir prior to delivery, so only agents that are stable in solution at body temperature can be used. Because pumps deliver precisely controlled amounts of therapeutic agents, they may find additional important applications, particularly when coupled with implanted biosensors for feedback control. *See* BIOELECTRONICS.

Many disadvantages of controlled drug delivery via pumps can be avoided by using controlled-release polymers as delivery vehicles. For a specific therapeutic agent, the rate, pattern, and duration of drug release can be modified by selecting the appropriate biocompatible polymer and method of device fabrication. *See* PHARMACOLOGY; POLYMER.

The best example of controlled-release polymer systems are the cylindrical silicone-based subdermal implants that release contraceptive steroids at a constant rate for years following implantation and provide economical, reliable, long-term protection against unwanted pregnancy. An intrauterine device with a controlled-release poly(ethylene-covinyl acetate) coating delivers contraceptive steroids directly to the reproductive tract; local release of certain agents can reduce the overall drug dose and, therefore, reduce or eliminate side effects produced by drug toxicity in other tissues. *See* BIRTH CONTROL.

Transdermal controlled-delivery devices are similar in design to implantable reservoir systems. A single flat polymer membrane is placed between a drug reservoir and the skin. The polymer membrane is designed to control the rate of drug permeation into the skin over a period of several hours to 1 day. Transdermal delivery systems have been produced for agents that can penetrate the skin easily, such as nitroglycerin, scopolamine, clonidine, estradiol, and nicotine.

When nondegradable polymers are used for implanted delivery systems, the polymer must be surgically removed at the end of therapy. This procedure can be eliminated by the use of biodegradable polymers, which dissolve following implantation. Biodegradable polymers, which were first developed as absorbable sutures in the 1960s, are usually employed as matrix devices. Of the polymers tested, poly(lactide-co-glycolide) has been used most frequently. Most importantly, small microspheres of biodegradable polymers can be produced as injectable or ingestible delivery systems; injectable poly(lactide-co-glycolide) microspheres that release a peptide are used for the treatment of prostate cancer in humans. The chemistry of the biodegradable polymers can be exploited in other ways to achieve controlled delivery, for example, by linking drugs to the polymer matrix through degradable covalent bonds. [W.M.Sa.]

Drug resistance

The ability of an organism to resist the action of an inhibitory molecule or compound. Examples of drug resistance include disease-causing bacteria evading the activity of antibiotics, the human immunodeficiency virus resisting antiviral agents, and human cancer cells replicating despite the presence of chemotherapy agents. There are many ways in which cells or organisms become resistant to drugs, and some organisms have developed many resistance mechanisms, each specific to a different drug. Drug resistance is best understood as it applies to bacteria, and the increasing resistance of many common disease-causing bacteria to antibiotics is a global crisis.

Genetic basis. Some organisms or cells are innately or inherently resistant to the action of specific drugs. In other cases, the development of drug resistance involves a change in the genetic makeup of the organism. This change can be either a mutation in a chromosomal gene or the acquisition of new genetic material from another cell or the environment.

Organisms may acquire deoxyribonucleic acid (DNA) that codes for drug resistance by a number of mechanisms. Transformation involves the uptake of DNA from the environment. Once DNA is taken up into the bacterial cell, it can recombine with the recipient organism's chromosomal DNA. This process plays a role in the development and spread of antibiotic resistance, which can occur both within and between species.

Transduction, another mechanism by which new DNA is acquired by bacteria, is mediated by viruses that infect bacteria (bacteriophages). Bacteriophages can integrate their DNA into the bacterial chromosome.

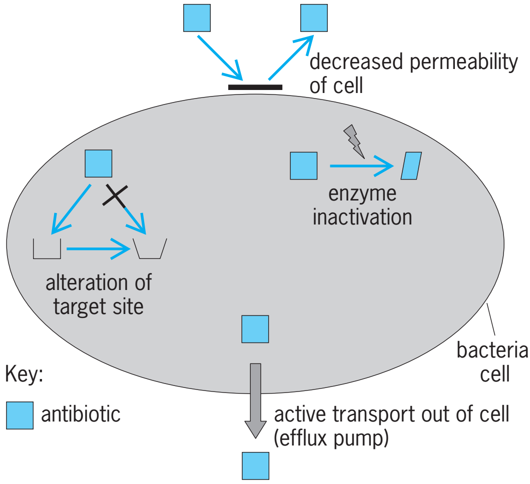
Conjugation is the most common mechanism of acquisition and spread of resistance genes among bacteria. This process, which requires cell-to-cell contact, involves direct transfer of DNA from the donor cell to a recipient cell. While conjugation can involve cell-to-cell transfer of chromosomal genes, bacterial resistance genes are more commonly transferred on nonchromosomal genetic elements known as plasmids or transposons. *See* DEOXYRIBONUCLEIC ACID (DNA).

Mechanisms of resistance. The four most important antibiotic resistance mechanisms are alteration of the target site of the antibiotic, enzyme inactivation of the antibiotic, active transport of the antibiotic out of the bacterial cell, and decreased permeability of the bacterial cell wall to the antibiotic (see illustration).

By altering the target site to which an antibiotic must bind, an organism may decrease or eliminate the activity of the antibiotic. Alteration of the target site is the mechanism for one of the most problematic antibiotic resistances worldwide, methicillin resistance among *Staphylococcus aureus*. *See* BACTERIAL GENETICS.

The most common mechanism by which bacteria are resistant to antibiotics is by producing enzymes that inactivate the drugs. For example, β-lactam antibiotics (penicillins and cephalosporins) can be inactivated by enzymes known as β-lactamases.

Active transport systems (efflux pumps) have been described for the removal of some antibiotics (such as tetracyclines, macrolides, and quinolones) from bacterial cells. In these situations, even though the drug can enter the bacterial cell, active



Four common mechanisms of antibiotics resistance.

efflux of the agent prevents it from accumulating and interfering with bacterial metabolism or replication.

Bacteria are intrinsically resistant to many drugs based solely on the fact that the drugs cannot penetrate the bacterial cell wall or cell membrane. In addition, bacteria can acquire resistance to a drug by an alteration in the porin proteins that form channels in the cell membrane. The resistance that *Pseudomonas aeruginosa* exhibits to a variety of penicillins and cephalosporins is mediated by an alteration in porin proteins.

Promoters. In the hospital environment, many factors combine to promote the development of drug resistance among bacteria. Increasing use of powerful new antibiotics gives selective advantage to the most resistant bacteria. In addition, advances in medical technology allow for the survival of sicker patients who undergo frequent invasive procedures. Finally, poor infection control practices in hospitals allow for the unchecked spread of already resistant strains of bacteria.

Outside the hospital environment, other important factors promote antibiotic resistance. The overuse of antibiotics in outpatient medicine and the use of antibiotics in agriculture exert selective pressure for the emergence of resistant bacterial strains. The spread of these resistant strains is facilitated by increasing numbers of children in close contact at day care centers, and by more national and international travel.

Control. A multifaceted worldwide effort will be required to control drug resistance among disease-causing microorganisms. Ongoing programs to decrease the use of antibiotics, both in the clinics and in agriculture, will be necessary. The increased use of vaccines to prevent infection can help limit the need for antibiotics. Finally, the development of novel classes of antibiotics to fight emerging resistant bacteria will be required. *See* ANTIBIOTIC; BACTERIA. [D.J.D.]

Drumlin A streamlined, oval-shaped hill which has been shaped by flowing glacial ice. The long axis is parallel to the direction of ice flow, the up-glacier slope is usually steeper than the lee slope, and composition includes a variety or combination of materials—till, outwash, or bedrock. Drumlins are highly localized, but where present, they occur in large numbers. Some drumlins are clearly erosional in origin, but in others till deposition appears to have been synchronous with drumlin formation. Thus, one or both processes must be operative at some time in the subglacial environment where drumlins form. [W.H.J.]

Dry ice A solid form of carbon dioxide, CO_2, which finds its largest application as a cooling agent in the transportation of perishables. It is nontoxic and noncorrosive and sublimes directly from a solid to a gas, leaving no residue. At atmospheric pressure it sublimes at −109.6°F (−78.7°C). Slabs of dry ice can easily be cut and used in shipping containers for frozen foods, in refrigerated trucks, and as a supplemental cooling agent in refrigerator cars. *See* CARBON DIOXIDE; REFRIGERATION. [C.F.K.]

Drydocking A technique used to remove a ship from the water so that the underwater portion may be inspected, repaired, maintained, or altered. Occasionally underwater repairs may be undertaken while a ship is afloat; however, at regular intervals, or as dictated by emergency, it may be necessary to expose all of the underwater portion, regardless of whether the ship is a small harbor tug or a large transoceanic liner.

The four types of dry docks are known as marine railways, floating dry docks, graving docks, and mechanical lift docks. The size of the ship usually determines which type is used.

The marine railway consists of a cradle of wood or steel with rollers on which the ship may be hauled out of the water along a fixed inclined track leading up the bank of a waterway. The advantages of a marine railway lie in the economy of the original construction and the relative low cost of maintenance. A marine railway is ideal for ships up to 5000 tons.

The floating dry dock may be constructed of wood, steel, or concrete. The dock is submerged, to provide the required depth of water over the keel blocks, by partially filling its tanks with water. The ship to be drydocked is then positioned within, the tanks of the dock are rapidly pumped out by powerful pumps located within the dock walls, and the ship is lifted out of the water.

The graving dock consists of an excavation in the ground with a thick concrete base supported, if necessary, by piling and surrounded on three sides by earth held back by timbers, stone, cement, or steel supports, or a combination of these materials. The entrance, or seaward end of the dock, is usually closed by a caisson of the pontoon type which, when flooded, is trimmed down into position. The dock is flooded, the caisson is floated, and the ship enters the dry dock and is positioned over the keel blocks. The caisson is then replaced and submerged, the dock is pumped out, and the ship settles on the keel blocks. This process is reversed when the ship is ready to leave the dock.

The mechanical lift dock is somewhat similar in action to the floating dry dock. The vessel, after taking up on the keel and bilge blocks in the dock, is bodily lifted clear of the water. The mechanical platform dock has much more flexibility than other types and has increased greatly in size and use. [L.C.R.]

Drying An operation in which a liquid, usually water, is removed from a wet solid in equipment termed dryers. The use of heat to remove liquids distinguishes drying from mechanical dewatering methods such as centrifugation, decantation or sedimentation, and filtration, in which no change in phase from liquid to vapor is experienced. Drying is preferred to the term dehydration, which usually implies removal of water accompanied by a chemical change. Drying is a widespread operation in the chemical process industries. It is used for chemicals of all types, pharmaceuticals, biological materials, foods, detergents, wood, minerals, and industrial wastes. Drying processes may evaporate liquids at rates varying from only a few ounces per hour to 10 tons per hour in a single dryer. Drying temperatures may be as high as 1400°F (760°C), or as low as −40°F (−40°C) in freeze drying. Dryers range in size from small cabinets to spray dryers with steel towers 100 ft (30 m) high and 30 ft (9 m) in diameter. The materials dried may be in the form of thin solutions, suspensions, slurries, pastes, granular materials, bulk objects, fibers, or sheets. Drying may be accomplished by convective heat transfer, by conduction from heated surfaces, by radiation, and by dielectric heating. In general, the removal of moisture from liquids (that is, the drying of liquids) and the drying of gases are classified as distillation processes and adsorption processes, respectively, and they are performed in special equipment usually termed distillation columns (for liquids) and adsorbers (for gases and liquids). Gases also may be dried by compression. *See* ADSORPTION; DISTILLATION.

Drying of solids. In the drying of solids, the desirable end product is in solid form. Thus, even though the solid is initially in solution, the problem of producing this solid in dry form is classed under this heading. Final moisture contents of dry solids are usually less than 10%, and in many instances, less than 1%.

The mechanism of the drying of solids is reasonably simple in concept. When drying is done with heated gases, in the most general case, a wet solid begins to dry as though the water were present alone without any solid, and hence evaporation proceeds as it would from a so-called free water surface, that is, as water standing in an open pan. The period or stage of drying during this initial phase, therefore, is commonly referred to as the constant-rate period because evaporation occurs at a constant rate and is independent of the solid present. The presence of any dissolved salts will cause the evaporation rate to be less than that of pure water. Nevertheless, this lower rate can still be constant during the first stages of drying.

A fundamental theory of drying depends on a knowledge of the forces governing the flow of liquids inside solids. Attempts have been made to develop a general theory of drying on the basis that liquids move inside solids by a diffusional process. However, this is not true in all cases. In fact, only in a limited number of types of solids does true diffusion of liquids occur. In most cases, the internal flow mechanism results from a combination of forces which may include capillarity, internal pressure gradients caused by shrinkage, a vapor-liquid flow sequence caused by temperature gradients, diffusion, and osmosis. Because of the complexities of the internal flow mechanism, it has not been possible to evolve a generalized theory of drying applicable to all materials. Only in the drying of certain bulk objects such as wood, ceramics, and soap has a significant understanding of the internal mechanism been gained which permits control of product quality.

Most investigations of drying have been made from the so-called external viewpoint, wherein the effects of the external drying medium such as air velocity, humidity, temperature, and wet material shape and subdivision are studied with respect to their influence on the drying rate. The results of such investigations are usually presented as drying rate curves, and the natures of these curves are used to interpret the drying mechanism.

When materials are dried in contact with hot surfaces, termed indirect drying, the air humidity and air velocity may no longer be significant factors controlling the rate. The “goodness” of the contact between the wet material and the heated surfaces, plus the surface temperature, will be controlling. This may involve agitation of the wet material in some cases.

Drying equipment for solids may be conveniently grouped into three classes on the basis of the method of transferring heat for evaporation. The first class is termed direct dryers; the second class, indirect dryers; and the third class, radiant heat dryers. Batch dryers are restricted to low capacities and long drying times. Most industrial drying operations are performed in continuous dryers. The large numbers of different types of dryers reflect the efforts to handle the larger numbers of wet materials in ways which result in the most efficient contacting with the drying medium. Thus, filter cakes, pastes, and similar materials, when preformed in small pieces, can be dried many times faster in continuous through-circulation dryers than in batch tray dryers. Similarly, materials which are sprayed to form small drops, as in spray drying, dry much faster than in through-circulation drying.

Drying of gases. The removal of 95–100% of the water vapor in air or other gases is frequently necessary. Gases having a dew point of −40°F (−40°C) are considered commercially dry. The more important reasons for the removal of water vapor from air are (1) comfort, as in air conditioning; (2) control of the humidity of manufacturing atmospheres; (3) protection of electrical equipment against corrosion, short circuits, and electrostatic discharges; (4) requirement of dry air for use in chemical processes where moisture present in air adversely affects the economy of the process; (5) prevention of water adsorption in pneumatic conveying; and (6) as a prerequisite to liquefaction.

Gases may be dried by the following processes: (1) absorption by use of spray chambers with such organic liquids as glycerin, or aqueous solutions of salts such as lithium chloride, and by use of packed columns with countercurrent flow of sulfuric acid, phosphoric acid, or organic liquids; (2) adsorption by use of solid adsorbents such as activated alumina, silica gel, or molecular sieves; (3) compression to a partial pressure of water vapor greater than the saturation pressure to effect condensation of liquid water; (4) cooling below dew point of the gas with surface condensers or coldwater sprays; and (5) compression and cooling, in which liquid desiccants are used in continuous processes in spray chambers and packed towers—solid desiccants are generally used in an intermittent operation that requires periodic interruption for regeneration of the spent desiccant.

Desiccants are classified as solid adsorbents, which remove water vapor by the phenomena of surface adsorption and capillary condensation (silica gel and activated alumina); solid absorbents, which remove water vapor by chemical reaction (fused anhydrous calcium sulfate, lime, and magnesium perchlorate); deliquescent absorbents, which remove water vapor by chemical reaction and dissolution (calcium chloride and potassium hydroxide); or liquid absorbents, which remove water vapor by absorption (sulfuric acid, lithium chloride solutions, and ethylene glycol).

The mechanical methods of drying gases, compression and cooling and refrigeration, are used in large-scale operations, and generally are more expensive methods than those using desiccants. Such mechanical methods are used when compression or cooling of the gas is required.

Liquid desiccants (concentrated acids and organic liquids) are generally liquid at all stages of a drying process. Soluble desiccants (calcium chloride and sodium hydroxide) include those solids which are deliquescent in the presence of high concentrations of water vapor.

Deliquescent salts and hydrates are generally used as concentrated solutions because of the practical difficulties in handling, replacing, and regenerating the wet corrosive solids. The degree of drying possible with solutions is much less than with corresponding solids; but, where only moderately low humidities are required and large volumes of air are dried, solutions are satisfactory. *See* DESICCANT; EVAPORATION; FILTRATION; HEAT TRANSFER; HUMIDIFICATION; UNIT OPERATIONS; VAPOR PRESSURE. [W.R.M.]

Drying oil An oil that readily undergoes autoxidation and polymerization to form a hard, dry film on exposure to air. Drying oils are relatively highly unsaturated; that is, they are composed of triglycerides constructed from unsaturated fatty acids. The best drying oils contain several nonconjugated double bonds per molecule.

Raw (untreated) drying oils are not suitable for paints and varnishes because they polymerize too slowly, and various methods have been introduced to improve the polymerization process. One method involves boiling the oil after addition of soluble resin-acid salts. Boiled oil dries in approximately one-fifth the time in which raw oil dries. Blown oil, produced by blowing air through the oil (to which driers have been added) at about 120°C (248°F), is said to have superior wetting or surface-covering properties. Stand oil has been partially polymerized, with admixture of driers, by heating to 260–280°C (500–536°F). This material is used extensively in antifouling paints, printing inks, and linoleum, as well as in varnishes and enamels. Linseed oil is the most widely used drying oil in paints and varnishes. *See* DRIER (PAINT). [E.B.R.]

Dryolestida An extinct order of mammals related to the living marsupials and eutherian (placental) mammals; formerly known as the Pantotheria or Eupantotheria. Along with the closely related symmetrodonts, they were the most diverse group of mammals during the Jurassic. They are often found in some of the same quarries that yield the giant sauropod dinosaurs. Most were about the size and shape of a shrew or mouse, with teeth adapted for chopping up a diet of insects, and they apparently were adapted for living in trees like squirrels. *See* EUTHERIA; MARSUPIALIA; SYMMETRODONTA.

For over a century, dryolestoids were placed in the order Pantotheria, a taxonomic wastebasket for Mesozoic mammals that were not members of other groups. Recent research has shown that the dryolestoids were primitive in many features but highly advanced in others. Their complex mosaic of features showed the transition from archaic mammals such as the platypus and some extinct Mesozoic mammals (which still retain reptilian characteristics) to the marsupials and placentals. In addition, their unique specializations (such as seven to nine highly unusual molars) show that they were not ancestral to marsupials or placentals, but an early side branch of mammalian evolution that lived before and then contemporaneously with the earliest marsupials and placentals. *See* THERIA. [D.R.Pr.]

Duality (physics) The state of having two natures, which is often applied in physics. The classic example is wave-particle duality. The elementary constituents of nature—electrons, quarks, photons, gravitons, and so on—behave in some respects like particles and in others like waves.

Duality is often used in a more precise sense. It indicates that two seemingly different, theoretical descriptions of a physical system are actually mathematically equivalent. Such an occurrence is very useful. Various properties and phenomena are clearer in one or the other of the descriptions, and calculations that are difficult or impossible in one description may be simple in the other. In the case of wave-particle duality, the wave description corresponds to a theory of quantized fields, where the field variables are governed by an uncertainty principle. The particle description corresponds to a Feynman integral over all particle paths in spacetime. The quantized-field and path integral theories sound very different but are mathematically equivalent, making identical predictions. *See* Feynman integral; Nonrelativistic quantum theory; Quantum field theory; Quantum mechanics; Uncertainty principle; Wave mechanics.

Weak-strong duality. In some systems, there is weak-strong duality, meaning that when the coupling constant g of the original description is large that of the dual description, g', is small; for example $g' = 1/g$. When g is large, so the interactions in the original description are strong and the perturbation theory in this description is highly inaccurate, then perturbation theory in the dual description gives a very accurate description.

Duality in superstring theory. It is believed that a complete theory of all particles and interactions must be based on quantization of one-dimensional objects (loops) rather than points: this is superstring theory. In superstring theory there is again the problem that perturbation theory is the main tool, giving an incomplete description of the physics. The situation has greatly improved with the discovery that weak-strong duality is a general property of string theory. In fact, there are five known string theories, and all are dual to one another. A notable feature in string theory is that in addition to strings and solitons, duality requires certain other objects as well: D-branes, which are local disturbances to which strings become fixed. Remarkably, the same methods have also been used to solve some long-standing problems regarding the quantum mechanics of black holes. *See* Black hole; Quantum gravitation; Superstring theory. [J.Pol.]

Dubnium A chemical element, symbol Db, atomic number 105. It was synthesized and identified unambiguously in March 1970 at the heavy-ion linear accelerator (HILAC) at the Lawrence Radiation Laboratory, Berkeley, University of California. The discovery team consisted of A. Ghiorso and colleagues. *See* Periodic table.

The dubnium isotope, with a half-life of 1.6 s, decayed by emitting alpha particles with energies of 9.06 (55%), 9.10 (25%), and 9.14 (20%) MeV. It was shown to be of mass 260 by identifying lawrencium-256 as its daughter by two different methods.

Previous work on dubnium was reported in 1968 by G. N. Flerov and colleagues at Dubna Laboratories in Russia. They claimed to have discovered two isotopes of dubnium produced by the bombardment of ^{243}Am by ^{22}Ne ions. However, the Lawrence Radiation Laboratory work did not confirm these findings (due to energy and decay differences). *See* Nuclear chemistry. [A.Gh.]

Ducted fan A propeller or multibladed fan inside a coaxial duct or cowling, also called a ducted propeller or a shrouded propeller, although in a shrouded propeller the ring is usually attached to the propeller tips and rotates. The duct serves to protect the fan blades from adjacent objects and to protect objects from the revolving blades, but more importantly, the duct prevents radial flow of the fluid at the blade tips. Fan efficiency remains high over a wider speed range with a properly shaped duct than without. However, fan efficiency is sensitive to duct shape at off-center design conditions. *See* Ducted flow; Fan.

Ducted fans are used in axial-flow blowers or compressors of several stages for turbine engines. A ducted fan engine is a gas turbine arranged to move a larger mass of air than passes through the turbine, the additional air leaving at lower exit velocity and hence higher jet propulsion efficiency for moderate-speed aircraft than obtainable with a simple turbojet. *See* Gas turbine; Turbofan; Turbojet. [F.H.R.]

Dumortierite A nesosilicate mineral with composition $Al_7(BO)_3SiO_4)_3O_3$. Dumortierite crystallizes in the orthorhombic system but well-formed crystals are rare; the mineral usually occurs in parallel or radiating fibrous aggregates. There is one direction of poor cleavage. The hardness is 7 on Mohs scale, and the specific gravity is 3.26–3.36. The mineral has a vitreous luster and a color that varies not only from one locality to another but in a single specimen. It may be pink, green, blue, or violet. Dumortierite is found in schists and gneisses and more rarely in pegmatites. In the United States it occurs at Dehesa, California, and at Rochester, Nevada, where it has been mined for the manufacture of high-grade porcelain. *See* Silicate minerals. [C.S.Hu.]

Dune Mobile accumulation of sand-sized material that occurs along shorelines and in deserts because of wind action. Dunes are typically located in areas where winds decelerate and undergo decreases in sand-carrying capacity. Dunefields are composed of rhythmically spaced mounds of sand that range from about 3 ft (1 m) to more than 650 ft (200 m) in height and may be spaced as much as 5000 ft (1.5 km) apart. Smaller accumulations of windblown sand, typically ranging in height from 0.25 to 0.6; in. (5 to 15 mm) and in wavelength from 3 to 5 in. (7 to 12 cm), are known as wind ripples. Dunes and ripples are two distinctly different features. The lack of intermediate forms shows that ripples do not grow into dunes. Ripples commonly are superimposed upon dunes, typically covering the entire upwind (stoss) surface and much of the downwind (leeward) surface as well.

Virtually any kind of sand-sized material can accumulate as dunes. The majority of dunes are composed of quartz, an abundant and durable mineral released during weathering of granite or sandstone. Dunes along subtropical shorelines, however, are commonly composed of grains of calcium carbonate derived in part from the breakdown of shells and coral. Along the margins of seasonally dry lakes, dunes may be composed of gypsum (White Sands, New Mexico) or sand-sized aggregates of clay minerals (Laguna Madre, Texas). *See* Clay minerals; Gypsum; Quartz.

The leeward side of most dunes is partly composed of a slip face, that is, a slope at the angle of repose. For dry sand, this angle is approximately 33°. When additional sand is deposited at the top of such a slope, tonguelike masses of sand avalanche to the base of the slope. The dune migrates downwind as material is removed from the gently sloping stoss side of the dune and deposited by avalanches along the slip face. Much of the sand on the leeward side of the dune is later reworked by side winds into wind ripple deposits. Because the coarsest grains preferentially accumulate at the crests of wind ripples, the layering in wind ripple deposits is distinctive and relatively easily recognized—each thin layer is coarser at its top than at its base.

Dunes can be classified on the basis of their overall shape and number of slip faces. Three kinds of dunes exist with a single slip face; each forms in areas with a single dominant wind direction. Barchans are crescent-shaped dunes; their arms point downwind. They develop in areas in which sand is in small supply. If more sand is available, barchans coalesce to form sinuous-crested dunes called barchanoid ridges. Transverse dunes with straight crests develop in areas of abundant sand supply. The axis of each of these dune types is oriented at right angles to the dominant wind, and the dunes migrate rapidly relative to other

Linear dune, Imperial County, California.

dune types. The migration rate of individual dunes is quite variable, but in general, the larger the dune, the slower the migration rate. In the Mojave Desert of southern California, barchans having slip faces 30 ft (10 m) long migrate about 50 ft (15 m) per year.

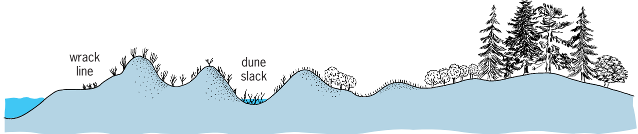
Dunes having more than one slip face develop in areas with more complex wind regimes. Linear dunes, sometimes called longitudinal or self dunes, possess two slip faces which meet along a greatly elongated, sharp crest (see illustration). Some linear dunes in Saudi Arabia reach lengths of 120 mi (190 km). Experimental evidence has shown that linear dunes are the result of bidirectional winds that differ in direction by more than 90°. The trend of these dunes is controlled by wind direction, strength, and duration, but the nature of the wind regime cannot be deduced from a knowledge of dune trends. Star dunes bear many slip faces and consist of a central, peaked mound from which several ridges radiate. Because they do not migrate appreciably, they grow in height as sand is delivered to them, some reaching 1000 ft (300 m).

Plant growth appears to be important to the growth and maintenance of two types of dunes. Coppice dunes are small mounds of sand that are formed by the wind-baffling and sand-trapping action of desert plants. The crescentic shape of parabolic dunes gives them a superficial resemblance to barchan dunes, but their arms point upward. Plants commonly colonize and anchor only the edges of a dune, leaving the body of the dune free to migrate. The retarded migration rate of the dune margin leads to the formation of the trailing arms of a parabolic dune. *See* DUNE VEGETATION.

Other dune types are dependent on special topographic situations for their formation. Climbing dunes develop on the upwind side of mountains or cliffs; falling dunes are formed at the sheltered, downward margin of similar features. [D.B.Lo.]

Dune vegetation Plants occupying sand dunes and the slacks, or swales, and flats between them. The density and diversity of dune vegetation are greater on coastal dunes than on desert dunes. *See* DUNE.

A zonation pattern is evident in the vegetation of the coastal dunes (see illustration). A wrack, or debris, line occurs at the upper limit of the beach. Seeds caught in decaying plant material and other debris washed in on the high tides germinate here and trap windblown sand, initiating the formation of a dune. The foredunes, also called the primary dunes, are those closest to the water and lie behind the wrack line. The plants on these dunes, mostly grasses, are tolerant to sea spray, high winds, and sand accretion. Behind the primary dunes are the secondary dunes, sometimes called the dune field. In this more favorable environment, the vegetation is denser and more diverse; the foredunes block sea spray and reduce wind velocity. The dune slacks are the low areas between dunes and are frequently a result of a blowout, an area where sand has been blown away down to where the sand is moist and close to the water table. Plants typical of wetlands often vegetate these areas. Shrub communities also inhabit the dune field and often form dense patches of vegetation. A maritime forest may be found behind the secondary dunes. In coastal barrier beach or island locations, a salt marsh adjacent to a bay or sound may lie behind the forest.



A coastal dune profile.

Although the plant species occupying the sand dunes of the United States vary from coast to coast, their functions and adaptations are essentially the same. Plants growing on sand dunes are adapted to the environment. The plants closest to the sea are usually the most tolerant of salt spray. The plants in the wrack line must be tolerant to salinity, wind, and burial by sand.

The foredune plants must be tolerant of sand burial, sea spray, and a nutrient-poor substrate. By a system of underground stems called rhizomes, they overcome burial by sand and spread throughout the dune with new shoots arising from buds on the rhizomes. The roots and rhizomes of these dune grasses are important in stabilizing the dune sand and preventing wind erosion. The foredune plants participate in dune formation; by slowing the wind, they favor sand deposition. Furthermore, some of these plants have specialized bacterium named *Azotobacter* associated with their roots, and these bacteria fix atmospheric nitrogen into a form usable by the plant.

The plants in the dune slacks have morphological and physiological adaptations for growth in flooded areas. For example, the sedge American three-square contains large air spaces (aerenchyma) in its stems and roots, which provide an oxygen pathway from the shoots above the water to the oxygen-deprived roots in the flooded soil. When these plants are flooded, they increase their production of the hormone ethylene, which may stimulate the production of aerenchymatous tissue. [D.M.Se.]

Dunite An ultramafic igneous rock composed of at least 90% olivine. Important accessory minerals (abundances usually less than 1%) found in different occurrences of dunite include chromian spinel, low- or high-calcium pyroxenes (enstatite and diopside), and plagioclase. If these minerals constitute greater than 10% of the rock, it is called chromitite, peridotite, or troctolite, respectively. Low-temperature alteration (less than 750°F or 400°C) causes hydration of olivine to the mineral serpentine and, where extensive, may transform dunite to the metamorphic rock serpentinite. The dun color is a characteristic feature of the weathered rock. *See* CHROMITE; OLIVINE; PERIDOTITE; PYROXENE; SERPENTINITE.

Dunite is ultrabasic in composition, meaning that it is low in silica compared to most crustal rocks (<45% silica) and is generally very high in magnesium (up to 54%). In some occurrences, notably in continental layered intrusions, however, the olivine may be very iron rich (variety hortonolite), and the rock can contain as much as 40% iron. Dunite is notably poor in alumina, soda, and lime; and while it may be relatively nickel rich, many other critical trace elements are nearly missing. Thus, weathering of dunite forms soils to which most terrestrial plants are poorly adapted, and such soils often host unusual plant species such as the carnivorous cobra lily and the miniature rhododendron *Kalmiopsis leachiana* found in the coast ranges of Oregon and California.

The most important occurrence of dunite is in its association with rocks believed to have come from the Earth's mantle (principally peridotite) where it marks the location of former conduits through which magmas have been transported out of the Earth to the crust. In the oceans, it is infrequently dredged from the great oceanic transform faults cutting the ocean ridges, exposed in tectonic windows in disrupted and uplifted ocean crust in association with serpentinized mantle peridotite. Important dunite bodies crosscutting tectonically exposed mantle sections on the walls and floors of rift valleys have been found in the central Atlantic and eastern Pacific oceans far from transform faults. The suggestion is that the flow of magma out of the mantle upwelling beneath ocean ridges is not uniform, and is therefore important in controlling the formation and structure of the two-thirds of the Earth's crust that is formed in the oceans. *See* Earth; Mid-Oceanic Ridge; Rift valley; Transform fault.

Dunite has been extensively quarried as a building stone because of its unusual pale water-green color, but is little used now because of its high susceptibility to acid rain. Dunite is also used for refractory materials for furnaces. Olivine in dunite is occasionally of gem quality. Dunite is also the principal host of deposits of the mineral chromite. The hortonolite-dunite pipes found in the Bushveld Complex of South Africa have also been mined for platinum-group minerals. *See* Gem; Igneous rocks; Petrology; Refractory. [H.J.B.D.]

Dust and mist collection The physical separation and removal of solid or liquid particles from a gas in which they are suspended. Such separation is required for one or more of the following purposes: (1) to collect a product which has been processed or handled in gas suspension, as in spray-drying or pneumatic conveying; (2) to recover a valuable product inadvertently mixed with processing gases, as in kiln or smelter exhausts; (3) to eliminate a nuisance, as a fly-ash removal; (4) to reduce equipment maintenance, as in engine intake air filters; (5) to eliminate a health, fire, explosion, or safety hazard, as in bagging operations or nuclear separations plant ventilation air; and (6) to improve product quality, as in cleaning of air used in processing pharmaceutical or photographic products.

All particle collection systems depend upon subjecting the suspended particles to some force which will drive them mechanically to a collecting surface. The known mechanisms by which such deposition can occur may be classed as gravitational, inertial, physical or barrier, electrostatic, molecular or diffusional, and thermal or radiant. There are also mechanisms which can be used to modify the properties of the particles or the gas to increase the effectiveness of the deposition mechanisms. For example, the effective size of particles may be increased by condensing water vapor upon them or by flocculating particles through the action of a sonic vibration. Usually, larger particles simplify the control problem. To function successfully, any collection device must have an adequate means for continuously or periodically removing collected material from the equipment.

Devices for control of particulate material may be considered, by structural or application similarities, in seven principal categories as follows: gravity setting chamber, inertial device, packed bed, cloth collector, scrubber, electrostatic precipitator, and air filter. *See* Air filter; Chemical separation techniques; Electrostatic precipitator; Mechanical separation techniques; Unit operations. [C.E.La.]

Dust storm A strong, turbulent wind carrying large clouds of dust. In a large storm, clouds of fine dust may be raised to heights well over 10,000 ft (3000 m) and carried for hundreds or thousands of miles (1 mi = 1.6 km).

Sandstorms differ by the larger mass, more rapid setting speeds of the particles involved, and the stronger transporting winds required. The sand cloud seldom rises above 3.3–6.6 ft (1–2 m) and is not carried far from the place where it was raised.

Dust storms cause enormous erosion of the soil, as in the dust bowl disasters of 1933–1937 in the Great Plains of the United States. Besides causing acute physical discomfort, they present a severe hazard to transportation by reducing the visibility to very low ranges. Conditions required are an ample supply of fine dust or loose soil, surface winds strong enough to stir up the dust, and sufficient atmospheric instability for marked vertical turbulence to occur.

Small dust particles increase scattering of light, mainly in short (blue) wavelengths. The Sun often appears a deep orange or red when seen through a dust cloud; however, optical effects are variable. Large particles are effective reflectors, and an observer in an aircraft above a dust storm may see a solid sheet with an apparent dust horizon. [C.W.N.]

Dwarf star A star whose state of evolution resembles that of the Sun. The term "dwarf star" derives from the work of Ejnar Hertzsprung and Henry Norris Russell, who distinguished two kinds of stars, large ones called giants (or supergiants) and smaller ones called dwarfs. The term "dwarf" is synonymous with "main sequence star" (luminosity class V) and implies not so much size as evolutionary condition. Dwarfs are stars that, like the Sun, fuse hydrogen into helium in their cores, the thermonuclear reactions providing energy and support. Dwarfs range over the entire spectral sequence. At the cool limit (where spectral class M converts to L), they have effective temperatures around 2000 K (3100°F), absolute visual magnitudes of +20, and bolometric luminosities of about 10^{-4} times the solar luminosity. At the hot O3 limit, the values are respectively 55,000 K (100,000°F), −7, and over 10^6 solar. The Sun, a G2 dwarf, falls in the middle at 5780 K (9950°F) and an absolute visual magnitude of +4.83. These properties are produced by a mass range from 0.08 solar mass for warm L dwarfs, below which full hydrogen fusion cannot be turned on, to over 100 solar masses at class O3. *See* Giant star; Hertzsprung-Russell diagram; Magnitude (astronomy); Sun.

At the high-mass end, above about 10 solar masses, the dwarf stage lasts 2–20 million years, and O stars turn into supergiants and supernovae. At class G8 and a mass of 0.8 solar, the lifetime equals the age of the Milky Way Galaxy, and dwarfs between this limit and 10 solar masses become white dwarfs. *See* Spectral type; Star; Stellar evolution; Stellar rotation; Supergiant star; Supernova; White dwarf star. [J.B.Ka.]

Dwarfism and gigantism Underdevelopment and overdevelopment of the skeleton, respectively. Skeletal growth is a complex process and can be distributed in many ways. For example, overstimulation by excessive growth-hormone production during childhood can produce gigantism. This is usually due to a pituitary tumor. Insufficient stimulation of skeletal growth, resulting from hormonal, metabolic, or nutritional disturbances, leads to reduced height with normal body proportions. The shortness of stature depends on the degree of the disturbance; the designation proportionate dwarfism is used in severe cases. Proportionate dwarfism may or may not be genetic. *See* Pituitary gland.

Commonly, the term dwarfism is applied to short individuals with abnormal body proportions resulting from disturbances of bone growth itself. The bones of either limbs or trunk can be most affected. The disorders, called chondrodysplasias, number well over 100 and show a wide variation in clinical features: some appear at birth, others become evident in later childhood. The severity ranges from conditions in which infants die at birth to conditions compatible with normal life. In most instances, however, the abnormal skeleton creates medical problems.

Almost all of the chondrodysplasias are inherited as mendelian or single-gene traits. However, because of reduced fertility and a high incidence of new mutations for certain traits, most individuals with these disorders are born to parents of average stature. *See* Human genetics; Skeletal system disorders. [W.A.Ho.]

Dyadic A mathematical abstraction corresponding to an expression of the type $\boldsymbol{\beta}\gamma + \boldsymbol{\delta}\epsilon + \cdots$, in which the elements (dyad symbols) consist of two vector symbols in juxtaposition without the intervention of either the dot (·) or cross (×). Essentially, a dyad is an ordered pair of vectors subject to certain rules of operation. The first symbolic factor in a dyad ($\boldsymbol{\beta}$ in $\boldsymbol{\beta}\gamma$, for example) is called the antecedent and the second the consequent. *See* Calculus of vectors. [H.V.C.]

Dye A colored substance, also called a dyestuff, which imparts more or less permanent color to other materials. *See* Dyeing.

Customarily, colored water-insoluble substances are called pigment. Dyes are generally water-soluble, although some are soluble only during application, after which they become insoluble. *See* Pigment.

The mechanism by which soluble colored substances enter the internal structure of fibers and there become fixed has been variously explained in terms of the physical and chemical concepts of the times when the explanations were given. It is said to be an adsorption phenomenon, a salt formation, a quasi-chemical union caused by hydrogen bonding, or an ether linkage, and in some cases it is considered to be a true solution effect. The end result, however, is that the dye has imparted a color (not necessarily that of the solid dye itself) to the fiber which is more or less resistant to washing or removal by similar mechanical operations. The dye is said to be fixed on and to have affinity for the material it has colored. The material is designated as the substrate. If the color is quite resistant to washing and light, it is called a fast color; if the color is easily removed or fades quickly, it is a fugitive dye.

Dyestuffs may be classified in various ways: according to color (blue, red, and so on); origin (natural—from vegetable and animal matter—or synthetic); chemical structure (the most precise); kinds of material to which they are applied (cloth, paper, leather, plastic, food, and biological specimens); and method of application (used most frequently by the practical dyer). [W.Mi.]

Dyes that form a covalent bond with the substrate during the dyeing process are known as reactive dyes. They offer improved washfastness, improved brightness, and improved rubbing fastness and shade range. Reactive dyes are one of the more important single types of cellulosic dye. To a lesser degree, they are used for polyamide fibers. The simplicity of continuous application and the brightness of reactive dyes make them useful in printing as well as dyeing. [D.R.B.; D.H.A.]

Dyeing The application of color-producing agents to material, usually fibrous or film, in order to impart a degree of color permanence demanded by the projected end use. True dyeing covers mechanisms in which molecules of material to be dyed become involved by various means with the molecules of the coloring matter, or small aggregates thereof. There is some overlapping between true dyeing and other methods of coloring, which are called dyeing in the industry. Products which are commonly dyed include textile fibers, plastic films, anodized aluminum, fur, wood, paper, leather, and some foodstuffs. *See* Dye.

Dyeing is accomplished by dissolving or dispersing the colorant in a suitable vehicle (usually water) and bringing this system into contact with the material to be dyed. Although many dye molecules or aggregates may adhere to the material surface when they meet, dyeing does not occur until the adhering dye particles migrate within the fibers or films. All dyeing processes are designed to accomplish ultimately penetration of the undyed substance by the colorant.

Assistants are materials which do not impart color to the product to be dyed but promote or retard dyeing. Usually, they affect the dye molecule.

Swelling agents are assistants which open up the structure of the fiber temporarily so that dye molecules or aggegates may enter more freely and reach otherwise inaccessible dye sites.

Carriers are agents (often solvents of low water solubility) which accelerate dyeing by breaking up or dissolving dye aggregates and bringing them to the fiber-water interface in a size small enough to be absorbed by the material.

Dye retarders are a class of dyeing assistants, usually inorganic or organic salts, which slow up the dyeing process by forming evanescent compounds with the dye, by buffering or depressing the ionization of an acid assistant, or by temporarily occupying the more active or more accessible dye sites on the fiber, later to be dislodged therefrom by the dye.

Aftertreating agents are salts, resins, or other products (more frequently applied to cellulosic fibers) to render the colored fabric more resistant to the effects of washing, perspiration, or fading by ozone or combustion gases. More often than not, their application causes a loss in light fastness of the dyed material.

Textiles. Cellulose fibers, such as cotton and rayon, are most commonly dyed by immersion of the fibers in a solution of direct dyes using an electrolyte such as common salt as assistant and then boiling this dyebath. Such dyeings usually exhibit only commercial (minimum) resistance to washing. Treatment of the properly dyed fibers with resins and copper, for example, increases the resistance to washing with minimum loss of light resistance.

Synthetic fibers, such as cellulose acetates and triacetate (Arnel), are dyed in a supension of solvent-soluble dyes by immersion. Polyamide synthetic fibers are dyed like wool with acid, metallized acid, neutral metallized, or fiber-reactive mordant dyes, azoics, and selected direct dyes from an acid bath. Special processes have also been developed for acrylic, polyester, and propylene fibers. *See* Textile chemistry.

Nontextile materials. Anodized aluminum is readily dyed by many textile dyes. Light and weather resistance undreamed of in textile applications of some of these same dyes is achieved.

Paper pulp is usually dyed in the paper beater by dyes normally employed for cotton; on occasion, it is tinted by wool dyes, and it is frequently tinted by addition of pigments to the beater. Finished paper is also colored by passing it over rollers which supply dye or colored coatings to its surface (calender staining).

Leather is dyed at low temperatures with the classes of dyes normally used for wool and cotton. Formic acid is normally used to exhaust the dye. For dress gloves, leather is usually colored by applying the dye on the grain surface, leaving the flesh side undyed. Leather is also dyed with natural dyes such as logwood, fustic, and quercitron. Leather fresh from tanning and containing considerable moisture is dyed in Europe by tumbling with dry water-soluble dye.

Most food products which are artificially colored are not actually dyed. Maraschino cherries, however, are dyed for several hours with food dyes, then washed and placed in flavored syrup.

Many plastic materials may be dyed by processes similar to those employed for textiles. Nylon, cellulose acetate, polyethylene, polypropylene, and polyester resins are dyeable with dyes which color these materials in yarn form. *See* Manufactured fiber; Natural fiber. [J.E.Lo.]

Dynamic braking A technique for braking in which mechanical energy is converted to heat or electrical energy in order to slow or stop motion. An all-mechanical dynamic brake consists of rotating vanes that circulate a viscous fluid in a manner that generates heat. This is one way that the power of the wind is harnessed for space heating. An electric dynamic brake consists of an electric dynamo in which the mechanical energy is converted to electric form, and either converted to heat in a resistor or returned to the supply lines. Typically, electric braking is accomplished with the same machine that serves as the drive motor. Electric dynamic braking is employed in electric vehicles, elevators, and other electrically driven devices that start and stop frequently. *See* Wind power.

The most common type of dynamic braking will be explained for a direct-current (dc) motor. To accomplish braking action, the supply voltage is removed from the armature of the motor but not from the field. The armature is then connected across a resistor. The electromotive force generated by the machine, now acting as a generator driven by the mechanical system, forces current in the reverse direction through the armature. Thus a torque is produced to oppose rotation, and the load decelerates as its energy is dissipated, mostly in the external resistor, but to some extent in core and copper losses of the machine. *See* DIRECT-CURRENT MOTOR.

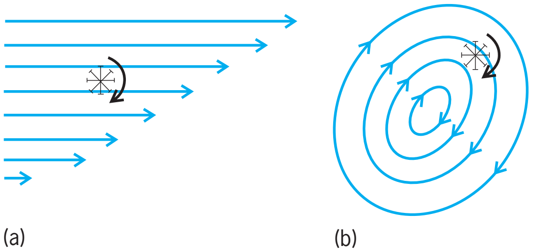
Electric braking can also be accomplished by causing the energy of the rotating system to be converted in the armature to electrical energy and then returned to the supply lines. This mode of operation, called regenerative braking, occurs when the counterelectromotive force exceeds the supply voltage.

Interchanging two of the lines supplying a three-phase alternating-current (ac) induction motor also produces braking. In this case, called plugging, the direction of the electromagnetic torque on the rotor is reversed to cause deceleration. Both the energy of the system and the energy drawn from the supply lines are expended in copper and core losses in the machine as heat. The power lines must be disconnected when the rotor comes to rest. *See* ALTERNATING-CURRENT GENERATOR; ELECTRIC POWER GENERATION; ELECTRIC ROTATING MACHINERY; INDUCTION MOTOR; TRANSMISSION LINES. [A.R.E.]

Dynamic instability A state of fluid flow in which the distribution of mass and momentum is unstable. Fluid flows are subject to a variety of instabilities which generally cause the flow to become more complex and which often lead to turbulent, chaotic flow. Instabilities are responsible for a variety of phenomena in natural flows, including cyclones, hurricanes, and thunderstorms in the atmosphere; mantle convection in the Earth's interior; and granules and supergranules in stellar atmospheres. A great deal of research in the geophysical and astrophysical sciences has focused on flow instabilities; and instability plays an important role in engineering problems ranging from naval engineering and aeronautics to the design of efficient heating and cooling systems. *See* FLUID FLOW; TURBULENT FLOW.

Fluid instabilities may be broadly divided into two classes: convective and dynamic. While convective instabilities can be understood rather easily in terms of forces acting on displaced parcels of fluid, dynamic instabilities are more varied and more challenging to understand. This broad class of fluid instabilities is responsible for the cyclones and anticyclones that dominate the weather in middle and high latitudes, as well as meanders and rings in ocean currents such as the Gulf Stream. These instabilities are ultimately responsible for the lack of predictability of complex flows such as are found in the atmosphere. *See* CONVECTIVE INSTABILITY; CYCLONE; WIND.

Many, but not all, dynamic instabilities can be understood with the aid of a vorticity principle and an invertibility principle. The vorticity of a fluid can be thought of as the rate of rotation of a rigid paddle wheel embedded in the flow (see illustration). [Mathematically, it is the curl of the vector velocity field.] The rotation can be brought about by shear (a change in the speed of the flow in the direction across the flow) and by the curvature of the flow. Vorticity is important for two reasons. First, in two-dimensional flows, vorticity is conserved; that is, if the paddle wheel is followed around it is observed that its rate of rotation remains constant. Second, in such flows, it is possible to work backward from knowledge of the vorticity at every point in the fluid to find the flow field at every point. This is called the invertibility principle. Basically, a clockwise vorticity at a point in the fluid will induce a clockwise rotation of the fluid nearby; the total velocity field in the fluid can then be found by adding the velocities induced by all the vorticities at each point. *See* CALCULUS OF VECTORS.



The vorticity of a fluid is related to the rate at which a rigid paddle wheel would rotate if placed in the flow. (*a*) The paddle wheel rotates because the velocity of the fluid varies in a direction perpendicular to the flow. (*b*) Rotation is generated by the curvature of the flow.

The flow of the Earth's atmosphere is three-dimensional. Under this circumstance, vorticity is not conserved because fluid converging on or diverging from a point in the fluid causes it to spin faster or slower. (The principle at work here is the conservation of angular momentum.) Fortunately, the Earth's atmosphere is usually stably stratified; that is, a parcel displaced upward will be colder than its environment and will accelerate downward toward its original position. In this sense the atmosphere is convectively stable. It is possible to identify a quantity that reflects the air's density and at the same time is conserved as long as no heat is added to or subtracted from the air. This quantity is called the potential temperature (θ) and is related to temperature and pressure by the expression below, where T is the temperature in

$$\theta = T\left(\frac{1000}{p}\right)^{0.287}$$

kelvins and p is the pressure in millibars. Generally, θ increases upward in the atmosphere: slowly in the troposphere (a layer of air that extends upward to roughly 6 mi or 10 km) and more rapidly in the stratosphere (a layer of air between about 6 and 18 mi, or 10 and 30 km). *See* STRATOSPHERE.

The criterion for the dynamic instability of large-scale three-dimensional flows is analogous to barotropic instability of two-dimensional flows. The necessary condition for this kind of instability is that potential vorticity must be a maximum or minimum somewhere on a surface of constant θ. The type of instability that results from maxima or minima of potential vorticity in a fluid is called internal baroclinic instability. This type of instability can draw on both the kinetic energy of the original flow and the potential energy that occurs when there are horizontal variations of density.

Observations of the Earth's atmosphere show that the potential vorticity of the troposphere in middle and high latitudes is nearly uniform. But when a gently sloping θ surface is followed into the stratosphere, a large increase of potential vorticity occurs. Even so, there is no localized maximum or minimum of potential vorticity, but just a large gradient of the quantity, concentrated near the boundary between the troposphere and stratosphere. (Many meteorologists define the stratosphere as a region of large potential vorticity.) For this reason, internal baroclinic instability seldom occurs in the atmosphere. *See* ATMOSPHERE. [K.A.Em.]

Dynamic meteorology The study of those motions of the atmosphere that are associated with weather and climate. Atmospheric motions span an enormous range of spatial and temporal scales; dynamic meteorology concentrates mainly on large-scale and mesoscale motions. Large-scale motions are those with horizontal scales in excess of a few hundred kilometers and time scales longer than a day. Such motions are strongly influenced by the rotation of the Earth and by the vertical thermal stratification of the atmosphere. Mesoscale motions have horizontal scales in the range of a few kilometers to a few hundred kilometers; they are often associated with convective clouds and precipitation.

The mechanics and thermodynamics of the unsaturated atmosphere are governed by three fundamental conservation laws: (1) conservation of mass, expressed by the mass continuity equation; (2) conservation of momentum, expressed by Newton's second law of motion; and (3) conservation of thermodynamic energy, expressed by the first law of thermodynamics. For saturated conditions, conservation of water substance must also be considered. *See* CONSERVATION OF MASS; CONSERVATION OF MOMENTUM; CORIOLIS ACCELERATION; NEWTON'S LAWS OF MOTION; THERMODYNAMIC PRINCIPLES.

Statics. The vertical structure of the atmosphere is determined by the equation of state for an ideal gas and by the hydrostatic relationship. The former expresses the relationship among pressure, density, and temperature at any point; the latter expresses the balance between the upward-directed component of the pressure-gradient force (associated with the approximate exponential decrease of pressure with height) and the downward-directed gravity force. The equation of state and hydrostatic equation may be combined to form the hypsometric equation (1), which relates the geopotential height differences

$$Z_2 - Z_1 = \frac{R}{g}\int_{p_2}^{p_1} T\, d\ln p \qquad (1)$$

$(Z_2 - Z_1)$ between two pressure surfaces p_2 and p_1 to the mean temperature T in the layer between the two surfaces; and where R (the gas constant for dry air) $= 287\ \text{J} \cdot \text{kg}^{-1} \cdot \text{K}^{-1}$ and g (the acceleration of gravity) $= 9.81\ \text{m} \cdot \text{s}^{-2}$. Thus, pressure decreases more rapidly with height in cold air than in warm air. *See* GAS; HYDROSTATICS.

Except in regions of active precipitation, where the heating rate due to latent heat of condensation is large, temperature changes following the motion of individual parcels of air are controlled primarily by adiabatic expansion and compression as the air parcels move to lower or higher pressure. The thermodynamic state of such parcels can be characterized by the potential temperature θ, as in Eq. (2), where p_0 [$= 10^5$ pascals

$$\theta = t\left(\frac{p_0}{p}\right)^{R/C_p} \qquad (2)$$

(1000 millibars)] is a reference pressure and cp ($= 1004\ \text{J} \cdot \text{kg}^{-1} \cdot \text{K}^{-1}$) is the specific heat at constant pressure. The potential temperature is the temperature that a parcel of air at pressure p and temperature T would acquire if it were moved adiabatically to pressure p_0. When all diabatic heat sources can be neglected, θ remains constant in time for each air parcel. Normally, θ increases with altitude in the atmosphere, so that an air parcel displaced upward (downward) has a value of θ less (greater) than that of its environment, and hence experiences a net buoyancy force that tends to return it to its equilibrium level. The atmosphere is then said to be statically stable. When θ is constant with height, a condition that occurs when the temperature decreases with height at a rate $10^\circ\text{C} \cdot \text{km}^{-1}$ ($30^\circ\text{F} \cdot \text{mi}^{-1}$), the atmosphere is said to be neutrally stable; if θ decreases with height, the atmosphere is absolutely unstable and convective motion develops spontaneously. If an air parcel is saturated, upward displacement causes water vapor to condense and release its latent heat of condensation; the potential temperature is then no longer conserved.

The hydrostatic relationship implies that pressure decreases monotonically with altitude. Pressure may thus be substituted for height as the independent vertical coordinate. If the atmosphere is everywhere statically stable so that θ increases monotonically with height, potential temperature can also be used as a vertical coordinate. Potential temperature coordinates are useful, for analysis of adiabatic motions, since in that reference frame prediction of adiabatic flow is reduced to a two-dimensional problem of following the motion on θ surfaces. Isobaric coordinates, in which pressure is the vertical coordinate, have the advantage of eliminating any explicit reference to the density field. These are the most commonly used vertical coordinates in dynamic meteorology. *See* CONVECTIVE INSTABILITY; DYNAMIC INSTABILITY; HYDROSTATICS; ISOBAR (METEOROLOGY).

Baroclinic instability. Baroclinic energy conversion processes are responsible for the growth and maintenance of most large-scale weather disturbances.

In midlatitudes in the troposphere, potential temperature normally decreases from Equator to pole on isobaric surfaces. This decrease does not occur uniformly, but tends to be concentrated in the jet stream, a narrow band of strong westerly winds in the upper troposphere that encircles the globe in midlatitudes. *See* JET STREAM.

When the shear of the zonal wind is sufficiently strong so that the meridional gradient of potential vorticity on a constant potential temperature surface is locally reversed, or when there is a nonvanishing gradient of potential temperature at the surface of the Earth, the linearized equations have solutions in the form of exponentially growing disturbances. These baroclinically unstable modes have growth rates, structures, and scales similar to those observed in developing extratropical cyclones. Baroclinic instability provides a mode whereby infinitesimal disturbances may amplify into large-amplitude storms. However, in many cases it appears that storms in the atmosphere grow through nonlinear interactions involving preexisting disturbances. Such processes must generally be studied by numerical simulations on high-speed computers.

Mesoscale convective systems. For horizontal scales less than several hundred kilometers, the major energy source is not baroclinic instability; it is latent heat release by cumulonimbus clouds. The convective storms associated with such clouds can occur only when the atmosphere is conditionally unstable [see Eq. (2)], sufficient moisture is present, and there is an initial disturbance strong enough to lift air parcels high enough to release the conditional instability. Mesoscale convective systems take a variety of forms. Among these are hurricanes, squall lines, and mesoscale convective complexes. *See* HURRICANE; MESOMETEOROLOGY; SQUALL LINE.

Numerical weather prediction. In current global weather prediction models, a mixture of techniques is often employed. Nearly all models use finite difference representations for the vertical coordinate and time; the horizontal variation is generally represented either by a network of grid points at uniform intervals of latitude and longitude or by a finite set of spherical harmonics. *See* SPHERICAL HARMONICS.

To predict the weather dynamically, it is necessary to solve the dynamics equations by integrating in time, starting from an initial state of the atmospheric variables determined from observations. In practice, observational errors and poor data coverage, particularly over the oceans, make it impossible to exactly determine the initial state of the atmosphere. Moreover, the state determined from observations generally does not properly represent the true dynamical balance among the pressure and wind fields. This imbalance introduces noise that is interpreted as high-frequency inertia-gravity waves. If a prediction is attempted from such an initial state, the noise rapidly dominates the true, slowly evolving weather disturbances. In order to prevent the growth of such spurious noise, the analysis must be initialized by processing it in a manner that assures a dynamical balance between the pressure and wind fields while preserving the actual observations as closely as possible. However, even if the initial state were known perfectly, there still would be a limit beyond which errors would dominate the forecast. *See* WEATHER FORECASTING AND PREDICTION.

Global climate modeling. In addition to their role in weather prediction, dynamical models can also be used to simulate global climate. Climate is the study of the average state of the atmosphere and its seasonal and interannual variability. Climate is determined by the joint influence of energy sources and sinks at the Earth's surface, and the transformation and transport of energy in the atmosphere and the oceans. Models that simulate these processes are usually referred to as general circulation models. Such models must contain accurate representations of all the important physical processes that influence the circulation. *See* ATMOSPHERE; CLIMATE MODELING; METEOROLOGY; WIND. [J.R.H.]

Dynamic nuclear polarization The creation of assemblies of nuclei whose spin axes are not oriented at random, and which are in a steady state that is not a state of thermal equilibrium. Under commonly occurring conditions, the spin axes of nuclei (with nonzero spin) are oriented at random; where this is not so, the nuclei are said to be polarized. Assemblies of polarized nuclei are not in a state of thermal equilibrium except under rather extreme conditions (for example, temperatures below 10 millikelvins and magnetic fields greater than several teslas), and therefore schemes have been devised to produce polarized assemblies, in a steady state which is not a state of thermal equilibrium, under less extreme conditions of temperature and so forth. Such schemes constitute dynamic nuclear polarization.

Among the many applications of polarized nuclei are the following. Nuclear forces are spin-dependent, and although the spin-dependent part can be found by using unpolarized assemblies, the experiments are simpler and their interpretation is clearer if polarized nuclei are used. Assemblies of polarized nuclei have a lower geometrical symmetry than assemblies of randomly oriented nuclei, and so these have been used to investigate the fundamental symmetries of nature. Polarized nuclei have been used to enhance the signal in free precession magnetometers and similar instruments, and the use of an assembly of polarized nuclei as a gyroscope has also been suggested. *See* MAGNETOMETER; NUCLEAR ORIENTATION; PARITY (QUANTUM MECHANICS); SPIN (QUANTUM MECHANICS). [J.M.D.]

Dynamic similarity A relationship existing between two fluid flows when they have identical types of forces that are parallel at all corresponding points, with magnitudes related by a constant scale factor. Dynamic similarity makes it possible to scale results from model tests to predict corresponding results for the full-scale prototype.

Dynamic similarity requires faithful reproduction of detail on the model (geometric similarity); the same flow pattern, including boundary shapes (kinematic similarity); and test conditions that match relevant dimensionless ratios between model and prototype. Dynamically similar flows are said to be homologous. It may not be possible in a practical test to match all dimensionless parameters. It is most important to match parameters that represent the dominant physical effects. Thus, correct simulation of viscous effects requires that Reynolds number be matched; Mach number may be ignored if compressibility effects are not important. In ship model tests, Froude number must be matched to duplicate wave patterns; the effect of Reynolds number on viscous drag may be predicted analytically. *See* DIMENSIONAL ANALYSIS; DIMENSIONLESS GROUPS; FLUID MECHANICS; FROUDE NUMBER; MACH NUMBER; MODEL THEORY; REYNOLDS NUMBER. [A.T.McD.]

Dynamical Time The independent variable in the differential equations of motion of orbiting celestial bodies in a theory of relativity. The bodies move in accord with Newton's laws of motion and gravitation. Several types of dynamical time have been defined for different origins and theories of relativity. Integration of the equations, combined with observed positions, leads to an ephemeris, which lists coordinates as a function of dynamical time. *See* EPHEMERIS.

Dynamical Time is a uniform scale of time, unlike the mean solar scale Universal Time (UT), based on the Earth's rotation, which has variations in rotational speed. In 1952 the International Astronomical Union (IAU) defined a dynamical scale and named it Ephemeris Time (ET). *See* EARTH ROTATION AND ORBITAL MOTION.

Also, in 1952 the U.S. Naval Observatory began a program to obtain Ephemeris Time rapidly by photographing the Moon and nearby stars of known position. In 1958 a joint program with the National Physical Laboratory at Teddington, England, gave 9,192,631,770 cycles per second of Ephemeris Time as the frequency of its cesium-beam atomic clock. *See* ATOMIC TIME.

Comparisons between Ephemeris Time and Atomic Time (AT) showed no definite systematic difference other than a constant. Therefore, Ephemeris Time could be obtained from Atomic Time with very high accuracy, and immediately.

In 1976 the IAU defined two timelike arguments based on International Atomic Time (French acronym, TAI). Terrestrial Dynamical Time (TDT) was for use with geocentric ephemerides. In effect, TDT = TAI + 32.184 s. Barycentric Dynamical Time (TDB) was the argument to be used when the origin was at the barycenter of the solar system. TDT and TDB differ only by periodic relativistic terms. Thus, Dynamical Time, which was based formerly on motions of bodies in the solar system, was now derived from Atomic Time in the form of timelike arguments.

The use of the word dynamical for scales that do not involve dynamics caused some problems. In 1991 the IAU replaced TDT by Terrestrial Time (TT). Also, it introduced terminologies Geocentric Coordinate Time (TCG) and Barycentric Coordinate Time (TCB). *See* CELESTIAL MECHANICS; RELATIVITY; TIME. [W.M.]

Dynamics That branch of mechanics which deals with the motion of a system of material particles under the influence of forces, especially those which originate outside of the system under consideration. From Newton's third law of motion, namely, to every action there is an equal and opposite reaction, the internal forces cancel in pairs and do not contribute to the motion of the system as a whole, although they determine the relative motion, if any, of the several parts.

Particle dynamics refers to the motion of a single particle under the influence of external forces, particularly electromagnetic and gravitational forces. The dynamics of a rigid body is the study of the motion, under given forces, of a system of particles, the distances between which are postulated to be constant throughout the motion.

In classical dynamics the basic relation that enables the motion to be determined once the force is known is Newton's second law of motion, which states that the resultant force on a particle is equal to the product of the mass of the particle times its acceleration. For a many-particle system it becomes impracticable to write and solve this equation for each individual particle and, in general, the motion may be computed only on a statistical basis (that is, by the methods of statistical mechanics) unless, as for a few particles or a rigid body, the number of degrees of freedom is sufficiently small. *See* DEGREE OF FREEDOM (MECHANICS); KINEMATICS; KINETICS (CLASSICAL MECHANICS); NEWTON'S LAWS OF MOTION; RIGID-BODY DYNAMICS; STATISTICAL MECHANICS. [H.C.Co./B.G.]

Dynamometer A device for measuring the torque, force, or power available from a rotating shaft. The shaft speed is measured with a tachometer, while the turning force or torque of the shaft is measured with a scale or by another method. Power may be read from the instrumentation or calculated from shaft speed and torque. *See* TACHOMETER.

The two types are the transmission dynamometer and the absorption dynamometer. The transmission dynamometer transmits the force while measuring the elastic twist of the output shaft. An absorption dynamometer absorbs the power and dissipates it as heat by restraining the output shaft mechanically with a friction brake, hydraulically with a water brake, or electrically with an electromagnetic force. Since the restraining element tends to rotate with the output shaft, the force of the shaft can be determined by measuring the force required to arrest the rotation of the restraining element. Torque is then calculated by multiplying the force times the length of the lever arm, or the distance through which the force acts. *See* TORQUE.

One type of electric dynamometer consists of a direct-current (dc) machine with the stator cradle-mounted in antifriction bearings. The rotor is connected to the shaft of the machine under test. The field current is introduced through flexible leads.

The stator is constrained from rotating by a radial arm of known length to which is attached a scale for measuring the force required to prevent rotation. The torque of the connected machine is found from the product of the lever arm length and the scale reading, after correcting the scale reading by the amount of the zero torque reading.

The most common use of the dynamometer is in determining the power of an electric motor or engine of a car, truck, or other vehicle. A dynamometer that connects to the engine crankshaft is an engine dynamometer. One that has rollers turned by the vehicle drive wheels is a chassis dynamometer; this type is widely used in the automotive industry for mileage accumulation, emissions, fuel economy, and performance testing of cars and trucks. [D.L.An.]

Dysprosium A metallic rare-earth element, Dy, atomic number 66 and atomic weight 162.50. The naturally occurring element is composed of seven stable isotopes. Dysprosium forms a white oxide, Dy_2O_3, which dissolves in acid to give a yellowish-green solution. For properties of the metal *see* RARE-EARTH ELEMENTS; *See also* PERIODIC TABLE.

The metal is attacked readily by air at high temperatures, but at room temperatures, in massive blocks, it is fairly stable in the atmosphere and remains shiny for long periods of time. Dysprosium is paramagnetic, but as the temperature is lowered, it becomes antiferromagnetic at the Néel point (178 K or −139°F) and ferromagnetic at the Curie point (85 K or −306.4°F). At very low temperatures, the metal shows strong anisotropic magnetic properties. [F.H.Sp.]

E

e (mathematics) The number e is usually defined as the limit approached by the expression

$$\left(1+\frac{1}{n}\right)^n$$

as n approaches infinity. If the given expression is expanded by the binomial theorem, and if one uses the theorem that the limit of the quotient of two polynomials of equal degree as the variable tends to infinity is equal to the ratio of the coefficients of highest degree, one obtains the expansion in relation (1). It can be shown

$$e = 1 + \frac{1}{1} + \frac{1}{1\cdot 2} + \frac{1}{1\cdot 2\cdot 3} + \cdots + \frac{1}{1\cdot 2\cdot 3\cdots n} + \cdots \qquad (1)$$

by elementary methods that e is irrational; that is, it cannot be represented as the quotient of two integers. Furthermore, e is transcendental; it does not satisfy any algebraic equation with integral coefficients.

By the method outlined above, it may be shown that the limit of

$$\left(1+\frac{x}{n}\right)^n$$

as n tends to infinity is e^x, and moreover that relation (2) holds.

$$e^x = 1 + \frac{x}{1} + \frac{x^2}{1\cdot 2} + \cdots + \frac{x^n}{1\cdot 2\cdot 3\cdots n} + \cdots \qquad (2)$$

The function e^x is of great importance in mathematical analysis and is encountered in numerous problems in applied mathematics. *See* Binomial theorem; Calculus; Logarithm. [A.N.L.; S.Bo.]

Ear (vertebrate) The organ which sends information about sound to the brain, constituting the sense of hearing, as well as vestibular information about the orientation of the head in space. The vertebrate ear is generally divided into three regions that have discrete functions: The inner ear is found in all vertebrates, and it subsumes both hearing and balance (functions). The external ear and the middle ear, not found in all vertebrates, enhance hearing. *See* Hearing (vertebrate).

Ear structure. The inner ear is embedded in the ear (or otic) capsule and has a common embryological development in all vertebrate groups. In comparing the inner ears of different vertebrates, the major structural differences are associated with the auditory part of the ear. With few exceptions, the vestibular portion of the inner ear is developmentally, structurally, and functionally nearly the same in all vertebrates.

The middle ear and external ear are not found in the fishes. All tetrapods (amphibians, reptiles, birds, and mammals) have a middle ear with a tympanic membrane. Reptiles, birds, and mammals also have an external auditory meatus (or canal) which extends from the tympanic membrane to the external surface of the head. Mammals generally have an external structure, the pinna, that helps “collect” and carry the sound to the ear canal and then to the tympanum. The major difference in the middle ear among tetrapods is that it has a single ear bone, or ossicle (often called the columella or stapes), in amphibians, reptiles, and birds, while mammals have three middle-ear bones (malleus, incus, and stapes).

The basic sensory unit in the inner ear is the sensory hair cell. These specialized cells are morphologically similar in all of the epithelial structures of the ear in all vertebrates (and in the lateral line of fishes and amphibians), but they may have either auditory or vestibular functions depending upon the associated superstructure. The superstructure serves to facilitate the transmission of vibrations from the environment to the hair cells. For the vestibular apparatus, the superstructure blocks external vibratory energy, but sensitizes the sensory hair cells to the pull of gravity and to acceleratory and deceleratory movements of the head. *See* Lateral line system.

The sensory hair cell is a columnar, polarized structure from whose apex extend thin cilia that resemble hairs. Each hair cell has many such cilia, making up a ciliary bundle which bends in response to motional energy. The cilia in each bundle include many stereocilia and a single, eccentrically positioned kinocilium. The cilia extend into an extracellular fluid-filled space, with their tips embedded in a gelatinous membrane. *See* Cilia and flagella.

The sensory hair cell is the detector of motion, either produced by compression and rarefaction of molecules due to sound waves, or imparted by movement of the head against gravity. This motion produces bending of the ciliary bundles, and this in turn results in a change in configuration of the membrane overlying the stereocilia and opening of channels in the membrane. It is generally thought that these channels admit calcium into the cell, and this in turn interacts with other components of the cell. Ultimately, the energy generated by these interactions causes release of neurotransmitter at the base of the cell, and results in stimulation of afferent neurons which contact the cell. *See* Neurobiology; Synaptic transmission.

Fishes. In elasmobranchs and bony fishes the inner ear is located in the brain (cranial) cavity somewhat behind the eye. The inner ear has several regions, including three semicircular canals and otolith organs. Other than the very primitive jawless fishes which have one or two semicircular canals, all other vertebrates have three canals. All fishes, amphibians, reptiles, and birds have three otolith organs—the saccule, utricle, and lagena—while mammals do not have the lagena (Fig. 1).

At one end of each endolymph-filled semicircular canal is a widened area, the ampulla, which has a sensory area called the crista (or crista ampullaris). The crista contains large numbers of sensory hair cells, as well as other cells which provide support for the hair cells. At the base of the hair cells are nerve endings from the vestibular branch of the eighth cranial nerve. Each of the otolith organs also has a sensory area, called a macula, that contains hair cells and supporting cells. The cilia of the otolithic organs are embedded in a thin gelatinous membrane that also contains very dense calcium carbonate crystals. In elasmobranchs, primitive fishes, and all tetrapods, these crystals are called otoconia. In most bony fishes the crystals are fused into a single mass in each otolith organ called the otolith.

Fishes are able to detect a wide range of sound using their inner ear. Tetrapods detect sounds that impinge on the tympanic membrane and then are carried by the middle-ear bones to the inner ear, where the sounds set the fluids of the ear into motion and thus stimulate the sensory hair cells. In fishes, however, this kind of pathway is not needed since sound is already traveling through

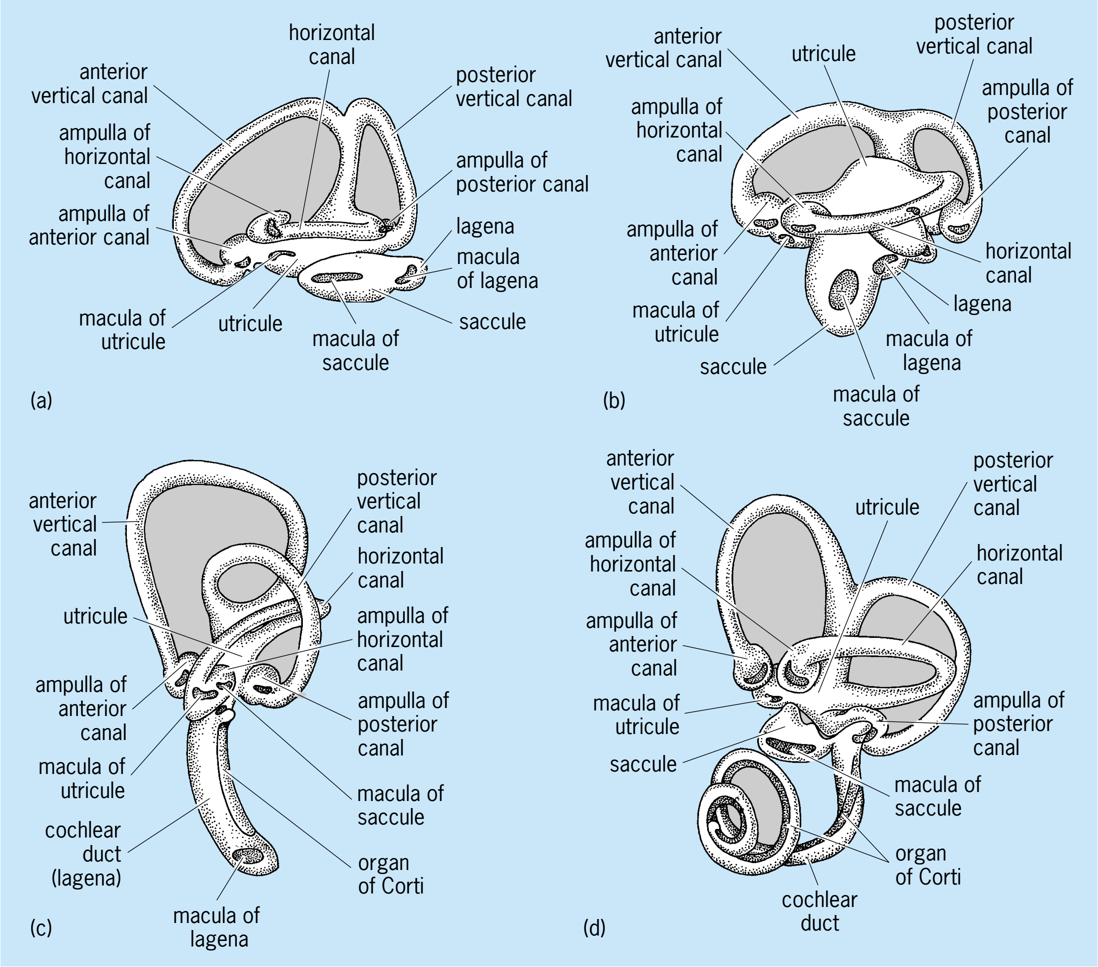


Fig. 1. Left-ear external view of the membranous labyrinths of (*a*) teleost, (*b*) frog, (*c*) bird, and (*d*) mammal. (*After A. S. Romer, The Vertebrate Body, 3d ed., Saunders, 1962*)

water. Indeed, since the fish's body is the same density as that of water, sound would travel right through the fish were it not for the otoconia or otoliths. Since these structures are much denser than the fish's body and the water, they stay still while the fish's body and the attached sensory hair cells move with the sound field. Since the stereocilia are attached to both the top of the hair cells and to the otoconia or otolith, they are bent as their base moves with the macula and their tops stand still with the otoliths. This bending sends signals to the nerves and then to the brain, indicating the presence of a sound. Most fishes detect sounds from 30 to 800 or 1000 Hz, with best hearing from 200 to 500 Hz. However, some fishes, called hearing specialists, have evolved special mechanisms to enhance hearing to 3000 or 4000 Hz. The hearing specialists use a secondary structure, the swim bladder, to enhance hearing capabilities. The swim bladder is a bubble of gas found in the abdominal cavity of most bony fishes, and it is used primarily for buoyancy control, though it may also be used in sound production in some species. Since the swim bladder is filled with gas, its density is different from that of the rest of the fish, and in a sound field the walls of the swim bladder are set into vibration and act as a small sound source to send sounds to the ear. *See* SWIM BLADDER.

Tetrapods. Many structural and functional features of the fish inner ear are also found in the tetrapod ear. The inner ear of tetrapods is embedded in the otic bones of the skull, with the membranous labyrinth attached to the bony labyrinth by connective tissue but suspended in perilymphatic fluid. There are three semicircular canals, with cristae, and, except in mammals which do not have a lagena, the three otolithic organs (Fig. 1*b*, *c*, *d*). In their morphology and physiology the vestibular parts of fish and tetrapod ears are nearly the same. For the most part, the tetrapod otolithic organs function only as vestibular organs rather than playing an auditory role as they do in fishes.

Amphibians. The tympanic membrane of frogs and toads is located on the lateral surface of the head. Attached to its inner aspect is a small rodlike bone, the stapes, or columella, which runs through the air space of the middle-ear cavity and plugs a small hole, the oval window, beyond which are the inner-ear fluids. The frog's tympanic membrane collects sound energy and transmits it through the columella to the inner-ear fluids. In the lagenar portion of the amphibian's membranous labyrinth are two areas of hair cells, the amphibian and basilar papillae, that are found in no other vertebrate group. The basilar papilla lies on the posterior wall of the saccule between the oval window and the round window, another membrane-covered opening between middle ear and inner ear. Vibratory energy enters the inner ear at the oval window, passes through the basilar and amphibian papillae causing them to vibrate, and then dissipates at the round window. *See* AMPHIBIA.

Birds and reptiles. In most reptiles and birds the tympanic membrane lies not on the surface of the head but internally, at the end of the tube called the external auditory meatus. A middle-ear cavity (with its eustachian tube to the mouth) lies medial to the tympanic membrane. A single ossicle, the columella, crosses this cavity from the tympanic membrane to the oval window at the inner ear. While both birds and reptiles have saccule, utricle, and lagena, as well as semicircular canals, they also have a newly evolved end organ, the basilar papilla, which is the part of

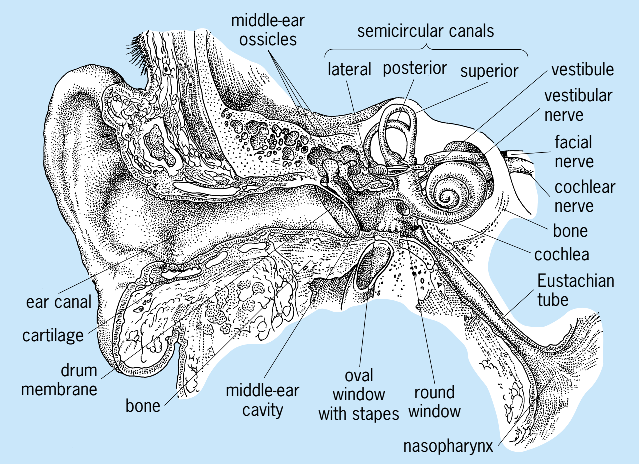

Fig. 2. Schematic drawing of the human ear. (*After M. Brödel, Three Unpublished Drawings of the Anatomy of the Human Ear, Saunders*)

the ear used for hearing in both groups of animals. (The avian and reptilian basilar papilla is thought to be a totally different structure, in terms of evolution and embryonic origin, than the basilar papilla found in amphibians.) The basilar papilla in birds and reptiles is often also called the cochlea, and there is some evidence to suggest that this end organ is directly related to the mammalian cochlea. The basilar papilla in reptiles is generally somewhat shorter than that found in birds, and there is considerable variation in the specific structure of this end organ in different species. The basilar papilla contains sensory hair cells. In birds, the basilar papilla sensory hair cells are differentiated into short and tall hair cells, which may have different functions in hearing. *See* Aves; Reptilia.

Mammals. The mammalian ear consists of three parts: the external ear which receives the sound waves; the middle ear which transmits the vibrations by a series of three small bones; and the inner, or internal, ear, a complex bony chamber placed deep in the skull (Fig. 2). The external auditory meatus plus the newly evolved pinna, a cartilaginous structure projecting from the ear, compose the external ear. The shape and size of the pinna vary greatly. The auditory function of the pinna varies widely in different species. In some species the pinna is moved in the direction of a sound source and helps the animal focus sound to the external auditory meatus and then down the ear canal. In other species, such as humans, the pinna may have a lesser function, but even in humans the pinna helps to discriminate between sounds coming from the front and back of the head so that the person can better tell the direction of a sound source. *See* Mammalia.

As in other tetrapods, the first gill slit is modified as a middle-ear cavity, communicating with the pharynx by way of the eustachian tube. In other tetrapods this tube is permanently open, while in mammals it is usually closed. Instead of the single columella of other tetrapods, the mammalian middle ear has three bones, closely articulated with one another. The innermost is the stapes, which fits into the oval window of the inner ear and is homologous with the columella. Attached to the tympanic membrane is the malleus, and lying between the malleus and stapes is the incus. In spite of having additional bones, the mammalian middle ear functions basically as do those of amphibians, reptiles, and birds in transforming aerial vibrations into fluid vibrations within the inner ear.

In the mammalian inner ear the vestibular apparatus is much like that of other tetrapods. The auditory portion, however, is elongated and coiled into a snail shape. This structure is called the cochlea. The epithelium of the basilar papilla, called the organ of Corti, is more differentiated in mammals than in other tetrapods. The number of turns in the cochlea varies. At the base of the cochlea is the oval window, which carries sound energy into the inner ear, and the round window, where this energy is dissipated after traveling in the cochlea.

Running the length of the coiled cochlea are three channels; the uppermost, the scala vestibule, and the lowest, the scala tympani, are filled with perilymph. In the center is the scala media, or cochlear duct. The cochlear duct is filled with endolymph, and it is separated from the scala vestibule above by the thin Reissner's membrane and from the scala tympani below by the basilar membrane.

The basilar membrane is suspended on both sides by ligaments or bone. The basilar membrane varies regularly in width, being narrow at the base (where it is most responsive to high frequencies) and wide at the apex (where it is most responsive to low frequencies). Resting upon the basilar membrane is the organ of Corti. The organ of Corti contains several cell types in addition to the auditory hair cells. The hair cells lying on the internal side of the pillar cells are called the inner hair cells, and those lying on the external side are called the outer hair cells. There may be up to 20,000 sensory hair cells in a cochlea of a normal young human, although the number of hair cells declines with age as a result of normal cell death, damage due to some medications, and trauma caused by loud sounds. A healthy teenager may hear sounds from below 20 Hz to upward of 20,000 Hz, while an adult 40 or 50 years old may hear sounds only to 14,000 Hz (or even less). This loss of hearing is associated with death of sensory hair cells.

Sounds entering the mammalian inner ear at the oval window travel along the basilar membrane from basal to apical ends, causing vibrations of the membrane. Different frequencies maximally excite different regions of the basilar membrane based on differences in the stiffness of the membrane itself. The response of the different regions of the organ of Corti to specific frequencies is also thought to be enhanced by the sensory hair cells themselves. Whereas early investigations suggested that both inner and outer hair cells were involved in detection of sound per se, recent evidence suggests that the inner hair cells have the major role in hearing, while the outer hair cells modify the function of the ear and help to enhance the sensitivity of the inner hair cells. *See* Hearing (human). [A.N.P.; D.B.W.]

Ear protectors Objects or devices which insert into the ear canal (called earplugs) or cover the outer ear (called earmuffs) and which have a variety of applications. They may protect the ears from exposure to caustic materials, extremely cold temperatures, or excessive noise; serve as a barrier against solid particles collecting on the surface of the outer ear (auricle); prevent accidental injuries from flying objects in industrial activities, from contact during physical activities, or from excessive heat or fire; prevent moisture or solid particles from entering the ear canal; reduce noise to acceptable levels so signals are heard better through earphones; and protect the outer ear from direct sun rays. The purpose for wearing ear protectors determines the characteristics of the device to be used.

The most common use of ear protectors is to protect hearing from excessive noise; therefore "hearing protector" is a most appropriate term. Advances in materials used to construct hearing protection devices have led to significant improvements in both attenuation and comfort for users. The use of hearing protectors can prevent both temporary (auditory fatigue) and permanent noise-induced hearing losses, and may actually enhance a person's ability to hear in the presence of excessive noise. *See* Hearing (human). [D.C.Ga.]

Early modern humans The earliest representatives of people anatomically similar to living humans evolved from more archaic humans approximately 100,000 years ago. The process by which they emerged from and eventually replaced those late archaic humans remains unclear. It is likely that they evolved locally from such predecessors in northeastern Africa. Over the succeeding 50,000 years, their range expanded and contracted with changing global climatic cycles to include at times the Mediterranean Near East and portions of northern Africa. Early modern humans and their biology and way of life, therefore, initially had little advantage over late archaic humans. *See* NEANDERTALS.

Early modern humans were biologically the same as modern peoples and would blend in with living peoples. They differed from living people primarily in their tendency to have a rugged, athletic build. These populations were generally tall, males being 175–180 cm (5 ft 10 in.) and females 160–165 cm (5 ft 4 in.) on average. As a result of these tall bodies and muscularity, their brains were relatively large, averaging about 1500 cm^3 (90 $in.^3$) as opposed to averages of about 1350 cm^3 (80 $in.^3$) common for recent humans. Yet, when their brain sizes are scaled against estimated body weights, their brains were relatively the same size as those of living humans.

Early modern humans were successful hunters and gatherers, occupying most of the inhabitable regions of the Old World. They lived by hunting small to medium-size animals, especially antelopes, deer, goats, and occasional horses and cattle, and by gathering wild plants, fish, and shellfish for food. Their effectiveness as hunters and gatherers was due in part to their technology. They developed elaborate stone tool technologies, producing long blades that became blanks for tools with replaceable cutting edges and points. They were also the first to fire clay into ceramics, and they wove carrying bags with a variety of techniques. Yet, their ability to live effectively as hunters and gatherers depended upon their extensive knowledge of the environment. This knowledge was communicated through the first elaborate symbolic systems known, which consisted of a variety of geometric notational systems and the first representational art. They were also the first humans to commonly wear jewelry, and hence to modify their personal social images, suggesting more complex social roles than were previously known. Although these behavioral advances are associated with early modern humans, most of them appear only after about 50,000 years ago and hence are associated with the dispersal of modern humans. *See* FOSSIL HUMAN. [E.T.]

Earphones A class of energy transducers capable of receiving alternating current and generating acoustic waves resembling very closely the characteristics of that current. The movement of an element (diaphragm) is accomplished by magnetic attraction, electrostatic attraction, or the piezoelectric effect (the expansion or contraction of certain crystalline substances in response to electric charges). Earphone systems include the driver element with its diaphragm and arrangements for magnetic flux, or electrostatic or direct electric charge, plus a casing, one or more acoustic cavities and ports, acoustic damping and insulation, and some arrangement for coupling the driver to the human ear. The wiring connecting the precedent amplifier to the driver, which may be incorporated into the earphone system, may in modern systems be a complicated circuit which feeds, for each of two stereophonic channels, some part of the current to each ear. The time delays and energy ratios at the two earphones (each of which may contain two drivers) can be appropriately adjusted so that the listener is given the illusion that the sound sources are not "within the head" but are externalized appropriately in all three planes of space. The various types of earphones are described below. *See* TRANSDUCER.

The magnetic type is a permanently magnetized diaphragm that is moved in and out by an electromagnet energized by alternating current. Dynamic earphones are actually small dynamic loudspeakers. In some, a small coil fed by the sound source is bonded to the membranous diaphragm. Alternating current in the coil thus drives the diaphragm toward and away from a permanent magnet in the rear of the casing. In another configuration, the coil is relatively large and is attached to the diaphragm only at its edge. A miniature magnetic earphone is a small unit of which the output port fits snugly into a plastic olive in the ear canal. These are widely used with small radios, with the more powerful hearing aids, by television commentators, in business transcription devices, and in many other communications situations. *See* HEARING AID.

Efficiency is increased if the mass of the diaphragm is reduced to a minimum. The electrostatic earphone utilizes a thin (2.5–12 micrometers) metallized plastic film, on which a large constant electrostatic charge is placed by an auxiliary unit. The motion of the diaphragm is controlled by the audio signal impressed on perforated wire mesh plates on either side. The assembly is mounted in a relatively large cavity and coupled to the head by a circumaural cushion. Such earphones are light and comfortable and have excellent frequency-response and transient-distortion characteristics.

The diaphragm of a dynamic-electrostatic (or orthodynamic) earphone is a permanently polarized electret of fluorocarbon. Consequently the need for an added source of polarization voltage (a drawback inherent to electrostatic earphones) is eliminated. *See* ELECTRET TRANSDUCER.

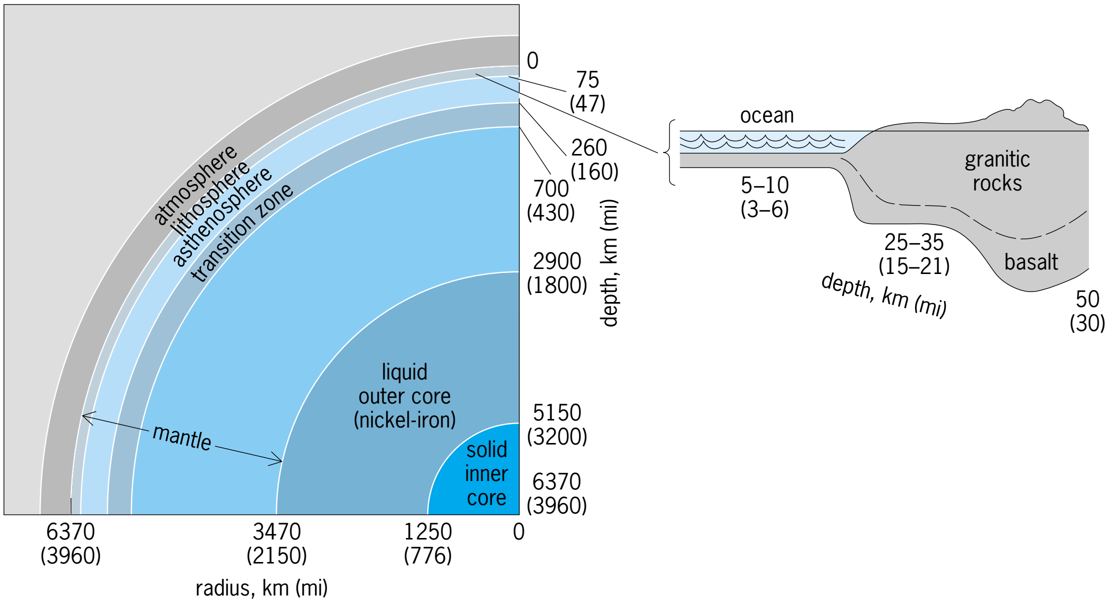
Certain crystalline substances expand and contract when alternating voltage is applied. In some piezoelectric earphones, a crystal element is coupled mechanically to the center of a small (about 2.5 cm diameter) cone. Such earphones can be lightweight and cheap and may be acceptable for speech communication. *See* PIEZOELECTRICITY.

Any single-channel recording of a real acoustic event will, when played back to an earphone in one ear, sound "in the head." Even stereo recordings from two channels played back to earphones on two ears, while furnishing the illusion of movement, still are not externally localized by the listener. Externalization is improved if some of the signal from the left channel is time-delayed and applied also to the right earphone (the same, of course, for the right channel to the left earphone), and it is also improved if a realistic ratio is achieved between the acoustic energy density ratio from the "direct" versus the "indirect" sound sources (as from reflective walls). Stereophonic earphone systems have been built which incorporate these time delays and ratios, and which furthermore feed the signal from the right channel of an artificial-head stereophonic recording to the left earphone (and the left channel to the right earphone) through frequency filters which simulate the differential acoustic effects at various frequencies of the head and external ears in the original recording situation. Thus the eardrums under earphones are presented with the exact acoustic conditions generated by a loudspeaker or other sound source in an actual room, and such earphone systems very materially advance the important psychoacoustic feature of externalization of sound and of acoustic realism generally. *See* LOUDSPEAKER; MICROPHONE; SOUND-REPRODUCING SYSTEMS; STEREOPHONIC SOUND. [J.D.H.]

Earth The third planet from the Sun and the largest of the four inner, or terrestrial, planets. The Sun is an average-sized, middle-aged star situated toward the outer edge of one of the spiral arms of the Milky Way Galaxy. So far as is known, Earth is unique in the solar system in having life. Whether life exists in the universe beyond the solar system is unknown. *See* GALAXY, EXTERNAL; MILKY WAY GALAXY; PLANET; SOLAR SYSTEM; STAR; SUN; UNIVERSE.

Earth has one natural satellite, the Moon. Otherwise, Earth's nearest neighbors in space are Venus, which is about 108×10^6 km (67×10^6 mi) from the Sun, and Mars, about 228×10^6 km (141×10^6 mi) from the Sun. Earth is about 150×10^6 km (93×10^6 mi) from the Sun. *See* MARS; MERCURY (PLANET); MOON; VENUS.

Earth completes an orbit around the Sun in 365 days, 5 h, 48 min, 46 s; the orbit defines the length of the year. The length of the day is determined by the period of Earth's rotation about



Principal layers of Earth.

its axis. The fact that the year is not a whole number of days has affected the development of the calendar. *See* Calendar.

Earth rotates on its axis once each day. The axis of rotation is perpendicular to the Equator, and the Equator is inclined at about 23.5° to the plane of Earth's orbit around the Sun. As Earth moves in its orbit, the north spin axis, or north geographic pole, points in the direction of the star Polaris, making it the North Star or polestar. One result of the tilt of the Equator relative to the orbital plane is that different parts of Earth receive differing amounts of sunlight through the year; this is the primary cause of seasons. *See* Equator; Polaris; Rotational motion.

Earth is an oblate spheroid. The mean equatorial radius is 6378.139 km (3963.37 mi), and the polar radius is 6356.779 km (3950.10 mi), the difference being 21.360 km (13.27 mi).

Earth's mass is 5.976×10^{27} g (0.2108×10^{27} oz), being the sum of 5.974×10^{27} g (0.2107×10^{27} oz) for solid Earth, 1.4×10^{24} g (0.049×10^{24} oz) for the ocean, and 5.1×10^{21} g (0.18×10^{21} oz) for the atmosphere. Earth's average density is 5.518 g/cm^3, which is just about double the density of the common rocks that form at Earth's surface, indicating that Earth's interior is more dense than the surface. Seismic studies have confirmed that Earth is layered both compositionally and mechanically (see illustration). *See* Atmosphere; Density; Earth interior; Oceanography; Seismology.

The deepest compositional layer is the core, which is divided into a solid inner core and a liquid outer core. Both the inner and outer core have the same composition, believed to be nickel-iron plus a small amount of lighter elements such as sulfur and silicon. Electric currents moving in the molten metal outer core are believed to be the origin of Earth's magnetic field. Above the core is the mantle which, on the basis of density of rare rock samples brought up from deep in the mantle in kimberlite pipes, and other evidence, is believed to be composed of silicate minerals, and in particular olivine and pyroxene. A rock composed largely of olivine and pyroxene is called a peridotite. *See* Olivine; Peridotite; Pyroxene; Silicate minerals.

Above the mantle is Earth's crust, and between the crust and the mantle there is a pronounced seismic discontinuity known as the Mohorovičić discontinuity, or Moho. The crust is of two kinds, both of which are less dense and compositionally different from the peridotitic mantle below. Beneath the ocean the crust is basaltic in composition and about 8 km (5 mi) thick. The crust beneath the continents is granitic in composition and averages 35 km (21.7 mi) in thickness but ranges up to 80 km (49.7 mi), as beneath Tibet. The oceanic crust is geologically young because it is continually created and destroyed through the process of plate tectonics. No part of the oceanic crust that is older than about 180×10^6 years has yet been discovered. The continental crust is much older than the oceanic crust. Continental rocks as old as 4×10^9 years have been discovered in Canada, and the fact that they are highly deformed indicates a long and eventful history. *See* Earth crust; Granite; Moho (Mohorovičić discontinuity); Plate tectonics.

The surface of solid Earth has a bimodal distribution of elevations. If the water from the ocean could be removed, it would be apparent that continents stand high (average elevation is 840 m or 2755 ft above sea level), while the ocean floor sits low (average elevation is 3800 m or 12,464 ft below sea level). This difference in elevation arises because rigid lithosphere floats on the weak asthenosphere, and because the density of oceanic lithosphere (that is, lithosphere capped by oceanic crust) is greater than the density of continental lithosphere.

On the continents, mountain belts are the most dramatic features. They range in elevation from Mount Everest, 8848 m (29,030 ft), in the Himalaya Mountains to older, deeply eroded ranges that are now barely above sea level. Granitic and metamorphic rocks are generally exposed in the cores of mountain ranges. The overlying rocks that cover most of the Earth's surface are sedimentary, mainly of shallow marine origin, that may or may not have been deformed. The deformation is the result of compression and tension that causes folding and faulting, and may be accompanied by intrusion and metamorphism. Movements and collisions of tectonic plates are the principal cause of mountain building. Mountains generally are formed over several tens of millions of years. The rocks deformed in the process are generally marine sedimentary rocks formed along the margins of continents. *See* Deep-marine sediments; Marine sediments; Metamorphic rocks; Orogeny; Sedimentary rocks.

The topographic features underlying the oceans are similarly diverse and reveal more evidence of a dynamic Earth. The continental shelf, an area covered by shallow water, generally less than 150 m (500 ft) deep, surrounds the continents at most places. Such areas are generally underlain by continental, granitic rocks, and are submerged parts of the continents. Continental slopes are the transition between the continental shelf and the ocean floors. Their tops are generally less than 150 m below sea level, and they slope down to about 4400 m (14,000 ft). They are narrow, steep features, with slopes generally between 2 and 6°, but some are up to 45°. They are generally underlain by thick accumulations of sedimentary rocks. *See* SEA-FLOOR IMAGING.

Submarine trenches and their associated volcanic island arcs are formed as a result of a tectonic plate of lithosphere sinking into the mantle beneath the edge of an overriding plate. The deepest place on Earth is in the Mariana Trench, 11,022 m (36,152 ft) below sea level.

The ocean floor is the most widespread surface feature of Earth. Beneath an average of 4.4 km (2.75 mi) of seawater are about 2.3 km (1.4 mi) of sedimentary rocks with some intercalated basalt, and below that is the oceanic crust, consisting of 4–6 km (2.5–3.7 mi) of basaltic rocks. Interrupting the ocean floor at many places are submarine mountains formed by basaltic volcanoes. Some of these volcanoes are very large and form oceanic islands such as the Hawaiian Islands.

New oceanic lithosphere capped by basaltic crust is created at the mid-ocean ridges, and this newly formed plate moves away from the ridges. The tectonic plates formed in this way may carry continents on them, and are the mechanism of continental drift. Paleomagnetic data from the continents indicate that the continents have moved relative to each other. The tectonic plates capped by basaltic crust plates are consumed at the trench-volcanic island arc areas. *See* PALEOMAGNETISM; SUBDUCTION ZONES.

As well as the ridge and the trench, a third type of plate boundary occurs where two plates slide past each other at a transform fault. Such collisions account for the deformed rocks found in the crust. *See* TRANSFORM FAULT.

The evidence for continental drift in the geological past includes matching of rock types, ages, fossils, climates, and structures (mountain ranges), as well as the paleomagnetic data. Evidence showing or suggesting present movements consists of shallow earthquakes along mid-ocean ridges and transform faults that offset them; deep earthquakes associated with deep-sea trench-volcanic island arc areas; direct measurement of movement; volcanic activity at mid-ocean ridges; and volcanic activity at trench-island arc areas. *See* GEODESY.

Earth's temperature and gravitation are such that an atmosphere is present. The major constituents are nitrogen and oxygen. A thin ozone layer in the atmosphere shields the Earth from lethal ultraviolet radiation from the Sun. The atmosphere, especially oxygen, and the presence of water, both at the surface and in the atmosphere, make life possible. Precipitation, mainly rain, results in running water such as streams and rivers on the continents. Running water is the main cause of erosion of the continents, and most of the landscapes have been eroded by water, although some are eroded by wind or ice (glaciers). *See* EROSION; GLACIOLOGY; GRAVITY; NITROGEN; OXYGEN; OZONE; WATER.

Earth, along with the rest of the solar system, is believed to have formed about 4.55×10^9 years ago. This age is determined by dating radioactive isotopes in meteorities. Meteorites are believed to be fragments produced by collisions among small bodies formed by the same process that created the solar system. Theoretical studies of the Sun and other studies of radioactive isotopes also suggest a similar age. *See* EARTH, AGE OF. [B.J.S.]

Earth, gravity field of The field of gravitational attraction of the Earth. Since, at the Earth's surface, the small centrifugal force due to the Earth's rotation is inseparably superimposed on the attraction, the gravity field is usually understood to include also the effect of the centrifugal force.

The resultant of gravitation (pure attraction) and centrifugal force is called gravity. Gravity is the force that acts on the body at rest with respect to the Earth since the effects of attraction and of centrifugal force cannot be separated because of the equivalence of gravitational and inertial mass; thus gravity determines the weight of a body. The gravity potential W is the sum of the gravitational potential V and the potential of centrifugal force, which is given by a simple analytical expression and may be considered as known.

A body moving with respect to the Earth is also affected by the Coriolis force. Like centrifugal force, the Coriolis force is an inertial force due to the Earth's rotation, but unlike centrifugal force, it does not possess a potential and hence cannot be easily incorporated into the gravity field. Therefore Coriolis force is not considered in the context of terrestrial gravitation. This is perfectly adequate since this force is zero for bodies at rest with respect to the Earth, and almost all measuring systems are at rest. *See* CORIOLIS ACCELERATION; GRAVITATION.

The gravity vector $\mathbf{g}$ represents the force of gravity on a unit mass. It is the gradient vector of the gravity potential, $\mathbf{g} = \text{grad}\, W$. The magnitude of the gravity vector is the intensity of gravity, or briefly, gravity g. The dimension of g is force per unit mass, or acceleration. The SI unit is $\text{m} \cdot \text{s}^{-2}$. The cgs unit gal ($1\ \text{gal} = 1\ \text{cm} \cdot \text{s}^{-2}$), named after Galileo, is still frequently used, especially the milligal ($1\ \text{mgal} = 10^{-3}\ \text{gal} = 10^{-5}\ \text{m} \cdot \text{s}^{-2}$). Gravity g on the Earth's surface varies from about 978 gals at the Equator to about 983 gals at the poles. The direction of the gravity vector defines the vertical, or plumb line.

The surfaces of constant gravity potential, $W = \text{const}$, are called equipotential surfaces or level surfaces. The surface of a quiet lake is part of a level surface. So is the surface of the oceans, after some obvious idealization; the whole level surface so defined is called the geoid. After C. F. Gauss, the geoid is considered as the mathematical surface of the Earth, as opposed to the visible topographical surface. The plumb lines intersect the level surfaces orthogonally; they are not quite straight but very slightly curved.

The quantity that is measured most commonly is the gravity g. The determination of g as such is called an absolute gravity measurement. Usually only relative gravity measurements are performed, determining the difference between, or the quotient of, the gravity values at two different points. The direction of the gravity vector, which gives the plumb line in space, is measured by astronomical methods. Differences in the gravity potential W are obtained by geodetic leveling. Finally, certain derivatives of g and similar quantities are measured by instruments such as the torsion balance.

Satellite methods have enormously improved knowledge of the gravity field. In the future, new satellite technologies will advance gravity-related measurements, to be studied along with classical theoretical measurements, which will fully retain their importance. *See* GRAVITY.

For most purposes, the Earth's gravitational field may be considered invariable in time. However, it is subject to extremely small periodic variations due to tidal effects. These are caused by the attraction of the Sun and Moon. The attraction acts directly by superimposing itself onto the Earth's gravitational attraction; and it acts also indirectly by slightly deforming the Earth and shifting the waters of the oceans, so that the attracting terrestrial masses themselves are modified.

The lunar effect on gravity attains a maximum of 0.20 mgal, and the solar effect, a maximum of 0.09 mgal; both are well within the measuring accuracy of modern gravimeters. The results of stationary gravimeters recording variations of gravity may be used to draw conclusions as to the elastic behavior of the Earth under the influence of tidal stresses. *See* EARTH TIDES.

Anomalies of the terrestrial gravitational field are caused by mass irregularities. These may be the visible irregularities of topography such as mountains; or they may be invisible subsurface density anomalies. This is the reason why it is possible to use gravity measurements for investigating the underground structure of the Earth's crust. Thus analysis of gravity is applied by geophysicists and geologists for studying general features of the crust, and by exploration geophysicists for searching for shallow density irregularities that might indicate the presence of mineral deposits.

Geodetic instruments employ spirit levels and other devices to orient them with respect to the horizontal or, what amounts to the same thing, to the plumb line. Since the plumb line is defined by the gravitational field, it can be understood why this field enters essentially into almost all geodetic measurements, even into apparently purely geometric ones. In return, geodetic techniques are among the most efficient means for determining the gravitational field. The "mathematical figure of the Earth" for the purpose of geodesists, the geoid, is defined as a surface of constant potential *W*. "Heights above the sea level" are heights above the geoid; their determination is therefore a physical as well as a geometric problem. (Geodetic theories have been developed which employ only quantities referred to the Earth's topographical surface; but here the gravitational field enters in an even more complicated way.) Thus geodesy is essentially concerned with the Earth's gravitational field and its determination; the theory of the figure of the Earth is to a large extent equivalent to the theory of terrestrial gravitation. *See* Geodesy. [H.Mor.]

Earth, heat flow in The Earth's heat flow is defined as the amount of heat escaping per unit time from the interior across each unit area of the Earth's solid surface. The movement of heat within the Earth and its eventual loss through the surface are central elements in the modern theory of plate tectonics. The plate movements over the surface of the Earth are seen as one manifestation of a heat engine at work in the interior, and the heat flow at the surface as the exhaust from the engine. *See* Earth interior; Plate tectonics.

Because heat flows from the warmer to the cooler parts of a body, the observation that the Earth's temperature increases with depth clearly implies that heat is escaping from the interior by conduction through the rocky crust. William Thomson (Lord Kelvin) used the heat flow in estimating the age of the Earth. He argued that as the Earth cooled, following its formation and solidification from molten rock, the rate at which the temperature increased with depth (the geothermal gradient) lessened over time, and thus by measuring the geothermal gradient the length of time that the Earth had been cooling could be estimated. Such an estimate is based on the assumption that all the heat being lost is drawn from the endowment of heat that the Earth possessed at the time of its initially molten condition. This assumption was later shown to be untenable because a significant fraction of the Earth's heat flow is derived not from the initial heat but from the decay of radioactive elements present in trace amounts within the Earth. Thus the Earth's heat should be thought of not as a finite quantity acquired at the time of formation and gradually dissipated over time, but as a quantity that in large part has been continually produced, albeit in diminishing amounts throughout the history of the Earth. *See* Earth, age of; Earth, convection in.

The most significant empirical relationship to emerge from heat flow studies is that heat flow generally decreases with increasing crustal age at the site of the measurement. In the oceans the significant age is the time of magmatic emplacement of the basaltic crust at a mid-ocean ridge. On the continents it is usually the age of the last major tectonic, magmatic, or thermal metamorphic event to have affected the measurement site. The pattern of the decrease in heat flow with age differs from ocean to continent. While both settings show a heat flow in the older segments of about 40–45 milliwatts per square meter, the oceanic heat flow shows a greater range over a shorter time interval than does the continental heat flow.

The heat production from radioactive decay contributes significantly to the heat flow from the Earth's interior. In fact, the entire surface heat flow on continents could arise within the crust if the surface concentrations of the important heat-producing isotopes such as are found in granites and gneisses persisted throughout the full thickness of the crust. However, probable lower crustal rocks such as granulites and migmatites have lesser concentrations of these isotopes, and so radiogenic heat production apparently decreases with depth in some manner. The principal heat-producing isotopes are thorium-232 (^{232}Th), uranium-238 (^{238}U), potassium-40 (^{40}K), and uranium-235 (^{235}U) with respective half-lives of 14.0, 4.47, 1.25, and 0.70×10^9 years. Other radioactive isotopes do not presently contribute significant heat because their decay chains are not sufficiently energetic, or their abundances are insignificant, or their half-lives are too short. The concentrations of uranium and thorium in rocks are generally in trace amounts measured in parts per million, while potassium is much more abundant, in the range of a few percent, of which a small but well-known fraction is ^{40}K. A range of values for the upper mantle is characteristic of various possible mantle rocks as inferred from xenoliths brought to the surface by igneous and tectonic processes. If the entire mantle had the lesser concentrations, then crustal and mantle radiogenic heat production would be less than half the present-day heat loss; whereas if the greater concentrations were representative of the mantle as a whole, radiogenic heat production would be about equal to the present-day heat loss.

The average heat flow over the entire Earth is 87 $\mathrm{mW \cdot m^{-2}}$ and is comparatively a trickle; it is sufficient to bring a thimbleful of water to a boil in about 2 years, or if collected over the area of a football field, would be adequate to light four 100-watt incandescent bulbs. The radiant energy from the Sun intercepted by the Earth is some 4000 times greater than the geothermal flux. The absorption and reradiation of the incident solar energy are the principal processes that determine the surface temperature of the Earth. The geothermal energy is of little significance to the surface temperature but is of paramount importance in considering the Earth's internal thermal condition. *See* Geologic thermometry; Geothermal power. [H.N.P.]

Earth crust The low-density outermost layer of the Earth above the Mohorovičić discontinuity (the Moho), a global boundary that is defined as the depth in the Earth where the compressional-wave seismic velocity increases rapidly or discontinuously to a value in excess of 4.7 mi/s (7.6 km/s; the upper mantle). The crust is also the cold, upper portion of the Earth's lithosphere, which in terms of plate tectonics is the mobile, outer layer that is underlain by the hot, convecting asthenosphere. *See* Asthenosphere; Lithosphere; Moho (Mohorovičić discontinuity); Plate tectonics.

Continental crust. The Earth's continental crust has evolved over the past 4 billion years, and is highly variable in geologic composition and internal structure. The worldwide mean thickness of continental crust is 24 mi (40 km), with a standard deviation of 5.4 mi (9 km). The thinnest continental crust (found in the Afar Triangle, northeast Africa) is about 9 mi (15 km) thick, and the thickest crust (the Himalayan Mountains in China) is about 47 mi (75 km) thick. Ninety-five percent of all continental crust has a thickness within two standard deviations of the mean thickness, between 13 mi (22 km) and 37 mi (58 km). The Antarctic continent has a crustal thickness of 24 mi (40 km) in the ancient, stable (cratonic) region of East Antarctica, and about 12 mi (20 km) in the recently stretched (extended) crust of West Antarctica. Continental margins, which mark the transition from oceanic to continental crust, range in thickness from about 9 mi (15 km) to 18 mi (30 km). *See* Continental margin.

Despite its geologic complexity, the continental crust may generally be divided into four layers: an uppermost sedimentary layer, and an upper, middle, and lower crust composed of crystalline rocks. The sedimentary cover of the continental crust is an important source of natural resources. This cover averages 0.6 mi (1 km) in thickness, and varies in thickness from zero (for example, on shields) to more than 9 mi (15 km) in deep basins. In stable continental crust of average thickness (25 mi or 40 km), the crystalline upper crust is commonly 6–9 mi (10–15 km) thick and has an average composition equivalent to a granite. The middle crust is 3–9 mi (5–15 km) thick and has a composition equivalent to a diorite; and the lower crust is 3–12 mi (5–20 km) thick and has a composition equivalent to a gabbro. Due to increasing temperature and pressure with depth, the metamorphic grade of rocks increases with depth, and the rocks within the deep continental crust generally are metamorphic rocks, even if they originated as sedimentary or igneous rocks. *See* Diorite; Gabbro; Granite; Metamorphic rocks.

Crustal properties vary systematically with geologic setting, which may be divided into six groups: orogens (mountain belts), shields and platforms, island arcs (volcanic arcs), continental magmatic arcs, rifts, extended (stretched) crust, and forearcs. Orogens are typified by thick crust [average thickness is 29 mi (46 km), but the maximum thickness is as much as 47 mi (75 km) in the Himalayas]. Shields and platforms, such as the Canadian Shield and the Russian Platform, commonly have an approximately 26-mi-thick (42-km) crust, including a 3–6 mi-thick (5–10 km) lower crust. In comparison with shields, island arcs (such as Japan) have thinner crusts and significantly shallower middle and lower crustal layers due to the intrusion of mafic (that is, low silica content) plutons. Continental magmatic arcs, such as the Cascades volcanoes of the northwestern United States, intrude preexisting continental crust, and therefore they are generally 3–9 mi (10–15 km) thicker than island arcs. Continental rifts, such as the East African and Rio Grande rifts, have an average crustal thickness of about 22 mi (36 km). Extended continental crust, such as the Basin and Range Province of the western United States, averages 18 mi (30 km) in thickness. Forearcs are regions that were formed oceanward of volcanic arcs, such as much of the west coast of North America. They typically have thin crust, about 15 mi (25 km), and have a thick (9 mi or 15 km) upper crustal section that consists of relatively low-density metasedimentary rocks. *See* North America; Oceanic islands; Pluton; Rift valley; Sedimentary rocks; Volcano.

At least three processes provide new continental crust. The first is the accretion and consolidation of island arcs, such as Japan or the Aleutian Islands, onto a continental margin. The second process is the tectonic underplating of oceanic crust at active subduction zones. In this process, the continental crust grows from below as oceanic crust is welded to the base of the continental margin, either when subduction stops or when subduction steps oceanward and a new trench is formed. This process has been identified in western Canada and southern Alaska. The third process is the magmatic inflation of the crust at continental arcs, rifts, and regions of crustal extension. This process has been identified in many regions. *See* Geodynamics.

[W.D.Mo.]

Oceanic crust. The surface of the ocean crust, except for some locally high volcanoes and plateaus, resides some 1–3 mi (2–5 km) below sea level, and about another kilometer below the average level of the continents. The ocean crust represents the youngest and geologically most dynamic portion of the Earth's surface. Most of it was produced at mid-ocean ridges during the process of sea-floor spreading. The ridges define the trailing edges, or accreting boundaries, of the major lithospheric plates that are moving about the surface of the Earth at present. Thus, the oldest rocks of the ocean crust date back no earlier than the rifting episodes that created most of these plates and initiated the most recent phase of continental drift, the Pangaean breakup, in Late Jurassic times. *See* Jurassic; Mid-Oceanic Ridge.

There are fault slices of types of ocean crust on land, known as ophiolites, where nearly or entirely complete cross sections through the crust can be mapped and sampled. These strongly indicate that the ocean crust consists in downward sequence of submarine extrusives (usually pillow basalts), feeder dikes (often vertically sheeted), or sills, gabbros, and peridotites. There is much uncertainty, however, about the extent to which typical ophiolites, most of which formed in island-arc or backarc environments, can represent abyssal ocean crust, which is produced at the major accreting plate boundaries. Moreover, the physical correspondence of the rocks in ophiolites to ocean crust is often complicated by their complex structure and extent of alteration and metamorphism, particularly in the ultramafic sections. *See* Opiolite.

[J.H.Na.]

Earth interior All of the Earth beneath the land surface and the ocean bottom, including the crust, the mantle, and the core. The interior is not accessible to direct observation. Nevertheless, a rather detailed model has been constructed on the basis of measurements made at or above the surface. Measurements of gravity, the geomagnetic field, surface heat flow, and surface deformation can all be used to put constraints on the Earth model, but the most detailed information about the interior is provided by seismic measurements. In the exploration of the Earth's interior, the seismic waves being analyzed are usually generated by earthquakes, and measurements are made of waves propagating through the interior of the body, waves propagating along the surface, and standing waves bringing the whole Earth into a state of oscillation. Such measurements, when properly interpreted, provide information about seismic-wave velocities in the Earth. Seismic-wave velocities can also be measured in laboratory experiments where rock samples are subjected to the high pressures and temperatures typical of conditions in the deep interior.

Several standard Earth models have been constructed in the past. One of the more comprehensive models was constructed in 1981 by A. Dziewonski and D. Anderson, the Preliminary Reference Earth Model (PREM). The principal regions of this model are listed in the table. *See* Earth.

Principal regions of a standard Earth model

Layer	Approximate depth range,* mi	(km)
(1) Ocean layer	0–1.8	(0–3)
(2) Upper and lower crust	1.8–15	(3–24)
(3) Lithosphere below the crust	15–50	(24–80)
(4) Asthenosphere (low-velocity zone)	50–140	(80–220)
(5) Upper mantle above phase or compositional changes near 240 mi (400 km)	140–240	(220–400)
(6) Transition region between phase or compositional changes near 240 and 416 mi (400 and 670 km)	240–416	(400–670)
(7) Lower mantle above core-mantle boundary layer	416–1703	(670–2741)
(8) Core-mantle boundary layer (D″)	1703–1796	(2741–2891)
(9) Outer core	1796–3200	(2891–5150)
(10) Inner core	3200–3959	(5150–6371)

*Depth ranges are uncertain, especially in the crust and upper mantle.

Seismic structure. The seismic structure of the Earth is studied by analyzing body waves, surface waves and free oscillations, and anisotropy. Body waves are generated by earthquakes or large (nuclear) explosions and are recorded by many seismic stations throughout the world. Body waves are characterized as P (primary) and S (secondary) waves. Both wave types are supported by a solid, but P waves have a higher velocity and arrive first. It is routine practice that the stations report the arrival time of the first P wave to an earthquake information center, where these data are used to locate the earthquake and determine its origin time. By subtracting the origin time from the arrival times, the travel times of waves from the earthquake to the stations are determined, and these travel times can be used to determine the seismic velocity structure of the Earth's interior. *See* Earthquake; Seismology.

Surface waves and free oscillations are also generated by earthquakes. The velocity with which surface waves propagate is a function of the frequency of the waves, that is, the surface waves are dispersive. The dispersion depends on the seismic velocity structure of the surface layers. The free oscillations of the Earth resonate only at certain discrete frequencies (the eigenfrequencies), that is, the free oscillation spectrum would be a line spectrum (in practice the lines are somewhat smeared because of dissipation of the oscillations). The eigenfrequencies depend on the velocity structure of the whole Earth. Thus surface waves and free oscillations provide an alternative data set for constructing velocity models. PREM is based on both travel times and free-oscillation data. *See* OSCILLATION.

Anisotropy refers to the directional dependence of the wave velocity. Anisotropy in the Earth's interior may be induced by flow of material containing noncubic crystals or elongated grains. Anisotropy has been observed in the lithosphere, especially under the oceans, and has been postulated for the asthenosphere. This anisotropy has been explained in terms of alignment of olivine crystals, which are thought to be the dominant material in these layers. Anisotropy may occur in deeper regions of the Earth as well, but is difficult to resolve. However, to account for the differences in travel time between P waves passing through the inner core in the equatorial and polar directions, respectively, it has been proposed that the inner core is anisotropic, although the physical mechanism is not understood. *See* LITHOSPHERE; OLIVINE.

Composition and state. The Earth comprises a crust, a mantle, and a core, so there is a compositional differentiation into at least three regions. Each of these regions is differentiated again, both vertically and, at least for the crust and upper part of the mantle, laterally. *See* ELEMENTS, GEOCHEMICAL DISTRIBUTION OF.

The Earth's crust is on average about 12 mi (20 km) thick but is thinner under oceans and thicker under continents. Thickness under some high mountain ranges may be up to 36 mi (60 km; the so-called mountain roots). The boundary between the crust and the underlying mantle is called the Mohorovičić discontinuity or, more usually, the Moho. The continental and oceanic portions of the crust have different compositions. Continental crust can be divided into a lighter, granitic upper crust and a lower crust that is more basaltic, like the oceanic crust. Despite the striking heterogeneity of the crust, some generalizations can be made. Both the crust and the mantle are rich in silicates, but the mantle has much more magnesium, and the crust has proportionally more of the relatively light elements such as calcium, aluminum, sodium, and potassium in the form of oxides. *See* EARTH CRUST; MOHO (MOHOROVIČIĆ DISCONTINUITY).

The mantle is the region between the crust and the core. It is common to make a distinction between the upper mantle and lower mantle, which are separated by the so-called 670-km discontinuity at a depth of 416 mi. The upper mantle includes the lithosphere below the crust, the asthenosphere, and the region of phase transformations (the transition zone). It contains also the subducting slabs of oceanic lithosphere. The difference between continental and oceanic crust extends to at least the bottom of the lithosphere and probably to the bottom of the asthenosphere. It is believed that the stiff lithosphere and the soft asthenosphere differ mainly in mechanical strength, not in composition. The shallow part of the upper mantle is likely to be relatively depleted in the light elements typical of the crust. On the other hand, the light elements do not seem to be underrepresented in estimates of the composition of the deeper parts of the upper mantle. It has been suggested that this region contains more eclogite, the high-pressure form of basalt, which is subducted with the oceanic lithosphere. Olivine is probably the most abundant upper-mantle mineral. At pressures prevailing near 240 mi (400 km) depth, it transforms to a denser structure (spinel). *See* BASALT; ECLOGITE; SPINEL.

The lower mantle, the mantle below 416 mi (670 km), appears to have a homogeneous composition down to the boundary layer above the core. Experimental results seem to indicate that mineralogy is dominated by ferromagnesium oxides (wüstite) and silicates (perovskite). The high-pressure perovskite phase of ferromagnesium silicate is thought to be the most abundant mineral of the Earth. *See* PEROVSKITE.

The core is the central region of the Earth. Its seismic and density structure are well matched by a solid inner core of iron or nickel iron and a liquid outer core of iron mixed with about 10% lighter material. Candidate light elements are sulfur and oxygen, with some preference for the former. The outer core can be taken as homogeneous for all practical purposes.

Core-mantle coupling is believed to be responsible for decade-long variations in the length of the day of up to about 5 milliseconds. The idea is that fluid flow in the outermost regions of the core is coupled to the mantle, so that the rotation rate of the mantle can fluctuate in response to time variations of the flow in the core. This view is supported by an observed correlation between the decade variations in the length of the day and certain variations of the geomagnetic field (the latter being associated with core flow). The coupling may be electromagnetic or topographic. It has been suggested that topographic coupling can be quite effective, provided that there is indeed topography on the core-mantle boundary (of the order of a few hundred meters). *See* GEOMAGNETISM. [D.J.D.]

Earth rotation and orbital motion

The rotation of the Earth about its axis is demonstrated by the classical Foucault pendulum experiment. Its revolution in its orbit around the Sun is shown by (1) the annual parallactic displacement of relatively nearby stars against the background of more distant stars, and (2) the aberration of light, causing an apparent annual displacement of all stars on the celestial sphere. However, because the Earth is not truly a rigid symmetric body and because it interacts with other members of the solar system gravitationally, these motions vary with time. *See* ABERRATION (ASTRONOMY); FOUCAULT PENDULUM; ORBITAL MOTION; PARALLAX (ASTRONOMY).

Rotation of the Earth. Until recent times the rotation of the Earth has served as the basis for timekeeping. The assumption was made that the rotational speed of the Earth was essentially constant and repeatable, and that the length of the day which resulted from this constant rotational speed was naturally useful as a measure of the passage of time. Astronomical observations, however, have shown that the speed with which the Earth is rotating is not constant with time. The variations in rotational speed may be classified into three types: secular, irregular, and periodic. The secular variation of the rotational speed refers to the apparently linear increase in the length of the day due chiefly to tidal friction. This effect causes slowing of the Earth's rotational speed and lengthening of the day by about 0.0005 to 0.0035 s per century.

The irregular changes in speed have caused the length of the day to vary by as much as 0.01 s over the past 200 years. Irregular changes consist of so-called decade fluctuations with characteristic periods of 5–10 years as well as variations that occur at shorter time scales. The decade fluctuations are apparently related to processes occurring within the Earth. The higher-frequency variations are now known to be largely related to the changes in the total angular momentum of the atmosphere. *See* ATMOSPHERIC GENERAL CIRCULATION.

Periodic variations are associated with periodically repeatable physical processes affecting the Earth. Tides raised in the solid Earth by the Moon and the Sun produce periodic variations in the length of the day of the order of 0.0005 s with periods of 1 year, $\frac{1}{2}$ year, 27.55 days, and 13.66 days. Seasonal changes in global weather patterns occurring with approximately annual and semiannual periods also cause variations in the length of the day of this order. *See* EARTH TIDES; TIME.

Revolution about the Sun. The motion of the Earth about the Sun is seen as an apparent annual motion of the Sun along the ecliptic. A large number of astronomical observations of the positions of the Sun and other solar system objects have been made and are being made continuously. This information is required to determine the nature of the motion of the Earth about the Sun. Observations are analyzed using the mathematical methods of celestial mechanics to provide improved estimates of the motions of the solar system objects in the future and to describe the past motions of the objects. The description of the apparent motion of the Sun in the sky provides the determination of the orbit of the Earth. *See* CELESTIAL MECHANICS.

The true period of the revolution of the Earth around the Sun is determined by the time interval between successive returns of the Sun to the direction of the same star. This interval is the sidereal year of 365 days 6 h 9 min 9.51 s of mean solar time or 365.25636 mean solar days. The period between successive returns to the moving vernal equinox is known as the tropical year of 365 days 5 h 48 min 45.2 s or 365.24219 days. The length of the tropical year is regarded as the length of the year in common usage for calendars. The period of time between successive passages at perihelion (the closest approach of the Earth to the Sun) is called the anomalistic year of 365 days 6 h 13 min 53.26 s or 365.25964 days. The lengths of the years listed above are given for the year 2000. These values vary slowly as a consequence of the long-period perturbations of the Earth's orbit by other planets. *See* CALENDAR; PERTURBATION (ASTRONOMY).

The mean distance from the Earth to the Sun, or the semimajor axis of the Earth's orbit, was the original definition of the astronomical unit (AU) of distance in the solar system. Its absolute value fixes the scale of the solar system and the whole universe in terms of terrestrial standards of length. The distance between the Earth and the Sun can be determined by a variety of methods. The most precise method relies on measurement of the travel time of electromagnetic signals reflected from objects in the solar system or received from artificial interplanetary probes. The currently adopted value of the astronomical unit is $1.495978706 \times 10^{11}$ m (92,955,807 mi). *See* ASTRONOMICAL UNIT.

The eccentricity of the Earth's orbit can be accurately determined from the variable speed of the Sun's apparent motion along the ecliptic and the laws of elliptic motion. The adopted value of the eccentricity is 0.0167086171540.

The fact that the Equator of the Earth is inclined in space by about 23.5° to the orbital plane of the Earth (the ecliptic) causes the Northern Hemisphere to be exposed to the more direct rays of the Sun during part of the Earth's revolution around the Sun. The Southern Hemisphere receives the more direct rays 6 months, or a half revolution, later. This effect causes the seasons. *See* SEASONS.

Other motions. In addition to the rotation of the Earth and its orbital motion about the Sun, the Earth experiences various small motions about its center of mass. Precession and nutation are examples, and these are caused by the gravitational attraction of the Sun and Moon on the nonspherical Earth. *See* NUTATION (ASTRONOMY AND MECHANICS); PRECESSION OF EQUINOXES.

Because the axis of symmetry of the Earth is not aligned precisely with the axis of rotation, the Earth also executes a motion about its center of mass known as polar motion. This motion, caused by geophysical and meteorological effects on and within the Earth, is not predictable with accuracy, and must be observed continuously to provide the most precise information on the orientation of the Earth. Polar motion is characterized mainly by an approximately 435-day and a 365-day periodic circular motion of the axis of rotation on the surface of the Earth. The radius of the circular motion is of the order of 16 ft (5 m), but this may vary. *See* EARTH; PLANET; PLANETARY PHYSICS. [D.D.McC.]

Earth sciences Sciences that involve attempts to understand the nature, origin, evolution, and behavior of the Earth or of its parts and to comprehend its place in the universe, especially in the solar system. Understanding has advanced primarily through improved appreciation of the complex, usually cyclical interactions that take place among distinct parts of the Earth such as the lithosphere, atmosphere, hydrosphere, and biosphere. Geophysics is the study of the physics of the Earth, emphasizing its physical structure and dynamics. Geochemistry is the study of the chemistry of the Earth, dealing with its composition and chemical change. Geology is the study of the solid Earth and of the processes that have formed and modified it throughout its 4.5-billion-year history. *See* GEOCHEMISTRY; GEODESY; GEOLOGY; GEOPHYSICS; SOLAR SYSTEM.

Many branches of geology are considered separate sciences. Mineralogy is the study of the composition, structure, and properties of minerals. Petrology involves understanding how rocks originate and evolve, as well as rock description and classification. Specialties related to petrology include sedimentology and volcanology. Stratigraphy is the study of the origin, age, and development of layered, generally sedimentary rocks. Paleontology is the study of ancient (fossil) life. Historical geology is the study of the evolution of the Earth and its life. Geomorphology is the study of landscapes and their evolution. Seismology is the study of earthquakes and their effects. Structural geology is the study of deformed rocks. Engineering geology relates to the support of human constructions by underlying rock. *See* ENGINEERING GEOLOGY; GEOLOGY; GEOMORPHOLOGY; HYDROLOGY; MINERALOGY; PALEONTOLOGY; PETROGRAPHY; PETROLOGY; SEISMOLOGY; STRATIGRAPHY; STRUCTURAL GEOLOGY; VOLCANOLOGY.

Oceanography is the study of the oceans; limnology, the study of lakes; hydrology, the study of underground and surface water; and glaciology, the study of glaciers, ice caps, and ice sheets. These disciplines address the study of water in and on the Earth. The gaseous outer parts of the planet are the province of the atmospheric sciences, including meteorology, which is concerned with the weather and weather forecasting; climatology, which deals with longer-term and regional variations; and aeronomy which, because it deals with the outermost ionized region of the atmosphere, is much concerned with solar terrestrial interactions, including the aurora borealis and aurora australis. The biosphere embodies all life on Earth, and its study includes molecular biology, zoology, botany, and ecology. Geography, the study of all that happens at the Earth's surface, has been distinct insofar as it has encompassed not only physical and biological sciences but also the social sciences, including aspects of political science and economics. This distinction is fading rapidly as other earth sciences become more involved with social considerations. [K.Bu.]

Earth tides Cyclic motions of the Earth, sometimes over a foot or so in height, depending on latitude, caused by the same lunar and solar forces which produce tides in the sea. These forces also react on the Moon and Sun, and thus are significant in astronomy in evaluations of the dynamics of the three bodies. For example, the secular spin-down of the Earth due to lunar tidal torques is best computed from the observed acceleration of the Moon's orbital velocity. In oceanography, earth tides and ocean tides are very closely related. *See* GEODESY; TIDE.

By far the most widely used earth tide instruments are the tiltmeter and the gravimeter. Both instruments have the merits of portability, high potential precision, and low cost. Thus they are able to advance economically an important mission—the global mapping of earth tides and ocean tides. [L.B.S./J.T.K.]

Earthquake The sudden movement of the Earth caused by the abrupt release of accumulated strain along a fault in the interior. The released energy passes through the Earth as seismic waves (low-frequency sound waves), which cause the shaking. Seismic waves continue to travel through the Earth after the fault motion has stopped. Recordings of earthquakes, called seismograms, illustrate that such motion is recorded all over the Earth for hours, and even days, after an earthquake.

Earthquakes are not distributed randomly over the globe but tend to occur in narrow, continuous belts of activity. Approximately 90% of all earthquakes occur in these belts, which define the boundaries of the Earth's plates. The plates are in continuous motion with respect to one another at rates on the order of centimeters per year; this plate motion is responsible for most geological activity.

Plate motion occurs because the outer cold, hard skin of the Earth, the lithosphere, overlies a hotter, soft layer known as the asthenosphere. Heat from decay of radioactive minerals in the Earth's interior sets the asthenosphere into thermal convection. This convection has broken the lithosphere into plates which move about in response to the convective motion. As the plates move past each other, little of the motion at their boundaries occurs by continuous slippage; most of the motion occurs in a series of rapid jerks. Each jerk is an earthquake. This happens because, under the pressure and temperature conditions of the shallow part of the Earth's lithosphere, the frictional sliding of rock exhibits a property known as stick-slip, in which frictional sliding occurs in a series of jerky movements, interspersed with periods of no motion—or sticking. In the geologic time frame, then, the lithospheric plates chatter at their boundaries, and at any one place the time between chatters may be hundreds of years. *See* PLATE TECTONICS.

The periods between major earthquakes is thus one during which strain slowly builds up near the plate boundary in response to the continuous movement of the plates. The strain is ultimately released by an earthquake when the frictional strength of the plate boundary is exceeded. *See* FAULT AND FAULT STRUCTURES.

Most great earthquakes occur on the boundaries between lithospheric plates and arise directly from the motions between the plates. These may be called plate boundary earthquakes. There are many earthquakes, sometimes of substantial size, that cannot be related so simply to the movements of the plates. At many plate boundaries, earthquakes occur over a broad zone—often several hundred miles wide—adjacent to the plate boundary. These earthquakes, which may be called plate boundary-related earthquakes, are secondarily caused by the stresses set up at the plate boundary. Some earthquakes also occur, although infrequently, within plates. These earthquakes, which are not related to plate boundaries, are called intraplate earthquakes. The immediate cause of intraplate earthquakes is not understood.

In addition to the tectonic types of earthquakes described above, some earthquakes are directly associated with volcanic activity. These volcanic earthquakes result from the motion of undergound magma that leads to volcanic eruptions.

Earthquakes often occur in well-defined sequences in time. Tectonic earthquakes are often preceded, by a few days to weeks, by several smaller shocks (foreshocks), and are nearly always followed by large numbers of aftershocks. Foreshocks and aftershocks are usually much smaller than the main shock. Volcanic earthquakes often occur in flurries of activity, with no discernible main shock. This type of sequence is called a swarm.

Earthquakes range enormously in size, from tremors in which slippage of a few tenths of an inch occurs on a few feet of fault, to the greatest events, which may involve a rupture many hundreds of miles long, with tens of feet of slip.

The size of an earthquake is given by its moment: average slip times the fault area that slipped times the elastic constant of the Earth. The units of seismic moment are dyne-centimeters. An older measure of earthquake size is magnitude, which is proportional to the logarithm of moment. Magnitude 2.0 is about the smallest tremor that can be felt. Most destructive earthquakes are greater than magnitude 6; the largest shock known was the 1960 Chile earthquake, with a moment of 10^{30} dyne-centimeters (10^{23} newton-meters) or magnitude 9.5. It involved a fault 600 mi (1000 km) long slipping 30 ft (10 m).

The intensity of an earthquake is a measure of the severity of shaking and its attendant damage at a point on the surface of the Earth. The same earthquake may therefore have different intensities at different places. The intensity usually decreases away from the epicenter (the point on the surface directly above the onset of the earthquake), but its value depends on many factors and generally increases with moment. Intensity is usually higher in areas with thick alluvial cover or landfill than in areas of shallow soil or bare rock. Poor building construction leads to high intensity ratings because the damage to structures is high. Intensity is therefore more a measure of the earthquake's effect on humans than an innate property of the earthquake.

Many additional effects may be produced by earthquake shaking, including landslides and tsunamis. *See* LANDSLIDE; TSUNAMI.

Earthquake prediction research has been going on for nearly a century. Unfortunately, successful earthquake predictions are extremely rare. There are two basic categories of earthquake predictions: forecasts (months to years in advance) and short-term predictions (hours or days in advance). Forecasts are based a variety of research, including the history of earthquakes in a specific region, the identification of fault characteristics (including length, depth, and segmentation), and the identification of strain accumulation. Data from these studies are used to provide rough estimates of earthquake sizes and recurrence intervals. [C.H.S.; K.M.S.]

East Indies A loosely defined region in southeast Asia comprising the countries of Malaysia, Brunei, and Indonesia. The islands of the East Indies extend for about 2800 mi (4500 km) from western Sumatra to New Guinea. They form part of a region of great geological and biological diversity.

Three broad geographic subdivisions can be made: (1) Sundaland, which comprises the shallow marine Sunda Shelf, peninsular southeast Asia, and the islands west of the Makassar and Lombok straits; (2) northern Australia, which includes the shallow marine Sahul and Arafura shelf areas and islands surrounding northern Australia and New Guinea; and (3) Wallacea, which comprises the islands south of the Philippines between Sundaland and northern Australia. Each division is an important geomorphological and biological region. The boundaries of Sundaland and northern Australia can be drawn at the 660-ft (200-m) bathymetric contour. Deep trenches with depths averaging 5 mi (8 km) border the margins of Sundaland with the Indian Ocean, and northern Australia with the Pacific Ocean. In contrast, within the area of Wallacea there are a number of deep troughs, and there are large variations in relief with volcanic and nonvolcanic mountains, typically up to 6600–9900 ft (2000–3000 m) in height, separated by deep marine basins underlain by extended continental and oceanic crust with depths of several kilometers. *See* ASIA; AUSTRALIA.

At present, almost all the islands lie in a belt close to the Equator within the Intertropical Convergence Zone (ITCZ). An equatorial climate prevails, with high rainfall and, except at higher elevations, high temperatures throughout the year. Diurnal variations are greater than the difference of mean temperatures of the hottest and coldest months. High relative humidity is normal in most lowland regions. Regionally, there are significant variations in rainfall, reflecting topography and position with respect to major landmasses and oceans, and each island's climate can be different. Borneo is the only large island within which there is broadly an ever-wet tropical climate. *See* CLIMATOLOGY; TROPICAL METEOROLOGY.

The shallow seas with narrow deep-water passages of Wallacea mean that the region is particularly important for oceanic circulation. The Indonesian throughflow is a current to the Indian Ocean which transports large amounts of warm water from the Pacific, influencing sea surface temperatures, salinity, and rainfall. The magnitude and variations of this current are important controls on the thermohaline balance of the Pacific and Indian oceans, and perhaps on global thermohaline circulation. Most water passes from the North Pacific via the Celebes Sea, Makassar Strait, Flores Sea, and Banda Sea. *See* EQUATORIAL CURRENTS; OCEAN CIRCULATION.

The East Indies are characterized by intensely active seismicity and volcanic activity. The correlation of seismicity, volcanicity, deep trenches, and strong negative gravity anomalies along the Sunda and Banda arcs was noted long before the formulation of the theory of plate tectonics; these are now known to be features characteristic of the subduction of oceanic lithosphere. The history of convergence of the Pacific, Indian-Australian, and Asian plates offers a broad explanation of the geological development and complexity of the region, but many small plates also need to be considered. However, the full details of the development of the region are still far from understood because of its size, relative inaccessibility, and the nature of the terrain. *See* CONTINENTAL DRIFT; GEODYNAMICS; PLATE TECTONICS.

The entire region is immensely rich in natural resources, in particular petroleum, minerals, and timber. Petroleum has been produced in large quantities on land in Sumatra, Borneo, and the Bird's Head of New Guinea since the mid-twentieth century. Most oil and gas provinces are in Cenozoic basins, and in the late 1990s the East Indies provided about 5% of annual world oil production. In recent years, exploration and production has moved offshore and is increasingly moving into deeper waters. Many parts of the region have considerable potential for geothermal energy production. Mineral production has been historically important, with major discoveries of tin, gold, and nickel. The late-twentieth-century discovery of major mineral deposits in the northern New Guinea margin suggests that the young island arcs of the region will continue to be targets for exploration, and large deposits are likely to be found both on and off shore. *See* EARTH RESOURCE PATTERNS. [R.Hai.]

Eating disorders Disorders characterized by abnormal eating behaviors and beliefs about eating, weight, and shape. The three major diagnoses are anorexia nervosa, bulimia nervosa, and binge eating disorder. In addition, there are many cases of abnormal eating that have only some of the features required for an eating disorder diagnosis; these cases are classified as eating disorders not otherwise specified. Obesity is classified as a general medical condition and not as an eating disorder (a psychiatric condition) because it is not consistently associated with psychological or behavioral problems.

There are also three childhood eating disorders: (1) Pica is a persistent pattern of eating nonnutritive substances in infants or young children. (2) Rumination disorder involves repeated regurgitation and rechewing of food. This behavior is not the result of a gastrointestinal or medical condition; the partially digested food comes back into the mouth without any observable nausea, disgust, or attempt to vomit. (3) Feeding disorder of infancy or early childhood is the persistent failure to eat adequately, as reflected in insufficient weight gain for age. Pica and rumination disorder are thought to be uncommon and frequently associated with developmental delays and mental retardation. Perhaps half of the pediatric hospitalizations for inadequate weight gain (which constitute 1–5% of all pediatric hospitalizations) may be due to feeding disorder of infancy or early childhood.

Anorexia nervosa. Anorexia nervosa is characterized by a refusal to maintain a minimal normal body weight (defined as 15% below average weight for height), an intense fear of becoming fat, and, if female, amenorrhea for at least 3 months. The majority of cases of anorexia nervosa are classified as restricting type; these individuals achieve abnormally low weight by severely dieting, fasting, and often by exercising compulsively. In severe cases, patients refuse to eat and can die of starvation or severe medical complications. Another subtype of anorexia nervosa is binge eating/purging type. Despite being emaciated or dangerously thin, persons with anorexia nervosa perceive themselves as overweight (distorted body image), deny the seriousness of their condition, and have an intense fear of becoming fat.

Anorexia nervosa occurs in roughly 1% of adolescent and young adult females. Most cases (90%) are female, and the majority are Caucasian and come from middle-class or higher socioeconomic groups. Anorexia nervosa is more prevalent in industrialized countries that share western views regarding thinness as an ideal. It develops most frequently during adolescence.

Persons with anorexia nervosa frequently manifest symptoms of depression and anxiety. The restricting type of anorexia nervosa is associated with obsessionality, rigidity, perfectionism, and overcontrol, whereas the binge/purge subtype is associated with greater mood instability and impulsivity across a wide range of areas, including substance abuse.

Although some cases of anorexia nervosa show no evidence of medical problems, prolonged starvation affects most organ systems, and a wide array of medical problems tend to be present. Long-term mortality from anorexia nervosa is estimated at 5–10% with most deaths resulting from starvation, cardiac events, or suicide.

The causes of anorexia nervosa are not yet understood but are likely to involve a complex combination of genetic, familial, psychological, and sociocultural factors. The onset of anorexia nervosa tends to follow a period of dieting and is frequently triggered by a stressful life events or transitions.

Since the starvation and weight loss can be life-threatening, initial treatment efforts need to focus on weight gain and the reestablishment of regular eating patterns. Inpatient hospitalization is frequently necessary. Although significant psychological issues tend to be present, it is generally ineffective to address these until weight has been stabilized. Once weight gain is achieved, psychotherapies can become useful. Relapse rates are high. *See* ANOREXIA NERVOSA; PSYCHOTHERAPY.

Bulimia nervosa. Bulimia nervosa is characterized by recurrent episodes of binge eating (eating large amounts of food while experiencing a subjective sense of lack of control over the eating), the regular use of extreme weight compensatory methods (for example, self-induced vomiting), and dysfunctional beliefs about weight and shape that unduly influence self-evaluation or self-worth.

Bulimia nervosa occurs in roughly 2% of adolescents and adults. It is most common in females (90% of cases), Caucasians, and middle-class or higher socioeconomic groups. The prevalence of bulimia has increased over the past few decades, and is also becoming more common in non-Caucasian groups.

Persons with bulimia nervosa have high rates of depression, anxiety, and substance abuse problems. Although this condition is less dangerous than anorexia nervosa, medical complications can occur. Dental erosion and periodontal problems are common. Electrolyte imbalance and dehydration can result in serious medical complications, including cardiac arrhythmias. In rare cases, esophageal bleeding and gastric ruptures occur.

Bulimia nervosa is likely to result from a combination of genetic, familial, psychological, and sociocultural factors. Although many persons have weight and diet concerns, the development of bulimia is thought to arise only in vulnerable individuals and usually after a stressful event. Bulimia nervosa is a self-maintaining vicious cycle.

Bulimia nervosa can often be treated successfully with outpatient therapies. Cognitive behavioral therapy and interpersonal psychotherapy have been found to be most effective for reducing binge eating and vomiting and improving associated concerns such as depression, self-esteem, and body image. These two therapies also have the best results over the long term. Certain types of pharmacotherapy, notably antidepressant medications, are also effective.

Binge eating disorder. Binge eating disorder is characterized by recurrent episodes of binge eating but, unlike bulimia nervosa, no extreme weight control behaviors (purging, laxatives, fasting) are present. Persons with binge eating disorder have chaotic eating patterns and frequently overeat as well as binge.

Although obesity is not required for the diagnosis, many people with binge eating disorder are overweight. Binge eating disorder is estimated to occur in 3% of the general population but in roughly 30% of obese persons. Binge eating disorder occurs most frequently in adulthood, affects men nearly as often as women, and occurs across different ethnic groups.

Obese binge eaters are characterized by higher levels of psychiatric problems (depression, anxiety, substance abuse) and psychological problems (poor self-esteem, body image dissatisfaction) than non-binge eaters and closely resemble persons with bulimia nervosa. Overweight persons with binge eating disorder are at high risk for further weight gain and weight fluctuations and associated medical complications. The etiology of binge eating disorder is unknown.

Cognitive behavioral therapy is effective for reducing binge eating and improving associated concerns such as depression, self-esteem, and body image, but does not seem to result in weight loss. There is some evidence that behavioral weight control treatment can reduce binge eating and facilitate weight loss. Antidepressant medications appear to reduce binge eating but do not produce weight loss; relapse is rapid after discontinuation of the medication. *See* AFFECTIVE DISORDERS. [C.M.G.]

Ebenales An order of flowering plants, division Magnoliophyta (Angiospermae) in the subclass Dilleniidae of the class Magnoliopsida (dicotyledons). The order consists of 5 families and about 1750 species, the Sapotaceae (about 800 species) and Ebenaceae (about 450 species) being the largest and most familiar families. The Ebenales are woody, chiefly tropical, sympetalous plants (those with flowers have the petals joined by their margins, at least toward the base, forming a basal tube, cup, or saucer) with usually twice as many stamens (including staminodes) as corolla lobes. Chicle (from *Manilkara sapota*, in the Sapotaceae) and ebony (*Diospyros ebeneum*) are obtained from members of the Ebenales. *See* CHICLE; DILLENIIDAE; EBONY; MAGNOLIOPHYTA. [A.Cr.]

Ebola virus Ebola viruses are a group of exotic viral agents that cause a severe hemorrhagic fever disease in humans and other primates. The four known subtypes or species of Ebola viruses are Zaire, Sudan, Reston, and Côte d'Ivoire (Ivory Coast), named for the geographic locations where these viruses were first determined to cause outbreaks of disease. Ebola viruses are very closely related to, but distinct from, Marburg viruses. Collectively, these pathogenic agents make up a family of viruses known as the Filoviridae.

Filoviruses have an unusual morphology, with the virus particle, or virion, appearing as long thin rods. A filovirus virion is composed of a single species of ribonucleic acid (RNA) molecule that is bound together with special viral proteins, and this RNA–protein complex is surrounded by a membrane derived from the outer membrane of infected cells. Infectious virions are formed when the virus buds from the surface of infected cells and is released. Spiked structures on the surface of virions project from the virion and serve to recognize and attach to specific receptor molecules on the surface of susceptible cells, allowing the virion to penetrate the cell. The genetic information contained in the RNA molecule directs production of new virus particles by using the cellular machinery to drive synthesis of new viral proteins and RNA. *See* RIBONUCLEIC ACID (RNA); VIRUS.

Although much is known about the agents of Ebola hemorrhagic fever disease, the ecology of Ebola viruses remains a mystery. The natural hosts of filoviruses remain unknown, and there has been little progress at unraveling the events leading to outbreaks or identifying sources of filoviruses in the wild. Fortunately, the incidence of human disease is relatively rare and has been limited to persons living in equatorial Africa or working with the infectious viruses. The virus is spread primarily through close contact with the body of an infected individual, his or her body fluids, or some other source of infectious material.

Ebola virus hemorrhagic fever disease in humans begins with an incubation period of 4–10 days, which is followed by abrupt onset of illness. Fever, headache, weakness, and other flulike symptoms lead to a rapid deterioration in the condition of the individual. In severe cases, bleeding and the appearance of small red spots or rashes over the body indicate that the disease has affected the integrity of the circulatory system. Individuals with Ebola virus die as a result of a shock syndrome that usually occurs 6–9 days after the onset of symptoms. This shock is due to the inability to control vascular functions and the massive injury to body tissues.

It appears that the immune response is impaired and that a strong cellular immune response is key to surviving infections. This immunosuppression may also be a factor in death, especially if secondary infections by normal bacterial flora ensue. *See* IMMUNOSUPPRESSION.

Outbreaks of Ebola virus disease in humans are controlled by the identification and isolation of infected individuals, implementation of barrier nursing techniques, and rapid disinfection of contaminated material. Diagnosis of Ebola virus cases is made by detecting virus proteins or RNA in blood or tissue specimens, or by detecting antibodies to the virus in the blood.

Dilute hypochlorite solutions (bleach), 3% phenolic solutions, or simple detergents (laundry or dish soap) can be used to destroy infectious virions. No known drugs have been shown to be effective in treating Ebola virus (or Marburg virus) infections, and protective vaccines against filoviruses have not been developed. [A.San.]

Ebony A genus, *Diospyros*, of the ebony family, containing more than 250 species. Some species are important for their succulent fruits, such as date plum, kaki plum, and persimmon, and several for their timber, particularly the heartwood, which is the true ebony of commerce. *See* EBENALES.

Although it is popularly supposed to be a black wood, most species have a heartwood that is only streaked and mottled with black. The heartwood is very brittle, and is difficult to work, but it has long been in demand. The sapwood is white, becoming bluish or reddish when cut.

Black ebony is used for knife handles, piano keys, finger boards of violins, hairbrush backs, inlays, and marquetry. Some of the woods called ebony, however, belong to different families, especially the pulse family, Leguminosae.

Persimmon (*D. virginiana*), of the southeastern United States, is one of numerous tropical or subtropical species. The species in tropical America are too small or rare to be of economic value, although several of them have black heartwood used locally for making walking sticks, inlays, and miscellaneous articles of turnery and carving. [A.H.G./K.P.D.]

Ebriida An order of flagellate Protozoa, subphylum Sarcomastigophora, class Phytamastigophorea. Two genera, *Ebria* and *Hermesinum*, remain of the once numerous order, as determined by fossil remains. They possess an internal solid siliceous skeleton forming a shallow flattened or slightly arched structure that is enclosed by clear cytoplasm. Skeleton form and structure are distinctive. These phytoflagellates do not have chromatophores.

The organisms are common in the inshore waters of the Atlantic Ocean and the Gulf of Mexico. However, numbers sufficient to influence the general ecology have not been observed. Their only occurrence seems to be marine, although somewhat lowered salinities are certainly tolerated. *See* PHYTAMASTIGOPHOREA; PROTOZOA. [J.B.L.]

Ecdysone The molting hormone of insects. It is a derivative of cholesterol. The most striking physiological activity of ecdysone is the induction of puffs (zones of gene activity) in giant chromosomes of the salivary glands and other organs of the midge *Chironomus*. The induction of puffs has been visualized as primary action of the hormone, indicating that ecdysone controls the activity of specific genes. It has been shown that ecdysone stimulates the synthesis of messenger RNA, among which is the messenger for dopa decarboxylase. This enzyme is involved in the biosynthesis of the sclerotizing agent *N*-acetyldopamine. *See* INSECTA. [P.K.]

Echinacea A superorder of Euechinoidea, having a rigid test, the periproct within the apical system, keeled teeth, a complete perignathic girdle, and branchial slits. J. Durham and R. Melville (1957) include five orders in this group. These were formerly distributed among the Stirodonta and Camarodonta in the classification of R. Jackson (1912). *See* ECHINODERMATA; ECHINOIDA; EUECHINOIDEA; HEMICIDAROIDA; PHYMOSOMATOIDA; SALENIOIDA; TEMNOPLEUROIDA. [H.B.F.]

Echinodermata A unique group of exclusively marine animals with a peculiar body architecture. They are headless with a fivefold radial symmetry. The body wall contains the endoskeleton, made of numerous independent calcareous plates which frequently support spines. The plates may be tightly interlocked or loosely associated. The spines may protrude through the outer epithelium, and are often used for defense. The skeletal plates of the body wall, together with their associated muscles and connective tissue, form a tough and sometimes rigid test which encloses the large coelom. A unique water-vascular system is involved in locomotion, respiration, food gathering, and sensory perception. This shows outside the body as rows of fluid-filled tube feet in conspicuous double lines or ambulacra. Within the body wall lie the ducts and fluid reservoirs necessary to protract and retract the tube feet by hydrostatic pressure. The nervous system arises from the embryonic ectoderm and consists of a ring around the mouth with connecting nerve cords associated with each ambulacrum. There may also be diffuse nerve plexuses lying below the outer epithelium. The coelom houses the alimentary canal and associated organs and in most groups the reproductive organs.

The larvae are usually planktonic with a bilateral symmetry, but the adults are usually sedentary and benthic. They inhabit all seas and oceans, ranging from the shores to the ocean depths.

The phylum comprises about 6000 existing species and many fossils, providing a good fossil record. Echinoderms first appeared in the Early Cambrian and have been evolving over 600 million years. During this vast time several divergent patterns have arisen. The surviving groups show few resemblances to the original stock. The existing representatives fall into three subphyla: Crinozoa (class Crinoidea: sea lilies and feather stars); Asterozoa (class Asteroidea: starfishes, and class Ophiuroidea: brittle stars), and Echinozoa (class Echinoidea: sea urchins, sand dollars and heart urchins); and class Holothuroidea: sea cucumbers). The fourth subphylum, Homalozoa, has no living representatives. Following is the outline of classification for the phylum.

Phylum Echinodermata
- Subphylum: Homalozoa
  - Class: Ctenocystoidea
  - Stylophora
  - Homostelea
  - Homoiostelea
- Subphylum: Crinozoa
  - Class: Eocrinoidea
  - Crinoidea
    - Subclass: Inadunata
    - Camerata
    - Flexibilia
    - Articulata
  - Class: Rhombifera
  - Diploporita
  - Parablastoidea
  - Edrioblastoidea
  - Paracrinoidea
  - Coronoidea
  - Blastoidea
- Subphylum: Echinozoa
  - Class: Helicoplacoidea
  - Camptostromatoidea
  - Edrioasteroidea
  - Echinoidea
    - Subclass: Perischoechinoidea
      - Order: Bothriocidaroida
      - Echinocystitoida
    - Subclass: Cidaroidea
      - Order: Cidaroida
    - Subclass: Euechinoidea
      - Superorder: Echinothuriacea
        - Order: Echinothurioida
      - Superorder: Diadematacea
        - Order: Diadematoida
        - Micropygoida
        - Pedinoida
      - Superorder: Echinacea
        - Order: Hemicidaroida
        - Salenioida
        - Phymosomatoida
        - Temnopleuroida
        - Echinoida
      - Superorder: Eognathostomata
        - Order: Pygasteroida
        - Holectypoida
      - Superorder: Neognathostomata
        - Order: Cassiduloida
        - Oligopygoida
        - Clypeasteroida
        - Neolampadoida
      - Superorder: Atelostomata
        - Order: Disasteroida
        - Holasteroida
        - Spatangoida
  - Class: Ophiocistioidea
  - Holothuroidea
- Subphylum: Asterozoa
  - Class: Asteroidea
    - Order: Platyasterida
    - Trichasteropsida
    - Paxillosida
    - Notomyotida
    - Valvatida
    - Forcipulatida
  - Class: Ophiuroidea
    - Order: Stenurida
    - Oegophiurida
    - Phrynophiurida
    - Ophiurida

Echinoderms evolved very rapidly near the beginning of the Paleozoic Era, and Lower Cambrian deposits contain such divergent branches of the phylum as Homalozoa, Helicoplacoidea, Edrioasteroidea, and Eocrinoidea. These are primitive sorts of echinoderms. Cystoids, crinoids, and blastoids, as well as all recognized main groups of asterozoans and echinozoans (except holothurians), appear in Ordovician strata. During the Paleozoic, numerous well-marked evolutionary trends are discernible in nearly all echinoderm groups, including free-moving forms (especially echinoids) as well as crinozoans. Many small classes of echinoderms became extinct during the Paleozoic, and the surviving groups, especially the crinoids, lost many members at the great Late Permian mass extinction. All groups of modern echinoderms have their origin in early Paleozoic stocks, and the lines of their phylogeny are mostly indicated by the fossil record. Echinoids predominate in Mesozoic and Cenozoic echinoderms. [R.C.Mo.; J.J.Se.]

Echinoida An order of Echinacea with a camarodont lantern, smooth test, imperforate noncrenulate tubercles, ambulacral plates of echinoid type, and shallow branchial slits. There are numerous tropical and temperate species, some of them remarkably adapted to living on coral reefs. The four included families (Parasaleniidae, Echinidae, Strongylocentrotidae, and Echinometridae) are principally distinguished by characters of the pedicellariae. *See* ECHINACEA; ECHINODERMATA; ECHINOIDEA.

[H.B.F.]

Echinoidea A class of Echinozoa known as the sea urchins. These animals have a compact body enclosed in a hard shell, or test, formed from regularly arranged plates which bear movable spines, or radioles (see illustration). There are no arms, but radii are represented by five double rows of tube feet arranged as meridians between the upper and lower poles of the body.

There are about 850 living species, and some 5000 fossil species have been recorded, included in 225 genera. They are classified in 18 orders, which are grouped in 3 subclasses. Sea urchins range in size from approximately 5 mm across the test to 20 cm (8 in.). They differ from other echinoderms in possessing echinochromes in the pigmentation complex. Although many species are dull or dark in color, some are brilliant shades of purple, red, green, or orange. Others species have particolored striped spines, and deep-sea forms may be white.

Sea urchins occur in all seas from low-tide level downward. The rounded (or regular) urchins feed mainly on algae, often hiding by day under stones held over the test by tube feet, and emerging at night or at high tide. The heart urchins and other exocyclic forms live buried in mud or sand, feeding on organic matter in the mud or on selected detritus.

Sea urchins move slowly, using muscles at the bases of the spines to swing the spines like stilts. The suctorial tube feet are used to ascend steep surfaces and as anchors.

The test is globular, or nearly so, in those forms in which the anus lies within the apical system. These are often called Regularia. In exocyclic forms the test tends to assume a secondary bilateral symmetry. The radial symmetry is always evident, however, and is five-part (pentamerous). *See* IRREGULARIA; REGULARIA.

The test is built up of regularly arranged plates which collectively form a rigid or sometimes flexible investing shell. In all echinoids since the Triassic the test is composed of 10 meridional areas. The meridians converge above and below at the upper and lower poles. The equatorial zone is termed the ambitus. Of the 10 meridional areas, 5 correspond to ambulacra, because each of them carries a double row of tube feet. The alternating 5 meridional areas are termed interambulacra, or interambs. They are usually wider than the ambulacra, or ambs (see illustration).

The mouth lies on the lower (oral) side of the test, surrounded by soft skin, the peristome. In endocyclic forms the mouth is central, but in exocyclic forms it may suffer displacement into the radius and lie opposite the interamb which contains the anus. The radius is then termed anterior. In endocyclic forms and in some of the exocyclic forms the mouth is furnished with a ring of five powerful jaws, each with one large tooth. The jaws and teeth collectively compose the so-called lantern.

Small grasping organs, pedicellariae, are well developed in echinoids, in which they take the form of a beak carried on a stalk. The beak is made up of three (sometimes only two) movable jaws, operated by muscles and sometimes provided with venom glands. They respond to tactile stimuli and seize any small organisms or particles which may touch the skin.

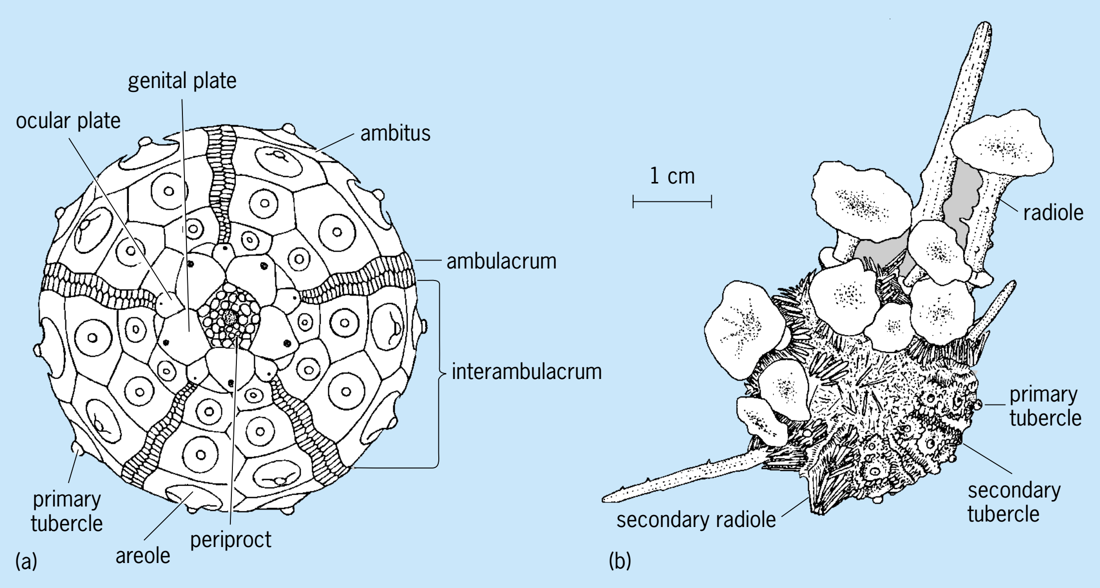
The tube feet evidently serve as tactile and taste organs. A few sea urchins have photosensitive eyespots on the upper surface of the test, scattered in the ectoderm. The ocular pores are not sensitive to light. Minute spherical stalked bodies attached to the skin in some echinoids are believed to be organs of balance.

The alimentary canal is tubular. It lies in the coelom, attached to the wall of the test by mesenteries. The stomach runs from the esophagus in a counterclockwise coil (as viewed from above), and the intestine retraces the route in reverse. The rectum passes upward to the anus.

Like starfishes, sea urchins seem to be sexually mature after 1 year, but continue to grow for several years. The life span is unknown, but may average 5–6 years in medium-sized species. The sexes are normally separate, although fertile hermaphrodites are known. Spines and some other organs are regenerated after injury. *See* ECHINODERMATA; EUECHINOIDEA; PERISCHOECHINOIDEA.

[H.B.F.]

Echinozoa A subphylum of free-living echinoderms in which the body is essentially globoid with meriodional symmetry. They lack arms, brachioles, or other appendages, and do not at any time exhibit pinnate structure. The Echinozoa range from the Early Cambrian to the present day. There are four classes that can definitely be placed here: (1) Edrioasteroidea, Lower Cambrian to lower Carboniferous echinozoans in which the mouth and anus were both directed upward and ambulacra (three to five in number) served as food-collecting



Structure of the naked echinoid test of *Goniocidaris parasol*. (*a*) Naked test. (*b*) Test with radioles.

areas; (2) Echinoidea, originating in the Middle Ordovician; (3) Ophiocistioidea of the Lower Ordovician through Middle Devonian; and (4) Holothuroidea, which apparently first appeared in the Devonian. Two other extinct echinoderm classes can be placed here for convenience: (5) Lower Cambrian Camptostromatoidea and (6) Lower Cambrian Helicoplacoidea. The latter class may be the sister group of both echinozoans and crinozoans.

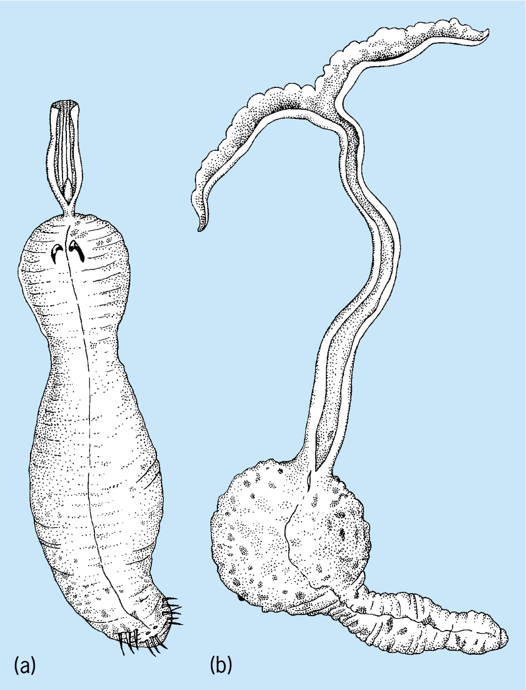
The oldest definite echinozoans are stromatocystitids of the Lower and Middle Cambrian. This group, which may have camptostromatids as its sister group, may have been ancestral to other edrioasteroids and, perhaps, other echinozoans. The asterozoans (asteroids and ophiuroids) may have been derived from the echinozoans, making the subphylum paraphyletic. *See* CAMPTOSTROMATOIDEA; ECHINODERMATA; ECHINOIDEA; EDRIOASTEROIDEA; HELICOPLACOIDEA; HOLOTHUROIDEA. [H.P.F.; J.J.Se.]

Echiurida

A small group of wormlike animals, once linked with the Sipuncula and Priapulida under the term Gephyrea, but now regarded as a separate phylum, with affinities to the annelid worms. They range from the topical to the polar seas, living buried in the sea floor from the intertidal area to depths of 30,000 ft (9000 m).

Their classification has always presented difficulties. In the classification of W. Fisher three orders—Echiuroinea, Xenopneusta (4 species), and Heteromyota (1 species)—are recognized, with one problematic species attached. By far the largest number of species are included in the Echiuroinea, which is divided into the families Bonellidae and Echiuridae. The classification of the Bonellidae is the most uncertain and now includes 21 genera with about 35 species. The Echiuridae are more stable with only 8 genera but more than 70 species.

The body is saclike or sausage-shaped and often highly colored. Anteriorly there is a prostomium which is readily detached. This may be very long and cleft at the tip (Bonellidae), or short and flaplike (Echiuridae; see illustration). The mouth, located at the base of the prostomium, leads into the gut, which is divided into several distinct regions. At the posterior end of the body are two very characteristic structures, the anal vesicles, for which an excretory function has been proposed.



Echiurida. (*a*) *Echiuris* and (*b*) *Bonellia*, half size.

The sexes are separate and similar in the Echiuridae. In the Bonellidae they are separate and very dissimilar, the male being minute and parasitic within or on the female. [M.E.Ri.]

Echo

A sound wave which has been reflected or otherwise returned with sufficient magnitude and time delay to be perceived in some manner as a sound wave distinct from that directly transmitted. Multiple echo describes a succession of separately indistinguishable echos arising from a single source. When the reflected waves occur in rapid succession, the phenomenon is often termed a flutter echo. Echoes and flutter echoes are generally detrimental to the quality of the acoustics of rooms. They may be minimized through the proper selection of room dimensions, room shape, and distribution of sound-absorbing materials.

Echoes have been put to a variety of uses in measurement problems. For example, the distance between two points can be measured by timing the duration required for a direct sound originating at one location to strike an object at the other point and to return an echo to the location of the initial source. Ultrasonic echo techniques have achieved considerable success in nondestructive testing of materials. *See* ECHO SOUNDER; ECHOCARDIOGRAPHY; REFLECTION OF SOUND; SONAR; SOUND; ULTRASONICS. [W.J.G.]

Echo box

A device used to check the output power and spectrum of a radar transmitter. It consists of a low-loss, tunable, resonant cavity connected to the antenna feed line through a fixed coupling circuit so that the fraction of output power supplied to the cavity is always constant. The signal level within the cavity depends on the strength of the portion of the transmitter output spectrum lying within the cavity's narrow passband, which can be tuned to traverse the entire frequency range of interest. A microammeter connected through a crystal rectifier to a loop within the cavity permits reading the signal level. The spectrum can be measured as the cavity is tuned to different frequencies. *See* RADAR. [R.I.B.]

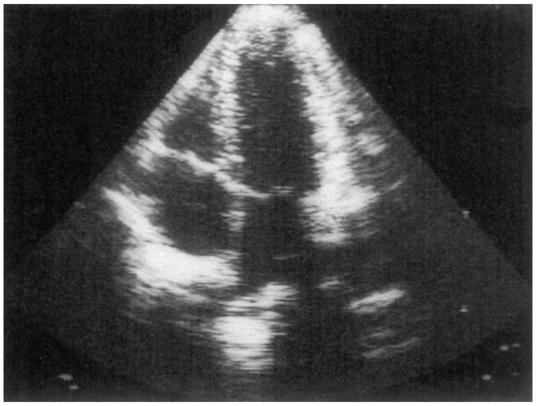
Echo sounder

A marine instrument used primarily for determining the depth of water by means of an acoustic echo. A pulse of sound sent from the ship is reflected from the sea bottom back to the ship, the interval of time between transmission and reception being proportional to the depth of the water. An echo sounder is really a type of active sonar. It consists of a transducer located near the keel of the ship which serves (in most models) as both the transmitter and receiver of the acoustic signal; the necessary oscillator, receiver, and amplifier which generate and receive the electrical impulses to and from the transducer; and a recorder or other indicator which is calibrated in terms of the depth of water.

Echo sounders, sometimes called fathometers, are used by vessels for navigational purposes, not only to avoid shoal water but as an aid in fixing position when a good bathymetric chart of the area is available. Some sensitive instruments are used by commercial fishers or marine biologists to detect schools of fish or scattering layers of minute marine life. Oceanographic survey ships use echo sounders for charting the ocean bottom. *See* SCATTERING LAYER; SONAR; UNDERWATER SOUND. [R.W.Mo.]

Echocardiography

A diagnostic procedure that uses ultrasound at a frequency of 2.5–10 mHz to provide an image of the heart. The principle is that the interface between tissues of different acoustical impedance causes the ultrasound to be reflected to the transducer which spends a fraction of each second receiving these echoes. There are many interfaces between blood and the various structures in the heart that contact blood, such as the heart walls, valves, and great vessels. Also, the surface of the heart reflects ultrasound because it is surrounded by the lungs, which are filled with air. *See* ULTRASONICS.



Two-dimensional echocardiogram from a position near the apex of the ventricles. The left ventricle is on the right, separated from the left atrium below by the mitral valve. The right ventricle is on the left, and the right atrium is below it with the tricuspid valve in between.

An ultrasound image of the heart is generated on a video monitor (see illustration). The image is generated by moving the ultrasound beam mechanically or electronically repeatedly through an arc. The transducer is usually applied to the anterior chest by using a coupling gel devoid of air. This procedure is referred to as transthoracic echocardiography. Small transducers can also be attached to probes placed in the esophagus behind the heart—a procedure known as transesophageal echocardiography; and during heart surgery the transducer can be placed directly on the heart—a procedure known as epicardial echocardiography. The closer the transducer is to the heart, the higher the resolution of the resulting images.

Two-dimensional echocardiography is completely harmless and provides such excellent images of the heart that it has largely replaced other more risky imaging techniques and those that require radiation exposure. It is unequaled for determining the anatomy and function of heart valves, detecting abnormal amounts of pericardial fluid, and defining the complex anatomy of congenital heart defects. Thus, two-dimensional echocardiography is frequently employed to evaluate suspected or overt heart disease.

Echocardiography can also be used to assess blood flow in the heart by employing the Doppler principle. Three basic types of Doppler echocardiographic systems are available on most ultrasound machines: continuous wave, pulsed, and color flow. In a continuous-wave (CW) Doppler system, sound is continuously transmitted and received. The advantage of continuous-wave Doppler is that the very high velocities of severe structural heart defects are accurately quantitated. Pulsed Doppler avoids the range ambiguity of the continuous-wave Doppler by being able to range-gate the returning echoes so that only certain areas in the sound beam are sampled. However, pulsed Doppler cannot resolve very high velocities. Pulsed and continuous-wave Doppler are useful for detecting and localizing increased velocities associated with obstructions to flow. In the third system, color-flow Doppler, small sample volumes (0.04–0.08 in. or 1–2 mm) throughout the two-dimensional echocardiographic image are sampled for velocity, and only velocities fast enough to result from blood movement are displayed, superimposed on the two-dimensional echocardiographic image and color-encoded. Color Doppler is excellent for displaying abnormal flow due to valve leakage or other structural defects. *See* DOPPLER EFFECT.

The complete echocardiographic examination also includes selective sampling along certain radians in the arced two-dimensional image, and displaying of the movement of the structures crossed by the radian over time in an analog fashion. This format is called time-motion echocardiography or M-mode echocardiography. It is adjunctive to two-dimensional and color-flow Doppler echocardiography for answering specific questions about heart structural dimensions and function. *See* HEART DISORDERS. [M.H.Cr.]

Echolocation The biological sonar that bats, porpoises, and certain other animals use to navigate without the visual system. Such animals have evolved the ability to perceive objects by emitting sounds and hearing the echoes that the objects reflect to their ears. The locations and characteristics of the objects are represented by acoustic properties of the echoes, and the ears and auditory systems of these animals act as the sonar receiver. The sense of hearing is specialized for converting echo information into displays of objects, which are perceived as acoustic images that guide the animal's behavior. The best-known examples of echolocating animals are bats (Microchiroptera) and porpoises and toothed whales (Cetacea). However, several other kinds of mammals also can echolocate. *See* SONAR.

Bats produce their ultrasonic sonar sounds from the larynx and broadcast them through the open mouth or through a specialized transmitting antenna formed around the nostrils. Porpoises produce their sonar sounds from structures located beneath the blowhole on the top of the head (through which they breathe) and project them into the water through the rounded, protuberant forehead, which contains acoustically specialized tissue. The sonar sounds of porpoises and whales are very brief impulses, or clicks, which contain a wide range of ultrasonic frequencies, all occurring at the same instant. The rate of emission of these sonar clicks depends in part upon the distance to objects that interest the animal, and can vary from several sounds per second to several hundred. Porpoises use their sonar to find fish and presumably to perceive objects beyond the relatively restricted range of vision under water. *See* CHIROPTERA; PHONORECEPTION; ULTRASONICS. [J.A.Sim.]

Echovirus One of the divisions of the enterovirus subgroup, within the picornavirus group of viruses. The name is derived from the term enteric cytopathogenic human orphan virus. More than 34 antigenic types exist. Only certain types have been associated with human illnesses, particularly with aseptic meningitis and febrile disease. Their epidemiology is similar to that of other enteroviruses. Echoviruses resemble polioviruses and coxsackieviruses in size (about 28 nanometers) and in many other properties. Diagnosis is made by isolation and typing of the viruses in tissue culture. Antibodies form during convalescence. *See* ANIMAL VIRUS; ENTEROVIRUS; PICORNAVIRIDAE. [J.L.Me.]

Eclipse The occultation (obscuring) of one celestial body by another. Solar and lunar eclipses take place at syzygies of the Sun, Earth, and Moon, when the three bodies are in a line. At a solar eclipse, the Moon blocks the view of the Sun as seen from the Earth. At a lunar eclipse, the Earth's shadow falls on the Moon, darkening it, and can be seen from wherever on Earth the Moon is above the horizon.

Solar eclipses. A solar eclipse can be understood as an occultation of the Sun by the Moon or, equivalently, the Moon's shadow crossing the Earth's surface. The darkest part of the shadow, from which the Sun is entirely hidden, is the umbra (Fig. 1). The outer part of the shadow, from which part of the Sun can be seen, is the penumbra.

Solar eclipses can be central, in which the Moon passes entirely onto the solar disk as seen from Earth, or partial, in which one side of the Sun always remains visible. Central eclipses can be total, in which case the Moon entirely covers the solar photosphere, making the corona visible for the period of totality, or annular, in which case the Moon's angular diameter is smaller than that of the Sun because of the positions of the Earth and Moon in their elliptical orbits. At an annular eclipse, a bright annulus of photospheric sunlight remains visible; it is normally thousands of times brighter than the corona, leaving the sky too blue for the corona to be seen.

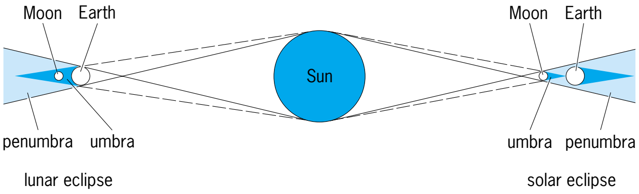


Fig. 1. Circumstances of solar and lunar eclipses (not to scale).

The plane of the Moon's orbit is inclined by 5° to the plane of the Earth's orbit (the ecliptic), so the Moon's shadow commonly passes above or below the Earth each month at new moon. But two to five times each year, the Moon's shadow reaches the Earth, and a partial, annular, or total eclipse occurs. The Moon is approximately 400 times smaller than the Sun but is also approximately 400 times closer, so its angular diameter in the sky is about the same as the Sun's. Thus the Moon fits approximately exactly over the photosphere, making the phenomenon of a total eclipse especially beautiful.

The partial phases of a total eclipse visible from the path of totality last over an hour. In the minute or two before totality, shadow bands—low-contrast bands of light and dark caused by irregularities in the Earth's upper atmosphere—may be seen to race across the landscape. As the Moon barely covers the Sun, photospheric light shines through valleys on the edge of the Moon, making dots of light—Baily's beads—that are very bright in contrast to the background. The last Baily's bead gleams so brightly that it appears as a jewel on a ring, with the band made of the corona; this appearance is known as the diamond ring effect. It usually lasts for 5–10 s, and in the clearest skies for as long as 40 s.

During the diamond ring effect, the solar chromosphere becomes visible around the limb of the Moon, glowing pinkish because most of its radiation is in the form of emission lines of hydrogen, mostly the red hydrogen-alpha line. Its emission-line spectrum apparently flashes into view for a few seconds, and is called the flash spectrum. As the advancing limb of the Moon covers the chromosphere, the corona becomes fully visible (Fig. 2). Its shape is governed by the solar magnetic field; common are equatorial streamers and polar tufts. At the maximum of the solar activity cycle, so many streamers exist that the corona appears round when it is seen in projection, as viewed from Earth. At the minimum of the solar activity cycle, only a few streamers exist so that the corona appears more elongated in projection. *See* SUN.

Fig. 2. Total solar eclipse of February 26, 1998, observed from Aruba, Netherlands Antilles. Image is composited from several exposures in order to show the wide dynamic range of intensity of the corona and to bring out the structures of the streamers. (*Jay M. Pasachoff and Wendy Carlos*)

Totality lasts from an instant up through somewhat over 7 min. At its end, the phenomena repeat, including chromosphere, diamond ring, Baily's beads, shadow bands, and the partial phases.

The paths of the Sun and Moon in the sky intersect at two points, the ascending node and the descending node. Only when both the Sun and the Moon are near a node can an eclipse occur. Thus eclipse seasons take place each year, whenever the Sun is near enough to the node so that an eclipse is possible. Each eclipse season is 38 days long. Because the Sun's gravity causes the orientation of the Moon's elliptical orbit to change with an 18.6-year cycle, the nodes slide along the ecliptic and a cycle of two eclipse seasons—an eclipse year—has a period of 346.6 days, shorter than a solar year. *See* MOON.

There must be at least one solar eclipse each eclipse season, so there are at least two each year. There may be as many as five solar eclipses in a calendar year, though most of these will be partial. Adding lunar eclipses (including penumbral lunar eclipses, which may not be noticeable), there may be seven eclipses in a year.

An important coincidence relates lunar months and eclipse years. A total of 223 lunar months (technically, synodic months, the period of the phases) takes 6585.32 days. A total of 19 eclipse years (passages of the Sun through the same node of the Moon's orbit) takes 6585.78 days, and 242 nodical months (passages of the Moon through the node) take 6585.36 days. Thus eclipses appear with this period of 18 years $11\frac{1}{3}$ days (plus or minus a day, depending on leap years), a period known as the saros. Further, 239 periods of the variation of distance of the Moon from the Earth, the anomalistic month, is 6585.54 days, so the relative angular sizes of the Sun and Moon are about the same at this interval. As a result of the saros, almost identical eclipses recur every 18 years $11\frac{1}{3}$ days. The significance of the $\frac{1}{3}$ day is that the Earth rotates one-third of the way around, and the eclipse path is shifted on the Earth's surface.

Even with advances in space technology, total solar eclipses are the best way of seeing the lower corona. Related eclipse studies include use of the advancing edge of the Moon to provide high spatial resolution for radio observations of the Sun and, historically, of celestial radio sources. *See* SOLAR CORONA.

The total phase of an eclipse is completely safe to watch with the naked eye. The total brightness of the corona is only that of the full moon, so is equally safe to watch. For direct observation of the partial phases, a special solar filter must be used. Fogged and exposed black-and-white (not color) film that contains silver and is developed to full density provides suitable diminution of the solar intensity across the entire spectrum. Inexpensive commercial solar filters made of aluminized Mylar can also be used. Gelatin "neutral-density" filters are actually not neutral in the infrared, and so should not be used. Neutral-density filters made by depositing chromium or other metals on glass are safe if they are ND4 or ND5, and are commercially available, as is #14 welder's glass. [J.M.P.]

Lunar eclipses. A lunar eclipse can occur only when the Moon is full and is near one of the nodes of its orbit. If the Moon enters only the penumbral cone of the Earth (Fig. 1), the eclipse is a penumbral one. If the Moon enters the umbra without being entirely immersed in it, a partial (umbral) eclipse occurs. The eclipse is total if the entire Moon enters the umbra.

The magnitude of an eclipse is the fraction of the diameter of the lunar disk which is eclipsed (in the umbra or in the penumbra) at maximum phase. If the magnitude is larger than 1, the eclipse is total. Penumbral eclipses are not observable unless their magnitude (in the penumbra) is greater than about 0.7.

If penumbral eclipses as well as umbral ones are taken into consideration, the least number of lunar eclipses during a calendar year is two, and the maximum number is five. If only umbral eclipses are considered, the least number of lunar eclipses in one calendar year is zero, and the maximum number is three.

When the Moon passes through the center of the Earth's shadow, the entire eclipse takes $5\frac{1}{3}$ to $6\frac{1}{4}$ h, depending on the

Moon's position in its orbit at the time of the eclipse. The first hour is spent in the penumbra (Fig. 1). No darkening is noticeable until about a quarter hour before the first contact with the umbra, because in the penumbra all of the Moon's side facing Earth is still receiving some direct sunlight. Then as the Moon enters the umbra, the eclipsed part of the Moon appears nearly black by contrast with the bright side of the disk. Approximately the second hour is required for all of the Moon to get into the umbra.

The diameter of the umbra where the Moon crosses it is about $2\frac{2}{3}$ times the Moon's diameter. The total phase of a lunar eclipse can last up to 107 min.

If the Earth had no atmosphere, the Moon would disappear from view while in the umbra. However, the Earth's atmosphere acts like a lens and bends the sunlight into the umbra. The longer waves of red light penetrate the atmosphere better than the shortwave blue light, which is scattered to form the blue of the sky. An observer on the Moon would see the Earth surrounded by a thin ring of bright sunset colors. This explains the usual reddish color of the totally eclipsed Moon. Extremely dark eclipses are due to major volcanic eruptions, whose dust temporarily increases the atmosphere's opacity. *See* Refraction of waves. [J.Mee.]

Eclipsing variable stars Double star systems in which the two components are too close to be seen separately but which reveal their duplicity by periodic changes in brightness as each star successively passes between the other and the Earth, that is, eclipses the other. Studies of the light changes and the radial velocity changes of each component permit the computation of the radii, masses, and densities of the components—important quantities that cannot be measured directly in single stars. In addition, these close double stars are useful in studies of mass loss and of stellar evolution. Since eclipsing stars are variable in light, they are included in general variable star catalogs under the same system of nomenclature. *See* Binary star.

It is now believed that all explosive variables (novae, recurrent novae, and so forth), with the exception of supernovae, are members of close binary systems. At least some of the x-ray sources are close binaries in this state. In a few of the eruptive variables, particularly those known as dwarf novae, rapid scintillation is found, presumably in each system from a hot spot where the transferring mass collides violently with a circumstellar disk of relatively low-density material revolving around the collapsed star; the scintillation stops periodically when the spot is eclipsed by the other component. *See* Nova; Stellar evolution. [F.B.W.]

Ecliptic The apparent path of the Sun across the sky over the course of a year. The Earth's mean orbit defines the ecliptic plane, and an observer on Earth sees the Sun, traveling in this plane over the course of a year, follow the ecliptic. The orbits of the Moon and planets are at slight angles to the ecliptic, but these objects never appear too far in the sky from the ecliptic, which is often drawn on star maps.

The ecliptic intersects the celestial equator at an angle of approximately $23\frac{1}{2}^\circ$, an angle known as the obliquity of the ecliptic. *See* Astronomical coordinate systems; Earth rotation and orbital motion. [J.M.P.]

Eclogite A very dense rock composed of red-brown garnet and the grape-green pyroxene omphacite. Eclogites possess basaltic bulk chemistry, and their garnets are rich in the components pyrope, almandine, and grossular, while the pyroxenes are rich in jadeite and diopside.

Eclogite occurrences may be subdivided into three broad categories: Group a eclogites are found as layers, lenses, or boudins in schists and gneisses seemingly of the amphibolite facies. Quartz, together with zoisite or kyanite, commonly occurs in these rocks. Amphibole of barroisitic composition may also be present. Group b eclogites are found as inclusions in kimberlites and basalts. They are frequently accompanied by xenoliths of garnet peridotite. Group c eclogites are found as blocks and lenses in schists of the glaucophane-schist facies. Such eclogites do not contain kyanite, rarely contain quartz, but bear amphibole, epidote, rutile, or sphene.

Eclogite is the name given to the highest-pressure facies of metamorphism; the critical mineral assemblage defining this facies is garnet + omphacite, together with kyanite or quartz in rocks of basaltic composition. Where sedimentary and granitic rocks have been metamorphosed under eclogite facies conditions, they result in spectacular omphacite + garnet + quartz-bearing mica schists and metagranitic gneisses such as are found in the Sezia-Lanzo zone of the western Alps. *See* Metamorphic rocks.

The high density of eclogite, together with its elastic properties, makes it a candidate for upper mantle material. Large quantifies of basaltic oceanic crust are returned to the mantle through the process of subduction, where prevailing high pressures convert it to eclogite. The quantity and distribution of eclogite within the mantle is not known; that it occurs is known from the nodules brought up in kimberlite pipes and in basalts. [T.J.B.H.]

Ecological communities Assemblages of living organisms that occur together in an area. The nature of the forces that knit these assemblages into organized systems and those properties of assemblages that manifest this organization have been topics of intense debate among ecologists since the beginning of the twentieth century. On the one hand, there are those who view a community as simply consisting of species with similar physical requirements, such as temperature, soil type, or light regime. The similarity of requirements dictates that these species be found together, but interactions between the species are of secondary importance and the level of organization is low. On the other hand, there are those who conceive of the community as a highly organized, holistic entity, with species inextricably and complexly linked to one another and to the physical environment, so that characteristic patterns recur, and properties arise that one can neither understand nor predict from a knowledge of the component species. In this view, the ecosystem (physical environment plus its community) is as well organized as a living organism, and constitutes a superorganism. Between these extremes are those who perceive some community organization but not nearly enough to invoke images of holistic superorganisms. *See* Ecosystem.

Every community comprises a given group of species, and their number and identities are distinguishing traits. Most communities are so large that it is not possible to enumerate all species; microorganisms and small invertebrates are especially difficult to census. However, particularly in small, well-bounded sites such as lakes or islands, one can find all the most common species and estimate their relative abundances. The number of species is known as species richness, while species diversity refers to various statistics based on the relative numbers of individuals of each species in addition to the number of species. The rationale for such a diversity measure is that some communities have many species, but most species are rare and almost all the individuals (or biomass) in such a community can be attributed to just a few species. Such a community is not diverse in the usual sense of the word. Patterns of species diversity abound in the ecological literature; for example, pollution often effects a decrease in species diversity.

The main patterns of species richness that have been detected are area and isolation effects, successional gradients, and latitudinal gradients. Larger sites tend to have more species than do small ones, and isolated communities (such as those on oceanic islands) tend to have fewer species than do less isolated ones of equal size. Later communities in a temporal succession tend to have more species than do earlier ones, except that the last (climax) community often has fewer species than the immediately preceding one. Tropical communities tend to be very species-rich, while those in arctic climates tend to be species-poor. This observation conforms to a larger but less precise rule that communities in particularly stressful environments tend to have few species.

Communities are usually denoted by the presence of species, known as dominants, that contain a large fraction of the community's biomass, or account for a large fraction of a community's productivity. Dominants are usually plants. Determining whether communities at two sites are truly representatives of the "same" community requires knowledge of more than just the dominants, however. "Characteristic" species, which are always found in combination with certain other species, are useful in deciding whether two communities are of the same type, though the designation of "same" is arbitrary, just as is the designation of "dominant" or "characteristic."

Communities often do not have clear spatial boundaries. Occasionally, very sharp limits to a physical environmental condition impose similarly sharp limits on a community. For example, serpentine soils are found sharply delimited from adjacent soils in many areas, and have mineral concentrations strikingly different from those of the neighboring soils. Thus they support plant species that are very different from those found in nearby nonserpentine areas, and these different plant species support animal species partially different from those of adjacent areas.

Here two different communities are sharply bounded from each other. Usually, however, communities grade into one another more gradually, through a broad intermediate region (an ecotone) that includes elements of both of the adjacent communities, and sometimes other species as well that are not found in either adjacent community. *See* ECOTONE.

The environment created by the dominant species, by their effects on temperature, light, humidity, and other physical factors, and by their biotic effects, such as allelopathy and competition, may entrain some other species so that these other species' spatial boundaries coincide with those of the dominants. *See* PHYSIOLOGICAL ECOLOGY (PLANT); POPULATION ECOLOGY.

More or less distinct communities tend to follow one another in rather stylized order. As with recognition of spatial boundaries, recognition of temporal boundaries of adjacent communities within a sere (a temporary community during a successional sequence at a site) is partly a function of the expectations that an observer brings to the endeavor. Those who view communities as superorganisms are inclined to see sharp temporal and spatial boundaries, and the perception that one community does not gradually become another community over an extended period of time confirms the impression that communities are highly organized entities, not random collections of species that happen to share physical requirements. However, this superorganismic conception of succession has been replaced by an individualistic succession. Data on which species are present at different times during a succession show that there is not abrupt wholesale extinction of most members of a community and concurrent simultaneous colonization by most species of the next community. Rather, most species within a community colonize at different times, and as the community is replaced most species drop out at different times. That succession is primarily an individualistic process does not mean that there are not characteristic changes in community properties as most successions proceed. Species richness usually increases through most of the succession, for example, and stratification becomes more highly organized and well defined. A number of patterns are manifest in aspects of energy flow and nutrient cycling. *See* ECOLOGICAL SUCCESSION.

Living organisms are characterized not only by spatial and temporal structure but by an apparent purpose or activity termed teleonomy. In the first place, the various species within a community have different trophic relationships with one another. One species may eat another, or be eaten by another. A species may be a decomposer, living on dead tissue of one or more other species. Some species are omnivores, eating many kinds of food; others are more specialized, eating only plants or only animals, or even just one other species. These trophic relationships unite the species in a community into a common endeavor, the transmission of energy through the community. This energy flow is analogous to an organism's mobilization and transmission of energy from the food it eats.

By virtue of differing rates of photosynthesis by the dominant plants, different communities have different primary productivities. Tropical forests are generally most productive, while extreme environments such as desert or alpine conditions harbor rather unproductive communities. Agricultural communities are intermediate. Algal communities in estuaries are the most productive marine communities, while open ocean communities are usually far less productive. The efficiency with which various animals ingest and assimilate the plants and the structure of the trophic web determine the secondary productivity (production of organic matter by animals) of a community. Marine secondary productivity generally exceeds that of terrestrial communities. *See* AGROECOSYSTEM; BIOLOGICAL PRODUCTIVITY.

A final property that any organism must have is the ability to reproduce itself. Communities may be seen as possessing this property, though the sense in which they do so does not support the superorganism metaphor. A climax community reproduces itself through time simply by virtue of the reproduction of its constituent species, and may also be seen as reproducing itself in space by virtue of the propagules that its species transmit to less mature communities. For example, when a climax forest abuts a cutover field, if no disturbance ensues, the field undergoes succession and eventually becomes a replica of the adjacent forest. Both temporally and spatially, then, community reproduction is a collective rather than an emergent property, deriving directly from the reproductive activities of the component species. *See* ALTITUDINAL VEGETATION ZONES; BOG; CHAPARRAL; DESERT; ECOLOGY; GRASSLAND ECOSYSTEM; MANGROVE; MUSKEG; PARAMO; PUNA.

[D.Sim.]

Ecological competition The interaction of two (or more) organisms (or species) such that, for each, the birth or growth rate is depressed and the death rate increased by the presence of the other organisms (or species). Competition is recognized as one of the more important forces structuring ecological communities, and interest in competition led to one of the first axioms of modern ecology, the competitive exclusion principle. The principle suggests that in situations where the growth and reproduction of two species are resource-limited, only one species can survive per resource.

The competitive exclusion principle was originally derived by mathematicians using the Lotka-Volterra competition equations. This model of competition predicts that if species differ substantially in competitive ability, the weaker competitor will be eliminated by the stronger competitor. However, a competitive equilibrium can occur if the negative effect of each species on itself (intraspecific competition) is greater than the negative effect of each species on the other species (interspecific competition). Because the competitive exclusion principle implies that competing species cannot coexist, it follows that high species diversity depends upon mechanisms through which species avoid competition. *See* MATHEMATICAL ECOLOGY.

In general, competitive exclusion can be prevented if the relative competitive abilities of species vary through time and space. Such variation occurs in two ways. First, dispersal rates into particular patches may fluctuate, causing fluctuations in the numerical advantage of a species in a particular patch. Second, competitive abilities of species may be environmentally dependent and, therefore, fluctuate with local environmental changes. Competitive exclusion can also be avoided if fluctuations in environmental factors reduce the densities of potentially competing species to levels where competition is weak and population growth is for a time insensitive to density.

Coexistence is not merely a result of environmental harshness or fluctuations but also involves the critical element of niche differentiation (that is, species must differ from one another if they are to coexist). However, the focus is not how species coexist by partitioning resources, but how species can coexist on the same resources by differing sufficiently in their responses to environmental conditions and fluctuations. *See* ECOLOGICAL COMMUNITIES; ECOLOGICAL SUCCESSION.

Competition theory has been applied to human-manipulated ecosystems used to produce food, fiber, and forage crops as well as in forestry and rangeland management. Although many characteristics of agricultural systems are similar to those of natural ecosystems, agricultural communities are unique because they are often managed for single-species (sometimes multi-species) production and they are usually characterized by frequent and intense disturbance. Studies of competition in agriculture have primarily examined crop loss from weed abundance under current cropping practices, and have evaluated various weed control tactics and intercropping systems. Factors that influence competition in agroecosystems include the timing of plant emergence, growth rates, spatial arrangements among neighbors, plant–plant-environment interactions, and herbivory. *See* ECOLOGY; ECOLOGY, APPLIED. [P.C.M.]

Ecological energetics The study of the flow of energy within an ecological system from the time the energy enters the living system until it is ultimately degraded to heat and irretrievably lost from the system. It is also referred to as production ecology, because ecologists use the word production to describe the process of energy input and storage in ecosystems.

Ecological energetics provides information on the energetic interdependence of organisms within ecological systems and the efficiency of energy transfer within and between organisms and trophic levels. Nearly all energy enters the biota by green plants' transformation of light energy into chemical energy through photosynthesis; this is referred to as primary production. This accumulation of potential energy is used by plants, and by the animals which eat them, for growth, reproduction, and the work necessary to sustain life. The energy put into growth and reproduction is termed secondary production. As energy passes along the food chain to higher trophic levels (from plants to herbivores to carnivores), the potential energy is used to do work and in the process is degraded to heat. The laws of thermodynamics require the light energy fixed by plants to equal the energy degraded to heat, assuming the system is closed with respect to matter. An energy budget quantifies the energy pools, the directions of energy flow, and the rates of energy transformations within ecological systems. *See* BIOLOGICAL PRODUCTIVITY; FOOD WEB; PHOTOSYNTHESIS.

The essentials of ecological energetics can be most readily appreciated by considering energy flowing through an individual; it is equally applicable to populations, communities, and ecosystems. Of the food energy available, only part is harvested in the process of foraging. Some is wasted, for example, by messy eaters, and the rest consumed. Part of the consumed food is transformed but is not utilized by the body, leaving as fecal material or as nitrogenous waste, the by-product of protein metabolism. The remaining energy is assimilated into the body, part of which is used to sustain the life functions and to do work—this is manifest as oxygen consumption. The remainder of the assimilated energy is used to produce new tissue, either as growth of the individual or as development of offspring. Hence production is also the potential energy (proteins, fats, and carbohydrates) on which other organisms feed. Production leads to an increase in biomass or is eliminated through death, migration, predation, or the shedding of, for example, hair, skin, and antlers.

Energy flows through the consumer food chain (from plants to herbivores to carnivores) or through the detritus food chain. The latter is fueled by the waste products of the consumer food chain, such as feces, shed skin, cadavers, and nitrogenous waste. Most detritus is consumed by microorganisms, although this food chain includes conspicuous carrion feeders like beetles and vultures. In terrestrial systems, more than 90% of all primary production may be consumed by detritus feeders. In aquatic systems, where the plants do not require tough supporting tissues, harvesting by herbivores may be efficient with little of the primary production passing to the detrivores.

Traditionally the calorie, a unit of heat energy, has been used in ecological energetics, but this has been largely replaced by the joule. Production is measured from individual growth rates and the reproductive rate of the population to determine the turnover time. The energy equivalent of food consumed, feces, and production can be determined by measuring the heat evolved on burning a sample in an oxygen bomb calorimeter, or by chemical analysis—determining the amount of carbon or of protein, carbohydrate, and lipid and applying empirically determined caloric equivalents to the values. The latter three contain, respectively, 16.3, 23.7, and 39.2 kilojoules per gram of dry weight. Maintenance costs are usually measured indirectly as respiration (normally the oxygen consumed) in the laboratory and extrapolated to the field conditions. Error is introduced by the fact that animals have different levels of activity in the field and are subject to different temperatures, and so uncertainty has surrounded these extrapolations. Oxygen consumption has been measured in animals living in the wild by using the turnover rates of doubly labeled water (D_2O).

Due to the loss of usable energy with each transformation, in an area more energy can be diverted into production by plants than by consumer populations. For humans this means that utilizing plants for food directly is energetically much more efficient than converting them to eggs or meat. *See* BIOMASS; ECOLOGICAL COMMUNITIES; ECOSYSTEM. [W.F.H.]

Ecological modeling The use of computer simulations or mathematical equations to address questions that cannot be answered solely by experiments or observations. Ecological models have two major aims: to provide general insight into how ecological systems or ecological interactions work; and to provide specific predictions about the likely futures of particular populations, communities, or ecosystems.

Models can be used to indicate general possibilities or to forecast the most likely outcomes of particular populations or ecosystems. Models differ in whether they are "basic" or are intended to address management decisions. As ecology has grown in its sophistication, models are increasingly used as decision support tools for policy-makers. Models of virtually every possible type of ecological interaction have been developed (competition, parasitism, disease, mutualism, plant-herbivore interactions, and so forth). The models vary in their level of detail. Some models simply keep track of the density of organisms, treating all organisms of any species as identical (mass action models). At the other extreme, the movement and fate of each individual organism may be tracked in an elaborate computer simulation (individual behavior models). *See* POPULATION ECOLOGY.

Simple algebraic models are very useful for indicating general principles and possibilities. In order to be a management tool, the model must be more complicated and detailed to reflect the specific situation under examination. For example, instead of a few equations, ecologists have modeled spotted owl populations and old growth forests in Washington using a detailed computer simulation that keeps track of habitat in real maps at the scale of hectares. In these simulation models, owls are moved as individuals from one hectare to another, and their fate (survival, death, or reproduction) is recorded in the computer's memory. By tracking hundreds or even thousands of owls moving around in this computer world, different forestry practices corresponding to different logging scenarios can be examined. *See* ECOLOGY, APPLIED; MATHEMATICAL ECOLOGY; SYSTEMS ECOLOGY.

A model is a formal way of examining the consequences of a series of assumptions about how nature works. Such models refine thinking and clarify what results are implied by any set of assumptions. As models become more complicated and specific, they can also be used to conduct experiments that are too expensive or impractical in the field.

One danger of ecological modeling is the uncertainty of the models and the shortage of supporting data. Properly used, models allow exploration of a wide range of uncertainty, pointing out the limits of current knowledge and identifying critical information required prior to management decision making. However, it would not be prudent to rely solely on the output of any model. *See* ECOLOGY. [P.Ka.]

Ecological succession A directional change in an ecological community. Populations of animals and plants are in a dynamic state. Through the continual turnover of individuals, a population may expand or decline depending on the success of its members in survival and reproduction. As a consequence, the species composition of communities typically does not remain static with time. Apart from the regular fluctuations in species abundance related to seasonal changes, a community may develop progressively with time through a recognizable sequence known as the sere. Pioneer populations are replaced by successive colonists along a more or less predictable path toward a relatively stable community. This process of succession results from interactions between different species, and between species and their environment, which govern the sequence and the rate with which species replace each other. The rate at which succession proceeds depends on the time scale of species' life histories as well as on the effects species may have on each other and on the environment which supports them. In some cases, seres may take hundreds of years to complete, and direct observation at a given site is not possible. Adjacent sites may be identified as successively older stages of the same sere, if it is assumed that conditions were similar when each seral stage was initiated. *See* ECOLOGICAL COMMUNITIES; POPULATION ECOLOGY.

The course of ecological succession depends on initial environmental conditions. Primary succession occurs on novel areas such as volcanic ash, glacial deposits, or bare rock, areas which have not previously supported a community. In such harsh, unstable environments, pioneer colonizing organisms must have wide ranges of ecological tolerance to survive. In contrast, secondary succession is initiated by disturbance such as fire, which removes a previous community from an area. Pioneer species are here constrained not by the physical environment but by their ability to enter and exploit the vacant area rapidly.

As succession proceeds, many environmental factors may change through the influence of the community. Especially in primary succession, this leads to more stable, less severe environments. At the same time interactions between species of plant tend to intensify competition for basic resources such as water, light, space, and nutrients. Successional change results from the normal complex interactions between organism and environment which lead to changes in overall species composition. Whether succession is promoted by changing environmental factors or competitive interactions, species composition alters in response to availability of niches. Populations occurring in the community at a point in succession are those able to provide propagules (such as seeds) to invade the area, being sufficiently tolerant of current environmental conditions, and able to withstand competition from members of other populations present at the same stage. Species lacking these qualities either become locally extinct or are unable to enter and survive in the community.

Early stages of succession tend to be relatively rapid, whereas the rates of species turnover and soil changes become slower as the community matures. Eventually an approximation to the steady state is established with a relatively stable community, the nature of which has aroused considerable debate. Earlier, the so-called climax vegetation was believed to be determined ultimately by regional climate and, given sufficient time, any community in a region would attain this universal condition. This unified concept of succession, the monoclimax hypothesis, implies the ability of organisms progressively to modify their environment until it can support the climatic climax community. Although plants and animals do sometimes ameliorate environmental conditions, evidence suggests overwhelmingly that succession has a variety of stable end points. This hypothesis, known as the polyclimax hypothesis, suggests that the end point of a succession depends on a complex of environmental factors that characterize the site, such as parent material, topography, local climate, and human influences.

Actions of the community on the environment, termed autogenic, provide an important driving force promoting successional change, and are typical of primary succession where initial environments are inhospitable. Alternatively, changes in species composition of a community may result from influences external to the community called allogenic.

Whereas intrinsic factors often result in progressive successional changes, that is, changes leading from simple to more complex communities, external (allogenic) forces may induce retrogressive succession, that is, toward a less mature community. For example, if a grassland is severely overgrazed by cattle, the most palatable species will disappear. As grazing continues, the grass cover is reduced, and in the open areas weeds characteristic of initial stages of succession may become established.

In some instances of succession, the food web is based on photosynthetic organisms, and there is a slow accumulation of organic matter, both living and dead. This is termed autotrophic succession. In other instances, however, addition of organic matter to an ecosystem initiates a succession of decomposer organisms which invade and degrade it. Such a succession is called heterotrophic. *See* BIOLOGICALS; EUTROPHICATION; FOOD WEB; PRODUCTIVITY.

Observed changes in the structure and function of seral communities result from natural selection of individuals within their current environment. Three mechanisms by which species may replace each other have been proposed; the relative importance of each apparently depends on the nature of the sere and stage of development.

1. The facilitation hypothesis states that invasion of later species depends on conditions created by earlier colonists. Earlier species modify the environment so as to increase the competitive ability of species which are then able to displace them. Succession thus proceeds because of the effects of species on their environment.

2. The tolerance hypothesis suggests that later successional species tolerate lower levels of resources than earlier occupants and can invade and replace them by reducing resource levels below those tolerated by earlier occupants. Succession proceeds despite the resistance of earlier colonists.

3. The inhibition hypothesis is that all species resist invasion of competitors and are displaced only by death or by damage from factors other than competition. Succession proceeds toward dominance by longer-lived species.

None of these models of succession is solely applicable in all instances; indeed most examples of succession appear to show elements of all three replacement mechanisms.

Succession has traditionally been regarded as following an orderly progression of changes toward a predictable end point, the climax community, in equilibrium with the prevailing environment. This essentially deterministic view implies that succession will always follow the same course from a given starting point and will pass through a recognizable series of intermediate states. In contrast, a more recent view of succession is based on adaptations of independent species. It is argued that succession is disorderly and unpredictable, resulting from probabilistic processes such as invasion of propagules and survival of individuals which make up the community. Such a stochastic view reflects the inherent variability observed in nature and the uncertainty of environmental conditions. In particular, it allows for succession to take alternative pathways and end points dependent on the chance outcome of interactions among species and between species and their environment.

Consideration of community properties such as energy flow supports the view of succession as an orderly process. The rate of gross primary productivity typically becomes limited also by the availability of nutrients, now incorporated within the community biomass, and declines to a level sustainable by release from decomposer organisms. Species diversity tends to rise rapidly at first as successive invasions occur, but declines again with the elimination of the pioneer species by the climax community.

Stochastic aspects of succession can be represented in the form of models which allow for transitions between a series of different "states." Such models, termed Markovian models, can apply at various levels: plant-by-plant replacement, changes in tree size categories, or transitions between whole communities. A matrix of replacement probabilities defines the direction, pathway, and likelihood of change, and the model can be used to predict the future composition of the community from its initial state. [P.Ran.]

Ecology The subdiscipline of biology that concentrates on the relationships between organisms and their environments; it is also called environmental biology. Ecology is concerned with patterns of distribution (where organisms occur) and with patterns of abundance (how many organisms occur) in space and time. It seeks to explain the factors that determine the range of environments that organisms occupy and that determine how abundant organisms are within those ranges. It also emphasizes functional interactions between co-occurring organisms. In addition to being a unique component of the biological sciences, ecology is both a synthetic and an integrative science since it often draws upon information and concepts in other sciences, ranging from physiology to meteorology, to explain the complex organization of nature.

Environment is all of those factors external to an organism that affect its survival, growth, development, and reproduction. It can be subdivided into physical, or abiotic, factors, and biological, or biotic, factors. The physical components of the environment include all nonbiological constituents, such as temperature, wind, inorganic chemicals, and radiation. The biological components of the environment include the organisms. A somewhat more general term is habitat, which refers in a general way to where an organism occurs and the environmental factors present there. *See* ENVIRONMENT.

A recognition of the unitary coupling of an organism and its environment is fundamental to ecology; in fact, the definitions of organism and environment are not separate. Environment is organism-centered since the environmental properties of a habitat are determined by the requirements of the organisms that occupy that habitat. For example, the amount of inorganic nitrogen dissolved in lake water is of little immediate significance to zooplankton in the lake because they are incapable of utilizing inorganic nitrogen directly. However, because phytoplankton are capable of utilizing inorganic nitrogen directly, it is a component of their environment. Any effect of inorganic nitrogen upon the zooplankton, then, will occur indirectly through its effect on the abundance of the phytoplankton that the zooplankton feed upon. *See* PHYTOPLANKTON; ZOOPLANKTON.

Just as the environment affects the organism, so the organism affects its environment. Growth of phytoplankton may be nitrogen-limited if the number of individuals has become so great that there is no more nitrogen available in the environment. Zooplankton, not limited by inorganic nitrogen themselves, can promote the growth of additional phytoplankton by consuming some individuals, digesting them, and returning part of the nitrogen to the environment.

Ecology is concerned with the processes involved in the interactions between organisms and their environments, with the mechanisms responsible for those processes, and with the origin, through evolution, of those mechanisms. It is distinguished from such closely related biological subdisciplines as physiology and morphology because it is not intrinsically concerned with the operation of a physiological process or the function of a structure, but with how a process or structure interacts with the environment to influence survival, growth, development, and reproduction.

Major subdivisions of ecology by organism include plant ecology, animal ecology, and microbial ecology. Subdivisions by habitat include terrestrial ecology, the study of organisms on land; limnology, the study of fresh-water organisms and habitats; and oceanography, the study of marine organisms and habitats.

The levels of organization studied range from the individual organism to the whole complex of organisms in a large area. Autecology is the study of individuals, population ecology is the study of groups of individuals of a single species or a limited number of species, synecology is the study of communities of several populations, and ecosystem, or simply systems, ecology is the study of communities of organisms and their environments in a specific time and place. *See* POPULATION ECOLOGY; SYSTEMS ECOLOGY.

Higher levels of organization include biomes and the biosphere. Biomes are collections of ecosystems with similar organisms and environments and, therefore, similar ecological properties. All of Earth's coniferous forests are elements in the coniferous forest biome. Although united by similar dynamic relationships and structural properties, the biome itself is more abstract than a specific ecosystem. The biosphere is the most inclusive category possible, including all regions of Earth inhabited by living things. It extends from the lower reaches of the atmosphere to the depths of the oceans. *See* BIOME; BIOSPHERE.

The principal methodological approaches to ecology are descriptive, experimental, and theoretical. Descriptive ecology concentrates on the variety of populations, communities, and habitats throughout Earth. Experimental ecology involves manipulating organisms or their environments to discover the underlying mechanisms governing distribution and abundance. Theoretical ecology uses mathematical equations based on assumptions about the properties of organisms and environments to make predictions about patterns of distribution and abundance. *See* THEORETICAL ECOLOGY. [S.J.McN.]

Ecology, applied The application of ecological principles to the solution of human problems and the maintenance of a quality life. It is assumed that humans are an integral part of ecological systems and that they depend upon healthy, well-operating, and productive systems for their continued well-being. For these reasons, applied ecology is based on a knowledge of ecosystems and populations, and the principles and techniques of ecology are used to interpret and solve specific environmental problems and to plan new management systems in the biosphere. Although a variety of management fields, such as forestry, agriculture, wildlife management, environmental engineering, and environmental design, are concerned with specific parts of the environment, applied ecology is unique in taking a view of whole systems, and attempting to account for all inputs to and outputs from the systems—and all impacts. In the past, applied ecology has been considered as being synonymous with the above applied sciences.

The objective of applied ecology management is to maintain the system while altering its inputs or outputs. Often, ecology management is designed to maximize a particular output or the quantity of a specific component. Since outputs and inputs are related, maximization of an output may not be desirable; rather, the management objective may be the optimum level. Optimization of systems can be accomplished through the use of systems ecology methods which consider all parts of the system rather than a specific set of components. In this way, a series of strategies or scenarios can be evaluated, and the strategy producing the largest gain for the least cost can be chosen for implementation.

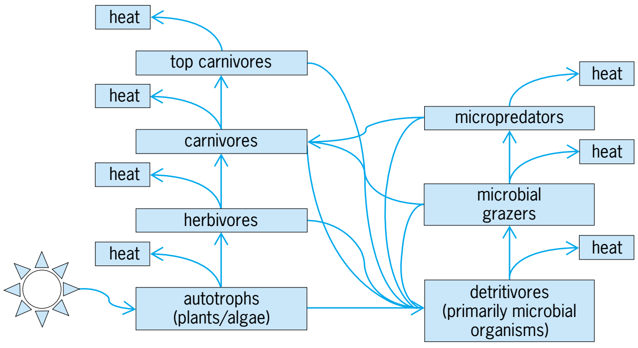
A variety of general environmental problems within the scope of applied ecology relate to the major components of the Earth: the atmosphere, water, land, and the biota. Applied ecology also is concerned with the size of the human population, since many of the impacts of human activities on the environment are a function of the number and concentration of people. *See* Ecology; Ecosystem; Human ecology; Systems ecology. [F.B.Go.]

Ecosystem A functional system that includes an ecological community of organisms together with the physical environment, interacting as a unit. Ecosystems are characterized by flow of energy through food webs, production and degradation of organic matter, and transformation and cycling of nutrient elements. This production of organic molecules serves as the energy base for all biological activity within ecosystems. The consumption of plants by herbivores (organisms that consume living plants or algae) and detritivores (organisms that consume dead organic matter) serves to transfer energy stored in photosynthetically produced organic molecules to other organisms. Coupled to the production of organic matter and flow of energy is the cycling of elements. *See* Ecological communities; Environment.

All biological activity within ecosystems is supported by the production of organic matter by autotrophs (organisms that can produce organic molecules such as glucose from inorganic carbon dioxide; see illustration). More than 99% of autotrophic production on Earth is through photosynthesis by plants, algae, and certain types of bacteria. Collectively these organisms are termed photoautotrophs (autotrophs that use energy from light to produce organic molecules). In addition to photosynthesis, some production is conducted by chemoautotrophic bacteria (autotrophs that use energy stored in the chemical bonds of inorganic molecules such as hydrogen sulfide to produce organic molecules). The organic molecules produced by autotrophs are used to support the organism's metabolism and reproduction, and to build new tissue. This new tissue is consumed by herbivores or detritivores, which in turn are ultimately consumed by predators or other detritivores.

Terrestrial ecosystems, which cover 30% of the Earth's surface, contribute a little over one-half of the total global photosynthetic production of organic matter—approximately 60×10^{15} grams of carbon per year. Oceans, which cover 70% of the Earth's surface, produce approximately 51×10^{15} g C y^{-1} of organic matter. *See* Biomass.

Food webs. Organisms are classified based upon the number of energy transfers through a food web (see illustration). Photoautotrophic production of organic matter represents the first energy transfer in ecosystems and is classified as primary production. Consumption of a plant by a herbivore is the second energy transfer, and thus herbivores occupy the second trophic level, also known as secondary production. Consumer organisms that are one, two, or three transfers from photoautotrophs are classified as primary, secondary, and tertiary consumers. Moving through a food web, energy is lost during each transfer as heat, as described by the second law of thermodynamics. Consequently, the total number of energy transfers rarely exceeds four or five; with energy loss during each transfer, little energy is available to support organisms at the highest levels of a food web. *See* Ecological energetics; Food web.



General model of energy flow through ecosystems.

Biogeochemical cycles. In contrast to energy, which is lost from ecosystems as heat, chemical elements (or nutrients) that compose molecules within organisms are not altered and may repeatedly cycle between organisms and their environment. Approximately 40 elements compose the bodies of organisms, with carbon, oxygen, hydrogen, nitrogen, and phosphorus being the most abundant. If one of these elements is in short supply in the environment, the growth of organisms can be limited, even if sufficient energy is available. In particular, nitrogen and phosphorus are the elements most commonly limiting organism growth. This limitation is illustrated by the widespread use of fertilizers, which are applied to agricultural fields to alleviate nutrient limitation. *See* Biogeochemistry; Nitrogen cycle.

Carbon cycles between the atmosphere and terrestrial and oceanic ecosystems. This cycling results, in part, from primary production and decomposition of organic matter. Rates of primary production and decomposition, in turn, are regulated by the supply of nitrogen, phosphorus, and iron. The combustion of fossil fuels is a recent change in the global cycle that releases carbon that has long been buried within the Earth's crust to the atmosphere. Carbon dioxide in the atmosphere traps heat on the Earth's surface and is a major factor regulating the climate. This alteration of the global carbon cycle along with the resulting impact on the climate is a major issue under investigation by ecosystem ecologists. *See* Air pollution; Conservation of resources; Ecology, applied; Human ecology; Water pollution. [J.B.Jo.]

Ecotone A geographic boundary or transition zone between two different groups of plant or animal distributions. The term has been used to denote transitions at different spatial scales or levels of analysis, and may refer to any one of several attributes of the organisms involved. For example, an ecotone could refer to physiognomy (roughly, the morphology or appearance of the relevant organisms), such as between the boreal forest and grassland biomes; or it could refer to composition, such as between oak-hickory and maple-basswood forest associations; or it could refer to both. Ecotones are generally distinguished from other geographic transitions of biota by their relative sharpness. The ecotone between boreal forest and prairie in central Saskatchewan occurs over a hundred kilometers or so, in contrast to the transition from tropical forest to savanna in South America or Africa that is associated with increasing aridity and is dispersed over hundreds of kilometers. The "tension zone" between broadleaf deciduous forests in south-cental Michigan and mixed forests to the north is similarly sharp. Ecotones are thought to reflect concentrated long-term gradients of one or more current environmental (rather than historical or human) factors. Though often climatic, these factors can also be due to substrate materials, such as glacial sediments or soils. Regardless of their specific environmental basis, most ecotones are thought to be relatively stable.

Ecotones are often reflected in the distributions of many biota besides the biota used to define them. The prairie-forest ecotone, for example, is defined not only by the dominant vegetation components but also by many faunal members of the associated ecosystems, such as insects, reptiles and amphibians, mammals, and birds, that reach their geographic limits there. *See* Alpine vegetation; Biome; Ecological communities; Ecosystem; Forest ecosystem; Grassland ecosystem; Life zones; Savanna; Zoogeography. [J.R.Har.]

Eddy current An electric current induced within the body of a conductor when that conductor either moves through a nonuniform magnetic field or is in a region where there is a change in magnetic flux. It is sometimes called Foucault current. Although eddy currents can be induced in any electrical conductor, the effect is most pronounced in solid metallic conductors. Eddy currents are utilized in induction heating and to damp out oscillations in various devices.

It is possible to reduce the eddy currents by laminating the conductor, that is, by building the conductor of many thin sheets that are insulated from each other rather than making it of a single solid piece. The laminations do not reduce the induced emfs, but if they are properly oriented to cut across the paths of the eddy currents, they confine the currents largely to single laminae, where the paths are long, making higher resistance. *See* CORE LOSS. [K.V.M.]

Edema An abnormal accumulation of fluid in the cells, tissue spaces, or cavities of the body, also known as dropsy. An excess of fluid in the pleural spaces is referred to as hydrothorax, in the pericardial sac as hydropericardium, and in the peritoneal cavity as ascites. Anasarca is a generalized subcutaneous edema.

There are three main factors in the formation of generalized edema and a fourth which plays an important role in the formation of local edema. They are (1) permeability of the capillary wall, (2) colloid osmotic pressure of the plasma proteins, (3) hydrostatic pressure in the capillaries, and (4) lymphatic obstruction.

The management of patients with edema is directed toward the treatment of the underlying medical condition. Diuretics are often used, most successfully in cardiac edema. [R.A.V.; I.N.]

Edentata A group of mammals that encompasses several orders of unusual fossil and living animals characterized by reduced or strongly modified teeth. Usually included in this group are the order Pholidota, the pangolins or scaly anteaters of Africa and Southeast Asia; the order Xenarthra, the true anteaters, armadillos, sloths, and their relatives derived mainly from South and Central America; and the extinct Palaeanodonta, an early Cenozoic group of burrowing mammals from North America. The term "edentate" means toothless. Historically a wide range of toothless mammals and mammals with reduced dentition have been incorporated in this taxonomic group, among them aardvarks and echidnas. Modern systematists restrict the term to pholidotans, xenarthrans, and palaeanodonts based on several shared anatomical specializations found exclusively in these three taxa. Only the pangolins and the true anteaters lack teeth entirely, but all edentates are characterized by a reduced dentition. Typically the incisor teeth are lacking, the tooth enamel is strongly reduced or absent (although enamel is retained in a few of the early fossil forms and in the embryos of living armadillos), and tooth replacement is lost. All three groups share digging adaptations, and specializations for feeding on ants and termites. In addition, pangolins and some xenarthrans have a scaly external body covering. Some mammalian systematists have suggested that edentates represent one of the most primitive groups of living placental mammals, although the matter is somewhat controversial. *See* DENTITION; TOOTH. [T.J.G.]

Ediacaran biota A widely distributed group of soft-bodied marine organisms that are preserved as fossils in rocks of latest Proterozoic age (600–543 million years ago; Ma). The biota characterizes a geological period, known as the Ediacarian or the Vendian, which precedes the widespread appearance of animals with mineralized skeletons. The name Ediacara refers to an abandoned mining area about 380 mi (600 km) north of Adelaide, South Australia.

Ediacaran trace fossil *Gordia* found on the sole of a sandstone bed in South Australia gives clear evidence for the existence of mobile animals in the late Precambrian.

Although Ediacaran fossils were described in the 1930s from southwest Africa (Namibia), it was the discovery in 1946 of abundant fossil "jellyfish" at Ediacara that sparked international interest in this biota. Subsequently, similar or identical fossils were found in England; Newfoundland; Russia, the Ukraine, Siberia; North Carolina; Canada; Nevada; and elsewhere. About 30 localities have been described, with the most diverse biotas found at Ediacara, Namibia, and on the coast of the White Sea in northern Russia. As some of these sites could not have been less than about 6000 mi (10,000 km) apart, no matter how the continents were arranged at the time, there is no doubt that the Ediacaran biota was a globally distributed marine biota.

Most known occurrences of Ediacaran organisms precede the earliest great radiation of skeletal fossils (archaeocyaths, trilobites, mollusks, brachiopods), or else they can be placed as latest Proterozoic on other evidence. Radiometric dates have confirmed that there was no significant time gap between the disappearance of the Ediacaran organisms and the Cambrian radiations. In fact, a few Ediacaran fossils have been found in Cambrian strata; the biota did not entirely die out before the Cambrian. *See* CAMBRIAN.

At almost all sites, the fossils are preserved as impressions in some kind of detrital sedimentary rock. Commonly, they are found on the bases of sandstone beds (South Australia), within sandstone beds (Namibia), or below volcanic ashes swept into deep water by wind and turbidity currents (Newfoundland). The organisms appear to have lived in continental shelf to slope environments and are normally preserved in sediments that were deposited under fairly quiet conditions below normal wave base.

At a conservative estimate there are probably 40–50 distinct genera or probable genera of Ediacaran organisms worldwide. Assigning these genera to higher taxa, however, has been controversial. A real problem is that few of these fossils can unequivocally be referred to living or extinct animal taxa. Because many of the fossils are simply circular structures with or without radial or concentric markings, they impart little information and are difficult to interpret. The recognition of many critical features is hampered by the nature of the preservation. In addition, many Ediacaran fossils, notably most forms from Namibia, are so unusual in shape that they cannot be placed firmly in any modern group. Many workers have placed the more unusual organisms in an extinct higher taxon of phylum grade, commonly named the Petalonamae. Others have used differences in symmetry and body organization to identify and characterize several major taxonomic groups regarded, in general, as extinct higher taxa of phylum or class grade. Some have proposed that all of the Ediacaran organisms were constructed on a single basic plan that was radically different from any other animal. According to this hypothesis, the Ediacarans were "quilted" organisms lacking heads, muscles, or digestive systems, and consisted of parallel sheetlike walls held together by regularly spaced internal partitions, and the whole organism was inflated by body fluids. Proponents of this hypothesis classify the Ediacaran organisms in an extinct kingdom of multicellular life, the Vendobionta. Still others have proposed that the Ediacaran organisms belonged to extant kingdoms other than the animals; they were lichens, algae, or single-celled or colonial protists. Controversy still reigns, but in all likelihood no hypothesis is entirely incorrect.

The marks left in soft sediments by otherwise unknown animals provide another source of knowledge of late Precambrian animal life. The figure-8-shaped trail in the illustration indicates that animals capable of directed, muscular, gliding motion (like that of a garden snail) coexisted with more typical members of the Ediacaran biota. In a similar fashion, strings of fecal pellets demonstrate the existence of animals with one-way guts, and closely meandering marks imply an ability for systematic grazing. There is little evidence for vertical burrowing in rocks of this age.

Although many Ediacaran fossils are enigmatic, there is sound evidence that sponges, cnidarians, bilaterian worms, and possibly arthropods and other phyla were present. This implies that the Animalia originated even farther back in time. The largest Ediacaran fossils, reaching up to 3 ft (1 m) in length, are flattened "fronds" that had large surfaces compared with their volumes. Proponents of the Vendobionta hypothesis have claimed that such large organisms, lacking guts or muscles, must have been photosynthetic or chemosynthetic and probably contained symbiotic, photosynthetic microorganisms. However, such a lifestyle is also found in modern reef corals and various other marine animals. Alternatively, the high ratio of surface to volume may represent adaptations to an atmosphere and hydrosphere relatively low in oxygen. *See* PALEONTOLOGY. [B.Ru.; B.Wa.]

Eel The name for a number of unrelated fish included in the orders Anguilliformes and Cypriniformes.

The true eels are members of the Anguilliformes, which is also known as the Apodes (see table). There are several hundred species, most of which are marine. They are most common in the shallower waters of tropical and subtropical seas, although a few species do occur in colder waters or at considerable depths. *See* ANGUILLIFORMES.

Scientific and common names of some species of true eels

Scientific name	Common name
Muraena helena	Moray eel
Phisodonopis boro	Indian eel
Simenchelys parasiticus	Pug-nosed eel
Anguilla rostrata	American eel
Anguilla vulgaris	European eel
Conger conger	Conger eel

The family Gymnotidae of the order Cypriniformes contains about 32 species which are found in fresh waters of Central and South America. The electric eel (*Electrophorus electricus*), the largest and best-known species of the family, may grow to a length of 8 ft (2.4 m) and weigh 60 lb (27 kg). It can produce an electric shock from its electric organs, which extend almost the length of the body. The bodies of the members of this family are eellike and may be naked or scaled. *See* CYPRINIFORMES; ELECTRIC ORGAN (BIOLOGY). [C.B.C.]

Effective dose 50 A term used chiefly to characterize the potency of a drug by the amount required to produce a response in 50% of the subjects to whom the drug is given; also known as ED_{50} or median effective dose.

Median effective dose is most commonly applied in connection with drugs, but it may be used when various other sources of stimuli, for example, x-rays, are under consideration. The response must be of the kind known as quantal, or all-or-nothing, where the investigator is simply able to report that the response either was or was not elicited.

The median effective dose is a well-defined quantity only when the test animal, the end response, and such factors as the route of injection of a drug and the state of nutrition of the animal are specified. [C.W.]

Effector systems Those organ systems of the animal body which mediate overt behavior. Injury to an effector system leads to loss or to subnormal execution of behavior patterns mediated by the system, conditions termed paralysis and paresis, respectively.

Overt behavior consists of either movement or secretion. Movement results from contraction of muscle. Secretion is a function of glands. Neither muscular contraction nor glandular secretion is autonomous but is regulated by an activating mechanism which may be either neural or humoral. In neurally activated systems the effector organ, whether muscle or gland, is supplied by nerve fibers originating from cell bodies situated in the central nervous system or in peripherally located aggregates of nerve cell bodies known as ganglia.

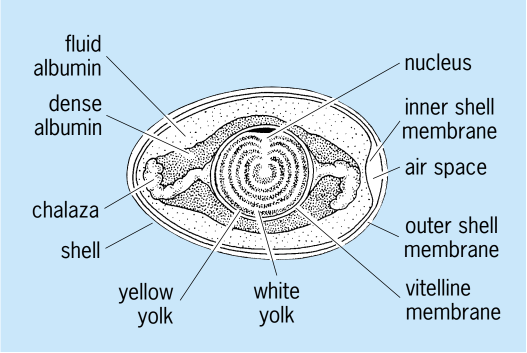
In other effector systems (humeromuscular and humeroglandular) the activating agent is normally a blood-borne chemical substance produced in an organ distant from the effector organ. For example, uterine smooth muscle is uninfluenced by the uterine nerve activity but contracts vigorously when the blood contains pitocin, a chemical substance elaborated by the posterior lobe of the hypophysis.

Finally, some effector systems are hybrid in the sense that both nerves and humors regulate their functions. The smooth muscle of arterioles contracts in response to either nerve stimulation or epinephrine. Secretion of hydrochloric acid by the gastric mucosa is increased by activation of the vagus nerve or by the presence in the blood of histamine. Effector systems with both neural and humoral regulation are never completely paralyzed by denervation but may be deficient in reaction patterns when the quick integrated activation provided by neural regulation is essential. *See* NERVOUS SYSTEM (VERTEBRATE). [T.C.R.; H.D.P.]

Efficiency The ratio, expressed as a percentage, of the output to the input of power (energy or work per unit time). As is common in engineering, this concept is defined precisely and made measurable. Thus, a gear transmission is 97% efficient when the useful energy output is 97% of the input, the other 3% being lost as heat due to friction. A boiler is 75% efficient when its product (steam) contains 75% of the heat theoretically contained in the fuel consumed. All automobile engines have low efficiency (below 30%) because of the total energy content of fuel converted to heat; only a portion provides motive power, while a substantial amount is lost in radiator and car exhaust. [F.R.E.C.]

Efflorescence The spontaneous loss of water (as vapor) from hydrated crystalline solids. The thermodynamic requirement for efflorescence is that the partial pressure of water vapor at the surface of the solid (its dissociation pressure) exceed the partial pressure of water vapor in the air. A typical efflorescent substance is Glauber's salt, $Na_2SO_4 \cdot 10H_2O$. The spontaneous loss of water normally requires that the crystal structure be rearranged, and consequently, efflorescent salts usually go to microcrystalline powders when they lose their water of hydration. *See* PHASE EQUILIBRIUM; VAPOR PRESSURE. [R.L.S.]

Egg (fowl) A single, large, living, female sex cell enclosed in a porous, calcareous shell through which gases may pass. Although they vary in size, shape, and color, the eggs of chickens, ducks, geese, and turkeys are essentially the same in structure and content (see illustration). Inward from the shell are the outer and inner shell membranes which are also permeable to gases. The membranes are constructed to prevent rapid evaporation of moisture from the egg but to allow free entry of oxygen, which is necessary for life. Air begins to penetrate the shell soon after the egg is laid, and it tends to accumulate in a space between the two membranes at the large end of the egg. *See* CELL (BIOLOGY).



Egg of a bird. (*After L. P. Sayles, ed., Biology of the Vertebrates, 3d ed., Macmillan, 1949*)

The inner shell membrane surrounds a mass of fluid albumin which, in turn, encloses a body of dense albumin; these two types of protoplasm constitute the so-called egg white. The central part of the egg is occupied by the yolk, which contains the vital egg nucleus and its associated parts. The yolk consists of alternating layers of yellow and white yolk. The yolk, enclosed by the vitelline membrane, is held in place by the chalaza which is anchored at each end of the egg and prevents undue mechanical disturbance. *See* Cell nucleus; Yolk sac. [J.F.F.]

Eggplant A warm-season vegetable (*Solanum melongena*) of Asiatic origin belonging to the plant order Polemoniales (formerly Tubiflorales). Eggplant is grown for its usually egg-shaped fleshy fruit and is eaten as a cooked vegetable. Popular purple-fruited varieties (cultivars) are Black Beauty and a number of hybrid varieties; fruits of other colors, including white, brown, yellow, and green, are used chiefly for ornamental purposes. Florida and New Jersey are important eggplant-producing states. *See* Solanales. [H.J.C.]

Ehrlichiosis A tick-borne infection that often is asymptomatic but also can produce an illness ranging from a few mild symptoms to an overwhelming multisystem disease. Ehrlichiosis is included with those infections that are said to be emerging, either because they have been recognized only recently or because they were previously well known but now are occurring more frequently.

Human ehrlichiosis is caused by two distinct species: *E. chaffeensis* and an unnamed ehrlichial species. In the United States, *Ehrlichia chaffeensis* infects primarily mononuclear blood cells; the disease produced by this species is referred to as human monocytic ehrlichiosis. The other ehrlichial species invades granulocytic blood cells, causing human granulocytic ehrlichiosis. The latter organism closely resembles *E. equi*, a species that infects horses.

Both of these ehrlichia species are transmitted to humans by the bite of infected ticks. *Ehrlichia chaffeensis* occurs most commonly in the south-central and southeastern states, where it is associated primarily with the Lone Star tick (*Amblyomma americanum*); it is also transmitted by the common dog tick (*Dermacentor variabilis*). The agent of human granulocytic ehrlichiosis is found in the upper midwestern states of Wisconsin and Minnesota, as well as in several northeastern states. This agent seems to be transmitted principally by the deer tick (*Ixodes scapularis*). Although ticks (the vector) are the mode of transmission of ehrlichial infections to humans, the ticks must acquire the ehrlichial organisms from animal sources (the reservoir hosts).

The forms of the disease caused by the two ehrlichial species are indistinguishable. Illness occurs most often during April–September, corresponding to the period when ticks are most active and humans are pursuing outdoor activities. In ehrlichiosis, the incubation period can last from 1 to 3 weeks after exposure to the infected tick. Thereafter, individuals develop fever, chills, headache, and muscle pains. Gastrointestinal symptoms such as nausea, vomiting, and loss of appetite also are common. Laboratory abnormalities regularly include anemia, low white blood cell and platelet counts, and abnormal liver function. More severely ill individuals also may manifest abnormalities of the central nervous system, lungs, and kidneys. Because the clinical presentation is nonspecific, the diagnosis of ehrlichiosis may not be immediately apparent. Prolonged intervals between the onset of illness and the administration of appropriate therapy can lead to more severe disease symptoms and a greater risk of fatality. *See* Clinical microbiology; Hemorrhage; Infection.

An important clue to the diagnosis of human granulocytic ehrlichiosis is the recognition of cytoplasmic vacuoles filled with ehrlichiae (morulae) in circulating neutrophils. Careful examination of stained smears of peripheral blood often yields such findings in human granulocytic ehrlichiosis. In disease caused by *E. chaffeensis*, laboratory diagnosis usually is made by detecting an increase in species-specific antibodies in serum specimens obtained during the acute and convalescent phases of the illness. However, such serologic testing is of no use in establishing the diagnosis before treatment is initiated. Therefore, therapy must be initiated on clinical suspicion.

Ehrlichiosis closely resembles another tick-borne illness, Rocky Mountain spotted fever, except that the rash, characteristic of spotted fever, is usually absent or modest. Hence, ehrlichiosis has been referred to as spotless fever. Fortunately, both diseases can be treated with tetracycline antibiotics. Most individuals respond to tetracycline therapy within 48–72 h. *See* Rickettsioses.

The avoidance of tick bites is fundamental to preventing ehrlichiosis. [W.Scha.; S.M.St.]

Eicosanoids A family of naturally occurring, biologically active substances derived from 20 carbon polyunsaturated fatty acids such as arachidonic acid. Members of the family include prostaglandins, thromboxanes, leukotrienes, and epoxyeicosatrienoic acids (EETs). Functioning as local hormones, they are synthesized and exert their biological actions in the same tissue. Many have physiological and pathological effects on the cardiovascular, pulmonary, reproductive, and digestive systems.

Physiologically and pathologically, eicosanoids are local hormones. They are synthesized and exert their action in a tissue, and only certain eicosanoids are made by the cells of a tissue. As a result, the action of an eicosanoid is usually discrete and related to the physiological demands of the tissue.

The prostaglandins, leukotrienes, TXA_2, and anandamide act by binding to and activating membrane receptor proteins. Distinct receptors have been identified for many eicosanoids. The existence of receptor subgroups explains how some eicosanoids such as PGE_2 have multiple actions.

The prostaglandins and TXA_2 have several actions that are necessary for maintaining normal homeostasis and organ integrity. PGE_2 and PGI_2 are potent vasodilators. These prostaglandins are synthesized in the blood vessel in response to vasoconstrictors and antagonize their effects. This action protects the organ from intense vasoconstriction and maintains nutritive blood flow. They also inhibit gastric acid secretion and may exert other cellular protective effects. In their absence, gastric ulcers develop. TXA_2 is made principally by platelets. It causes vasoconstriction and promotes platelet aggregation. These actions prevent excessive blood loss when a blood vessel is damaged or severed. PGI_2 is made by the blood vessel wall and has the opposite effects. It prevents intravascular platelet aggregates from forming and obstructing blood flow. The balance between the proaggregatory or vasoconstrictor action of TXA_2 and the antiaggregatory or vasodilator action of PGI_2 is critical to cardiovascular homeostasis. $PGF_{2\alpha}$ contracts uterine smooth muscle. With menstruation and destruction of the uterine lining, arachidonic acid is released and metabolized to $PGF_{2\alpha}$. Contraction of the uterine smooth muscle by $PGF_{2\alpha}$ contributes to the pain associated with menstruation. In pregnancy, an increase in prostaglandin synthesis is a major determinant of the onset of labor.

Increased synthesis of PGE_2 and PGI_2 mediates the vasodilation and pain sensitization associated with inflammation and arthritic conditions. Inhibitors of cyclooxygenase-1 and -2 (important catalysts in the synthesis of prostaglandins) such as aspirin and ibuprofen relieve the signs and symptoms of inflammation. However, they also block the constitutive, homeostatic functions of the prostaglandins by blocking cyclooxygenase-1, which can result in renal failure and gastric ulcers. Selective cyclooxygenase-2 inhibitors such as celecoxib are anti-inflammatory without the deleterious effects on homeostatic functions of the prostaglandins.

The leukotrienes are synthesized by leukocytes, and they also serve as inflammatory mediators. LTB_4 is chemotactic and promotes leukocyte aggregation. Thus, it attracts other inflammatory cells to the site of inflammation and sequesters them. LTC_4, LTD_4, and LTB_4 increase capillary permeability, causing the leakage of fluid and protein from the vasculature into the tissue. This contributes to the swelling associated with inflammation. LTC_4 and LTD_4 also cause bronchiolar constriction and increase mucus formation in the airways. These actions are thought to contribute to bronchial asthma. Inhibitors of 5-lipoxygenase and leukotriene receptor antagonists are useful in treating inflammation and bronchial asthma.

The EETs and 20-HETE (hydroxyeicosatetraenoic acid) are involved in the regulation of vascular tone and organ blood flow. In the blood vessel, EETs are synthesized by the endothelial cells in response to vasodilator hormones. The EETs diffuse to the adjacent smooth muscle cells and exert their action. They open potassium channels and hyperpolarize the smooth muscle cell membrane. This results in vasodilation. Thus, EETs serve as mediators of vasodilation. 20-HETE is made by smooth muscle cells in response to increases in intravascular pressure. It is a mediator of myogenic tone in blood vessels. In the blood vessel wall, 20-HETE and the EETs are counterregulatory mechanisms that control blood flow. *See* ARTERIOSCLEROSIS; ARTHRITIS; ASTHMA; GOUT; PAIN; ULCER. [W.B.C.]

Eigenfunction One of the solutions of an eigenvalue equation. A parameter-dependent equation that possesses nonvanishing solutions only for particular values (eigenvalues) of the parameter is an eigenvalue equation, the associated solutions being the eigenfunctions (sometimes eigenvectors). In older usage the terms characteristic equation and characteristic values (functions) are common. Eigenvalue equations appear in many contexts, including the solution of systems of linear algebraic equations (matrix equations), differential or partial differential equations, and integral equations. The importance of eigenfunctions and eigenvalues in applied mathematics results from the widespread applicability of linear equations as exact or approximate descriptions of physical systems. However, the most fundamental application of these concepts is in quantum mechanics where they enter into the definition and physical interpretation of the theory. Only linear eigenvalue equations will be discussed. *See* EIGENVALUE (QUANTUM MECHANICS); ENERGY LEVEL (QUANTUM MECHANICS); NONRELATIVISTIC QUANTUM THEORY; QUANTUM MECHANICS. [J.M.R.]

Eigenvalue (quantum mechanics) If an equation containing a variable parameter possesses nontrivial solutions only for certain special values of the parameter, these solutions are called eigenfunctions and the special values are called eigenvalues.

The eigenfunction-eigenvalue relation is of particular importance in quantum mechanics because of its prominence in the equations which relate the mathematical formalism of the theory with physical results. *See* QUANTUM MECHANICS. [D.P.]

Einsteinium A chemical element, Es, atomic number 99, a member of the actinide series in the periodic table. It is not found in nature but is produced by artificial nuclear transmutation of lighter elements. All isotopes of einsteinium are radioactive, decaying with half-lives ranging from a few seconds to about 1 year. *See* ACTINIDE ELEMENTS; PERIODIC TABLE; RADIOACTIVITY.

Einsteinium is the heaviest actinide element to be isolated in weighable form. The metal is chemically reactive, is quite volatile, and melts at 860°C (1580°F); one crystal structure is known. *See* TRANSURANIUM ELEMENTS. [S.G.T.; G.T.S.]

El Niño In general, an invasion of warm water into the central and eastern equatorial Pacific Ocean off the coast of Peru and Ecuador, with a return period of 4–7 years. El Niño events come in various strengths: weak, moderate, strong, very strong, and extraordinary. The size of an El Niño event can be determined using various criteria: the amount of warming of sea surface temperatures in the central and eastern Pacific from their average condition; the areal extent of that warm water anomaly; and the length of time that the warm water lingers before being replaced by colder-than-average sea surface temperatures in this tropical Pacific region.

Under normal conditions the winds blow up the west coast of South America and then near the Equator turn westward to Asia. The surface water is piled up in the western Pacific, and the sea level there is several tens of centimeters above average while the sea level in the eastern Pacific is below average. As the water is pushed toward the west, cold water from the deeper part of the ocean along the Peruvian coast wells up to the surface to replace it. This cold water is rich with nutrients, making the coastal upwelling region along western South America among the most productive fisheries in the world. *See* UPWELLING.

Every 4–7 years those winds tend to die down and sometimes reverse, allowing the warm surface waters that piled up in the west to move back toward the eastern part of the Pacific Basin. With reduced westward winds the surface water also heats up. Sea level drops in the western Pacific and increases in the eastern part of the basin. El Niño condition can last for 12–18 months, sometimes longer, before the westward flowing winds start to pick up again. Occasionally, the opposite also occurs: the eastern Pacific becomes cooler than normal, rainfall decreases still more, atmospheric surface pressure increases, and the westward winds become stronger. This irregular cyclic swing of warm and cold phases in the tropical Pacific is referred to as ENSO (El Niño Southern Oscillation).

El Niño is considered to be the second biggest climate-related influence on human activities, after the natural flow of the seasons. Although the phenomenon is at least thousands of years old, its impacts on global climate have only recently been recognized. Due to improved scientific understanding and forecasting of El Niño's interannual process, societies can prepare for and reduce its impacts considerably. *See* CLIMATOLOGY; MARITIME METEOROLOGY; TROPICAL METEOROLOGY. [M.H.G.]

Numerical models that couple the atmosphere to the ocean have been used to successfully predict the sea surface temperature of the tropical Pacific a year or so in advance. The basic reason that the cycle is predictable is that ENSO evolves slowly and regularly. If the initial state of the atmosphere-ocean system can be characterized accurately, the classification of this state in the ENSO sequence is made (even if it is not completely recognizable in each system separately), and the future evolution of the cycle can be predicted. *See* CLIMATE MODELING. [E.S.S.]

Elasmobranchii A subclass of the class Chondrichthyes, the cartilaginous fishes. The elasmobranchs are distinguished by separate gill openings, amphistylic or hyostylic jaw suspension, and sensory ampullae (of Lorenzini) in the head region. Characters shared with members of the other subclass (Holo-cephali) include a variably calcified cartilaginous endoskeleton, placoid scales, urea-retention mechanism, clasper organs in the male for internal fertilization, and the absence of an air (swim) bladder. *See* BATOIDEA; CHONDRICHTHYES; CLADOSELACHII; SELACHII. [B.S.]

Elasticity The property whereby a solid material changes its shape and size under the action of opposing forces, but recovers its original configuration when the forces are removed. The theory of elasticity deals with the relations between the forces acting on a body and the resulting changes in configuration, and is important in many branches of science and technology, for instance, in the design of structures, in the theory of vibration and sound, and in the study of the forces between atoms in crystal lattices.

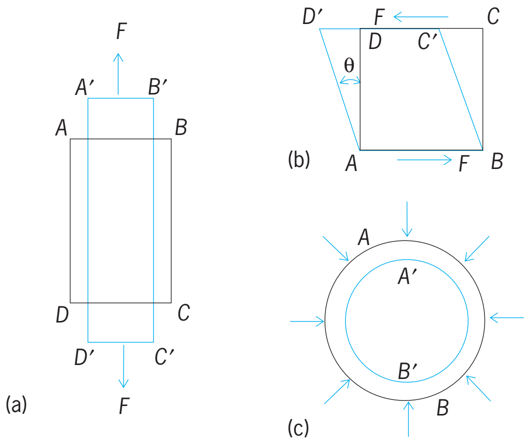
The forces acting on a body are expressed as stresses and measured as force per unit area. Thus if a bar *ABCD* of square cross section (illus. *a*) is fixed at one end and subjected to a force *F* uniformly distributed over the other end *DC*, the stress is $F/(DC)^2$. This stress causes the bar to become longer and thinner and to assume the shape $A'B'C'D'$. The strain is measured by the ratio (change in length)/(original length), that is, by $(B'C' - BC)/(BC)$. According to Hooke's law, stress is proportional to strain, and the ratio of stress to strain is therefore a constant, in this case the Young's modulus, denoted by E, so that $E = F(BC)/(DC)^2\,(B'C' - BC)$. *See* HOOKE'S LAW; STRESS AND STRAIN; YOUNG'S MODULUS.

Poisson's ratio σ is the ratio of lateral strain to longitudinal strain so that $\sigma = BC(DC - D'C')/DC(B'C' - BC)$. The bar of illustration *a* is in a state of tension, and the stress is tensile; if the force *F* were reversed in direction, the stress would be compressive. Stresses of this type are called direct or normal stresses; a second type of stress, known as tangential or shear stress, is shown in illus. *b*. In this case, the configuration *ABCD* becomes $ABC'D'$, with the shear forces *F* acting in the directions *AB* and *CD*. The shear strain is measured by the angle θ, and if the body is originally a cube, the shear stress is $F/(DC)$. The ratio of stress to strain, $F/(DC)^2\,\theta$, is the shear or rigidity modulus G, which measures the resistance of the material to change in shape without change in volume.

A further elastic constant, the bulk modulus k, measures the resistance to change in volume without changes in shape, and is shown in illus. *c*. The original configuration is represented by the circle *AB*, and under a hydrostatic (uniform) pressure *P*, the circle *AB* becomes the circle $A'B'$. The bulk modulus is then $k = Pv/\Delta v$, where $\Delta v/v$ is the volumetric strain. The reciprocal of the bulk modulus is the compressibility.

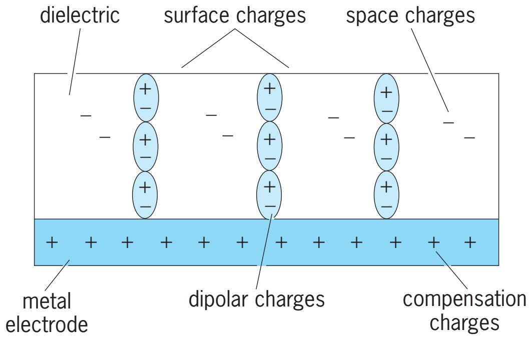
The elastic constants may be determined directly in the way suggested by their definitions; for instance, Young's modulus can be determined by measuring the relative extension of a rod or wire subjected to a known tensile stress. Less direct methods are, however, usually more convenient and accurate. Prominent among these are the dynamic methods involving frequency of vibration and velocity of sound propagation. The elastic constants can be expressed in terms of frequency of (or velocity in) regularly shaped specimens, together with the dimensions and density, and by measuring these quantities, the elastic constants can be found. The elastic constants can also be determined from the flexure and torsion of bars. *See* ULTRASONICS.

In practice, stress is only proportional to strain, and the strain is only completely recoverable within certain limits called the elastic limits of the material. Above the elastic limits, the material is subject to time-dependent effects, and as the stress is further increased, the ultimate strength of the material is approached. *See* PLASTICITY; STRENGTH OF MATERIALS. [R.F.S.H.]



Stresses on a bar. (*a*) Direct or normal stress. (*b*) Tangential or shear stress. (*c*) Change in volume with no change in shape. (All deformations are exaggerated.)

Electret A solid dielectric with a quasi-permanent electric moment. Electrets may be classified as real-charge electrets and dipolar-charge electrets. Real-charge electrets are dielectrics with charges of one polarity at or near one side of the dielectric and charges of opposite polarity at or near the other side, while dipolar-charge electrets are dielectrics with aligned dipolar charges. Some dielectrics are capable of storing both real and dipolar charges. An example of a charge arrangement of an electret metallized on one surface is shown in the illustration. *See* POLARIZATION OF DIELECTRICS.



Schematic cross section of an electret disk metallized on one side.

Modern electrets used in research and in applications are often films of 5–50 micrometers thickness (foil electrets) consisting of a suitable material. They are frequently metallized on one or both sides, depending on the intended use.

Important commercial applications of real-charge electrets are in electroacoustic and electromechanical transducers, in air filters, and in electret dosimeters. Also of interest are biological applications based on the blood compatibility of charged polymers or on their favorable influence on wound or fracture healing. Commercial applications of dipolar electrets are in piezoelectric transducers and in pyroelectric detectors. *See* AIR FILTER; DIELECTRIC MATERIALS; DOSIMETER; ELECTRET TRANSDUCER; ELECTRICAL INSULATION. [G.M.Se.]

Electret transducer A device for the conversion of acoustical or mechanical energy into electrical energy, and vice versa, which utilizes a quasi-permanently charged dielectric material (electret). Examples are certain microphones and headphones. Electret devices are therefore self-biased electrostatic or condenser transducers. They thus exhibit all the advantages of this transducer class, such as wide dynamic range and flat response over a frequency range of several decades, without requiring the external bias necessary in conventional transducers of this kind. *See* ELECTRET; ELECTROSTATICS; TRANSDUCER.

The basic component of all modern electret transducers is a "foil electret" consisting of a thin film of insulating material that has been electrically charged to produce an external electric field. Strongly insulating materials capable of trapping charge carriers, such as the halocarbon polymers, in particular polyfluoroethylenepropylene (Teflon), are best suited for this purpose. Before charging, the material is either metallized on one side or backed up with a metal electrode.

A simple implementation of the most widely used electret transducer is the foil-electret microphone. The diaphragm, typically 0.5- or 1-mil (12- or 25-micrometer) Teflon metallized on one surface, is charged to 100–200 microcoulombs/m^2 (65–130 nanocoulombs/in.^{2}) corresponding to an external bias of about 200 V. The nonmetallized surface of this foil electret is placed next to a backplate, leaving a shallow air layer. The stiffness of the air layer can be decreased (and thus the sensitivity of the microphone can be improved) by connecting the air layer to a larger cavity by means of small holes through the backplate. The backplate is either a metal disk or a metal-coated dielectric. The electrical output of the microphone is taken between the backplate, which is insulated from the outer case, and the metal side of the foil. The output is fed into a high-impedance preamplifier. *See* Microphone.

Compared with conventional electrostatic transducers, electret microphones have the following advantages: they do not require a dc bias; they have three times higher capacitance per unit area, resulting in a better signal-to-noise ratio; and they are not subject to destructive arcing between foil and backplate in humid atmospheres and under conditions of water condensation.

Apart from its use in electroacoustic transducers, such as microphones and earphones, the electret principle has been applied to electromechanical transducers. Examples are touch or key transducers, Korotkov sound pickups, impact-sensitive line transducers, relay switches, and optical display panels.

Because of their favorable properties, simplicity, and low cost, electret transducers have been used often both as research tools and in the commercial market. Among the research applications are microphones for use in acousto-optic spectroscopy, applied to the detection of air pollution and to the study of reaction kinetics of gases and optical absorption of solids. Other applications of electret microphones have been in aeronautics and shock-tube studies. The wide frequency range of electret transducers made possible their application in infrasonic atmospheric studies and in ultrasonic investigations of liquids and solids. In addition, ultrasonic arrays of electret microphones have been used in acoustic holography. Research uses of electromechanical electret transducers have been in such diverse areas as vibration analysis and leak detection in space stations. In these applications, the simplicity and reliability of electret transducers are of importance. *See* Acoustical holography; Infrasound; Photoacoustic spectroscopy; Shock tube; Ultrasonics.

Of all commercial applications of electret devices, the high-fidelity electret microphone for amateur, professional, studio, and cassette recorder use is most prominent, accounting for more than one-half of the entire output of high-fidelity microphones. *See* Sound recording. [G.M.Se.]

Electric charge

A basic property of elementary particles of matter. One does not define charge but takes it as a basic experimental quantity and defines other quantities in terms of it.

According to modern atomic theory, the nucleus of an atom has a positive charge because of its protons, and in the normal atom there are enough extranuclear electrons to balance the nuclear charge so that the normal atom as a whole is neutral. Generally, when the word charge is used in electricity, it means the unbalanced charge (excess or deficiency of electrons), so that physically there are enough "nonnormal" atoms to account for the positive charge on a "positively charged body" or enough unneutralized electrons to account for the negative charge on a "negatively charged body."

In line with this usage, the total charge q on a body is the total unbalanced charge possessed by the body. For example, if a sphere has a negative charge of 1×10^{-10} coulomb, it has 6.24×10^8 electrons more than are needed to neutralize its atoms. The coulomb is the unit of charge in the meter-kilogram-second (mks) system of units. *See* Coulomb's law; Electrical units and standards; Electrostatics. [R.P.Wi.]

Electric contact

A part, in an electrical switching device, made of conducting material, for the purpose of closing, opening, or changing the conductive path of an electrical circuit. To open or close a circuit, an electric contact is made to come in contact with or separate from its mating part. Devices embodying contacts for these purposes are electric switches, relays, contactors, and circuit breakers. Contacts may be actuated directly or through a linkage that is driven either manually, mechanically, electromagnetically, hydraulically, or pneumatically.

An electric contact is also an essential part of a variable resistor. In such an application the contact or wiper provides a moving connection to the resistive element. *See* Rheostat. [T.H.L.]

Electric current

The net transfer of electric charge per unit time. It is usually measured in amperes. The passage of electric current involves a transfer of energy. Except in the case of superconductivity, a current always heats the medium through which it passes.

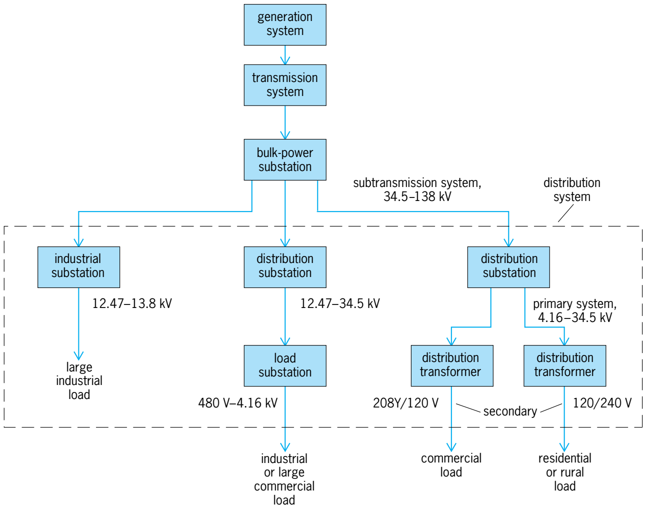
On the other hand, a stream of electrons or ions in a vacuum, which also may be regarded as an electric current, produces no local heating. Measurable currents range in magnitude from the nearly instantaneous 10^5 or so amperes in lightning strokes to values of the order of 10^{-16} ampere, which occur in research applications.

All matter may be classified as conducting, semiconducting, or insulating, depending upon the ease with which electric current is transmitted through it. Most metals, electrolytic solutions, and highly ionized gases are conductors. Transition elements, such as silicon and germanium, are semiconductors, while most other substances are insulators. *See* Alternating current; Conduction (electricity); Direct current; Displacement current; Electric insulator; Semiconductor; Superconductivity. [J.W.St.]

Electric distribution systems

Systems that comprise those parts of an electric power system between the subtransmission system and the consumers' service switches. It includes distribution substations; primary distribution feeders; distribution transformers; secondary circuits, including the services to the consumer; and appropriate protective and control devices. Sometimes, the subtransmission system is also included in the definition.

The subtransmission circuits of a typical distribution system (see illustration) deliver electric power from bulk power sources to the distribution substations. The subtransmission voltage is usually between 34.5 and 138 kV. The distribution substation,



Overview of the power system from generation to consumer's switch.

which is made up of power transformers together with the necessary voltage-regulating apparatus, bus-bars, and switchgear, reduces the subtransmission voltage to a lower primary system voltage for local distribution. The three-phase primary feeder, which usually operates at voltages from 4.16 to 34.5 kV, distributes electric power from the low-voltage bus of the substation to its load center, where it branches into three-phase subfeeders and three-phase and occasionally single-phase laterals. Most of the three-phase distribution system lines consist of three-phase conductors and a common or neutral conductor, making a total of four wires. Single-phase branches (made up of two wires) supplied from the three-phase mains provide power to residences, small stores, and farms. Loads are connected in parallel to common power-supply circuits. *See* Alternating current; Electric power transmission. [T.Gö.]

Electric field A condition in space in the vicinity of an electrically charged body such that the forces due to the charge are detectable. An electric field (or electrostatic field) exists in a region if an electric charge at rest in the region experiences a force of electrical origin. Since an electric charge experiences a force if it is in the vicinity of a charged body, there is an electric field surrounding any charged body.

The electric field intensity (or field strength) $\mathbf{E}$ at a point in an electric field has a magnitude given by the quotient obtained when the force acting on a test charge q' placed at that point is divided by the magnitude of the test charge q'. Thus, it is force per unit charge. A test charge q' is one whose magnitude is small enough so it does not alter the field in which it is placed. The direction of $\mathbf{E}$ at the point is the direction of the force $\mathbf{F}$ on a positive test charge placed at the point. Thus, $\mathbf{E}$ is a vector point function, since it has a definite magnitude and direction at every point in the field, and its defining equation is Eq. (1).

$$\mathbf{E} = \mathbf{F}/q' \qquad (1)$$

Electric flux density or electric displacement $\mathbf{D}$ in a dielectric (insulating) material is related to $\mathbf{E}$ by either of the equivalent equations shown as Eqs. (2), where $\mathbf{P}$ is the polarization of the

$$\mathbf{D} = \epsilon_0\mathbf{E} + \mathbf{P} \quad \mathbf{D} = \epsilon\mathbf{E} \qquad (2)$$

medium, and ϵ is the permittivity of the dielectric which is related to ϵ_0, by the equation $\epsilon = k\epsilon_0$, k being the relative dielectric constant of the dielectric. In empty space, $\mathbf{D} = \epsilon_0\mathbf{E}$.

In addition to electrostatic fields produced by separations of electric charges, an electric field is also produced by a changing magnetic field. *See* Electric charge; Electromagnetic induction; Potentials. [R.P.Wi.]

Electric filter A transmission network used to selectively modify the components of a signal according to their frequencies. In most cases a filter is used to enhance signals of desired frequencies while suppressing signals of undesired frequencies. An ideal filter would pass only desired frequencies while completely suppressing all unwanted frequencies, without any dispersion in time of the frequencies. Unfortunately, ideal filters are impossible to achieve.

Electric filters are used in most electronic communication systems. Whether communication is over wire, free space, or optical fiber, multiple channels of information can be multiplexed on different frequency bands. Unwanted signals and noise are introduced along the communications path. The main function of electric filters is to separate the desired signal or channel from all others and from any noise or interference. For example, an AM radio receiver may have a low-pass filter after the antenna to separate the AM frequency band from higher frequency bands and, elsewhere in the radio, a band-pass filter to select the desired station out of the AM band. *See* Electrical communications; Multiplexing and multiple access; Radio receiver.

Although electronic filters are commonly thought of as devices for conferring selectivity to communication paths, they are used in almost every part of electronic equipment, such as the damping element in phase-locked loops, cleanup devices for frequency sources, and pulse expansion and compression devices for radar. One of the simplest and most common filters is the bypass capacitor used to restrict high-frequency electronic noise. *See* Electrical noise; Phase-locked loops; Radar.

Application ranges of various filter types

Filter type	Frequency range	Bandwidth (% of center frequency)
LC	0–5 GHz	>0.5
Crystal	5 kHz–300 GHz	0.01–5
Ceramic	300 kHz–50 MHz	0.5–20
Mechanical	1 kHz–700 kHz	0.02–10
Surface-acoustic-wave (SAW) resonator	30 kHz–2 GHz	0.01–0.1
SAW transversal	30 kHz–2 GHz	0.2–50
Active	<100 kHz	>0.5
Switched capacitor	<40 kHz	>0.5
Digital	<10 MHz	>0.1
Microwave	0.5 GHz–200 GHz	>0.5
Ceramic dielectric resonator (CDR)	0.7 GHz–5 GHz	>0.1

Filters are characterized in multiple ways. The expression low-pass, Butterworth, *LC* describes a filter. The descriptior low-pass indicates the relation of the passed to the rejected frequencies. Butterworth describes the type of polynomials in the transfer function. *LC* indicates the construction method. This filter is made of inductors (*L*'s) and capacitors (*C*'s).

Filters are classified by the relationship of the frequencies that are selectively passed, referred to as the passband, to those which are attenuated, referred to as the stopband. An ideal low-pass filter passes all frequencies below a specified cutoff frequency and rejects those above. A high-pass filter does the opposite. An ideal band-pass filter will pass a band of frequencies while rejecting all others; a band-reject filter will reject a band of frequencies and pass all others.

An all-pass filter passes all frequencies but does, however, modify the time delay characteristics. It normally corrects delay distortions caused by other sections of a communication path.

All the above classifications are based on frequency-domain considerations. In addition, there are two terms that apply to the time-response characteristics of a filter. A finite impulse response (FIR) filter, when exposed to a change in input, will settle to a steady state within a finite amount of time. An infinite impulse response (IIR) filter will continue oscillating in a decaying manner forever.

A further consideration in classifying a filter is whether the frequency response is constant in time or varies. If it varies with time, as a function of the input signal, it is known as an adaptive filter. This type of filter finds use in speech and image enhancement and echo cancellation.

Because filters are used over wide frequency and bandwidth ranges and with such varying performance criteria, many methods have been devised for creating a filter function (see table).

Acoustic filters include crystal, ceramic, mechanical, and surface-acoustic-wave (SAW) filters. These devices convert electrical energy to mechanical vibrations, process the signal acoustically, and then convert the energy back to an electrical form. The equations describing a mechanically vibrating resonator, where energy is cycled between kinetic motion and stress, match those of an inductor and capacitor (*LC*) attached in parallel, where energy is cycled between the electric field of the capacitor and the magnetic field of the inductor. However, the mechanical resonators have much higher *Q*'s and better stability than the *LC* circuit. With the addition of a transducer to convert electrical energy to acoustic, the *LC* circuits can be replaced with mechanical resonators. *See* Resonance (acoustics and mechanics); Transducer.

Many techniques are used to create filters. Inductors are replaced with transistor networks in active filters, discussed below, to reduce size and cost. By using an analog-to-digital converter the transfer function can be created mathematically by a digital processor. At high frequencies, transmission lines and waveguide structures replace lumped elements. *See* DIGITAL FILTER; INTEGRATED-CIRCUIT FILTER; MICROWAVE FILTER; SWITCHED CAPACITOR. [D.P.H.]

An active filter comprises resistors, capacitors, and active elements such as operational amplifiers. It is also referred to as an active-*RC* filter.

Active filters can realize the same filter characteristics as passive ones comprising resistor, capacitor, and inductor elements. They have, however, several advantages over their passive counterparts:

1. Active filters can provide gain, and are frequently used to simultaneously match filtering (frequency-determining) and gain specifications.

2. They are readily implemented in integrated-circuit technology, whereas the inductor element of passive filters is not readily realized. As a result, the active filter is inexpensive, and is attractive for its small size and weight. In addition, it is readily included with other signal-processing functions on a single integrated circuit. *See* INTEGRATED CIRCUITS.

3. The design of active filters is considerably simpler than that of passive ones. In addition, it is easy to provide for variability, which can be used to change filter characteristics by electrical input signals.

The active filter also has some disadvantages:

1. Since the active filter contains electronic components, it requires a power supply, which adds to the complexity of the realization. The electronic components also place restrictions on the level of the signals that can be applied to the filter and on the noise component that the filter may add to the filtered signal. *See* ELECTRONIC POWER SUPPLY.

2. The mathematical process by which the active filter produces filtering characteristics in general requires the use of internal feedback. When this feedback is positive, the resulting filter may be very sensitive to lack of precision in component values, and the effects of aging and environmental conditions. *See* FEEDBACK CIRCUIT.

In general, active filters are designed with the assumption that the active elements are ideal (no parasitics). For example, the operational amplifier is assumed to have infinite gain, infinite input impedance, zero output impedance, and an infinite frequency range (gain-bandwidth). All practical filter realizations must be evaluated for the effect that the nonideal parasitics have on actual filter performance. One of the most troublesome of the parasitics is the operational-amplifier gain bandwidth. Typically, for a given application, tuning charts may be developed which can be used to provide compensation for such operational-amplifier limitations. *See* AMPLIFIER; CIRCUIT (ELECTRONICS); OPERATIONAL AMPLIFIER. [L.P.Hu.]

Electric furnace An enclosed space heated by electric power. The furnace may be in such forms as a refractory crucible, a large tiltable refractory basin with a capacity of 100 tons (91 metric tons) and a removable roof, or a long insulated chamber equipped with a continuous conveyor. Heat is provided by an arc to the charge or melt (direct-arc furnace), by an arc between electrodes (indirect-arc furnace), or by an arc confined for concentrated heating by an electromagnetic field (plasma-arc furnace). Heat may also be produced by current flowing in the melt. *See* ELECTROMETALLURGY; PYROMETALLURGY.

Because the source of heat is nonchemical, electric furnaces are especially desirable in melting alloys of controlled composition. Temperature is also readily controlled. The arc furnace may be used to smelt ores or to refine metals or alloys. Induction furnaces are widely used to melt alloys for castings. Because electric furnaces can be enclosed, they are used for operations that require controlled or inert atmospheres, such as growing crystals or annealing. When sealed and evacuated, they are used in degassing metals. Furnaces with hearth resistors are used for operations below melting temperatures, such as annealing, and with infrared heat lamps, for drying paints or setting glues. *See* ARC HEATING; ELECTRIC HEATING; HEAT TREATMENT (METALLURGY); KILN; REFRACTORY. [F.H.R.]

Electric heating Methods of converting electric energy to heat energy by resisting the free flow of electric current. Electric heating has several advantages: it can be precisely controlled to allow a uniformity of temperature within very narrow limits; it is cleaner than other methods of heating because it does not involve any combustion; it is considered safe because it is protected from overloading by automatic breakers; it is quick to use and to adjust; and it is relatively quiet. For these reasons, electric heat is widely chosen for industrial, commercial, and residential use.

Resistance heaters produce heat by passing an electric current through a resistance—a coil, wire, or other obstacle which impedes current and causes it to give off heat. Heaters of this kind have an inherent efficiency of 100% in converting electric energy into heat. Devices such as electric ranges, ovens, hot-water heaters, sterilizers, stills, baths, furnaces, and space heaters are part of the long list of resistance heating equipment. *See* RESISTANCE HEATING.

Dielectric heaters use currents of high frequency which generate heat by dielectric hysteresis (loss) within the body of a nominally nonconducting material. These heaters are used to warm to a moderate temperature certain materials that have low thermal conducting properties; for example, to soften plastics, to dry textiles, and to work with other materials like rubber and wood. *See* DIELECTRIC HEATING.

Induction heaters produce heat by means of a periodically varying electromagnetic field within the body of a nominally conducting material. This method of heating is sometimes called eddy-current heating and is used to achieve temperatures below the melting point of metal. For instance, induction heating is used to temper steel, to heat metals for forging, to heat the metal elements inside glass bulbs, and to make glass-to-metal joints. *See* INDUCTION HEATING.

Electric-arc heating is really a form of resistance heating in which a bridge of vapor and gas carries an electric current between electrodes. The arc has the property of resistance. Electric-arc heating is used mainly to melt hard metals, alloys, and some ceramic metals. *See* ARC HEATING.

Electricity is one choice for heating houses, but with only a 35% efficiency rate, electricity has been a less attractive option than the direct use of gas and oil for heating homes. Common electric heating systems in houses are central heating employing an electric furnace with forced air circulation; central heating employing an electric furnace with forced water circulation; central heating using radiant cables; electrical duct heaters; space (strip) heaters which use radiation and natural convection for heat transfer; and portable space heaters. [M.S.C.]

Electric insulator A material that blocks the flow of electric current across it. Insulators are to be distinguished from electrolytes, which are electronic insulators but ionic conductors. Electric insulators are used to insulate electric conductors from one another and to confine electric currents to specified pathways, as in the insulation of wires, electric switchgear, and electronic components. They provide an electrical, mechanical, and heat-dissipation function. The electrical function of an insulator is characterized by its resistivity, its dielectric strength (breakdown voltage), and its dielectric constant (relative permittivity). Insulators can be solid, liquid, or gaseous.

The resistivity of a material is a measure of the electric current density that flows across it in response to an applied electric field. Solid and liquid insulators have direct-current resistivities of

10^{10} ohm-meters at room temperature as compared to 10^{-8} Ω-m for a good metal or 10^{-3} Ω-m for a fast ionic conductor. *See* BAND THEORY OF SOLIDS; ELECTRICAL RESISTANCE; ELECTRICAL RESISTIVITY; SEMICONDUCTOR.

A material used in the electrical industry for insulation, capacitors, or encapsulation may be exposed to large voltage gradients that it must withstand for the operating life of the system. Failure occurs if an electric short-circuit develops across the material. Such a failure is called dielectric breakdown. The breakdown voltage gradient, expressed in kilovolts per millimeter, is a measure of the dielectric strength. Dielectric breakdown of a solid is destructive; liquids and gases are self-healing.

An insulator is also known as a dielectric. The dielectric constant *k* is defined as the ratio of the capacitance of a flat-plate condenser, or capacitor, with a dielectric between the plates to that with a vacuum between the plates; this ratio is also the relative permittivity of the dielectric. The dielectric constant is a measure of the ability of the insulator to increase the stored charge on the plates of the condenser as a result of the displacement of charged species within the insulator. *See* CAPACITANCE; CAPACITOR; DIELECTRIC MATERIALS; PERMITTIVITY.

Successful application of solid insulating materials also depends on their mechanical properties. Insulation assemblies commonly must withstand thermal-expansion mismatch, tension, compression, flexing, or abrasion as well as a hostile chemical-thermal environment. The introduction of cracks promotes the penetration of moisture and other contaminants that promote failure, and the presence of pores may cause damaging corona discharge on the surface of a high-voltage conductor. As a result, composite materials and engineered shapes must be tailored to meet the challenges of a particular operational environment. *See* CORONA DISCHARGE.

For example, glasses and varnishes are used as sealants, and oil is used to impregnate high-voltage, paper-insulated cables to eliminate air pockets. Porcelain is a commonly used material for the suspension of high-voltage overhead lines, but it is brittle. Therefore, a hybrid insulator was developed that consists of a cylindrical porcelain interior covered by a mastic sealant and a silicone elastomer sheath heat-shrunk onto the porcelain core. The circular fins of the outer sheath serve to shed water. However, twisted-pair cables insulated with poly(tetrafluoroethylene) are used for high-speed data transmission where a small dielectric constant of the insulator material is needed to reduce signal attenuation. *See* CONDUCTOR (ELECTRICITY); ELECTRIC POWER TRANSMISSION; FLUORINE; PORCELAIN; SILICONE RESINS.

Liquid or gas insulation provides no mechanical strength, but it may provide a cheap, flexible insulation not subject to mechanical failure. Biphenyls are used as insulating liquids in capacitors; alkyl benzenes in oil-filled cables; and polybutenes for high-pressure cables operating at alternating-current voltages as high as 525 kV. Sulfur hexafluoride (SF_6) is a nonflammable, nontoxic electron-attracting gas with a breakdown voltage at atmospheric pressure more than twice that of air. Fluorocarbons such as C_2F_6 and C_4F_8 as well as the Freons are also used, and breakdown voltages have been increased significantly in gas mixtures through a synergistic effect. Used as an insulating medium in high-voltage equipment at pressures up to 10 atm (1 megapascal), sulfur hexafluoride can reduce the size of electrical substations by a factor of 10 over that of air-insulated equipment. Enclosure of metal cable in a metallic conduit filled with sulfur hexafluoride gas has been used to shield nearby workers from exposure to high electric fields. *See* CIRCUIT BREAKER; FLUOROCARBON; POLYCHLORINATED BIPHENYLS.

Finally, the ability to transfer heat may be an overriding consideration for the choice of an electric insulator. Electrical machines generate heat that must be dissipated. In electronic devices, the thermal conductivity of the solid substrate is a primary consideration. Where mechanical considerations permit, circulating liquid or gaseous insulation is commonly used to carry away heat. Liquids are particularly good transporters of heat, but they are subject to oxidation. In transformers, for example, the insulators are generally mineral or synthetic oils that are circulated, in some places with gaseous nitrogen to inhibit oxidation, to carry away the heat generated by the windings and magnetic core. *See* ELECTRICAL INSULATION; TRANSFORMER. [J.B.G.]

Electric organ (biology) An effector organ found in six different groups of fishes; output is an electric pulse. Voltages large enough to aid in prey capture or predator deterrence are produced by various strongly electric fishes. These include the electric eel (*Electrophorus electricus*) from South America; the electric catfish (*Malapterurus electricus*) from Africa; the family of electric rays, Torpedinidae, which are widely distributed in the world's oceans; and possibly the stargazer genus, *Astroscopus*, of the western Atlantic. Weakly electric fishes emit a lower voltage, the energy source for an active electrosensory system that monitors electrical impedance in the environment. These weak signals also serve in intra- and interspecific communication. There are three groups of weakly electric fishes. First, the South American knifefishes, the Gymnotiformes, are a large and diverse group of several families that also include *Electrophorus*. Second, the electrically active African Mormyriformes are composed of the numerous species of the family Mormyridae and the single species *Gymnarchus niloticus* in the family Gymnarchidae. Finally, many species of skates and rays of the family Rajidae occur in marine waters around the world.

The strongly electric fishes are remarkable for the high voltage and power of their discharges. For example, the electric eelgenerates pulses in excess of 500 V. In contrast, a large torpedo generates a smaller voltage, about 50 V in air, but the maximum current is larger, and the peak pulse power can exceed 1 kW (or about 1 hp). The electric organs may constitute a substantial fraction of the body mass. The weakly electric fishes have much smaller organs emitting pulses of a few tenths of a volt to several volts; such amplitudes that are still large compared to those recorded outside ordinary, nonelectric fishes.

Electric organ discharge is explicable in terms of the properties of ordinary excitable cells, that is, those of nerve and muscle. The single generating cells of electric organs are called electrocytes. They are modified striated muscle fibers that have lost the ability to contract, although they retain muscle filaments to varying degrees, and they produce electric signals as muscle fibers do.

A question often asked about the strongly electric fishes is how they keep from electrocuting themselves. When immersed in water, they do not appear to be at all affected by their own discharges, although their electroreceptors are undoubtedly activated. In air, when the organ is not loaded down by the conductivity of the water, they often do twitch when they discharge their organs, but as would be expected, they are much more resistant than other fishes. One factor is that their nerves and central nervous system are well insulated by many layers of connective and fatty tissue, Whether their brains are more resistant to stunning by a given current density has not been determined; certainly the excitability of individual cells is no different from that in animals in general. [M.V.L.B.]

Electric power generation The production of bulk electric power for industrial, residential, and rural use. Although limited amounts of electricity can be generated by many means, including chemical reaction (as in batteries) and engine-driven generators (as in automobiles and airplanes), electric power generation generally implies large-scale production of electric power in stationary plants designed for that purpose. The generating units in these plants convert energy from falling water, coal, natural gas, oil, and nuclear fuels to electric energy. Most electric generators are driven either by hydraulic turbines, for conversion of falling water energy; or by steam or gas turbines, for conversion of fuel energy. Limited use is being made of geothermal energy, and developmental work is progressing in the use of solar energy in its various forms. *See* ELECTRIC POWER SYSTEMS; GENERATOR; PRIME MOVER.

An electric load (or demand) is the power requirement of any device or equipment that converts electric energy into light, heat, or mechanical energy, or otherwise consumes electric energy as in aluminum reduction, or the power requirement of electronic and control devices. The total load on any power system is seldom constant; rather, it varies widely with hourly, weekly, monthly, or annual changes in the requirements of the area served. The minimum system load for a given period is termed the base load or the unity load-factor component. Maximum loads, resulting usually from temporary conditions, are called peak loads, and the operation of the generating plants must be closely coordinated with fluctuations in the load. The peaks, usually being of only a few hours' duration, are frequently served by gas or oil combustion-turbine or pumped-storage hydro generating units. The pumped-storage type utilizes the most economical off-peak (typically 10 P.M. to 7 A.M.) surplus generating capacity to pump and store water in elevated reservoirs to be released through hydraulic turbine generators during peak periods. This type of operation improves the capacity factors or relative energy outputs of base-load generating units and hence their economy of operation.

The size or capacity of electric utility generating units varies widely, depending upon type of unit; duty required, that is, base-, intermediate-, or peak-load service; and system size and degree of interconnection with neighboring systems. Base-load nuclear or coal-fired units may be as large as 1200 MW each, or more. Intermediate-duty generators, usually coal-, oil-, or gas-fueled steam units, are of 200 to 600 MW capacity each. Peaking units, combustion turbines or hydro, range from several tens of megawatts for the former to hundreds of megawatts for the latter. Hydro units, in both base-load and intermediate service, range in size up to 825 MW.

The total installed generating capacity of a system is typically 20 to 30% greater than the annual predicted peak load in order to provide reserves for maintenance and contingencies.

Voltage regulation is the change in voltage for specific change in load (usually from full load to no load) expressed as percentage of normal rated voltage. The voltage of an electric generator varies with the load and power factor; consequently, some form of regulating equipment is required to maintain a reasonably constant and predetermined potential at the distribution stations or load centers. Since the inherent regulation of most alternating-current (ac) generators is rather poor (that is, high percentage-wise), it is necessary to provide automatic voltage control. The rotating or magnetic amplifiers and voltage-sensitive circuits of the automatic regulators, together with the exciters, are all specially designed to respond quickly to changes in the alternator voltage and to make the necessary changes in the main exciter or excitation system output, thus providing the required adjustments in voltage. A properly designed automatic regulator acts rapidly, so that it is possible to maintain desired voltage with a rapidly fluctuating load without causing more than a momentary change in voltage even when heavy loads are thrown on or off.

In general, most modern synchronous generators have excitation systems that involve rectification of an ac output of the main or auxiliary stator windings, or other appropriate supply, using silicon controlled rectifiers or thyristors. These systems enable very precise control and high rates of response. *See* SEMICONDUCTOR RECTIFIER; VOLTAGE REGULATOR.

Computer-assisted (or on-line controlled) load and frequency control and economic dispatch systems of generation supervision are being widely adopted, particularly for the larger new plants. Strong system interconnections greatly improve bulk power supply reliability but require special automatic controls to ensure adequate generation and transmission stability. Among the refinements found necessary in large, long-distance interconnections are special feedback controls applied to generator high-speed excitation and voltage regulator systems.

Synchronization of a generator to a power system is the act of matching, over an appreciable period of time, the instantaneous voltage of an alternating-current generator (incoming source) to the instantaneous voltage of a power system of one or more other generators (running source), then connecting them together. In order to accomplish this ideally the following conditions must be met:

1. The effective voltage of the incoming generator must be substantially the same as that of the system.
2. In relation to each other the generator voltage and the system voltage should be essentially 180° out of phase; however, in relation to the bus to which they are connected, their voltages should be in phase.
3. The frequency of the incoming machine must be near that of the running system.
4. The voltage wave shapes should be similar.
5. The phase sequence of the incoming polyphase machine must be the same as that of the system.

Synchronizing of ac generators can be done manually or automatically. In manual synchronizing an operator controls the incoming generator while observing synchronizing lamps or meters and a synchroscope, or both. The operator closes the connecting switch or circuit breaker as the synchroscope needle slowly approaches the in-phase position.

Automatic synchronizing provides for automatically closing the breaker to connect the incoming machine to the system, after the operator has properly adjusted voltage (field current), frequency (speed), and phasing (by lamps or synchroscope). A fully automatic synchronizer will initiate speed changes as required and may also balance voltages as required, then close the breaker at the proper time, all without attention of the operator. Automatic synchronizers can be used in unattended stations or in automatic control systems where units may be started, synchronized, and loaded on a single operator command. *See* ALTERNATING-CURRENT GENERATOR; GAS TURBINE; GEOTHERMAL POWER; HYDROELECTRIC GENERATOR; NUCLEAR POWER; PHASE-ANGLE MEASUREMENT; STEAM ELECTRIC GENERATOR; SYNCHROSCOPE; WATERPOWER; WIND POWER. [E.C.S.]

Electric power measurement The measurement of the time rate at which electrical energy is being transmitted or dissipated in an electrical system. The potential difference in volts between two points is equal to the energy per unit charge (in joules/coulomb) which is required to move electric charge between the points. Since the electric current measures the charge per unit time (in coulombs/second), the electric power p is given by the product of the current i and the voltage υ (in joules/second = watts), as in Eq. (1).

$$p = \upsilon i \qquad \text{(watts)} \tag{1}$$

See ELECTRIC CURRENT; ELECTRICAL UNITS AND STANDARDS; POWER.

Alternate forms of the basic definition can be obtained by using Ohm's law, which states that the voltage across a pure resistance is proportional to the current through the element. This results in Eq. (2), where R is the resistance of the element and

$$p = i^2 R = \frac{\upsilon^2}{R} \qquad \text{(watts)} \tag{2}$$

i and υ are the current through and voltage across the resistive element. Other commonly used units for electric power are milliwatts (1 mW = 10^{-3} W), kilowatts (1 kW = 10^3 W), megawatts (1 MW = 10^6 W), and, in electromechanical systems, horsepower (1 hp = 746 W). *See* ELECTRICAL RESISTANCE; OHM'S LAW.

These fundamental expressions yield the instantaneous power as a function of time. In the dc case where υ and i are each constant, the instantaneous power is also constant. In all other cases where υ or i or both are time-varying, the instantaneous power is also time-varying. When the voltage and current are periodic with the same fundamental frequency, the instantaneous power is also periodic with twice the fundamental frequency. In this case a much more significant quantity is the average power, since in most cases the electric power is converted to some other form such as heat or mechanical power and the rapid fluctuations of the power are smoothed by the thermal or mechanical inertia of the output system.

The measurement of power in a dc circuit can be carried out by simultaneous measurements of voltage and current by using standard types of dc voltmeters and ammeters. The product of the readings typically gives a sufficiently accurate measure of dc power. If great accuracy is required, corrections for the power used by the instruments should be made. In ac circuits the phase difference between the voltage and current precludes use of the voltmeter-ammeter method unless the load is known to be purely resistive. When this method is applicable, the instrument readings lead directly to average power since ac voltmeters and ammeters are always calibrated in rms values. *See* AMMETER; VOLTMETER.

In power-frequency circuits the most common instrument for power measurement is the moving-coil, dynamometer wattmeter. This instrument can measure dc or ac power by carrying out the required multiplication and averaging on a continuous analog basis. The instrument has four terminals, two for current and two for voltage, and reads the average power directly. It can be built with frequency response up to about 1 kHz. *See* WATTMETER.

Electronic wattmeters are available which give a digital indication of average power. Their primary advantage, in addition to minimizing errors in reading the instrument, is that the frequency range can be greatly extended, up to 100 kHz or more, with good accuracy.

Measurement of the total power in a polyphase system is accomplished by combinations of single-phase wattmeters or by special polyphase wattmeters which are integrated combinations of single-phase wattmeter elements. A general theorem called Blondel's theorem asserts that the total power supplied to a load over N wires can be measured by using $N - 1$ wattmeters. The theorem states that the total power in an N-wire system can be measured by taking the sum of the readings of N wattmeters so arranged that each wire contains the current coil of one wattmeter. One voltage terminal of each wattmeter is connected to the same wire as its current coil, and the second voltage terminal is connected to a common point in the circuit. If this common point is one of the N wires, one wattmeter will read zero and can be omitted.

At frequencies significantly above power frequencies, dynamometer wattmeters become inaccurate and cannot be used. The newer digital wattmeters have usable ranges well above audio frequencies and make accurate audio-frequency power measurements quite feasible. Generally, however, power measurements at higher frequencies are based on indirect methods.

For frequencies up to a few hundred megahertz, the voltage across a standard resistance load can be measured and the power calculated from V^2/R. Instruments which combine the resistive load and voltmeter are called absorption power meters.

A diode may be used as a detector for radio-frequency (rf) power measurement. This type of instrument is simple and easy to use but is less accurate than thermally based systems. *See* DIODE.

A thermocouple consists of two dissimilar metals joined at one end. When the joined end is heated and the other end is at a lower temperature, an electric current is produced (the thermoelectric or Seebeck effect). The current is proportional to the temperature difference between the two ends. For electric power measurements, the hot end is heated by a resistor supplied from the rf power source to be measured. Modern devices use thin-film techniques to make the thermocouple and resistor to ensure good thermal coupling. The output is a low-level dc signal as in diode detector systems. *See* THERMOCOUPLE.

A bolometer is basically an electric bridge circuit in which one of the bridge arms contains a temperature-sensitive resistor. In principle, the temperature is detected by the bridge circuit. Bolometric bridges use either barreters or thermistors as the temperature-sensitive resistor. The thermistor, which has largely replaced the barreter since it is more rugged, is a semiconductor device with a negative temperature coefficient. For rf power measurements, the thermistor is fabricated as a small bead with very short lead wires so that essentially all the resistance is in the bead. *See* BARRETTER; BOLOMETER; THERMISTOR.

The most accurate high-frequency power measurement methods involve calorimetric techniques based on direct determination of the heat produced by the input power. The power to be measured is applied to the calorimeter, and the final equilibrium temperature rise is recorded. Then the input signal is removed, and dc power applied until the same equilibrium temperature is attained. The dc power is then the same as the signal power. Calorimeter methods are usually used in standards laboratories rather than in industrial applications. *See* CALORIMETRY; ELECTRICAL MEASUREMENTS. [D.W.N.]

Electric power substation An assembly of equipment in an electric power system through which electrical energy is passed for transmission, distribution, interconnection, transformation, conversion, or switching. *See* ELECTRIC POWER SYSTEMS.

Specifically, substations are used for some or all of the following purposes: connection of generators, transmission or distribution lines, and loads to each other; transformation of power from one voltage level to another; interconnection of alternate sources of power; switching for alternate connections and isolation of failed or overloaded lines and equipment; controlling system voltage and power flow; reactive power compensation; suppression of overvoltage; and detection of faults, monitoring, recording of information, power measurements, and remote communications. Minor distribution or transmission equipment installation is not referred to as a substation.

Substations are referred to by the main duty they perform. Broadly speaking, they are classified as: transmission substations, which are associated with high voltage levels; and distribution substations, associated with low voltage levels. *See* ELECTRIC DISTRIBUTION SYSTEMS.

Substations are also referred to in a variety of other ways:

1. Transformer substations are substations whose equipment includes transformers.

2. Switching substations are substations whose equipment is mainly for various connections and interconnections, and does not include transformers.

3. Customer substations are usually distribution substations on the premises of a larger customer, such as a shopping center, large office or commercial building, or industrial plant.

4. Converter stations are complex substations required for high-voltage direct-current (HVDC) transmission or interconnection of two ac systems which, for a variety of reasons, cannot be connected by an ac connection. The main function of converter stations is the conversion of power from ac to dc and vice versa. The main equipment includes converter valves usually located inside a large hall, transformers, filters, reactors, and capacitors.

5. Most substations are installed as air-insulated substations, implying that the bus-bars and equipment terminations are generally open to the air, and utilize insulation properties of ambient air for insulation to ground. Modern substations in urban areas are esthetically designed with low profiles and often within walls, or even indoors.

6. Metal-clad substations are also air-insulated, but for low voltage levels; they are housed in metal cabinets and may be indoors or outdoors.

7. Acquiring a substation site in an urban area is very difficult because land is either unavailable or very expensive. Therefore, there has been a trend toward increasing use of gas-insulated substations, which occupy only 5–20% of the space occupied by the air-insulated substations. In gas-insulated substations, all live equipment and bus-bars are housed in grounded metal

enclosures, which are sealed and filled with sulfur hexafluoride (SF_6) gas, which has excellent insulation properties.

8. For emergency replacement or maintenance of substation transformers, mobile substations are used by some utilities.

An appropriate switching arrangement for "connections" of generators, transformers, lines, and other major equipment is basic to any substation design. There are seven switching arrangements commonly used: single bus; double bus, single breaker; double bus, double breaker; main and transfer bus; ring bus; breaker-and-a-half; and breaker-and-a-third. Each breaker is usually accompanied by two disconnect switches, one on each side, for maintenance purposes. Selecting the switching arrangement involves considerations of cost, reliability, maintenance, and flexibility for expansion.

A substation includes a variety of equipment. The principal items are transformers, circuit breakers, disconnect switches, bus-bars, shunt reactors, shunt capacitors, current and potential transformers, and control and protection equipment. *See* BUS-BAR; CIRCUIT BREAKER; ELECTRIC PROTECTIVE DEVICES; ELECTRIC SWITCH; RELAY; TRANSFORMER; VOLTAGE REGULATOR.

Good substation grounding is very important for effective relaying and insulation of equipment; but the safety of the personnel is the governing criterion in the design of substation grounding. It usually consists of a bare wire grid, laid in the ground; all equipment grounding points, tanks, support structures, fences, shielding wires and poles, and so forth, are securely connected to it. The grounding resistance is reduced enough that a fault from high voltage to ground does not create such high potential gradients on the ground, and from the structures to ground, to present a safety hazard. Good overhead shielding is also essential for outdoor substations, so as to virtually eliminate the possibility of lightning directly striking the equipment. Shielding is provided by overhead ground wires stretched across the substation or tall grounded poles. *See* GROUNDING; LIGHTNING AND SURGE PROTECTION. [N.G.H.]

Electric power systems A complex assemblage of equipment and circuits for generating, transmitting, transforming, and distributing electrical energy.

Electricity in the large quantities required to supply electric power systems is produced in generating stations, commonly called power plants. Such generating stations, however, should be considered as conversion facilities in which the heat energy of fuel (coal, oil, gas, or uranium) or the hydraulic energy of falling water is converted to electricity. *See* ELECTRIC POWER GENERATION; HYDRAULIC TURBINE; NUCLEAR REACTOR; POWER PLANT; STEAM TURBINE.

The transmission system carries electric power efficiently and in large amounts from generating stations to consumption areas. Such transmission is also used to interconnect adjacent power systems for mutual assistance in case of emergency and to gain for the interconnected power systems the economies possible in regional operation.

Another approach to high-voltage long-distance transmission is high-voltage direct current (HVDC), which offers the advantages of less costly lines, lower transmission losses, and insensitivity to many system problems that restrict alternating-current systems. Its greatest disadvantage is the need for costly equipment for converting the sending-end power to direct current, and for converting the receiving-end direct-current power to alternating current for distribution to consumers. *See* TRANSMISSION LINES.

As systems grow and the number and size of generating units increase, and as transmission networks expand, higher levels of bulk-power-system reliability are attained through properly coordinated interconnections among separate systems. Most of the electric utilities in the contiguous United States and a large part of Canada now operate as members of power pools, and these pools in turn are interconnected into one gigantic power grid known as the North American Power Systems Interconnection. The operation of this interconnection, in turn, is coordinated by the North American Electric Reliability Council (NERC). Each individual utility in such pools operates independently, but has contractual arrangements with other members in respect to generation additions and scheduling of operation. Their participation in a power pool affords a higher level of service reliability and important economic advantages.

Power delivered by transmission circuits must be stepped down in facilities called substations to voltages more suitable for use in industrial and residential areas. *See* ELECTRIC POWER SUBSTATION.

That part of the electric power system that takes power from a bulk-power substation to customers' switches, commonly about 35% of the total plant investment, is called distribution. [W.C.H.]

The operation and control of the generation-transmission-distribution grid is quite complex because this large system has to operate in synchronism and because many different organizations are responsible for different portions of the grid. In North America and Europe, many public and private electric power companies are interconnected, often across national boundaries. Thus, many organizations have to coordinate to operate the grid, and this coordination can take many forms, from a loose agreement of operational principles to a strong pooling arrangement of operating together.

Power-system operations can be divided into three stages: operations planning, real-time control, and after-the-fact accounting. The main goal is to minimize operations cost while maintaining the reliability (security) of power delivery to customers. Operations planning is the optimal scheduling of generation resources to meet anticipated demand in the next few hours, weeks, or months. This includes the scheduling of water, fossil fuels, and equipment maintenance over many weeks, and the commitment (start-up and shutdown) of generating units over many hours. Real-time control of the system is required to respond to the actual demand of electricity and any unforeseen contingencies (equipment outages). Maintaining security of the system so that a possible contingency cannot disrupt power supply is an integral part of real-time control. After-the-fact accounting is the tracking of purchases and sales of energy between organizations so that billing can be generated.

For loosely coordinated operation of the grid, each utility takes responsibility for the operation of its own portion while exchanging all relevant information. For pool-type operations, a hierarchy is set up where the operational decisions may be made centrally and then implemented by each utility. For a large utility, there may be another level in the hierarchy where the decisions are further distributed to different geographical areas of the same utility. All of this requires significant data communication as well as engineering computation within a utility as well as between utilities. The use of modern computers and communications makes this possible, and the heart of system operations in a utility is the energy control center.

The monitoring and control of a power system from a centralized control center became desirable quite early in the development of electric power systems, when generating stations were connected together to supply the same loads. As electrical utilities interconnected and evolved into complex networks of generators, transmission lines, distribution feeders, and loads, the control center became the operations headquarters for each utility. Since the generation and delivery of electrical energy are controlled from this center, it is referred to as the energy control center or energy management system. [A.Bo.]

Electric power transmission The transport of generator-produced electric energy to loads. An electric power transmission system interconnects generators and loads and generally provides multiple paths among them. Multiple paths increase system reliability because the failure of one line does not cause a system failure. Most transmission lines operate with three-phase alternating current (ac). The standard frequency in

North America is 60 Hz; in Europe, 50 Hz. The three-phase system has three sets of phase conductors. Long-distance energy transmission occasionally uses high-voltage direct-current (dc) lines. *See* ALTERNATING CURRENT; DIRECT CURRENT; DIRECT-CURRENT TRANSMISSION.

The electric power system can be divided into the distribution, subtransmission, and transmission systems. With operating voltages less than 34.5 kV, the distribution system carries energy from the local substation to individual households, using both overhead and underground lines. With operating voltages of 69-138 kV, the subtransmission system distributes energy within an entire district and regularly uses overhead lines. With operating voltage exceeding 230 kV, the transmission system interconnects generating stations and large substations located close to load centers by using overhead lines. *See* TRANSMISSION LINES.

Overhead alternating-current transmission. Overhead transmission lines distribute the majority of the electric energy in the system. A typical high-voltage line has three phase conductors to carry the current and transport the energy, and two grounded shield conductors to protect the line from direct lightning strikes. The usually bare conductors are insulated from the supporting towers by insulators attached to grounded towers or poles. Lower-voltage lines use post insulators, while the high-voltage lines are built with insulator chains or long-rod composite insulators. The normal distance between the supporting towers is a few hundred feet.

Transmission lines use ACSR (aluminum cable, steel reinforced) and ACAR (aluminum cable, alloy reinforced) conductors. In an ACSR conductor, a stranded steel core carries the mechanical load, and layers of stranded aluminum surrounding the core carry the current. An ACAR conductor is a stranded cable made of an aluminum alloy with low resistance and high mechanical strength. ACSR conductors are usually used for high-voltage lines, and ACAR conductors for subtransmission and distribution lines. Ultrahigh-voltage (UHV) and extrahigh-voltage (EHV) lines use bundle conductors. Each phase of the line is built with two, three, or four conductors connected in parallel and separated by about 1.5 ft (0.5 m). Bundle conductors reduce corona discharge. *See* CONDUCTOR (ELECTRICITY).

Transmission lines are subject to environmental adversities, including wide variations of temperature, high winds, and ice and snow deposits. Typically designed to withstand environmental stresses occurring once every 50–100 years, lines are intended to operate safely in adverse conditions.

Variable weather affects line operation. Extreme weather reduces corona inception voltage, leading to an increase in audible noise, radio noise, and telephone interference. Load variation requires regulation of line voltage. A short circuit generates large currents, overheating conductors and producing permanent damage.

The power that a line can transport is limited by the line's electrical parameters. Voltage drop is the most important factor for distribution lines; where the line is supplied from only one end, the permitted voltage drop is about 5%.

Conductor temperature must be lower than the temperature which causes permanent elongation. A typical maximum steady-state value for ACSR is 212°F (100°C), but in an emergency temperatures 10–20% higher are allowed for a short period of time (10 min to 1 h).

Corona discharge is generated when the electric field at the surface of the conductor becomes larger than the breakdown strength of the air. The oscillatory nature of the discharge generates high-frequency, short-duration current pulses, the source of corona-generated radio and television interference. Surface irregularities such as water droplets cause local field concentration, enhancing corona generation. Thus, during bad weather, corona discharge is more intense and losses are much greater. Corona discharge also generates audible noise with two components: a broad-band, high-frequency component, which produces crackling and hissing, and a 120-Hz pure tone. *See* CORONA DISCHARGE; ELECTRICAL INTERFERENCE.

Transmission-line conductors are surrounded by an electric field which decreases as distance from the line increases, and depends on line voltage and geometry. At ground level, this field induces current and voltage in grounded bodies, causes corona in grounded objects, and can induce fuel ignition. Utilities limit the electric field at the perimeter of right-of-ways to about 1000 V/m. An ac magnetic field around the transmission line also decreases with distance from the line. *See* ELECTRIC FIELD.

Lightning strikes produce high voltages and traveling waves on transmission lines, causing insulator flashovers and interruption of operation. Steel grounded shield conductors at the tops of the towers significantly reduce, but do not eliminate, the probability of direct lightning strikes to phase conductors. *See* LIGHTNING AND SURGE PROTECTION.

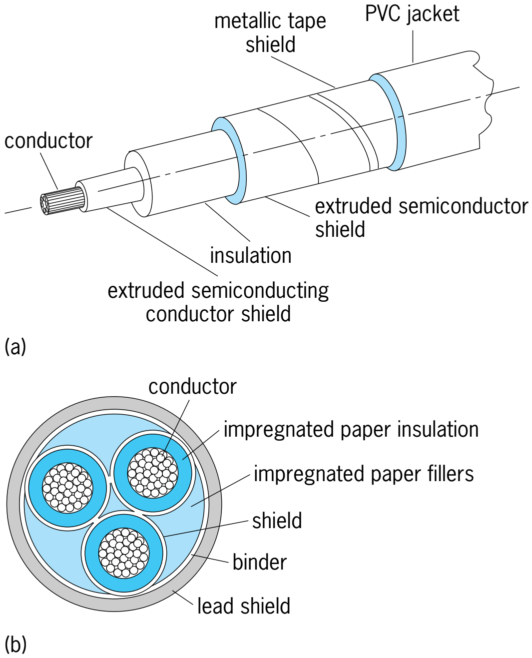
The operation of circuit breakers causes switching surges that can result in interruption of inductive current, energization of lines with trapped charges, and single-phase ground fault. Modern circuit breakers, operating in two steps, reduce switching surges to 1.5–2 times the 60-Hz voltage. *See* CIRCUIT BREAKER.

Line current induces a disturbing voltage in telephone lines running parallel to transmission lines. Because the induced voltage depends on the mutual inductance between the two lines, disturbance can be reduced by increasing the distance between the lines and shielding the telephone lines. *See* ELECTRICAL SHIELDING; INDUCTIVE COORDINATION.

Underground power transmission. Most cities use underground cables to distribute electrical energy. These cables virtually eliminate negative environmental effects and reduce electrocution hazards. However, they entail significantly higher construction costs.

Underground cables are divided into two categories: distribution cables (less than 69 kV) and high-voltage power-transmission cables (69–500 kV).

Extruded solid dielectric cables dominate in the 15–33-kV urban distribution system. In a typical arrangement (illus. *a*), the stranded copper or aluminum conductor is shielded by a semiconductor layer, which reduces the electric stress on the



Underground distribution cables. (*a*) Extruded solid dielectric cable. (*b*) Three-phase oil-impregnated paper-insulated cable. (*After R. Bartnikas Srivastava, Elements of Cable Engineering, Sandford Educational Press, 1980*)

conductor's surface. Oil-impregnated paper-insulated distribution cables are used for higher voltages and in older installations (illus. *b*).

Cable temperatures vary with load changes, and cyclic thermal expansion and contraction may produce voids in the cable. High voltage initiates corona in the voids, gradually destroying cable insulation. Low-pressure oil-filled cable construction reduces void formation. A single-phase concentric cable has a hollow conductor with a central oil channel. Three-phase cables have three oil channels located in the filler.

Submarine cables. High-voltage cables are frequently used for crossing large bodies of water. Water provides natural cooling, and pressure reduces the possibility of void formation. A typical submarine cable has cross-linked polyethylene insulation, and corrosion-resistant aluminum alloy wire armoring that provides tensile strength and permits installation in deep water. *See* ELECTRIC POWER SYSTEMS. [G.G.K.]

Electric protective devices

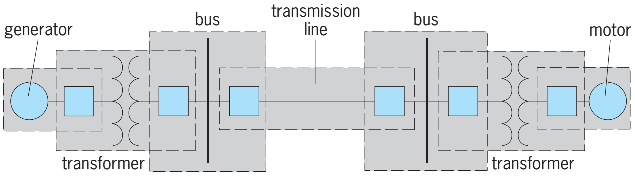
Electric protective devices Equipment applied to electric power systems to detect abnormal and intolerable conditions and to initiate appropriate corrective actions. These devices include lightning arresters, surge protectors, fuses, and relays with associated circuit breakers, reclosers, and so forth.

From time to time, disturbances in the normal operation of a power system occur. These may be caused by natural phenomena, such as lightning, wind, or snow; by falling objects such as trees; by animal contacts or chewing; by accidental means traceable to reckless drivers, inadvertent acts by plant maintenance personnel, or other acts of humans; or by conditions produced in the system itself, such as switching surges, load swings, or equipment failures. Protective devices must therefore be installed on power systems to ensure continuity of electrical service, to limit injury to people, and to limit damage to equipment when problem situations develop. Protective devices are applied commensurately with the degree of protection desired or felt necessary for the particular system.

Protective relays. These are compact analog or digital networks, connected to various points of an electrical system, to detect abnormal conditions occurring within their assigned areas. They initiate disconnection of the trouble area by circuit breakers. These relays range from the simple overload unit on house circuit breakers to complex systems used to protect extrahigh-voltage power transmission lines. They operate on voltage, current, current direction, power factor, power, impedance, temperature. In all cases there must be a measurable difference between the normal or tolerable operation and the intolerable or unwanted condition. System faults for which the relays respond are generally short circuits between the phase conductors, or between the phases and grounds. Some relays operate on unbalances between the phases, such as an open or reversed phase. A fault in one part of the system affects all other parts. Therefore relays and fuses throughout the power system must be coordinated to ensure the best quality of service to the loads and to avoid operation in the nonfaulted areas unless the trouble is not adequately cleared in a specified time. *See* FUSE (ELECTRICITY); RELAY.

Zone protection. For the purpose of applying protection, the electric power system is divided into five major protection zones: generators; transformers; buses; transmission and distribution lines; and motors (see illustration). Each block represents a set of protective relays and associated equipment selected to initiate correction or isolation of that area for all anticipated intolerable conditions or trouble. The detection is done by protective relays with a circuit breaker used to physically disconnect the equipment. For other areas of protection *see* GROUNDING; UNINTERRUPTIBLE POWER SYSTEM.

Fault detection. Fault detection is accomplished by a number of techniques, including the detection of changes in electric current or voltage levels, power direction, ratio of voltage to current, temperature, and comparison of the electrical quantities flowing into a protected area with the quantities flowing out, also known as differential protection.



Zones of protection on simple power system.

Differential protection. This is the most fundamental and widely used protection technique. The system compares currents to detect faults in a protection zone. Current transformers on either side of the protection zone reduce the primary currents to small secondary values, which are the inputs to the relay. For load through the equipment or for faults outside of the protection zone, the secondary currents from the two transformers are essentially the same, and they are directed so that the current through the relay sums to essentially zero. However, for internal trouble, the secondary currents add up to flow through the relay.

Overcurrent protection. This must be provided on all systems to prevent abnormally high currents from overheating and causing mechanical stress on equipment. Overcurrent in a power system usually indicates that current is being diverted from its normal path by a short circuit. In low-voltage, distribution-type circuits, such as those found in homes, adequate overcurrent protection can be provided by fuses that melt when current exceeds a predetermined value.

Small thermal-type circuit breakers also provide overcurrent protection for this class of circuit. As the size of circuits and systems increases, the problems associated with interruption of large fault currents dictate the use of power circuit breakers. Normally these breakers are not equipped with elements to sense fault conditions, and therefore overcurrent relays are applied to measure the current continuously. When the current has reached a predetermined value, the relay contacts close. This actuates the trip circuit of a particular breaker, causing it to open and thus isolate the fault. *See* CIRCUIT BREAKER.

Distance protection. Distance-type relays operate on the combination of reduced voltage and increased current occasioned by faults. They are widely applied for the protection of higher voltage lines. A major advantage is that the operating zone is determined by the line impedance and is almost completely independent of current magnitudes.

Overvoltage protection. Lightning in the area near the power lines can cause very short-time overvoltages in the system and possible breakdown of the insulation. Protection for these surges consists of lightning arresters connected between the lines and ground. Normally the insulation through these arresters prevents current flow, but they momentarily pass current during the high-voltage transient to limit overvoltage. Overvoltage protection is seldom applied elsewhere except at the generators, where it is part of the voltage regulator and control system. In the distribution system, overvoltage relays are used to control taps of tap-changing transformers or to switch shunt capacitors on and off the circuits. *See* LIGHTNING AND SURGE PROTECTION.

Undervoltage protection. This must be provided on circuits supplying power to motor loads. Low-voltage conditions cause motors to draw excessive currents, which can damage the motors. If a low-voltage condition develops while the motor is running, the relay senses this condition and removes the motor from service.

Underfrequency protection. A loss or deficiency in the generation supply, the transmission lines, or other components of the system, resulting primarily from faults, can leave the system with an excess of load. Solid-state and digital-type underfrequency relays are connected at various points in the system to detect this resulting decline in the normal system frequency. They operate to disconnect loads or to separate the system into areas so that the available generation equals the load until a balance is reestablished.

Reverse-current protection. This is provided when a change in the normal direction of current indicates an abnormal condition in the system. In an ac circuit, reverse current implies a phase shift of the current of nearly 180° from normal. This is actually a change in direction of power flow and can be directed by ac directional relays.

Phase unbalance protection. This protection is used on feeders supplying motors where there is a possibility of one phase opening as a result of a fuse failure or a connector failure. One type of relay compares the current in one phase against the currents in the other phases. When the unbalance becomes too great, the relay operates. Another type monitors the three-phase bus voltages for unbalance. Reverse phases will operate this relay.

Reverse-phase-rotation protection. Where direction of rotation is important, electric motors must be protected against phase reversal. A reverse-phase-rotation relay is applied to sense the phase rotation. This relay is a miniature three-phase motor with the same desired direction of rotation as the motor it is protecting. If the direction of rotation is correct, the relay will let the motor start. If incorrect, the sensing relay will prevent the motor starter from operating.

Thermal protection. Motors and generators are particularly subject to overheating due to overloading and mechanical friction. Excessive temperatures lead to deterioration of insulation and increased losses within the machine. Temperature-sensitive elements, located inside the machine, form part of a bridge circuit used to supply current to a relay. When a predetermined temperature is reached, the relay operates, initiating opening of a circuit breaker or sounding of an alarm. [J.L.Bl.]

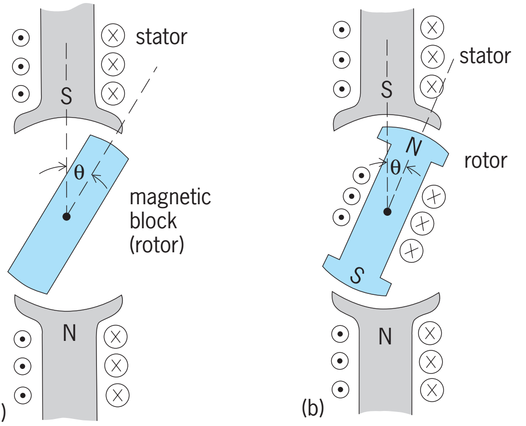
Electric rotating machinery

Any form of apparatus, having a rotating member, which generates, converts, transforms, or modifies electric power. Essentially all of the world's electric power is produced by rotating electrical generators, and about 70% of this energy is consumed in driving electric motors. Electric machines are electromechanical energy converters; generators convert mechanical energy into electrical energy and motors convert electrical energy into mechanical energy.

An electric machine can be constructed on the principle that a magnet will attract a piece of permeable magnetic material such as iron or magnetic steel. In illus. *a*, a pole structure is shown along with a magnetic block that is allowed to rotate. The magnetic block will experience a torque tending to rotate it counterclockwise to the vertical direction. This torque called a reluctance or saliency torque, will be in the direction to minimize the reluctance of the magnetic circuit. In illus. *b*, a winding is added to the rotor (the part which is allowed to rotate). In this case there is an additional torque on the rotor in the counterclockwise direction produced by the attraction of opposite poles. This torque will be approximately proportional to the sine of the angle θ. While the magnets in the illustration are electromagnets, permanent magnets could be used with the same effect. *See* MAGNET; WINDINGS IN ELECTRIC MACHINERY.

In these examples, if the rotor were allowed to move under the influence of the magnetic forces, it would eventually come to rest at an equilibrium position, $\theta = 0$. Since most applications require continuous motion and constant torque, it is necessary to keep the angle between the rotor magnetic field and the stator magnetic field constant. Thus, in the above examples, the stator magnetic field must rotate ahead of the rotor. *See* ALTERNATING CURRENT.

Although there are many variations, the three basic machine types are synchronous, induction, and direct-current machines. These machines may be used as motors or as generators, but the basic principles of operation remain the same. The synchronous machine runs at a constant speed determined by the line frequency. There is an alternating-current winding (normally on the stator) and a direct-current winding (normally on the rotor). *See* ALTERNATING-CURRENT GENERATOR; ALTERNATING-CURRENT MOTOR; SYNCHRONOUS MOTOR.



Devices illustrating principles of electric machines. (*a*) Permeable rotor and stator with magnetic pole structure. (*b*) Device with magnetic pole structures on both stator and rotor.

The induction machine is another alternating-current machine which runs close to synchronous speed. The alternating-current winding of the stator is similar to that of the synchronous machine. The rotor may have an insulated winding (wound rotor) but more commonly consists of uninsulated bars embedded in a laminated structure and short-circuited at the end (squirrel cage). There is normally no voltage applied to the rotor. The voltages are produced by means of Faraday's law of induction. In an induction motor the stator-produced flux-density wave rotates slightly faster than the rotor during normal operation, and the flux linkages on the rotor therefore vary at low frequency. The rotor currents induced by these time-varying flux linkages produce a magnetic field distribution that rotates at the same speed as the stator-produced flux wave. *See* INDUCTION MOTOR.

In a direct-current motor, direct current is applied to both the rotor and the stator. The stationary poles on the stator produce a stationary magnetic field distribution. Since the angle between the stator-produced poles and rotor-produced poles must remain constant, the direct-current machine uses a device known as a commutator which switches the current from one rotor circuit to another so that the resulting field is stationary. *See* DIRECT-CURRENT GENERATOR; DIRECT-CURRENT MOTOR; GENERATOR; MOTOR. [S.Sa.]

Electric spark

A transient form of gaseous conduction. This type of discharge is difficult to define, and no universally accepted definition exists. It can perhaps best be thought of as the transition between two more or less stable forms of gaseous conduction. For example, the transitional breakdown which occurs in the transition from a glow to an arc discharge may be thought of as a spark. *See* ELECTRICAL CONDUCTION IN GASES.

Electric sparks play an important part in many physical effects. Usually these are harmful and undesirable effects, ranging from the gradual destruction of contacts in a conventional electrical switch to the large-scale havoc resulting from lightning discharges. Sometimes, however, the spark may be very useful. Examples are its function in the ignition system of an automobile, its use as an intense short-duration illumination source in high-speed photography, and its use as a source of excitation in spectroscopy. In the second case the spark may actually perform the function of the camera shutter, because its extinction renders the camera insensitive. *See* SPECTROSCOPY; STROBOSCOPIC PHOTOGRAPHY. [G.H.M.]

Electric susceptibility A dimensionless parameter measuring the ease of polarization of a dielectric. In a vacuum, the electric flux density **D** (measured in coulombs/m^2) and electric field strength **E** (volts/m) are related by Eq. (1) where ϵ_0 is

$$\mathbf{D} = \epsilon_0 \mathbf{E} \tag{1}$$

the permittivity of free space, having the value 8.854×10^{-12} farad/m. In a dielectric material, polarization occurs, and the flux density has the value given by Eq. (2), where ϵ_r is the relative

$$\mathbf{D} = \epsilon_0 \epsilon_r \mathbf{E} = \epsilon_0 \mathbf{E} + \mathbf{P} \tag{2}$$

permittivity of the material and **P** is the polarization flux density. This can be written as Eq. (3), where $\chi_e = \epsilon_r - 1$ is known as the

$$\mathbf{P} = \epsilon_0 (\epsilon_r - 1)\mathbf{E} = \epsilon_0 \chi_e \mathbf{E} \tag{3}$$

electric susceptibility of the dielectric material. It is a measure of that part of the relative permittivity which is due to the material itself.

The electric susceptibility can be related to the polarizability α by expressing the polarization in terms of molecular parameters. Thus Eqs. (4) hold, where N is the number of molecules per unit

$$\begin{aligned} \mathbf{P} &= N\langle\boldsymbol{\mu}\rangle_{\text{avg}} = N\alpha\mathbf{E}_L \\ \chi_e &= \frac{N\alpha\mathbf{E}_L}{\epsilon_0 \mathbf{E}} \end{aligned} \tag{4}$$

volume, $\langle\boldsymbol{\mu}_{\text{avg}}\rangle$ is their average dipole moment, and $\mathbf{E}_L$ is the local electric field strength at a molecular site. At low concentrations, $\mathbf{E}_L$ approaches **E**, and the susceptibility is proportional to the concentration N. For a discussion of the properties and measurement of electric susceptibility *see* Permittivity; Polarization of dielectrics. [R.D.W.; A.E.Ba.]

Electric switch A device that makes, breaks, or changes the course of an electric circuit. Basically, an electric switch consists of two or more contacts mounted on an insulating structure and arranged so that they can be moved into and out of contact with each other by a suitable operating mechanism.

The term switch is usually used to denote only those devices intended to function when the circuit is energized or deenergized under normal manual operating conditions; as contrasted with circuit breakers, which have as one of their primary functions the interruption of short-circuit currents. Although there are hundreds of types of electric switches, their application can be broadly classified into two major categories: power and signal.

In power applications, switches function to energize or deenergize an electric load. On the low end of the power scale, wall switches are used in homes and offices for turning lights on and off; dial and push-button switches control power to electric ranges, washing machines, and dishwashers. On the high end of the scale are load-break switches and disconnecting switches in power systems at the highest voltages (several hundred thousand volts).

For power applications, when closed, switches are required to carry a certain amount of continuous current without overheating, and in the open position they must provide enough insulation to isolate the circuit electrically.

Load-break switches are required also to have the capability of interrupting the load current. Although this requirement is easily met in low-voltage and low-current applications, for high-voltage and high-current circuits, arc interrupters, similar to those used in circuit breakers are needed. In medium-voltage applications the most popular interrupter is the air magnetic type, in which the arc is driven into an arc chute by the magnetic field produced by the load current in a blowout coil. *See* Blowout coil; Circuit breaker.

Some load-break switches may also be required to have the capability of holding the contacts in the closed position during short-circuit conditions so that the contacts will not be blown open by electromagnetic forces when the circuit breaker in the system interrupts the short-circuit current.

For signal applications, switches are used to detect a specified situation that calls for some predetermined action in the electrical circuit. For example, thermostats detect temperature; when a certain limit is reached, contacts in the thermostat energize or deenergize another electrical switching device to control power flow.

Switches for signaling purposes are often required to have long life, high speed, and high reliability. Contaminants and dust must be prevented from interfering with the operation of the switch. For this purpose, switches are usually enclosed and are sometimes hermetically sealed.

Switches frequently are composed of many single circuit elements, known as poles, all operated simultaneously or in a predetermined sequence by the same mechanism. Switches are often typed by the number of poles and referred to as single-pole or double-pole switches, and so on. It is also common to express the number of possible switch positions per pole, such as a single-throw or double-throw switch. [T.H.L.]

Electric transient A temporary component of current and voltage in an electric circuit which has been disturbed. In ordinary circuit problems, a stabilized condition of the circuit is assumed and steady-state values of current and voltage are sufficient. However, it often becomes important to know what occurs during the transition period following a circuit disturbance until the steady-state condition is reached. Transients occur only in circuits containing inductance or capacitance. In general, transients accompany any change in the amount or form of energy stored in the circuit.

The study of transient phenomena is very broad. The mathematical requirements become severe and go far beyond the borders of all known mathematics. Transient analysis often requires the use of calculating machines, models, and tests. Fourier and Laplace transforms have proven indispensable in the modern treatment of transients and these disciplines need be mastered by anyone going far in the study of transients. The analysis of lumped-parameter circuits is comparatively easy. An electric circuit or system under steady-state conditions of constant, or cyclic, applied voltages or currents is in a state of equilibrium. However, the circuit conditions of voltage, current, or frequency may change or be disturbed. Also, circuit elements may be switched in or out of the circuit. Any change of circuit condition or circuit elements causes a transient readjustment of voltages and currents from the initial state of equilibrium to the final state of equilibrium. In a sense the transient may be regarded as superimposed on the final steady state, so that Eq. (1) applies.

$$\begin{pmatrix}\text{Instantaneous}\\ \text{condition}\end{pmatrix} = \begin{pmatrix}\text{final}\\ \text{condition}\end{pmatrix} + \begin{pmatrix}\text{transient}\\ \text{terms}\end{pmatrix} \tag{1}$$

Furthermore, since the instantaneous condition at the first instant of disturbance (time zero) must be the initial condition, it may be described by Eq. (2).

$$\begin{pmatrix}\text{Initial}\\ \text{condition}\end{pmatrix} = \begin{pmatrix}\text{final}\\ \text{condition}\end{pmatrix} + \begin{pmatrix}\text{transient terms}\\ \text{at time zero}\end{pmatrix} \tag{2}$$

In many practical cases transients are one of three types:

1. Single-energy transients, in which only one form of energy storage (either electromagnetic or electrostatic) is present; the transient exhibits simple exponential decay from the initial to the final conditions.

2. Double-energy transients, in which both forms of energy storage are present; the transient is either aperiodic or a damped sinusoid.

3. Combination of 1 and 2. [L.V.B.]

Electric vehicle A ground vehicle propelled by a motor that is powered by electrical energy from rechargeable batteries or other source onboard the vehicle, or from an external source in, on, or above the roadway. Examples are the golf cart, industrial truck and tractor, automobile, delivery van and other on-highway truck, and trolley bus. In common usage, electric vehicle refers to an automotive vehicle in which the propulsion system converts electrical energy stored chemically in a battery into mechanical energy to move the vehicle. This is classed as a battery-only-powered electric vehicle. The batteries provide the power to propel the vehicle, and to power the lights and all accessories such as air conditioning and radio. The other major class is the hybrid-electric vehicle, which has more than one power source such as battery power with a small internal combustion engine or a fuel cell. *See* AUTOMOBILE; BATTERY; BUS; FUEL CELL; TRUCK. [D.L.An.]

Electrical breakdown A large, usually abrupt rise in electric current in the presence of a small increase in electric voltage. Breakdown may be intentional and controlled or it may be accidental. Lightning is the most familiar example of breakdown.

In a gas, such as the atmosphere, the potential gradient may become high enough to accelerate the naturally present ions to velocities that cause further ionization upon collision with atoms. If the region of ionization does not extend between oppositely charged electrodes, the process is corona discharge. If the region of ionization bridges the gap between electrodes, thereby breaking down the insulation provided by the gas, the process is ionization discharge. When controlled by the ballast of a fluorescent lamp, for example, the process converts electric power to light. In a gas tube the process provides controlled rectification. *See* GAS TUBE.

In a solid, such as an insulator, when the electric field gradient exceeds 10^6 volts/cm, valence bonds between atoms are ruptured and current flows. Such a disruptive current heats the solid abruptly. In a semiconductor if the applied backward or reverse potential across a junction reaches a critical level, current increases rapidly with further rise in voltage. This avalanche characteristic is used for voltage regulation in the Zener diode. In a transistor the breakdown sets limits to the maximum instantaneous voltage that can safely be applied between collector and emitter. *See* BREAKDOWN POTENTIAL; ELECTRICAL INSULATION; TRANSISTOR; ZENER DIODE. [F.H.R.]

Electrical codes Systematic bodies of rules governing the practical application, installation, and interconnection of electrically operated equipment, devices, and electrical wiring systems.

The basic code used throughout the United States is the National Electrical Code, prepared under the direction of the National Fire Protection Association (NFPA). It is approved by the American National Standards Institute. The National Electrical Code is purely advisory as far as the National Fire Protection Association is concerned, but it is very widely used for legal regulatory purposes, The code is administered by various local inspection agencies, whose decisions govern its application to individual installations. The National Electrical Code is incorporated bodily or by reference in many municipal building ordinances, often with additional provisions or restrictions applicable in the particular locality. Some large cities have independent electrical codes; however, the actual provisions in most such codes tend to be basically similar to the National Electrical Code.

Compliance with the provisions of the code can effectively minimize fire and accident hazards in any electrical design. It sets forth requirements that constitute a minimum standard for the framework of electrical design. As stated in its introduction, the code is concerned with the “practical safeguarding of persons and of buildings and their contents from hazards arising from the use of electricity for light, heat, power, radio, signaling and for other purposes.” The National Electrical Code is recognized as a legal criterion of safe electrical design and installation. It is used in court litigation and by insurance companies as a basis for insuring buildings.

In addition to the National Electrical Code itself, other standards and recommended practices are made available by the National Fire Protection Association. These cover such special subjects as hospital operating rooms, municipal fire alarm systems, garages, aircraft hangars, and other equipment with great potential hazards due to improper design.

The National Electrical Safety Code (to be distinguished from the National Electrical Code) is published by the Institute of Electrical and Electronic Engineers, Inc. This code applies to the outdoor circuits of electric utility companies and to similar systems or equipment on commercial and industrial premises.

Standards on the construction and assembly of many types of electrical equipment, materials, and appliances are set forth in literature issued by the Underwriters’ Laboratories, Inc. The Underwriters’ Laboratories examines, tests, and determines the suitability of materials and equipment to be used according to code regulations. *See* WIRING. [J.F.McP.]

Electrical communications That branch of electrical engineering dealing with the transmission and reception of information. Information can be transmitted over many different types of pathways, such as satellite channels, underwater acoustic channels, telephone cables, and fiber-optic links. Characteristically, any communications link is noisy. The receiver never receives the information-bearing waveform as it was originally transmitted. Rather, what is received is, at best, the sum of what was transmitted and noise. In reality, what is more likely to be received is a distorted version of what was transmitted, with noise and perhaps interference. Consequently, the design and implementation of a communications link are dependent upon statistical signal-processing techniques in order to provide the most efficient extraction of the desired information from the received waveform. *See* COMMUNICATIONS CABLE; COMMUNICATIONS SATELLITE; DISTORTION (ELECTRONIC CIRCUITS); ELECTRICAL INTERFERENCE; ELECTRICAL NOISE; MICROWAVE; OPTICAL COMMUNICATIONS; RADIO-WAVE PROPAGATION; SIGNAL-TO-NOISE RATIO; TELEPHONE SERVICE; TRANSMISSION LINES; UNDERWATER SOUND; WAVEGUIDE.

Broadly speaking, there are two basic classes of communication waveforms, those involving analog modulation and those involving digital modulation. The former type implies that the modulation process allows the actual information signal to modulate a high-frequency carrier for efficient transmission over a channel; this is achieved by using the continuum of amplitude values of an analog waveform. Examples of analog modulation systems include amplitude-modulation (AM) and frequency-modulation (FM) systems, as well as a variety of others such as single-sideband (SSB), double-sideband (DSB), and vestigial-sideband (VSB) systems. In digital modulation systems, the initial information-bearing waveform, assuming it is in analog form (such as voice or video), is first sampled, then quantized, and finally encoded in a digital format for carrier modulation and transmission over the channel. *See* AMPLITUDE MODULATION; FREQUENCY MODULATION; MODULATION.

In many communication systems, multiple sources and multiple destinations are present, and the manner in which accessing the channel is achieved becomes important. Perhaps the most common examples of such multiple-access links are those used by commercial radio and television stations. These systems operate by assigning to each transmitted waveform a distinct frequency band which is adjacent to but nominally not overlapping with its neighboring bands. In this way, there is approximately no interference among the various users. This type of operation, known as frequency-division multiple accessing (FDMA), can be used with either analog or digital modulation formats. *See* MULTIPLEXING AND MULTIPLE ACCESS; RADIO; TELEVISION.

In many cases, the number of potential users is much greater than the number which can be simultaneously accommodated on the channel. However, if the percentage of time employed by each user is statistically very small, the users can compete for access to the channel. When a given user has a message ready for transmission, most of the time a vacant slot on the channel will be found, allowing data transmission. However, at times, all available slots on the channel are taken, and the user has to delay sending the message.

Systems that operate in this manner are referred to as random-access systems, and are typical of computer communication networks. Depending on the geographical size of such networks, they have come to have their own specialized names. For example, they are known as local-area networks (LANs) if they are concentrated over an area roughly the size of a few blocks or less. If the terminals which are farthest apart are within a few miles of one another, they are referred to as metropolitan-area networks (MANs). Networks that span still larger geographical distances are called wide-area networks (WANs). *See* DATA COMMUNICATIONS; LOCAL-AREA NETWORKS; WIDE-AREA NETWORKS. [L.B.M.]

Electrical conduction in gases The process by means of which a net charge is transported through a gaseous medium. It encompasses a variety of effects and modes of conduction, ranging from the Townsend discharge at one extreme to the arc discharge at the other. The current in these two cases ranges from a fraction of 1 microampere in the first to thousands of amperes in the second. It covers a pressure range from less than 10^{-4} atm (10 pascals) to greater than 1 atm (100 kilopascals). *See* ARC DISCHARGE; TOWNSEND DISCHARGE.

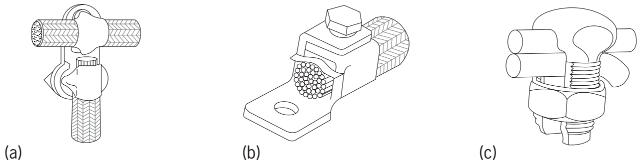
In general, the feature which distinguishes gaseous conduction from conduction in a solid or liquid is the active part which the medium plays in the process. Not only does the gas permit the drift of free charges from one electrode to the other, but the gas itself may be ionized to produce other charges which can interact with the electrodes to liberate additional charges. Quite apparently, the current voltage characteristic may be nonlinear and multivalued. *See* ELECTROLYTIC CONDUCTANCE; SEMICONDUCTOR.

The applications of the effects encountered in this area are of significant commercial and scientific value. A few commercial applications are thyratrons, gaseous rectifiers, ignitrons, glow tubes, and gas-filled phototubes. These tubes are used in power supplies, control circuits, pulse production, voltage regulators, and heavy-duty applications such as welders. In addition, there are gaseous conduction devices widely used in research problems. Some of these are ion sources for mass spectrometers and nuclear accelerators, ionization vacuum gages, radiation detection and measurement instruments, and thermonuclear devices for the production of power. [G.H.M.]

Electrical connector A device that joins electric conductors mechanically and electrically to other conductors and to the terminals of apparatus and equipment. The term covers a wide range of devices designed, for example, to connect small conductors employed in communication circuits, or at the other extreme, large cables and bus-bars.

Electrical connectors are applied to conductors in a variety of ways. Soldered connectors have a tube or hole of approximately the same diameter as the conductor. The conductor and connector are heated, the conductor inserted, and solder flowed into the joint until it is filled. Solderless connectors are applied by clamping the conductor or conductors in a bolted assembly or by staking or crimping under great mechanical force.

Typical connector types are in-line splice couplers, T-tap connectors, terminal lugs, and stud connectors. Couplers join conductors end to end. T-tap connectors join a through conductor to another conductor at right angles to it (illus. *a*). Terminal lugs join the conductor to a drilled tongue for bolting to the terminals of equipment (illus. *b*). Stud connectors join the conductor to equipment studs; the stud clamp is threaded or smooth to match the stud.



Types of connectors. (*a*) T-tap connector. (*b*) Terminal lug. (*c*) Split-bolt connector.

Split-bolt connectors are a compact construction widely used for splices and taps in building wiring. The bolt-shape casting has a wide and deep slot lengthwise. The conductors are inserted in the slot and the nut is drawn up, clamping the conductors together inside the bolt (illus. *c*).

Expansion connectors or flexible connectors allow some limited motion between the connected conductors. The clamp portions of the connector are joined by short lengths of flexible copper braid and may also be held in alignment by a telescoping guide.

Separable types consist of matched plugs and receptacles, which may be readily separated to disconnect a conductor or group of conductors from the circuit or system. Separable connectors are commonly used for the connection of portable appliances and equipment to an electric wiring system.

Locking types are designed so that, when coupled, they may not be separated by a strain or pull on the cord or cable. In a typical construction the plug is inserted and twisted through a small arc, locking it securely in place.

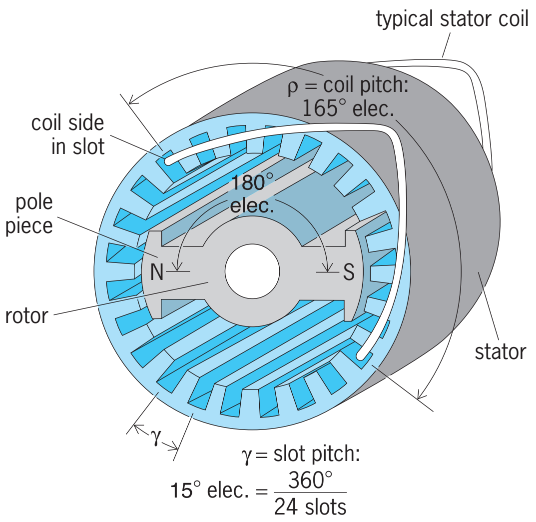
Plug receptacles, sometimes called convenience outlets, are a type of wiring device distributed throughout buildings for the attachment of cord plug caps from portable lamps and appliances. In residences at least one such outlet must be provided for every 12 linear feet (3.66 m) or major fraction of wall perimeter. Grounding receptacles have an additional contact that accepts the third round or U-shaped prong of a grounding attachment plug. *See* WIRING. [J.F.McP.]

Electrical degree A time interval equal to 1/360 of the time required for one complete cycle of alternating current. Mechanical rotation is often measured in degrees, 360° constituting one complete revolution. In describing alternating voltages and currents, the time for one complete cycle is considered to be equivalent to 360 electrical degrees (360°) or 2π electrical radians. For example, if the frequency f is 60 cycles per second (60 Hz), 360° corresponds to 1/60 second and 1 electrical degree to 1/21,600 second.

There is a definite relationship between electrical and mechanical degrees in rotating electric generators and motors. The illustration shows typical coil and angular relationships in a two-pole alternator. As the magnetic field in the machine moves relative to the coils in the armature winding, the coils are linked sequentially by the fluxes of north and south magnetic poles; two flux reversals induce one cycle of voltage in a given coil. Thus, in a two-pole machine 360° of electrical cycle corresponds to 360° of mechanical rotation, and an angle measured in mechanical degrees has the same value in electrical degrees. However, in a machine with more than two poles, one electrical cycle is generated per pair of poles per revolution. For example, a six-pole machine generates three cycles of voltage in each armature coil per revolution. In this case, each mechanical degree is equivalent to 3 electrical degrees. In general, the relationship below is valid,

$$\begin{array}{l}\text{Number of}\\ \text{electrical degrees}\\ \text{in a given angle}\end{array} = \frac{p}{2} \cdot \left(\begin{array}{l}\text{number of mechanical}\\ \text{degrees in that angle}\end{array}\right)$$

where p is the number of magnetic poles of either the rotor or the stator. It follows that the electrical angle between the centers of succeeding poles of opposite polarity is always 180 electrical degrees.



Coil and angular relationships in a two-pole alternator.

The concept of electrical degrees simplifies the analysis of multipolar machines by allowing them to be analyzed on a two-pole basis. Furthermore, it permits trigonometry to be used in solving alternating-current problems. *See* Alternating current; Electric rotating machinery; Generator; Motor; Windings in electric machinery. [G.McP.]

Electrical energy measurement The measurement of the integral, with respect to time, of the power in an electric circuit. The absolute unit of measurement of electrical energy is the joule, or the charge in coulombs times the potential difference in volts. The joule, however, is too small (1 watt-second) for use in commercial practice, and the more commonly used unit is the watt-hour (3.6×10^3 joules). The most common measurement application is in the utility field.

Electrical energy is one of the most accurately measured commodities sold to the general public. Many methods of measurement, with different degrees of accuracy, are possible. Basically, measurements of electric energy may be classified into two categories, direct-current power and alternating-current power. The fundamental concepts of measurement are, however, the same for both.

There are two types of methods of measuring electrical energy: electric instruments and timing means, and electricity meters.

Electric instruments and timing means make use of conventional procedures for measuring electric power and time. Typical methods are listed below. *See* Electric power measurement.

1. Measurement of energy on a direct-current circuit by reading the line voltage and load current at regular intervals over a measured period of time. *See* Current measurement; Voltage measurement.

2. Measurement of energy on a direct-current circuit by controlling the voltage and current at constant predetermined values for a predetermined time interval.

3. Measurement of energy on an alternating-current circuit by reading the watts input to the load at regular intervals over a measured period of time.

4. Measurement of energy on an alternating-current circuit by controlling the voltage, current, and watts input to the load at constant predetermined values.

5. Measurement of energy by recording the watts input to the load on a linear chart progressed uniformly with time.

Electricity meters are the most common devices for measuring the vast quantities of electrical energy used by industry and the general public. The same fundamentals of measurement apply as for electric power measurement, but in addition the electricity meter provides the time-integrating means necessary for electric energy measurement. A single meter is sometimes used to measure the energy consumed in two or more circuits. However, multistator meters are generally required for this purpose.

Watt-hour meters are generally connected to measure the losses of their respective current circuits. These losses are extremely small compared to the total energy being measured and are present only under load conditions. Watt-hour meters used for the billing of residential, commercial, and industrial loads are highly developed devices. *See* Electrical measurements. [W.H.Ha.]

Electrical engineering The branch of engineering that deals with electric and magnetic forces and their effects. *See* Electricity; Engineering; Magnetism.

Electrical engineers design computers and incorporate them into devices and systems. They design two-way communications systems such as telephones and fiber-optic systems, and one-way communications systems such as radio and television, including satellite systems. They design control systems, such as aircraft collision-avoidance systems, and a variety of systems used in medical electronics. Electrical engineers are involved with generation, control, and delivery of electric power to homes, offices, and industry. Electric power lights, heats, and cools working and living space and operates the many devices used in homes and offices. Electrical engineers analyze and interpret computer-aided tomography data (CAT scans), seismic data from earthquakes and well drilling, and data from space probes, voice synthesizers, and handwriting recognition. They design systems that educate and entertain, such as computers and computer networks, compact-disk players, and multimedia systems. *See* Character recognition; Communications satellite; Compact disk; Computer; Computerized tomography; Control systems; Digital computer; Electric heating; Electric power generation; Electric power systems.

The integration of communications equipment, control systems, computers, and other devices and processes into reliable, easily understood, and practical systems is a major challenge, which has given rise to the discipline of systems engineering. Electrical engineering must respond to numerous demands, including those for more efficient and effective lights and motors; better communications; faster and more reliable transfer of funds, orders, and inventory information in the business world; and the need of medical professionals for access to medical data and advice from all parts of the world. *See* Information systems engineering; Medical information systems; Systems engineering. [E.C.Jo.]

Electrical impedance The measure of the opposition that an electrical circuit presents to the passage of a current when a voltage is applied. In quantitative terms, it is the complex ratio of the voltage to the current in an alternating current (ac) circuit.

A generalized ac circuit may be composed of the interconnection of various types of circuit elements. The impedance of the circuit is given by $Z = V/I$, where Z is a complex number given by $Z = R + jX$. R, the real part of the impedance, is the resistance of the circuit, and X, the imaginary part of the impedance, is the reactance of the circuit. The units of impedance are ohms. *See* Electrical resistance; Reactance. [J.O.S.]

Electrical instability A condition that is generic to all physical systems that use the amplification of signals, power, or energy in various forms. Electrical circuits are perhaps the best-known example because the use of amplification is very common there. In order for instability to occur, a closed (circular) path must exist, and the net amplification around it must be sufficiently large that any random signal (for example, noise) that travels around the closed path grows uncontrollably. The condition is eventually limited by some physical aspect of the system such as nonlinearity, saturation, or power available. The energy to create the uncontrollable signal growth is obtained by conversion from some other form of energy. For example, a high-frequency electrical oscillation can draw its energy from a direct-current (dc) power supply. *See* ENERGY; LINEARITY; SATURATION.

There can be various degrees of stability and instability in an electrical circuit or system, and instability may be desirable or undesirable depending on the context. Desirable instability is displayed by a cross-coupled positive-feedback latch in a computer memory cell, or an oscillator that is used to create the high-frequency carrier wave of a radio transmitter. An undesirable instability might arise in the loss of control over a power transmission system due to surges on the generators, leading to a necessary decoupling of the system. Another example is the high-pitched whine heard when a radio-station telephone caller leaves the home radio receiver on and thus allows feedback from the radio receiver to the telephone, that is, a closed-loop signal path. *See* FEEDBACK CIRCUIT; OSCILLATOR.

Electrical instability can occur at zero frequency (dc), for example, in the cross-coupled memory latch, but its accidental occurrences are generally at high frequencies. A configuration may be designed to be stable at low frequencies, but inadvertent phase shifts or time delays at higher frequencies may create a positive-feedback situation. For this reason, the design of amplifiers, feedback control systems, and so forth necessarily involves much attention to the higher-frequency aspects even though the desired use may be primarily at lower frequencies. *See* AMPLIFIER; CONTROL SYSTEM STABILITY; CONTROL SYSTEMS. [M.A.Co.]

Electrical insulation A nonconducting material that provides electric isolation of two parts at different voltages. To accomplish this, an insulator must meet two primary requirements: it must have an electrical resistivity and a dielectric strength sufficiently high for the given application. The secondary requirements relate to thermal and mechanical properties. Occasionally, tertiary requirements relating to dielectric loss and dielectric constant must also be observed. A complementary requirement is that the required properties not deteriorate in a given environment and desired lifetime. *See* CONDUCTOR (ELECTRICITY).

Electric insulation is generally a vital factor in both the technical and economic feasibility of complex power and electronic systems. The generation and transmission of electric power depend critically upon the performance of electric insulation, and now plays an even more crucial role because of the energy shortage.

Requirements. The important requirements for good insulation are as follows.

The basic difference between a conductor and a dielectric is that free charge has high mobility on and in a conductor, whereas free charge has little or no mobility on or in a dielectric. Dielectric strength is a measure of the electric stress required to abruptly move substantial charge on or through a dielectric. It deteriorates with the ingress of water and with elevated temperature. For high-voltage (on the order of kilovolts) applications, dielectric strength is the most important single property of the insulation. *See* DIELECTRIC MATERIALS.

Resistivity is a measure of how much current will be drained away from the conductor through the bulk or along the surface of the dielectric. An insulator with resistivity equal to or greater than 10^{13} ohm-cm may be considered good. *See* ELECTRICAL RESISTIVITY.

When a dielectric is subjected to an alternating field, a time-varying polarization of the atoms and molecules in the dielectric is produced. The alternation of both the permanent and induced polarization in the dielectric results in power dissipation within the dielectric of which the power factor is a measure. This dielectric power loss is proportional to the product of the dielectric constant and the square of the electric field in the dielectric. Although it may be a loss that is small relative to other losses in most ambient-temperature applications, and even though it generally decreases at low temperatures, it is a relatively important loss for dielectrics to be used at cryogenic temperatures.

The dielectric constant, also known as the relative permittivity or specific inductive capacity, is a measure of the ability of the dielectric to become polarized, taken as the ratio of the charge required to bring the system to the same voltage level relative to the charge required if the dielectric were vacuum. It is thus a pure number, but is in fact not a constant, and may vary with temperature, frequency, and electric-field intensity.

In addition to the problem of intensification of the electric field in regions of relatively lower dielectric constant, a low-dielectric-constant insulation is desirable for two more compelling reasons. In ac transmission cables, the lower the dielectric constant, the more the current and the voltage will be in phase. This means that more usable power will be delivered, without the need for reactive compensation. Furthermore, in reducing the charging current (which is proportional to the dielectric constant), concomitant power losses (related to the square of the charging current) are also reduced. A high dielectric constant is desirable in capacitors, since the capacitance is proportional to it. *See* CAPACITANCE.

Properties. All insulators may be classified as either solid or fluid. Solid insulation is further divided into flexible and rigid types.

Solid insulation. Flexible hydrocarbon insulation is generally either thermoplastic or thermosetting. Thermosets are initially soft, and can be extruded by using only pressure. Following heat treatment, when they return to ambient temperature, they are tougher and harder. After thermosetting, nonrubber thermosets are harder, stronger, and have more dimensional stability than the thermoplastics. Thermoplastics are softened by heating, and when cool become hard again. They are heat-extruded.

Cellulose paper insulation is neither thermoplastic nor thermosetting. It is widely used in cables and rotating machinery in multilayers and impregnated with oil. It has a relatively high dielectric loss that hardly decreases with decreasing temperature, which rules it out for cryogenic applications. Because of its high dielectric strength, the high loss has not been a deterrent to its use in conventional ambient-temperature applications. However, the high dielectric strength deteriorates quickly if moisture permeates the paper.

Rigid insulation includes glass, mica, epoxies, ceramoplastics, porcelain, alumina, and other ceramics. Rather than being used to insulate wires and cables, except for mica, these materials are used in equipment terminations (potheads) and as support insulators (in tension or compression) for overhead lines whose primary dielectric is air. These rigid structures must be shock-resistant, be relatively water-impervious, and be able to endure corona discharges over their surfaces.

Fluid insulation. Liquids, gases, and vacuum fall in the category of fluid insulation. For all of these, the electrical structure must be such as to contain the fluid in the regions of high electric stress.

The main types of insulating liquids are the mineral oils, silicones, chlorinated hydrocarbons, and the fluorocarbons with dielectric strengths on the order of megavolts per centimeter. Many other liquids also have good dielectric strength, such as carbon tetrachloride, toluene, hexane, benzene, chlorobenzene, alcohol, and even deionized water.

Most gases have a dielectric constant of about 1, and low dielectric loss. Air is used as a dielectric in a wide variety of applications, ranging from electronics to high-voltage (765-kV) and high-power (2000-MW) electric transmission lines. Dry air is a reasonably good insulator. However, its dielectric strength decreases with increasing gap.

Vacuum (that is, pressures of less than 10^{-5} torr or 10^{-3} pascal) has one of the highest dielectric strengths in the gap ranging 0.1 to 1 mm. However, as the gap increases, its dielectric strength decreases rapidly. A perfect vacuum might be expected to be a perfect insulator, since there would be no charge carriers present to contribute to electrical conductance. That this is not so in practice arises because of the effects of a high electric field or high voltage at the surface of electrodes in vacuum, rather than because a perfect vacuum is far from being realized in the laboratory. The dielectric properties of vacuum can degenerate rapidly because vacuum offers no resistance to the motion of charge carriers, once they are introduced into the vacuum region. [M.R.]

Electrical interference

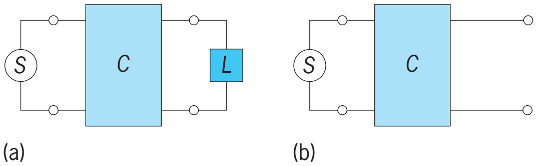
Disturbance to the normal or expected operation of electrical or electronic devices, equipment, and systems. Electrical interference is sometimes called radio-frequency interference (RFI) or electromagnetic interference (EMI). Electrical noise is a broader term that includes those phenomena that are generally termed electrical interference, but also includes naturally occurring currents or voltages that are more or less continuous and cannot be completely eliminated.

Electrical interference originates from one or more of the following: transmitters such as those used for broadcast, communication, radar, and navigation; artificial incidental emission sources such as from sparking of motor brushes, automotive ignition, and fluorescent lamps; and natural phenomena such as lightning and electrostatic discharges. The interference emissions may be radiated through space or conducted along the paths of electrical wires in power lines and signal cables. *See* COMMUNICATIONS CABLE; ELECTROMAGNETIC RADIATION; TRANSMISSION LINES.

There are several means of mitigating electrical interference, including grounding, bonding, shielding, filtering, and transient control. There are two major approaches. One is to reduce radiation from boxes, cabinets, racks, and consoles by the design of multilayer printed circuit boards and backplanes, or to use metal or metallized plastic cases with EMI-protected apertures. The other involves reduction of radiation to or from the interconnecting cable by using filter pin connectors or foil-wrap shields terminated with complete coverage by the connector backshell at the respective box bulkhead. *See* BONDING; ELECTRIC FILTER; ELECTRIC TRANSIENT; ELECTRICAL NOISE; ELECTRICAL SHIELDING; ELECTROMAGNETIC COMPATIBILITY. [D.R.J.W.]

Electrical loading

The connection of a specific circuit (called the load) to another circuit. Illustration *a* shows a source of electrical energy (*S*), a coupling circuit (*C*), and a load (*L*). In power transmission, *S* is the generator of the power plant, *C* represents the connecting transmission lines and transformers, and *L* is, for instance, a household with its electrical appliances. The entire system operates to supply the load demand of *L*, that is, the electrical energy required by the load. In a high-fidelity sound system, *S* is the output of the phonograph cartridge or the tape playback head, *C* is the amplifier, and *L* is the coil of the loudspeaker. *See* ELECTRIC POWER SYSTEMS; SOUND-REPRODUCING SYSTEMS.



Systems (*a*) under load and (*b*) under no load.

When the load is disconnected, the system operates under no-load conditions (illus. *b*).

Loading is used in certain wire-line transmissions in order to improve their characteristics. This is often done by connecting loading inductors along telephone lines, or along certain data transmission circuits. These inductors reduce the attenuation of the line, thus improving the transmission of signals. Waveguides, special antennas, and coaxial cables are often loaded with specific circuits to achieve specific purposes. *See* ANTENNA (ELECTROMAGNETISM); COAXIAL CABLE; INDUCTOR; TRANSMISSION LINES; WAVEGUIDE. [S.Kar.]

Electrical measurements

Measurements of the many quantities by which the behavior of electricity is characterized. Measurements of electrical quantities extend over a wide dynamic range and frequencies ranging from 0 to 10^{12} Hz. The International System of Units (SI) is in universal use for all electrical measurements. Electrical measurements are ultimately based on comparisons with realizations, that is, reference standards, of the various SI units. These reference standards are maintained by the National Institute of Standards and Technology in the United States, and by the national standards laboratories of many other countries. *See* ELECTRICAL UNITS AND STANDARDS.

Direct-current (dc) measurements include measurements of resistance, voltage, and current in circuits in which a steady current is maintained. Resistance is defined as the ratio of voltage to current. For many conductors this ratio is nearly constant, but depends to a varying extent on temperature, voltage, and other environmental conditions. The best standard resistors are made from wires of special alloys chosen for low dependence on temperature and for stability.

The SI unit of resistance, the ohm, is realized by means of a quantized Hall resistance standard. This is based upon the value of the ratio of fundamental constants h/e^2, where h is Planck's constant and e is the charge of the electron, and does not vary with time. *See* HALL EFFECT.

The principal instruments for accurate resistance measurement are bridges derived from the basic four-arm Wheatstone bridge, and resistance boxes. Many multirange digital electronic instruments measure resistance potentiometrically, that is, by measuring the voltage drop across the terminals to which the resistor is connected when a known current is passed through them. The current is then defined by the voltage drop across an internal reference resistor. For high values of resistance, above a megohm, an alternative technique is to measure the integrated current into a capacitor (over a suitably defined time interval) by measuring the final capacitor voltage. Both methods are capable of considerable refinement and extension. *See* ELECTRICAL RESISTANCE; HALL EFFECT; OHMMETER; RESISTANCE MEASUREMENT; WHEATSTONE BRIDGE.

The SI unit of voltage, the volt, is realized by using arrays of Josephson junctions. This standard is based on frequency and the ratio of fundamental constants e/h, so the accuracy is limited by the measurement of frequency. Josephson arrays can produce voltages between 200 μV and 10 V. At the highest levels of accuracy, higher voltages are measured potentiometrically, by using a null detector to compare the measured voltage against the voltage drop across a tapping of a resistive divider, which is standardized (in principle) against a standard cell. *See* JOSEPHSON EFFECT.

The Zener diode reference standard is the basis for most commercial voltage measuring instruments, voltage standards, and voltage calibrators. The relative insensitivity to vibration and other environmental and transportation effects makes the diodes particularly useful as transfer standards. Under favorable conditions these devices are stable to a few parts per million per year.

Most dc digital voltmeters, which are the instruments in widest use for voltage measurement, are essentially analog-to-digital converters which are standardized by reference to their built-in reference diodes. The basic range in most digital voltmeters is between 1 and 10 V, near the reference voltage. Other ranges are provided by means of resistive dividers, or amplifiers in which gain is stabilized by feedback resistance ratios. In this way these instruments provide measurements over the approximate range from 10 nanovolts to 10 kV. *See* DIGITAL-TO-ANALOG CONVERTER; MICROPROCESSOR; VOLTAGE MEASUREMENT; VOLTMETER; ZENER DIODE.

The most accurate measurements of direct currents less than about 1 A are made by measuring the voltage across the potential terminals of a resistor when the current is passed through it. Higher currents, up to about 50 kA, are best measured by means of a dc current comparator, which accurately provides the ratio of the high current to a much lower one which is measured as above. At lower accuracies, resistive shunts may be used up to about 5000 A, but the effective calibration of such shunts is a difficult process. *See* CURRENT COMPARATOR; CURRENT MEASUREMENT.

Alternating-current (ac) voltages are established with reference to the dc voltage standards by the use of thermal converters. These are small devices, usually in an evacuated glass envelope, in which the temperature rise of a small heater is compared by means of a thermocouple when the heater is operated sequentially by an alternating voltage and by a reference (dc) voltage. Resistors, which have been independently established to be free from variation with frequency, permit direct measurement of power frequency voltages up to about 1 kV. Greater accuracy is provided by multijunction (thermocouple) thermal converters, although these are much more difficult and expensive to make. Improvements in digital electronics have led to alternative approaches to ac measurement. For example, a line frequency waveform may be analyzed by using fast sample-and-hold circuits and, in principle, be calibrated relative to a dc reference standard. Also, electronic root-mean-square detectors may now be used instead of thermal converters as the basis of measuring instruments. *See* NONSINUSOIDAL WAVEFORM; THERMAL CONVERTERS.

Voltages above a few hundred volts are usually measured by means of a voltage transformer, which is an accurately wound transformer operating under lightly loaded conditions.

The principal instrument for the comparison and generation of variable alternating voltages below about 1 kV is the inductive voltage divider, a very accurate and stable device. They are widely used as the variable elements in bridges or measurement systems. *See* INDUCTIVE VOLTAGE DIVIDER.

Alternating currents of less than a few amperes are measured by the voltage drop across a resistor, whose phase angle has been established as adequately small by bridge methods. Higher currents are usually measured through the use of current transformers, which are carefully constructed (often toroidal) transformers operating under near-short-circuited conditions. The performance of a current transformer is established by calibration against an ac current comparator, which establishes precise current ratios by the injection of compensating currents to give an exact flux balance. *See* INSTRUMENT TRANSFORMER.

Commercial instruments for measurement of ac quantities are usually dc measuring instruments, giving a reading of the voltage obtained from some form of ac-dc transducer. This may be a thermal converter, or a series of diodes arranged to have a square-law response, in which case the indication is substantially the root-mean-square value. Some lower-grade instruments measure the value of the rectified signal, which is usually more nearly related to the peak value.

There has been a noticeable trend toward the use of automated measurement systems for electrical measurements, facilitated by the readiness with which modern digital electronic instruments may be interfaced with computers. Many of these instruments have built-in microprocessors, which improve their convenience in use, accuracy, and reliability. For power measurements, *see* ELECTRIC POWER MEASUREMENT; ELECTRICAL ENERGY MEASUREMENT; WATT-HOUR METER; WATTMETER. For measurements at frequencies above about 300 MHz, *see* MICROWAVE MEASUREMENTS. [R.G.Jon.; O.C.J.]

Electrical model

A mathematical description or electrical equivalent circuit that represents the behavior of a device or system. Models for complex systems are often represented by networks of models for simpler electrical devices such as resistors, capacitors, transistors, and transformers. By using analogies between current or voltage and other physical parameters, equivalent circuits can also be used to analyze thermal, mechanical, magnetic, and acoustic systems. A recurring issue in development and in application of models is the use of simplifying assumptions to allow a compromise between accuracy and complexity. A hierarchy of models often exists, ranging from highly accurate but complex physics-based nonlinear time-domain computer models to linear equivalent-circuit models suitable for hand calculation. The best model for a particular application is the simplest one that predicts the relevant behavior with acceptable accuracy. *See* EQUIVALENT CIRCUIT.

Electrical models can be divided into two categories: nonlinear, large-signal and linear, small-signal models. Each of these can be further divided into time-invariant and time- or frequency-dependent categories.

Large-signal models. These are usually derived by applying physical laws to generalized devices. This leads to a system of differential equations whose solution comprises the model. Such physically derived models are often highly complex, requiring lengthy computer solutions. An alternative approach is empirical modeling, in which a simple mathematical form is assumed for the model, with key physical parameters being determined by measurements on representative devices. *See* DIFFERENTIAL EQUATION.

There are two main application areas for large-signal models. One is to find the response of a system to time-varying inputs. The other is to determine the voltages and currents of a circuit with zero input variations, as a preliminary to small-signal analysis.

Small-signal modeling. In many applications, current and voltage variations are small enough that the device's characteristics are approximately independent of signal size. This allows the device to be represented by a simplified linear equivalent circuit. To find the values of the equivalent circuit's elements, the input signal is replaced with its average value, and all currents and voltages are found by using the large-signal model. The results represent the quiescent operating point or Q point for the circuit. All currents and voltages can be approximated by series expansions around the Q point.

Linearity has several benefits. One is the applicability of systematic solution methods for linear circuits that simplify both manual and computer solutions. Linearity also allows superposition: a linear system's response to the sum of two inputs equals the sum of its responses to the inputs applied separately. An important consequence of superposition is that the system is completely specified by its response to sinusoids of arbitrary frequency. This frequency response determines the output spectrum for arbitrary inputs. Linear circuits can be analyzed entirely in the frequency domain. *See* CIRCUIT (ELECTRONICS); GAIN; LINEARITY; RESPONSE; SUPERPOSITION THEOREM (ELECTRIC NETWORKS). [R.M.Fo.]

Electrical noise

Interfering and unwanted currents or voltages in an electrical device or system. Electrical noise, or simply noise, has a significant effect on the design and operation of almost all electrical and optical systems which are used to communicate or process information. Noise is responsible for the familiar static observed on home radio receivers, the clicking sounds on frequency-modulation (FM) radios operating in fringe (near-threshold) areas, and the "snow"-type granularity on the viewing screen of a television receiver displaying a weak signal. In general, noise provides the fundamental limitation to the range over which radio or optical signals can be transmitted and received with integrity. Noise is, therefore, of great importance to the engineers who design and operate such systems.

It is convenient to differentiate between noise which results from human activity and that which is naturally occurring. Noise which results from human activity, such as that generated by an electrical appliance or an automotive ignition, can usually be eliminated or minimized by good design practice (shielding, filtering, equipment location, and so forth). Naturally occurring noise can be further subdivided into that which is irregular or erratic in nature and that which is more or less continuous.

An example of noise which is irregular or erratic is that associated with an electrical storm. This type of noise is sometimes dealt with in the system design, but since it is only occasionally present, it does not ordinarily constitute a design limitation. On the other hand, naturally occurring noise which is essentially continuous in time is responsible for the fundamental limitation cited above. The remainder of the article therefore concentrates on this type of noise. *See* ATMOSPHERIC ELECTRICITY; CROSSTALK; ELECTRIC FILTER; ELECTRICAL INTERFERENCE; ELECTRICAL SHIELDING; ELECTROMAGNETIC COMPATIBILITY; ELECTRONIC EQUIPMENT GROUNDING; GROUNDING; STATIC.

Most noise generation is a consequence of the spontaneous fluctuations which occur within matter at the microscopic level. In electrical circuits these fluctuations give rise to what are commonly referred to as thermal noise and shot noise. Thermal noise is generated by the random motion of free electrons in a resistor or any conductor with resistance. The random motion, and thus the noise generated, is proportional to the temperature of the medium. At absolute zero temperature on the Kelvin scale (-459.67°F), all motion ceases and no noise is generated. Shot noise is most commonly identified with the fluctuations in the current of a vacuum tube caused by the random emission of electrons from its heated cathode. Shot noise is also observed in semiconductor devices as random fluctuations in carrier density when an electric field is applied. There are other types of noise associated with electrical circuits, but shot noise and thermal noise are by far the most important. *See* FREE-ELECTRON THEORY OF METALS; KINETIC THEORY OF MATTER; SEMICONDUCTOR; VACUUM TUBE.

In a system in which signals are transmitted through the atmosphere [for example, amplitude-modulation (AM) or FM radio broadcast, or satellite communications], the receiving system will always receive noise as well as the desired signals. This noise is a result of thermal radiation from the Earth, planets, Sun, Moon, the galaxy (galactic noise), radio-emitting stars, and atmospheric gases. In addition, there is a small background level of thermal radiation, uniformly distributed, which is believed associated with the big bang origin of the universe. All of these noise sources, weighted by the directional characteristics of the receiving antenna, will contribute to the overall system noise. *See* COSMIC BACKGROUND RADIATION; HEAT RADIATION; TERRESTRIAL RADIATION.

In an optical communications system, a signal level is represented by a number of energy packets called photons. The mean arrival rate of the photons at the detector is proportional to the optical intensity or signal strength. At the detector (a photodiode), the photons are absorbed, each creating a hole-electron pair and thus a current in which the electrons are randomly positioned in time and in which the mean number of electrons is proportional to the optical intensity. The statistical nature of this process gives rise to fluctuations in the number of photons representative of a given level and, subsequently, the number of electrons generated to represent that level. If the detector has internal gain as in an avalanche photodiode, each hole-electron pair can create additional hole-electron pairs. This process, however, is statistical in nature, resulting in a mean value of gain but giving rise to additional fluctuations in the generated current. *See* MICROWAVE SOLID-STATE DEVICES; OPTICAL COMMUNICATIONS; OPTICAL DETECTORS; PHOTODIODE; PHOTON. [R.W.K.]

Electrical noise generator A device that produces electrical noise for use in electrical measurements. Electrical noise generators are commonly employed to measure the noise figure or noise temperature of radio receivers. They are also used in various other tests in radar and communications systems. Celestial noise sources are used to calibrate large antennas.

Some standard types of noise generators are hot-wire, diode, gas-discharge tube, hot and cold loads (terminations), and radiostar. A hot-wire noise source consists of the filament of a lamp heated by direct current. Thermal noise having spectral density 4 kTR, where k is Boltzmann's constant and T and R are the temperature and resistance of the filament respectively, is generated across the terminals of the filament. A diode noise generator utilizes the temperature-limited shot effect to generate noise. At frequencies less than the reciprocal transit time of the diode, the noise spectral density is $2e\bar{I}$, where e is the charge on the electron and $\bar{I}$ is the average anode current. A gas-discharge noise generator, commonly referred to as a noise tube, consists of a fluorescent light tube enclosed in a waveguide. Noise generation is essentially thermal. The noise tube is commonly employed at microwave frequencies. Hot and cold loads consist of well-matched terminations, either transmission line or waveguide, held at a given temperature by using an oven or by applying cryogenic refrigeration. Noise generation is thermal. Common temperatures for noise-generating terminations are nominally 80 and 300 K (minus 316 and plus 80°F).

Celestial radio sources (radio stars) are commonly employed as reference noise sources for evaluating the characteristics of very low-noise, high-gain space communications receiving antennas. There are a number of accurately calibrated sources available—the choice depending on system parameters (frequency, antenna gain, system noise temperature, elevation angle, and so forth) and physical location. The most common radio sources employed are Cassiopeia A, Taurus A, Cygnus A, and Orion A. The first three are classified as nonthermal sources in which radiation results from relativistic electrons interacting with an interstellar magnetic field. The electrons are rotated in a plane perpendicular to the magnetic field direction, and radiation is characterized by a component polarized parallel to that plane. The polarized component is small, however, and the major portion of the radiation is unpolarized. The nonthermal sources have flux densities which decrease with increasing frequency and, consequently, tend to have a cutoff frequency above which they are not usable. Orion A is a thermal source in which radiation occurs from a hot, ionized cloud. Orion A has a constant flux density at frequencies above 2 GHz. As a point of reference, a typical value of thermal noise received from Cassiopeia A by a 10-m-diameter (33-ft) antenna operating in the C band (4–6 GHz) would be about 150 K (minus 190°F). *See* ELECTRICAL NOISE; POLARIZED LIGHT; RADIO ASTRONOMY. [R.W.K.]

Electrical resistance Opposition of a circuit to the flow of electric current. Ohm's law states that the current I flowing in a circuit is proportional to the applied potential difference V. The constant of proportionality is defined as the resistance R. Hence, Eq. (1) holds. If V and I are measured in volts and

$$V = IR \tag{1}$$

amperes, respectively, R is measured in ohms. Microscopically, resistance is associated with the impedance to flow of charge carriers offered by the material. For example, in a metallic conductor the charge carriers are electrons moving in a polycrystalline material in which their journey is impeded by collisions with imperfections in the local crystal lattice, such as impurity atoms, vacancies, and dislocations. In these collisions the carriers lose energy to the crystal lattice, and thus Joule heat is liberated in the conductor, which rises in temperature. The Joule heat P is given by Eq. (2).

$$P = I^2R = IV = \frac{V^2}{R} \tag{2}$$

See CRYSTAL DEFECTS; ELECTRICAL CONDUCTIVITY OF METALS; ELECTRICAL RESISTIVITY; JOULE'S LAW; OHM'S LAW. [P.A.S.]

Electrical resistivity The electrical resistance offered by a homogeneous unit cube of material to the flow of a direct current of uniform density between opposite faces of the cube. Also called specific resistance, it is an intrinsic, bulk (not thin-film) property of a material. Resistivity is usually determined by calculation from the measurement of electrical resistance of samples having a known length and uniform cross section according to the following equation, where ρ is the resistivity, R the measured resistance, A the cross-sectional area, and l the length. In the mks system (SI), the unit of resistivity is the ohm-meter. Therefore, in the equation below, resistance is expressed in ohms, and the sample dimensions in meters.

$$\rho = RA/l$$

The room-temperature resistivity of pure metals extends from approximately 1.5×10^{-8} ohm-meter for silver, the best conductor, to 135×10^{-8} ohm-meter for manganese, the poorest pure metallic conductor. Most metallic alloys also fall within the same range. Insulators have resistivities within the approximate range of 10^8 to 10^{16} ohm-meters. The resistivity of semiconductor materials, such as silicon and germanium, depends not only on the basic material but to a considerable extent on the type and amount of impurities in the base material. Large variations result from small changes in composition, particularly at very low concentrations of impurities. Values typically range from 10^{-4} to 10^5 ohm-meters. *See* ELECTRICAL INSULATION; ELECTRICAL RESISTANCE; SEMICONDUCTOR.

The temperature coefficients (changes with temperature) of resistivity of pure metallic conductors are positive. Resistivity increases by about 0.4%/K at room temperature and is nearly proportional to the absolute temperature over wide temperature ranges. As the temperature is decreased toward absolute zero, resistivity decreases to a very low residual value for some metals. The resistivity of other metals abruptly changes to zero at some temperature above absolute zero, and they become superconductors.

Metals, and some semiconductors in particular, exhibit a change in resistivity when placed in a magnetic field. Theoretical relations to explain the observed phenomena have not been well developed. [C.E.A.]

Electrical shielding

The imposition of a metal or composite barrier between one or more sources of electrical noise and their victims with the objective of reducing or eliminating electrical interference. Examples of the barrier are the case or housing of equipment; shields covering interconnecting cables between equipment; large cabinets, racks, or consoles; shielded (screen) rooms; and entire shielded buildings or vehicles.

The principal measure of a shield's performance is the shielding effectiveness. It is defined by the equation below, where SE_{dB}

$$SE_{\mathrm{dB}} = 20 \log_{10} \frac{F_b}{F_a}$$

is the shielding effectiveness in decibels, F_b is the electric (or magnetic) field strength before imposition of the barrier, and F_a is the electric (or magnetic) field strength after imposition of the barrier. *See* DECIBEL.

Shielding is obtained by the combination of reflection loss and absorption loss. The former is due to the impedance mismatch between the wave impedance of an oncoming wave and the surface impedance of the interposed barrier. Absorption loss corresponds to the attenuation due to skin effect at higher frequencies, and is dependent upon the frequency, conductivity, permeability, and thickness of the barrier. Shielding effectiveness is the sum of both losses. *See* ABSORPTION OF ELECTROMAGNETIC RADIATION; ATTENUATION (ELECTRICITY); RADAR-ABSORBING MATERIALS; REFLECTION AND TRANSMISSION COEFFICIENTS; REFLECTION OF ELECTROMAGNETIC RADIATION; SKIN EFFECT (ELECTRICITY).

Most intentional shields are made of metal to ensure high reflection losses. Even thin metals, such as household aluminum foils (with a thickness of about 1.5 mils or 0.038 mm), offer shielding effectiveness in excess of 100 dB. At low frequencies, these foils become electromagnetically transparent (that is, they do not attenuate magnetic fields). Thus, if there is a shielding problem due to the selection and makeup of the metal barrier, it is likely to occur only for low-frequency magnetic fields.

To obtain significant shielding to magnetic fields at low frequencies, the metal barrier must be very thick or composed of a highly permeable material such as Mumetal, Supermalloy, or Hypernom. Often such shields are fabricated in two or more layers, frequently laminated, to obtain good shielding properties per unit size or weight. *See* ELECTRICAL INTERFERENCE; ELECTRICAL NOISE. [D.R.J.W.]

Electrical units and standards

The process of measurement consists in finding out how many times the quantity to be measured contains a fixed quantity of the same kind, called a unit. The definitions of the units often involve complex physical theory and do not lend themselves readily to practical realization. The concrete representations of units are known as measurement standards. In practice, measurements are made by using an instrument calibrated against a local reference standard, which itself has been calibrated either directly or by several links in a traceability chain against the national standard held by the national standards laboratory.

Electrical and magnetic units. A proposal by W. E. Weber in 1851 led to the absolute cgs system in which all units of quantities to be measured could be derived from the base units of length, mass, and time—the centimeter, gram, and second. This system was widely adopted although it had three weaknesses: the size of the units was inconvenient for practical use; it was difficult to realize the units from their definitions; and there were separate sets of units for electrostatic and electromagnetic quantities, based respectively on the inverse-square laws of force between electric charges and between magnetic poles.

International units. The first weakness was resolved by international agreement in 1881 to fix the practical units—the volt, the ohm, and the ampere—at 10^8, 10^9, and 0.1 times the respective cgs electromagnetic units. The other weaknesses were avoided by the decisions of the 1908 International Congress in London, where realizations of these units in terms of easily reproducible standards were defined.

The mksa units. A more fundamental change resulted from a proposal by G. Giorgi in 1902. This led to the adoption of the mksa system of units, in which there are four base units: the meter, the kilogram, the second, and the ampere. Use of the meter and the kilogram instead of the centimeter and the gram gave units of a size more convenient for practical use, and use of the ampere as a base unit resolved the conflict between electrostatic and electromagnetic units while maintaining the magnitudes of the widely used practical units. This was a truly coherent system, in the sense that other units were derived from the base units without the need for factors of proportionality other than unity.

SI units. From the mksa system the present-day SI (Système Internationale), formally adopted in 1954, has developed, by the addition of further base units to include other fields of measurement. The seven base units of SI are the kilogram (kg; mass); second (s; time); meter (m; length); ampere (A; electric current); kelvin (K; thermodynamic temperature); candela (cd; luminous intensity); and mole (m; amount of substance). The units of other physical quantities (derived units) are derived from the base units by simple numerical relations.

The SI base unit for electrical measurements is the ampere (A), the unit of electric current. It is defined in terms of a hypothetical experiment as that constant current which, if maintained in two straight parallel conductors of infinite length, of negligible circular cross section, and placed 1 meter apart in vacuum, would produce between these conductors a force equal to 2×10^{-7} newton per meter of length.

The volt (V) is the unit of potential difference and of electromotive force. It is defined as the potential difference between two points of a conducting wire carrying a constant current of 1 ampere when the power dissipated between these points is equal to 1 watt. From the ampere and the volt, the ohm is derived by Ohm's law, and the other derived quantities follow in a similar manner by the application of known physical laws. *See* OHM'S LAW.

The remaining units of electrical and magnetic quantities are:

Coulomb (C): The unit of electric charge, equal to 1 ampere-second. The coulomb is the quantity of electricity carried in 1 second by a current of 1 ampere.

Farad (F): The unit of capacitance, equal to 1 coulomb per volt. The farad is the capacitance of a capacitor between the plates of which there appears a potential difference of 1 volt when it is charged by a quantity of electricity of 1 coulomb.

Henry (H): The unit of inductance, equal to 1 weber per ampere. The henry is the inductance of a closed circuit in which an electromotive force of 1 volt is produced when the electric current in the circuit varies uniformly at the rate of 1 ampere per second.

Ohm (Ω): The unit of electrical resistance, equal to 1 volt per ampere. The ohm is defined as the resistance between two points of a conductor when a constant potential difference of 1 volt, applied to these points, produces in the conductor a current of 1 ampere, the conductor not being the seat of any electromotive force.

Siemens (S): The unit of electrical conductance (the reciprocal of resistance), equal to 1 ampere per volt. It was formerly known as the mho.

Tesla (T): The unit of magnetic flux density, equal to 1 weber per square meter.

Weber (Wb): The unit of magnetic flux, equal to 1 volt-second. The weber is the magnetic flux which, linking a circuit of one turn, would produce in it an electromotive force of 1 volt if it were reduced to zero at a uniform rate in 1 second.

The mechanical units of frequency (hertz), energy or work (joule), and power (watt) are frequently involved in expressing electrical and magnetic quantities. The cgs units, such as the gauss, gilbert, maxwell, and oersted, formerly used, are not part of the SI and are now obsolete. *See* UNITS OF MEASUREMENT.

Electrical standards. Realization of the values of the electrical and other units from their SI definitions involves great experimental difficulties. For this reason, it is customary for national standards laboratories to maintain stable primary standards of the units against which other reference standards can be compared. From time to time, absolute determinations of the values of these primary standards are made in terms of their definitions. By the late 1980s, the Josephson effect and the quantum Hall effect had made possible the standardization of the volt and the ohm by relation to fundamental physical constants. The recommendation by the CCE of the values to be adopted for these constants in 1990 led to a complete change in primary electrical standards and the method of handling them; and all the major national laboratories, and the BIPM, now use this method. *See* FUNDAMENTAL CONSTANTS; HALL EFFECT; JOSEPHSON EFFECT.

For many years the primary standards maintained by most laboratories were the volt, in terms of the mean electromotive force of a group of Weston cells, and the ohm, using a group of standard resistors. A range of reference standards of other quantities are derived from these, including direct-current (dc) voltage and resistance at a variety of levels; alternating-current (ac) voltage, resistance, and power; capacitance and inductance; radio-frequency (rf) and microwave quantities; magnetic quantities and properties of materials; dielectric properties; and other quantities. These secondary standards are used for day-to-day measurements and for the calibration of local reference standards of other users in the national measurement system. *See* CAPACITANCE MEASUREMENT; ELECTRIC POWER MEASUREMENT; INDUCTANCE MEASUREMENT; MAGNETIC MATERIALS; MICROWAVE MEASUREMENTS; PERMITTIVITY; RESISTANCE MEASUREMENT; VOLTAGE MEASUREMENT.

[A.E.Ba.]

Electricity Physical phenomena involving electric charges, their motions, and their effects. The motion of a charge is affected by its interaction with the electric field and, for a moving charge, the magnetic field. The electric field acting on a charge arises from the presence of other charges and from a time-varying magnetic field. The magnetic field acting on a moving charge arises from the motion of other charges and from a time-varying electric field. Thus electricity and magnetism are ultimately inextricably linked. In many cases, however, one aspect may dominate, and the separation is meaningful. *See* ELECTRIC CHARGE; ELECTRIC FIELD; MAGNETISM.

The quantitative development of electricity began late in the eighteenth century. J. B. Priestley in 1767 and C. A. Coulomb in 1785 discovered independently the inverse-square law for stationary charges. This law serves as a foundation for electrostatics. *See* COULOMB'S LAW; ELECTROSTATICS.

In 1800 A. Volta constructed and experimented with the voltaic pile, the predecessor of modern batteries. It provided the first continuous source of electricity. In 1820 H. C. Oersted demonstrated magnetic effects arising from electric currents. The production of induced electric currents by changing magnetic fields was demonstrated by M. Faraday in 1831. In 1851 he also proposed giving physical reality to the concept of lines of force. This was the first step in the direction of shifting the emphasis away from the charges and onto the associated fields. *See* ELECTROMAGNETIC INDUCTION; ELECTROMAGNETISM; LINES OF FORCE.

In 1865 J. C. Maxwell presented his mathematical theory of the electromagnetic field. This theory, which proposed a continuous electric fluid, not only synthesized a unified theory of electricity and magnetism, but also showed optics to be a branch of electromagnetism. *See* ELECTROMAGNETIC RADIATION; MAXWELL'S EQUATIONS.

The developments of theories about electricity subsequent to Maxwell have all been concerned with the microscopic realm. Faraday's experiments on electrolysis in 1833 had indicated a natural unit of electric charge, thus pointing toward a discrete rather than continuous charge. The existence of electrons, negatively charged particles, was postulated by A. Lorenz in 1895 and demonstrated by J. J. Thomson in 1897. The existence of positively charged particles (protons) was shown shortly afterward (1898) by W. Wien. Since that time, many particles have been found having charges numerically equal to that of the electron. The question of the fundamental nature of these particles remains unsolved, but the concept of a single elementary charge unit is apparently still valid. *See* BARYON; ELECTROLYSIS; ELECTRON; ELEMENTARY PARTICLE; HYPERON; MESON; PROTON; QUARKS.

The sources of electricity in modern technology depend strongly on the application for which they are intended.

The principal use of static electricity today is in the production of high electric fields. Such fields are used in industry for testing the ability of components such as insulators and condensers to withstand high voltages, and as accelerating fields for charged-particle accelerators. The principal source of such fields today is the Van de Graaff generator. *See* PARTICLE ACCELERATOR.

The major use of electricity arises in devices using direct current and low-frequency alternating current. The use of alternating current, introduced by S. Z. de Ferranti in 1885–1890, allows power transmission over long distances at very high voltages with a resulting low-percentage power loss followed by highly efficient conversion to lower voltages for the consumer through the use of transformers. *See* ALTERNATING CURRENT; ELECTRIC CURRENT.

Large amounts of direct current are used in the electrodeposition of metals, both in plating and in metal production, for example, in the reduction of aluminum ore. *See* DIRECT CURRENT; ELECTROCHEMISTRY; ELECTROMETALLURGY; ELECTROPLATING OF METALS.

The principal sources of low-frequency electricity are generators based on the motion of a conducting medium through a magnetic field. The moving charges interact with the magnetic field to give a charge motion that is normal to both the direction of motion and the magnetic field. In the most common form, conducting wire coils rotate in an applied magnetic field. The rotational power is derived from a water-driven turbine in the case of hydroelectric generation, or from a gas-driven turbine or reciprocating engine in other cases. *See* ALTERNATING-CURRENT GENERATOR; DIRECT-CURRENT GENERATOR; ELECTRIC POWER GENERATION; GENERATOR.

Many high-frequency devices, such as communications equipment, television, and radar, involve the consumption of only moderate amounts of power, generally derived from low-frequency sources. If the power requirements are moderate and portability is needed, the use of ordinary chemical batteries is possible. Ion-permeable membrane batteries are a later development in this line. Fuel cells, particularly hydrogen-oxygen systems, are being developed. They have already found extensive application in earth satellite and other space systems. The successful use of thermoelectric generators based on the Seebeck effect in semiconductors has been reported. *See* BATTERY; FUEL CELL; ION-SELECTIVE MEMBRANES AND ELECTRODES; THERMOELECTRIC POWER GENERATOR; THERMOELECTRICITY.

The solar battery, also a semiconductor device, has been used to provide charging current for storage batteries in telephone service and in communications equipment in artificial satellites. *See* SOLAR CELL.

Direct conversion of mechanical energy into electrical energy is possible by utilizing the phenomena of piezoelectricity and magnetostriction. These have some application in acoustics and stress measurements. Pyroelectricity is a thermodynamic corollary of piezoelectricity. *See* MAGNETOSTRICTION; PIEZOELECTRICITY; PYROELECTRICITY. [W.Ar.]

Electrochemical equivalent

The mass of a substance, according to Faraday's law, produced or consumed by electrolysis with 100% current efficiency during the flow of a quantity of electricity equal to 1 faraday or 96,487 coulombs (1 coulomb corresponds to a current of 1 ampere during 1 second). Electrochemical equivalents are essential in the calculation of the current efficiency of an electrode process.

The electrochemical equivalent of a substance is equal to the gram-atomic or gram-molecular mass of this substance divided by the number of electrons involved in the electrode reaction. For example, the electrochemical equivalent of zinc, for which two electrons are required in order to deposit one atom, is Zn/2 or 65.37/2 g. Thus, the faraday is equal to the product of the charge of the electron times the number of electrons (the Avogadro number) required to react with 1 atom- or molecule-equivalent of substance. *See* COULOMETER; ELECTROLYSIS. [P.De.]

Electrochemical process

The principles of electrochemistry may be adapted for use in the preparation of commercially important quantities of certain substances, both inorganic and organic in nature. *See* ELECTROCHEMISTRY.

Inorganic processes. Inorganic chemical processes can be classified as electrolytic, electrothermic, and miscellaneous processes including electric discharge through gases and separation by electrical means. In electrolytic processes, chemical and electrical energy are interchanged. Current passed through an electrolytic cell causes chemical reactions at the electrodes. Voltaic cells convert chemicals into electricity. Electrothermic processes use electricity to attain the necessary temperature for reaction. For related information *see* ELECTROCHEMISTRY; ELECTROLYSIS; ELECTROLYTIC CONDUCTANCE; ELECTROMOTIVE FORCE (CELLS).

Electrolysis in aqueous solutions. The electrolysis of water to form hydrogen and oxygen, according to the reaction $2H_2O \rightarrow 2H_2 + O_2$, may be considered as the simplest process for aqueous electrolytes. It does not compete with hydrogen from propane or from natural gas and with oxygen from liquid air, except in small installations. While simplicity, high hydrogen purity requirement, and lower capital cost (in small plants) have justified electrolytic plants, severely rising energy costs have limited such applications. Heavy water, or deuterium oxide, used in moderating nuclear reactors is also a by-product of the electrolysis of water. *See* DEUTERIUM; HEAVY WATER; HYDROGEN; OXYGEN.

Metallurgical applications. Protective or decorative coatings on a base metal such as steel are obtained by electroplating. Plating may also be used to replace worn metal or to provide a wear-resistant surface. Electrogalvanizing is preferred over hot dipping for applying zinc to steel. Tin plate for containers is electrolytic. *See* ELECTROPLATING OF METALS; METAL COATINGS.

Electroforming is a method of forming or reproducing articles by electrodeposition. In contrast to electroplating, the product is removed from the base surface or mold. Electrodeposition of metal powders is used to produce particles in the 1- to 1000-micrometer range for use in powder metallurgy and metallic pigments. Electrolytic polishing of metals is accomplished by making the article anodic in an electrolyte of mixed acids. Electrolytic machining of metals is accomplished by making the metal part anodic in a suitable electrolyte. Electrorefining is a process for purifying metals and recovering their impurities, which at times are more valuable than the original metal. Electrowinning, sometimes termed aqueous electrometallurgy, involves processing of metallic ores by leaching solutions to obtain metal-containing electrolytes which can be processed with insoluble anodes and metal cathodes. *See* ELECTROMETALLURGY; ELECTROPOLISHING.

Alkali-chlorine processes. Electrolysis of alkali halides is the basis of the alkali-chlorine and chlorate industries. Chlorine, Cl_2, and caustic soda, NaOH (or caustic potash, KOH), are made by electrolysis of brine, a solution of sodium chloride, NaCl, in water. Hydrochloric acid electrolysis is of interest for recovery of chlorine from HCl resulting as a by-product from organic chlorinations. *See* CHLORINE.

Oxidations and reductions. These reactions occur in all cells, but in a narrower sense oxidation reactions are those in which oxygen or chlorine at the anode oxidizes some material to form a new compound; reduction reactions are those in which hydrogen, liberated at the cathode, reduces a material to a new product. There are no commercial applications of inorganic electrochemical reductions by this narrow definition.

Ion-permeable membrane cells. These utilize diaphragms made of ion-exchange resins. Cation-permeable membranes permit cations to pass through but not anions, whereas the reverse holds for anion-permeable membranes. Purification of sea water is the most important application. Salt has been recovered from sea water which has been concentrated in this way. *See* ION-SELECTIVE MEMBRANES AND ELECTRODES.

Fused-salt electrolysis. Aluminum, barium, beryllium, cerium and misch metal, fluorine, lithium, magnesium, sodium, molybdenum, thorium, titanium, uranium, and zirconium are obtained by electrolysis of fused salts, because water interferes with the desired reaction. Raw materials must all be purified before addition to fused-salt cells, because purification of the electrolyte is not economical as in aqueous electrolytes. Metallizing is a process of depositing a metal as an alloy on a substrate from a fused complex metal salt.

Electrothermics. The manufacture of many products requires temperatures higher than can be obtained by combustion methods. Electric heat can usually be developed at, or close to, the point where it is required, so that it is relatively quick. It permits easy control of the atmosphere for oxidizing, reducing, or neutral conditions.

Products of the electric furnace include iron and steel; ferroalloys; nonferrous metals and alloys; the exotic metals titanium, zirconium, hafnium, thorium, and uranium; and nonmetallic products such as calcium carbide, calcium cyanamide, sodium cyanide, silicon carbide, boron carbide, and graphite. *See* ELECTRIC FURNACE; PYROMETALLURGY.

Zone refining of metals for the electronics industry, such as silicon for diodes and transistors, is accomplished by induction melting of the metal in a narrow zone and slow movement of the molten zone in the metal ingot from one end to the other in an evacuated or inert gas–filled enclosure. Impurities move toward the end of the ingot. The operation is repeated until the desired purity is obtained. *See* ZONE REFINING.

Electrodialysis. This is the separation of low-molecular-weight electrolytes from aqueous solutions by migration of the electrolyte through semipermeable membranes in an electric field. It is used on an industrial scale for deashing starch hydrolyzates and whey, and in many municipalities for producing potable water from saline water. Its uses also include the concentration of liquid foods such as dairy products and citrus juices, the recovery of sulfite pulp waste and pickling acid, and the isolation of proteins. *See* Colloid; Dialysis.

Electrophoretic deposition. This is the deposition of a nonconductive material in a finely divided state from a suspension in an inert medium. Electrophoresis is the migration of colloidal particles, which acquire positive or negative charges in an electric field. The process is useful in electropainting; for instance, electropainting of automobile bodies and other objects has now been adopted on a large scale. Rubber latex is an example of a negatively charged colloid which can be plated on an anode. Electronic components can be coated with inorganic salts, oxides, and ceramics suspended in organic media. *See* Electrophoresis.

Electroendosmosis. This is the movement of a liquid with respect to an immobilized colloid in an electric field. The process is used in the dehydration of peat, dye pastes, and clay. It is also used commercially for dewatering soils in mining, road building construction, and other civil engineering works.

Electrostatic technique. The deposition of charged particles from suspension in gases has many useful applications. The Cottrell electrostatic precipitator removes dusts and mists from gases. *See* Dust and mist collection; Electrostatic precipitator.

Spray painting with a high voltage between the spray gun and the work is particularly effective in providing an even coating with an economical use of paint on irregular and open surfaces, such as a screen.

In xerography a sheet of plain paper is electrically sensitized in those areas corresponding to an original so that colored resin particles carrying an opposite charge are attracted and retained only on the sensitized areas, thus producing a visible image corresponding to the original.

Abrasive paper and cloth are coated with an adhesive and abrasive powders attracted to the base material in an electrostatic field. Pile fabrics can be produced in a similar manner, with the short fibers oriented by the electric field.

Organic processes. Organic electrochemistry was once regarded as a tantalizing area with many important laboratory achievements but few successes in commercial practice. This situation is changing, however, in that electroorganic processes are likely to prove commercially advantageous if they can fulfill either of two conditions: (1) performance under conditions of voltage corresponding thermodynamically to the conversion of an organic group to a reduced or oxidized group, with the cell products relatively easy to isolate and purify; (2) performance of a highly selective, specific technique to make an addition at a double bond, or to split a particular bond (for example, between carbon atoms 17 and 18 of a complex molecule having 25 carbon atoms).

Selectivity and specificity are highly important in electroorganic processes for the manufacture of complicated molecules of vitamins and hormones—as well as for the medicinal products whose action on pathogenic organisms is a function of their spatial arrangement, steric forms, and resonance.

The electrolytic approach can also be competitive for some low-cost, tonnage products. Here continuous processing is important, and only a single phase should be present, that is, a solution rather than an emulsion, dispersion, or mechanical mixture. Only for fairly valuable products is it practical to find a conducting solvent and then to engineer around it.

The electrolytic oxidation and reduction of organic compounds differ from the corresponding and more familiar inorganic reactions only in that organic reactions tend to be more complex and have low yields. The electrochemical principles are precisely those of inorganic reactions, while the procedures for handling the chemicals are precisely those of organic chemistry. [C.L.M.]

Electrochemical series A series in which the metals are listed in the order of their chemical reactivity, the most active at the top and the less reactive or more "noble" metals at the bottom. In a broader sense such an activity series need not be limited to the metals but may be carried on through the electronegative (nonmetallic) elements as well. *See* the table for a list of common elements.

Electrochemical series of the elements*

Lithium	Li
Potassium	K
Rubidium	Rb
Cesium	Cs
Radium	Ra
Barium	Ba
Strontium	Sr
Calcium	Ca
Sodium	Na
Lanthanum	La
Cerium	Ce
Magnesium	Mg
Scandium	Sc
Plutonium	Pu
Thorium	Th
Beryllium	Be
Uranium	U
Hafnium	Hf
Aluminum	Al
Titanium	Ti
Zirconium	Zr
Manganese	Mn
Vanadium	V
Niobium	Nb
Boron	B
Silicon	Si
Tantalum	Ta
Zinc	Zn
Chromium	Cr
Gallium	Ga
Iron	Fe
Cadmium	Cd
Indium	In
Thallium	Tl
Cobalt	Co
Nickel	Ni
Molybdenum	Mo
Tin	Sn
Lead	Pb
Germanium	Ge
Tungsten	W
Hydrogen	**H**
Copper	Cu
Mercury	Hg
Silver	Ag
Gold	Au
Rhodium	Rh
Platinum	Pt
Palladium	Pd
Bromine	Br
Chlorine	Cl
Oxygen	O
Fluorine	F

*According to standard oxidation potentials E° at 25°C (77°F).

The electrochemical series as it applies to metals was first established by laboratory experiments in which the purpose was to determine which metals would displace others from solutions of their salts. By exhaustive experiments it becomes possible to draw up a complete list in the order of chemical activity, in which the metals at the top of the list are those which are found to give up their electrons most readily (that is, are the most electropositive elements). Such a list is shown in the table, where lithium exhibits the most reactivity as a metal.

To obtain an accurate and reproducible activity series, it is best to use the electrode potential, or oxidation-reduction potential, which is defined as the voltage developed by a sample of pure metal immersed in a solution of one of its salts (at unit activity and at 25°C or 77°F) versus a hydrogen electrode immersed in hydrochloric or sulfuric acid of equivalent concentration. *See* Electrochemistry; Electrode potential; Electronegativity; Oxidation-reduction. [E.G.Ro.]

Electrochemical techniques Experimental methods developed to study the physical and chemical phenomena associated with electron transfer at the interface of an electrode and solution. The objective is to obtain either analytical or fundamental information regarding electroactive species in solution. Fundamental electrode characteristics may be investigated also.

The physical and chemical phenomena important in electrode processes generally occur very close to the electrode surface (usually within a few micrometers). Mass transfer of species involved in an electrode process to and from the bulk of solution is one important aspect. Inclusion of a large excess of inert electrolyte in most electrochemical systems eliminates electrical migration as an important means of mass transfer for electroactive species, and only convection and diffusion are considered.

Important chemical aspects of electrode processes include the oxidation or reduction occurring as a result of electron transfer, and coupled chemical reactions. Coupled reactions are initiated by production or depletion of the primary products or reactants at the electrode surface. Identification of the nature and mechanism of such coupled reactions is of particular importance in studies of electrode reactions of organic compounds, where multireaction cascades are often found to be initiated by electron transfer to or from an electrode.

The primary experimental variables involved in electrochemical techniques are the potential E, the current I, and the time t. Either the potential or current at the working electrode is controlled and the other observed as a function of time. The many ways in which either may be controlled give rise to a wide variety of controlled-potential or controlled-current techniques. In all such techniques it is necessary to specify whether mass transport of the electroactive species to the electrode is by convection or diffusion, since mathematical treatments of these two processes are quite different. Mass transport by convection is more efficient than diffusion by several orders of magnitude but is much more difficult to model mathematically.

The general scheme for electron transfer at an electrode in solution is shown in reaction (1), where O and R are the oxidized

$$O + ne^- \underset{k_b}{\overset{k_f}{\rightleftharpoons}} R \tag{1}$$

and reduced forms of the electroactive species and n is the number of electrons transferred. When k_f and k_b, the rate constants for the forward and back reaction, respectively, are very fast and O and R are not involved in preceding or following chemical reactions, the system is called reversible and the Nernst equation (2) holds. In this relation E is the electrode potential, $E^{\circ\prime}$ is the

$$E = E^{\circ\prime} + \frac{0.059}{n} \log \frac{C_O}{C_R} \tag{2}$$

formal standard potential for the redox couple, and C_O and C_R are concentrations at the electrode surface. In the following discussions, only reversible reduction processes will be considered, although oxidations are equally applicable. *See* ELECTROCHEMICAL PROCESS; ELECTRODE; ELECTRODE POTENTIAL; ELECTROLYSIS.

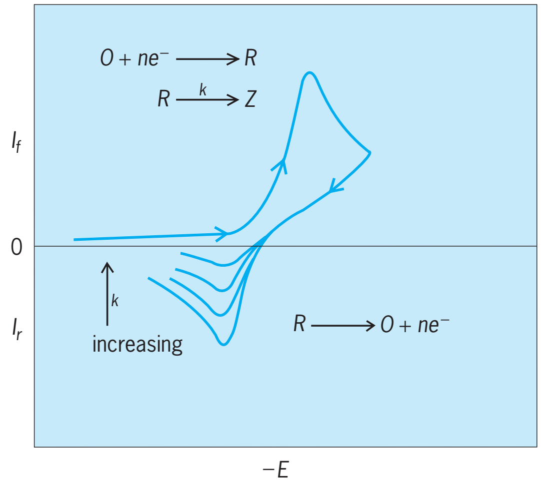
Controlled potential. A variety of methods of this type have been developed, depending on whether the electrode potential is held constant or varied during the experiment and on whether mass transport is by convection (stirring) or diffusion.

In constant potential with convection, known as controlled potential electrolysis, the electrode potential is held constant as the solution is stirred or the electrode is rotated at a constant rate. The current is controlled by the concentration of electroactive substance and the stirring rate. Complete conversion of the electroactive substance takes place at a first-order rate whose constant is determined by cell geometry and stirring efficiency. Under ideal circumstances, electrolysis is complete in a manner of minutes.

In constant potential with diffusion (chronoamperometry), when a reducing potential is imposed instantaneously on a stationary working electrode in quiescent solution, current will rise sharply and then decay as the electroactive species in the electrode vicinity is depleted by electrolysis. The magnitude of the current is proportional to the bulk concentration of electroactive species, and if the imposed potential is sufficiently negative of $E^{\circ\prime}$, the Nernst equation demands complete conversion to the reduced form. Under these conditions the current for this so-called potential-step experiment is diffusion-controlled and decays with $1/t^{1/2}$.

An important variant on this experiment is double-potential-step chronoamperometry, in which a second potential step is applied. During the initial step, electrolysis occurs, depleting the oxidized form O, but producing the reduced form R in the immediate vicinity of the electrode. If the potential is instantaneously switched back to the initial value after a time τ, species R will be reoxidized. A wide dynamic range of rate constants can be measured by varying τ.

Variable potential. Several procedures have been developed in this area. In linear sweep voltammetry (LSV), the potential of a stationary electrode in quiescent solution is varied by applying a linear voltage ramp to the electrode. The resulting signal is recorded as a plot of current versus potential.



Current-voltage curves in cyclic voltammetry.

The most widely used electrochemical technique is cyclic voltammetry, which bears the same relation to linear sweep voltammetry as double-potential-step chronoamperometry does to the single-step experiment. That is, at the end of the first linear ramp, the potential is swept linearly back to the initial potential. Typical cyclic voltammograms are shown in illustration for the case of reduction of O to R and subsequent decomposition of R to Z. The illustration shows a series of cyclic voltammograms corresponding to different values of the rate constant k. As in the double-step experiment, the appearance of the forward sweep is unaffected by the coupled chemical process. However, as k increases, the height of the peak on the reverse sweep due to reoxidation of R decreases. Sweep rates may be varied over a range of roughly 10^{-2} to 10^{2} V/s in conventional cyclic voltammetry. With proper experimental design this may be extended considerably, as high as 10^{5} V/s or greater by using microelectrodes (electrodes with diameters in the micrometer range).

Controlled current. Controlled current techniques, although easier to implement than those in which the potential is controlled, are not as selective and therefore have fallen out of favor in recent years. In chronopotentiometry, a constant current is imposed at the working electrode, and its potential is monitored with time. Coulostatic analysis involves application of a very large, short pulse of current to the electrode, after which the cell circuit is opened. The current pulse charges up the electrode-solution interface to a new potential, and the electrode discharges, and returns to its original potential, by reducing the electroactive species in solution. [A.J.Fr.]

Electrochemistry The science dealing with the chemical changes accompanying the passage of an electric current, or the reverse process in which a chemical reaction is used as the source of energy to produce an electric current, as in a battery. Ionic conduction in electrolytes (liquid solutions, molten salts, and certain ionically conductive solids) is a phase of electrochemistry. Conduction in metals, semiconductors, and gases is generally considered a portion of physics. Other aspects of electrochemistry are described below. *See* ELECTROLYTIC CONDUCTANCE.

Galvanic cells. These are better known as electric batteries. Many chemical reactions can be arranged to produce electrical energy by physically separating the reaction into two half-reactions, one supplying electrons to an electrode forming the negative terminal of the cell, and the other removing the electrons from the positive terminal. *See* BATTERY; FUEL CELL.

Electrodeposition. The most important type of chemical reaction brought about by the passage of electric current is the deposition of a metal at a cathode from a solution of its ions. Electroforming is a variety of electrodeposition in which an article to be reproduced is rendered conductive by spraying a thin metallic coating, then electroplated with a metallic deposit that is stripped from its substrate and filled with backing to reproduce the original article. Electrowinning is used for the commercial production of active metals, such as aluminum, magnesium, and sodium, from molten salts and others, such as copper, manganese, and antimony, from aqueous solution. Electrorefining is commonly used to purify metals such as silver, lead, and copper. The impure metal is used as the anode, and purified metal is deposited at the cathode. *See* ELECTROPLATING OF METALS.

Electrolytic processes. Many electrode reactions other than metal deposition are of commercial or scientific use. Electrolysis of brine to yield chlorine at the anode, hydrogen at the cathode, and sodium hydroxide in the electrolyte is an important industrial process. Many organic compounds can be prepared electrolytically. *See* ELECTROLYSIS.

Electroanalytical chemistry. Many electrochemical measurements are useful for analytical purposes. Electrodes that are commonly used for analytical purposes through measurement of their potentials include the glass electrode for pH measurements, and ion-selective electrodes for certain ions, such as sodium or potassium ion (special glass compositions), calcium ion (liquid membrane), and fluoride ion (doped lanthanum fluoride single crystals). Polarography involves the use of a dropping mercury electrode as one electrode of an electrolytic cell. Qualitative analysis is carried out by measurement of characteristic potentials (half-wave potentials) for electrode processes, and quantitative analysis by measurement of diffusion-controlled currents. Coulometry involves the application of Faraday's law for analytical purposes.

Other analytical applications of electrochemistry include chronopotentiometry (measurement of potential-time transients under constant current conditions), and linear sweep and cyclic voltammetry (measurement of currents with linear voltage scan). Several titration methods involve electrochemical measurements, for example, conductometric, potentiometric, and amperometric titrations. *See* POLAROGRAPHIC ANALYSIS; TITRATION.

Miscellaneous phenomena. Electrochemical transport of ions through synthetic or natural membranes is important for processes, such as desalination of water and electrodialysis. In biological systems, the transmittal of nerve impulses and the generation of electrical signals, such as brain waves, are basically of electrochemical origin. A set of related phenomena can be grouped together under electrokinetic behavior, including the motion of colloidal particles in an electric field (electrophoresis), the motion of the liquid phase relative to a stationary solid under the influence of a potential gradient (electroosmosis), and the inverse generation of a potential gradient caused by a flowing liquid (streaming potential). Alternating-current phenomena, such as dielectric behavior, double-layer charging, and faradaic rectification, may also be included in a general definition of electrochemistry. Corrosion and passivation of metals are electrochemical in nature. [H.A.L.]

Organic electrochemistry. Organic electrochemistry involves the study of the chemical reactions that take place when an electric current is passed through a solution containing one or more organic compounds. It is a highly interdisciplinary science. Understanding and fully developing a given organic electrochemical reaction may involve techniques of synthesis, purification, and identification of organic compounds, as well as theory and practice of a variety of sophisticated electroanalytical techniques, surface science, cell design, electronics, engineering scaleup, and materials modification. Organic electrochemistry has been of increasing interest for industrial applications in recent years because the costs of electrochemistry have been rising more slowly than the costs of conventional chemical reagents, and because electrochemical procedures can be environmentally less intrusive than other chemical processes. A number of so-called fine chemicals are made electrochemically on a scale ranging from several kilograms to several tons per day. A few chemicals are made on much larger scale; the best known is adiponitrile [$NC(CH_2)_4CN$], a key intermediate in the synthesis of nylon. *See* ORGANIC CONDUCTOR.

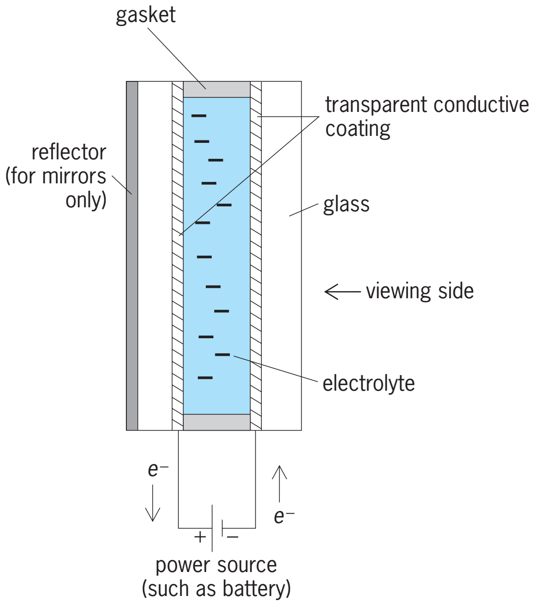
Cathodic organic reactions fall into several categories: cleavage of single bonds, reduction of functional groups, and reduction of large conjugated systems such as activated alkenes and aromatic compounds. Anodic reactions are equally diverse. The oldest and best-known anodic reaction is the Kolbe reaction, in which electrochemical oxidation of carboxylate ions yields dimeric products with evolution of carbon dioxide. A wide range of functional groups can be accommodated in this versatile reaction.

The powerful yet precisely controllable oxidizing and reducing conditions that can be achieved electrochemically are useful for generating novel organic intermediates, including carbocations, carbanions, radicals, radical ions, carbenes, nitrenes, and arynes. These reactive intermediates are frequently trapped by other organic substances added to the medium to extend the synthetic utility of an electrode reaction.

Voltammetric methods are commonly used to provide detailed mechanistic information. In these, the electrode potential is varied in a controlled fashion in the vicinity of the redox potential of the substrate, and the current response is measured as a function of experimental variables such as scan rate, concentration, and added reagents. Other methods include identification of the products from a preparative electrolysis (generally carried out at controlled potential in mechanistic experiments); coulometry, or measurement of the actual amount of current passed in the electrolysis; comparison of experimental responses with computer simulations of the theoretical behavior for various mechanisms; studies of changes in the structure of the electrode surface during electrolysis; and spectroscopic identification of intermediates. Microelectrodes, which have micrometer diameters, extend the speeds with which electrochemical measurements can be made, and thus permit measurement of even very fast rates of chemical reactions associated with electron transfers at electrodes. *See* REACTIVE INTERMEDIATES. [A.J.Fr.]

Electrochromic devices Self-contained, hermetically sealed, two-electrode electrolytic cells that change their ability to transmit (or reflect) light in response to a small bias (typically 1–2 V) applied across the two electrodes. The operation of electrochromic devices relies upon their electrochromic material content. These materials are organic or inorganic substances that are able to interconvert between two or more color states upon oxidation or reduction, that is, upon electrolytic loss or gain of electrons. The electrochromic materials that are appropriate for most practical applications are strong light absorbers in one redox state but colorless in another.

A typical electrochromic device is a sandwichlike structure with two glass plates and an electrolyte (see illustration). Each glass plate is coated on the inside with a transparent electrically conducting layer of indium-tin oxide, which operates as an electrode. Electrochromic mirrors include an additional reflective coating (for example, aluminum) on the outside of one of the glass plates. The electrolyte carries the ionic current inside the cell between the two electrodes, and it can be as simple as a salt (for example, sodium chloride, NaCl) dissolved in a dissociating solvent such as water. However, development has focused on gel and solid electrolytes, because they offer several advantages: they are easier to confine in the space between the electrodes; they function as laminators holding the two glass plates together; and their use minimizes the hydrostatic pressure that can cause substrate deformation and leakage problems, particularly in large-area devices such as smart windows.



Electrochromic device. The electrochromic materials can be either dissolved in the electrolyte or coated on the transparent electrodes.

State-of-the-technology electrochromic devices utilize two electrochromic materials with complementary properties: the first electrochromic material is normally reduced (ECM_1^{red}) and undergoes a colorless-to-colored transition upon oxidation (loss of electrons), while the second electrochromic material is normally oxidized (ECM_2^{ox}) and undergoes a similar transition upon reduction (gain of electrons). The electrochromic materials ECM_1^{red} and ECM_2^{ox} are selected so that they do not react with each other. The oxidation of ECM_1^{red} and the reduction of ECM_2^{ox} then are forced by the external power source (see illustration), which operates as an electron pump consuming energy in order to transfer electrons from one electrode to the other. Oxidation of ECM_1^{red} occurs at the positive electrode (anode) and is a source of electrons, while reduction of ECM_2^{ox} occurs at the negative electrode (cathode) and is a sink of electrons. This approach, known as complementary counterelectrode technology, has two distinct advantages. First, the long-term operating stability of the electrochromic cell is greatly enhanced, because providing both a source and a complementary sink of electrons within the same cell prevents any electrolytic decomposition of the electrolyte. Second, the reinforcing effect of two electrochromic materials changing color simultaneously enhances the contrast difference between the color states per unit charge consumed. Depending on the location of the two electrochromic materials within the electrochromic devices, three main types of such devices exist: solution, precipitation, and thin-film. *See* ELECTRODE; ELECTROLYTE; OXIDATION-REDUCTION.

Electrochromic devices are analogous to liquid-crystal devices in that they do not generate their own light but modulate the ambient light. Liquid-crystal devices require use of polarizers; consequently, their viewing angle is limited, and lateral size limitations are imposed because the spacing between the electrodes (thickness) must be controlled within a few micrometers over the entire device area. Electrochromic devices do not require polarizers, thereby allowing a viewing angle approaching 180°, and contrast ratios similar to black ink on white paper (20:1 or better); moreover, control of the thickness is not important. Other desirable features of electrochromic devices include inherent color, continuous gray scale, and low average power consumption for the thin-film-type devices. Furthermore, it has been shown that electrochromic thin films can be patterned with a 2–5-μm resolution to form a large number of display elements that can be matrix-addressed. Nevertheless, even though there is no apparent intrinsic limitation, the best cycling lifetimes claimed for electrochromic materials are of the order of 10–20 million cycles, while the lifetime of liquid-crystal devices is of the order of several hundred million cycles. This long lifetime has made liquid-crystal devices a very successful technology in matrix-addressed, flat-panel displays.

The larger tolerance in thickness variation for electrochromic devices renders them better suited than liquid-crystal devices for large-area light modulation applications, such as smart windows, space dividers, and smart mirrors. Another possible application is in large-area displays that do not need frequent refreshing, such as signs and announcement boards. Reconfigurable optical recording devices (for example, disks) have been proposed as a high-resolution application that is within the presently available lifetimes of electrochromic materials. *See* ELECTROCHEMICAL PROCESS; ELECTROCHEMISTRY; ELECTRONIC DISPLAY; ELECTROOPTICS; LIQUID CRYSTALS. [N.Le.]

Electroconvulsive therapy The technique of eliciting convulsions by applying an electric current through the brain of a human or an experimental animal for a brief period. Low current produces clonic (rapidly alternating muscle contraction and relaxation) convulsions, while high current produces tonic (steady muscle contraction) convulsions followed by clonic convulsions. Tonic convulsions cause loss of consciousness for a brief period. In the early 1930s drug-induced convulsions were used as treatment for mental disorders. In 1938 M. Cerletti and L. Bini introduced electroconvulsive therapy (ECT) treatments as a more convenient and reliable procedure. ECT subsequently replaced convulsive drugs and is still used in some circumstances as a treatment for severe mental depression. The bases of the effectiveness of ECT as a clinical treatment are not known. [J.L.McG.]

Electrode An electrical conductor through which an electric current enters or leaves a conducting medium, whether it be an electrolytic solution, solid, molten mass, gas, or vacuum. For electrolytic solutions, many solids, and molten masses, an electrode is an electric conductor at the surface of which a change occurs from conduction by electrons to conduction by ions. For gases and vacuum, the electrodes merely serve to conduct electricity to and from the medium. *See* ELECTRODE POTENTIAL; ELECTROLYSIS; ELECTROMOTIVE FORCE (CELLS). [W.J.H.]

Electrode potential The equilibrium potential difference between two conducting phases in contact, most often an electronic conductor such as a metal or semiconductor on the one hand, and an ionic conductor such as an electrolyte solution (a solution containing ions) on the other. Electrode potentials are not experimentally accessible, but the differences in potential between two electronic conductors making contact with the same ionic conductor (that is, the difference between two electrode potentials) can be measured. A useful scale of electrode potentials can therefore be obtained when a particular electrode potential is set equal to zero by definition. There are several conventions, based on different definitions of the zero point on the scale of electrode potential, but all tables use the so-called standard hydrogen convention. *See* ELECTRODE; REFERENCE ELECTRODE.

The interfacial potential difference is usually the consequence of the transfer of some charge carriers from one conducting phase to the other. For example, when a piece of silver, which contains silver ions and free, so-called conduction electrons, is in contact with an aqueous solution of silver nitrate, the only species common to the two phases are the silver ions. Their concentration (volume density) is constant in the metal but variable (from zero to the solubility limit of the silver salt used) in the solution. When more silver ions transfer from the solution to the metal than in the opposite direction, an excess of negatively charged nitrate ions remains in the solution, which therefore acquires a negative charge. However, the metal gains more silver ions than it loses, and therefore acquires a positive charge. Such a charge separation leads to a potential difference across the boundary between the two phases. The continued buildup of such charges makes the potential of the metal more and more positive with respect to that of the solution. This effect in turn leads to electrostatic repulsion of the silver ions in the solution phase immediately adjacent to the metal; these are the very metal ions that are candidates for transfer across the boundary. Consequently, the electrostatic repulsion decreases the tendency of silver ions to move from the solution to the metal, and eventually the process reaches equilibrium, at which point the tendency of ions to transfer is precisely counterbalanced by the repulsion of the candidate ions by the existing potential difference. At that potential, there is no further net transfer of charges between the contacting phases, although individual charges can still exchange across the phase boundary, a process which gives rise to the exchange current.

For a metal in contact with its metal ions of valence z, the potential difference E can be expressed in terms of a standard potential E° (describing the affinity of the metal for its ions) and the concentration c of these ions in solution through the Nernst equation (1), where R is the gas constant, T is the absolute temperature, and F is the Faraday.

$$E = E^\circ + (RT/zF)\ln c \tag{1}$$

When the metal ions in solution form a sparingly soluble salt, the solubility equilibrium can be used to convert a metal electrode responding to its own metal cations (positive ions) into an electrode responding to the concentration of anions (negative ions). Typical examples are the silver/silver chloride electrode, based on the low solubility of silver chloride ($AgCl$), and the calomel electrode, based on the poor solubility of calomel (Hg_2Cl_2).

An equilibrium potential difference between a metal and an electrolyte solution can also be established when the latter contains a redox couple, that is, a pair of chemical components that can be converted into each other by the addition or withdrawal of electrons, by reduction or oxidation respectively. In that case the metal often merely acts as the supplier or acceptor of electrons. When metal electrons are donated to the solution, the oxidized form of the redox couple is reduced; when the metal withdraws electrons from the redox couple, its reduced component is oxidized. Again, the buildup of a charge separation generates a potential difference, which counteracts the electrochemical charge transfer and eventually brings the process to equilibrium, a state in which the rate of oxidation is exactly equal to the rate of reduction. The dependence of the equilibrium electrode potential on the concentrations of c_{ox} and c_{red} of the oxidized and reduced forms respectively is described by a Nernst equation of the form (2), where n denotes the number of electrons

$$E = E^\circ + (RT/nF)\ln(c_{\mathrm{ox}}/c_{\mathrm{red}}) \tag{2}$$

(e^-) transferred between the oxidized species (Ox) and the reduced species (Red) in the reactions $\mathrm{Ox} + \mathrm{n}e^- \rightleftarrows \mathrm{Red}$. A typical example is the reduction of hydrogen ions H^+ to dissolved hydrogen molecules H_2, and vice versa, in which case the reactions are $2H^+ + 2e^- \rightleftarrows H_2$, and for which the Nernst equation is of the form (3).

$$E = E^\circ + (RT/2F)\ln(c_{H^+}^2/c_{H_2}) \tag{3}$$

Redox potentials involving a gas are often established slowly, if at all. For determinations of such a redox potential, platinum is often used as the metal, because it is chemically and electrochemically stable. *See* OXIDATION-REDUCTION.

Electrode potentials can also be established at double phase boundaries, such as that between two aqueous solutions separated by a glass membrane. This glass electrode is commonly used for measurements of the pH, a measure of the acidity or basicity of solutions. The mechanism by which the glass electrode operates involves ion exchange of hydrogen ions at the two glass-solution interfaces. *See* ION EXCHANGE.

In all the above examples, the two contacting phases can have only one type of charge carrier in common. Usually, no equilibrium potential difference is established when more than one type of charge carrier can cross the interface, but often (depending on the nature of the metal and of the chemical components of the solution, and sometimes also depending on the geometry of the contact region) an apparently stable potential can still be obtained, which corresponds to zero net charge transfer. This can be a so-called mixed potential, important in metal corrosion, or a junction potential, which figures in most measurements of electrochemical potentials and usually limits the accuracy and precision of such measurements, including that of the pH. *See* CORROSION.

In determining electrode potentials, there are several complications. In the first place, it follows from thermodynamics that the Nernst equation should be written in terms of activities rather than concentrations. The difference between these two parameters is often small but seldom completely negligible.

Second, measurements of potential differences always involve the potential difference between two metals rather than that between a metal and a solution. Therefore, electrode potentials as defined above cannot be measured either. Because these measurements involve a potential difference, there has been considerable confusion about the definition of that difference; that is, whether it is defined as the potential of the metal minus that of the solution, or the other way around. This is a matter of a sign convention. The problem is usually framed in terms of oxidation potentials versus reduction potentials.

There are four main applications for measurements of electrode potentials: (1) in the establishment of the oxidative and reductive power of redox systems, the so-called electromotive series; (2) as concentration probes, such as in pH measurements; (3) as sources of chemical equilibrium data; and (4) as the primary (or independent) variable in studies of electrode reactions.

[R.DeD.]

Electrodermal response

Electrodermal response A transient change in certain electrical properties of the skin, associated with the sweat gland activity and elicited by any stimulus that evokes an arousal or orienting response. Originally termed the psychogalvanic reflex, this phenomenon became known as the galvanic skin response. Electrodermal response (EDR) has replaced galvanic skin response as the collective term.

The skin of a relaxed person has a low electrical conductance (high resistance), and the skin surface is some 40 mV negative with respect to interior tissues. Sweat gland activity changes these electrical properties by increasing skin conductance and by changing the balance of positive and negative ions in the secreted fluid.

Tonic skin conductance varies with psychological arousal, rising sharply when the subject awakens and rising further with activity, mental effort, or especially stress. Phasic skin conductance responses are wavelike increases in skin conductance that begin 1–2 s after stimulus onset and peak within about 5 s. The amplitude of the skin conductance response varies with the subjective impact of the eliciting stimulus, which in turn varies with the intensity of the stimulus, its novelty or unexpectedness for the subject, and its meaning or signal value. Aroused subjects display spontaneous skin conductance responses, generated apparently by mental events or other internal stimuli; their frequency, like the tonic skin conductance level, increases with the level of arousal.

Electrodermal responses are measured in studies of emotion and stress, conditioning, habituation, and cognitive processing, that is, when it is desired to assess the differential or changing impact of a series of stimuli. *See* ELECTROENCEPHALOGRAPHY; LIE DETECTOR; SYMPATHETIC NERVOUS SYSTEM. [D.T.L.]

Electrodiagnosis Diagnosis employing equipment that can be used clinically to measure the intrinsic electrical activity of the heart (electrocardiography), the brain (electroencephalography), and skeletal muscles (electromyography). Electrodiagnostic procedures depend upon the difference in electrical potential between the interior and external surfaces of living cells. This potential is created by using cellular metabolic energy to maintain the concentration gradient of ions across the cell membrane. A discharge of the electrical potential (depolarization) by stimulation or injury occurs in a wave proceeding from cell to cell. These electrical forces are conducted through the tissues to the surface of the body where electrodiagnostic equipment amplifies and records the changes in potential. *See* ELECTROENCEPHALOGRAPHY; ELECTROMYOGRAPHY.

In a second type of electrodiagnostic procedure, signals elicited by electrical stimulation of a nerve are measured either over a muscle supplied by the nerve or along the nerve itself. A set of diagnostic tests called evoked potentials records the electrical responses of the brain that follow visual or auditory stimuli. [S.Marg.]

Electrodynamics The study of the relations between electrical, magnetic, and mechanical phenomena. This includes considerations of the magnetic fields produced by currents, the electromotive forces induced by changing magnetic fields, the forces on currents in magnetic fields, the propagation of electromagnetic waves, and the behavior of charged particles in electric and magnetic fields. Classical electrodynamics deals with fields and charged particles in the manner first systematically described by J. C. Maxwell, whereas quantum electrodynamics applies the principles of quantum mechanics to electrical and magnetic phenomena. Relativistic electrodynamics is concerned with the behavior of charged particles and fields when the velocities of the particles approach that of light. Cosmic electrodynamics is concerned with electromagnetic phenomena occurring on celestial bodies and in space. *See* ELECTROMAGNETISM; QUANTUM ELECTRODYNAMICS; RELATIVISTIC ELECTRODYNAMICS. [J.W.St.]

Electroencephalography The biomedical technology and science of recording the minute electric currents produced by the brains of human beings and other animals. Electroencephalography (EEG) has important clinical significance for the diagnosis of brain disease. The interpretation of EEG records has become a clinical specialty for neurological diagnosis.

The recording machine, the electroencephalograph, usually produces a 16-channel ink-written record of brain waves, the electroencephalogram. It is interpreted by an electroencephalographer. The placement of about 20 equally spaced electrodes pasted to the surface of the scalp is in accordance with the standard positions adopted by the International Federation of EEG, and is called the 10/20 system. Electrode positions are carefully measured so that subsequent EEGs from the same person can be compared. About 10 patterns or montages of combinations of electrode pairs are selected for transforming the spatial location from the scalp to the channels which are traced on the EEG pen writer.

The aggregate of synchronized neuronal activity from hundreds of thousands or millions of neurons acting together form the electrical patterns on the surface of the brain (brain waves). The cellular basis of the EEG depends on the spontaneous fluctuations of postsynaptic membrane potentials between the inside and the outside of the dendritic processes of postsynaptic cells. *See* SYNAPTIC TRANSMISSION.

Electrical voltage is transduced from the scalp by differential input amplifiers and amplified about a million times in order to drive the pens for the paper record. The recording usually takes 30–60 min during a relaxed waking state, and also during sleep when possible. Often, activating procedures are used, such as a flickering light stimulator and hyperventilation or overbreathing for about 3 min.

EEG waves are defined by form and frequency. Various frequencies are given Greek letter designations. Alpha rhythm is defined as 8–12-Hz sinusoidal rhythmical waves. Alpha waves are normally present during the waking and relaxed state and enhanced by closing the eyes. They are suppressed or desynchronized when the eyes are open, or when the individual is emotionally aroused or doing mental work. They may be synchronized by bright light flashes and driven over a wide range of frequencies by repetitive visual stimulation (alpha driving). They are of highest amplitude in the posterior regions of the brain. The alpha rhythm develops with age, reaching maturity by about 12 years, stabilizes, and then declines in frequency and amplitude in old age (over 65).

Beta rhythms are faster, low-voltage sinusoidal waves, usually about 14–30 Hz. They are more prominent in the frontal areas. They are often synchronized and prevalent during sedation with phenobarbital or with the use of tranquilizers and some sedative drugs.

Slower rhythms are theta and delta waves. Theta waves of 4–7 Hz usually replace the alpha rhythm during drowsiness and light sleep. Delta waves of 0.5–4 Hz are present during deep sleep in normal people of all ages and they are the primary waves present in the records of normal infants. Delta waves are almost always pathological in the waking records of adults.

The EEG reveals functional abnormalities of the brain, whether caused by localized structural lesions, essential paroxysmal states such as epilepsy, or toxic and abnormal metabolic conditions. The three major classes of abnormalities are asymmetries between the hemispheres, slow rhythms, and very sharp waves or spikes. Slow waves represent a depression of cerebral cortical activity or injury in the projection pathways beneath the recording electrodes. Sharp waves or spikes often indicate a hyperexcitable or irritable state of the cortex. During a full epileptic seizure attack, spikes become repetitive and synchronized over the whole surface of the brain. *See* SEIZURE DISORDERS.

The EEG is frequently used for the evaluation of comatose states. The record is slowed in all areas in coma, with delta waves predominating. If the EEG becomes isoelectric or flat for several hours, brain function is not recoverable and the coma may be considered terminal. "Brain death" is indicated by a flat EEG, recorded at the highest gain with widely spaced electrode positions and the absence of cerebral reflexes and spontaneous respiration. *See* DEATH.

Computer advances in the analysis of EEG signals that are emitted by the brain during sensory stimulation and motor responses have led to the discovery and measurement of electrical waves known as event-related potentials or evoked potentials. These responses are averaged by a computer to enhance the small signals and increase the signal-to-noise ratio, so that they may be graphed and seen.

The complexity of evoked potential and EEG analysis makes interpretation difficult in relation to where various components originate and their pattern of spread through time along the neural transmission pathways. In the 1980s, with the development of minicomputers and color graphics screens, the presentation of topographic information could be analyzed in sophisticated statistical ways for research and clinical purposes by electroencephalographers and neurophysiologists. This method is best known as brain electrical activity mapping (BEAM) and is used in many research investigations of brain activity patterns in learning and language dysfunctions, psychiatric disorders, aging changes and dementia, and studies of normal and impaired child development. Difficult neurological diagnostic problems that do not show anatomical deformities by brain scan methods may often be clarified by these new electrographic procedures. *See* BRAIN; NEUROBIOLOGY. [J.Co.]

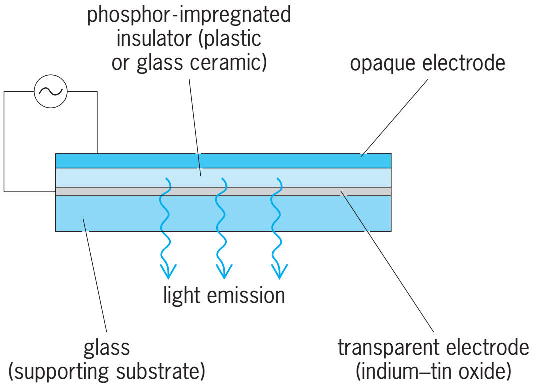
Electrokinetic phenomena Phenomena associated with the movement of charged particles through a continuous medium or with the movement of a continuous medium over a charged surface. The four principal electrokinetic phenomena are electrophoresis, electroosmosis, streaming potential, and sedimentation potential, or Dorn effect. These phenomena are related to one another through the zeta potential ζ of the electrical double layer which exists in the neighborhood of the charged surface. *See* ELECTROPHORESIS; STREAMING POTENTIAL. [Q.V.W.]

Electroless plating A chemical reduction process which, once initiated, is autocatalytic. The process is similar to electroplating except that no outside current is needed. The metal ions are reduced by chemical agents in the plating solutions, and deposit on the substrate. An advantage of electroless plating with current is the more uniform thickness of the surface coating.

Electroless plating is used for coating nonmetallic parts. Decorative electroless plates are usually further coated with electrodeposited nickel and chromium. There are also applications for electroless deposits on metallic substrates, especially when irregularly shaped objects require a uniform coating. Electroless copper is used extensively for printed circuits, which are produced either by coating the nonmetallic substrate with a very thin layer of electroless copper and electroplating to the desired thickness or by using the electroless process only. Electroless iron and cobalt have limited uses. Electroless gold is used for microcircuits and connections to solid-state components. Deeply recessed areas which are difficult to plate can be coated by the electroless process. *See* ELECTROPLATING OF METALS. [R.W.]

Electroluminescence A general term for the luminescence excited by the application of an electric field to a system, usually in the solid state. Solid-state electroluminescent systems can be made quite thin, leading to applications in thin-panel area light sources and flat screens to replace cathode-ray tubes for electronic display and image formation. *See* LUMINESCENCE.

Modern interest in electroluminescence dates from the discovery by G. Destriau in France in 1936 that when a zinc sulfide (ZnS) phosphor powder is suspended in an insulator (oil, plastic, or glass ceramic) and an intense alternating electric field is applied with capacitorlike electrodes, visible light is emitted. The phosphor, prepared from zinc sulfide by addition of a small amount of copper impurity, was later shown to contain particles of a copper sulfide (Cu_2S) phase in addition to copper in its normal role as a luminescence activator in the zinc sulfide lattice. The intensification of the applied electric field by the sharp conductive or semiconductive copper sulfide inhomogeneities is believed to underlie the mechanism of Destriau-type electroluminescence. Minority carriers are ejected from these high-field spots into the low- or moderate-field regions of the phosphor, where they recombine to excite the activator centers. The structure of a Destriau-type electroluminescent cell is shown in the illustration; the light is observed through the transparent indium–tin oxide electrode. *See* LIGHT PANEL.



Structure of powdered-phosphor (Destriau) electroluminescent cell, edge view (not to scale).

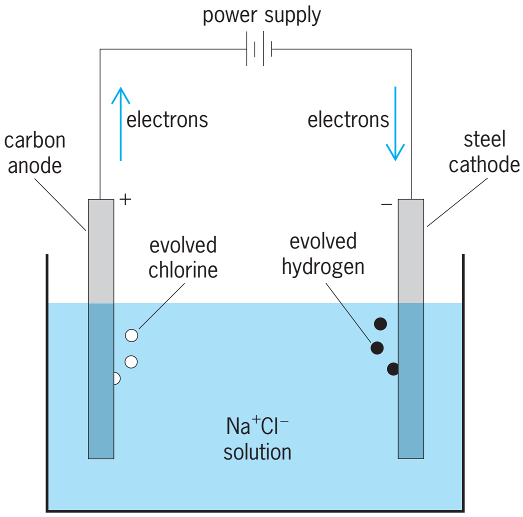
The application of electroluminescence to display and image formation received great impetus from work in the late 1960s and mid-1970s on thin-film electroluminescence (TFEL), giving rise to devices that are different in structure and mechanism from the Destriau conditions. The phosphor in these devices is not a powder but a thin (about 500 nanometers) continuous film prepared by sputtering or vacuum evaporation. The luminescence activators are manganese or rare-earth ions, atomic species with internal electronic transitions that lead to characteristic luminescence. The phosphor film does not contain copper sulfide or any other separate phase, and is sandwiched between two thin (about 200 nm) transparent insulating films also prepared by evaporative means. Conducting electrodes are applied to the outside of each insulating film; one of the electrodes is again a transparent coating of indium–tin oxide on glass, which serves as supporting substrate. If an imaging matrix is desired, both electrodes consist of grids of parallel lines, with the direction of the grid on one insulator (row) orthogonal to the other grid (column). By approximate circuitry the entire matrix can be scanned, applying voltage where desired to a phosphor element that is located between the intersection of a row and column electrode. A thin-film electroluminescent device acts like a pure capacitor at low applied voltage; no light is emitted until the voltage reaches a threshold value determined by the dielectric properties of the insulator and phosphor films. Above this threshold a dissipative current flows, and light emission occurs. The brightness increases very steeply with the applied voltage but is finally saturated. The light output, or average brightness, is roughly proportional to the frequency up to at least 5 kHz, and also depends on the waveform of the applied voltage.

The best thin-film electroluminescent phosphor is manganese-activated zinc sulfide, which emits yellow light peaking at 585 nm. Activation of zinc sulfide and certain alkaline earth sulfides with different rare earths has yielded many other promising electroluminescent phosphors emitting blue, green, red, and white, and making full-color matrix-addressed thin-film electroluminescent displays possible. The light output of thin-film electroluminescent displays has been very reliable, with typically only 10% loss after tens of thousands of hours of operation.

Injection electroluminescence results when a semiconductor *pn* junction or a point contact is biased in the forward direction. This type of emission, first observed from silicon carbide (SiC) in 1907, is the result of radiative recombination of injected minority carriers, with majority carriers being a material. Such emission has been observed in a large number of semiconductors. The wavelength of the emission corresponds to an energy equal, at most, to the forbidden band gap of the material, and hence in most of these materials the wavelength is in the infrared region of the spectrum. If a *pn* junction is biased in the reverse direction, so as to produce high internal electric fields, other types of emission can occur, but with very low efficiency. *See* JUNCTION DIODE; SEMICONDUCTOR; SEMICONDUCTOR DIODE.

Light emission may also occur when electrodes of certain metals, such as Al or Ta, are immersed in suitable electrolytes and current is passed between them. In many cases this galvanoluminescence is electroluminescence generated in a thin oxide layer formed on the electrode by electrolytic action. In addition to electroluminescence proper, other interesting effects (usually termed electrophotoluminescence) occur when electric fields are applied to a phosphor which is concurrently, or has been previously, excited by other means. These effects include a decrease or increase in steady-state photoluminescence brightness when the field is applied, or a burst of afterglow emission if the field is applied after the primary photoexcitation is removed. *See* PHOTOLUMINESCENCE. [J.H.S.; C.C.K.]

Electrolysis A means of producing chemical changes through reactions at electrodes in contact with an electrolyte by the passage of an electric current. Electrolysis cells, also known



Schematic diagram of an electrolysis cell in which the electrolyte is a solution of sodium chloride.

as electrochemical cells, generally consist of two electrodes connected to an external source of electricity (a power supply or battery) and immersed in a liquid that can conduct electricity through the movement of ions. Reactions occur at both electrode-solution interfaces because of the flow of electrons. Reduction reactions, where species add electrons, occur at the electrode called the cathode; oxidation reactions, where species lose electrons, occur at the other electrode, the anode. In the cell shown in the illustration, water is reduced at the cathode to produce hydrogen gas and hydroxide ion; chloride ion is oxidized at the anode to generate chlorine gas. Electrodes are typically constructed of metals (such as platinum or steel) or carbon. Electrolytes usually consist of salts dissolved in either water or a nonaqueous solvent, or they are molten salts. *See* ELECTROCHEMISTRY; ELECTRODE; ELECTROLYTE; OXIDATION-REDUCTION.

There are many industrial applications for the production of important inorganic chemicals. Chlorine and alkali are produced by the large-scale electrolysis of brine (the chloralkali process) in cells carrying out the same reactions as those shown in the illustration. Other chemicals produced include hydrogen and oxygen (via water electrolysis), chlorates, peroxysulfate, and permanganate.

The major electrolytic processes involving organic compounds are the hydrodimerization of acrylonitrile to produce adiponitrile and the production of tetraethyllead. Many other organic compounds have been studied on the laboratory scale.

Electroplating involves the electrochemical deposition of a thin layer of metal on a conductive substrate, for example, to produce a more attractive or corrosion-resistant surface. Chromium, nickel, tin, copper, zinc, cadmium, lead, silver, gold, and platinum are the most frequently electroplated metals. Metal surfaces can also be electrolytically oxidized (anodized) to form protective oxide layers. This surface-finishing technique is most widely used for aluminum but is also used for titanium, copper, and steel. *See* ELECTROPLATING OF METALS.

Metals can be purified by electrorefining. Here, the impure metal is used as the anode, which dissolves during the electrolysis. The metal is plated, in purer form, on the cathode. Copper, nickel, cobalt, lead, and tin are all purified by this technique. *See* ELECTROMETALLURGY.

Electroanalysis involves the use of electrolytic processes to identify and quantitate a species. Coulometric methods are based on measuring the quantity of electricity used for a desired process. Voltammetric methods allow characterization of species through an analysis of the effect of potential and electrolysis conditions on the observed currents. [A.J.Ba.]

Electrolyte A material that conducts an electric current when it is fused or dissolved in a solvent, usually water. Electrolytes are composed of positively charged species, called cations, and negatively charged species, called anions. For example, sodium chloride (NaCl) is an electrolyte composed of sodium cations (Na^+) and chlorine anions (Cl^-). The ratio of cations to anions is always such that the substance is electrically neutral. If two wires connected to a light bulb and to a power source are placed in a beaker of water, the light bulb will not glow. If an electrolyte, such as sodium chloride, is dissolved in the water, the light bulb will glow because the solution can now conduct electricity. The amount of electric current that can be carried by an electrolyte solution is proportional to the number of ions dissolved. Thus, the bulb will glow more brightly if the amount of sodium chloride in the solution is increased. *See* ELECTRIC CURRENT; ION.

Any substance that produces ions when dissolved is an electrolyte. These substances include ionic materials composed of simple monatomic ions, such as sodium chloride, or substances composed of polyatomic ions, such as ammonium nitrate (NH_4NO_3). When these substances are dissolved, hydrated ions are generated, as in reactions (1) and (2).

$$NaCl \rightarrow Na^+ + Cl^- \qquad (1)$$

$$NH_4NO_3 \rightarrow NH_4{}^+ + NO_3{}^- \qquad (2)$$

A special type of electrolyte is an acid, in which the cation is H^+. When acids are dissolved in water, H^+ ions are produced along with an anion, which can be either a monatomic ion, as in hydrochloric acid (HCl), or a polyatomic ion, as in nitric acid (HNO_3) or acetic acid ($HC_2H_3O_2$), as in reactions (3)–(5).

$$HCl \rightarrow H^+ + Cl^- \qquad (3)$$

$$HNO_3 \rightarrow H^+ + NO_3{}^- \qquad (4)$$

$$HC_2H_3O_2 \rightarrow H^+ + C_2H_3O_2{}^- \qquad (5)$$

Electrolytes such as sodium hydroxide (NaOH) that yield the hydroxyl (OH^-) anion when dissolved in water are called bases [reaction (6)]. Some molecules that do not contain ions, such as ammonia (NH_3), generate OH^- ions when dissolved in water as in reaction (7); these bases are also electrolytes. Polar covalent molecules, such as ethanol, dissolve in water but do not generate any ions and are called nonelectrolytes.

$$NaOH \rightarrow Na^+ + OH^- \qquad (6)$$

$$NH_3 + H_2O \rightarrow NH_4{}^+ + OH^- \qquad (7)$$

Many electrolytic substances completely dissociate into ions when they are dissolved in water. In these cases, the reactions shown above would proceed completely to the right, leaving only dissolved ions and no associated, electrically neutral molecules. For example, when sodium chloride is dissolved in water, all of the dissolved material is present as Na^+ and Cl^- ions, with no dissolved NaCl molecules. Substances that completely dissociate are called strong electrolytes, because every molecule dissolved generates ions that contribute to the electrical conductivity. Ionic substances, such as NaCl and NH_4NO_3, are strong electrolytes. Acids and bases that completely dissociate are called strong acids and strong bases, and these substances are also strong electrolytes. Hydrochloric acid (HCl) and HNO_3 are strong acids, so every molecule of HCl or HNO_3 that dissolves generates a H^+ cation and a Cl^- or $NO_3{}^-$ anion, respectively.

Some substances dissolve in water but do not dissociate completely. For example, when acetic acid is dissolved in water, some molecules dissociate to form H^+ and $C_2H_3O_2^-$ ions, while others remain associated as $C_2H_3O_2H$ units, which contain polar O-H bonds and are therefore readily soluble in water. Acids such as acetic acid that do not dissociate completely are called weak acids. Similarly, the reaction of ammonia with water in reaction (7) proceeds to only a small extent. Thus, some molecules of ammonia react with water to generate OH^- and NH_4^+ ions, but many simply remain as NH_3. Since each dissolved molecule of ammonia does not generate an OH^- anion, ammonia is said to be a weak base. *See* IONIC EQUILIBRIUM.

In biological systems, electrolytes play important roles in regulating kidney function and the retention of water. Electrolytes are also vital for providing the electric current needed for nerve impulses in neurons. *See* OSMOREGULATORY MECHANISMS. [H.H.T]

Electrolytic conductance The transport of electric charges, under electric potential differences, by particles of atomic or larger size. This phenomenon is distinguished from metallic conductance, which is due to the movement of electrons. The charged particles that carry the electricity are called ions.

Positively charged ions are termed cations; the sodium ion, Na^+, is an example. The negatively charged chloride ion, Cl^-, is typical of anions. The negative charges are identical with those of electrons or integral multiples thereof. The unit positive charges have the same magnitude as those of electrons but are of opposite sign. Colloidal particles, which may have relatively large weights, may be ions, and may carry many positive or negative charges. Electrolytic conductors may be solids, liquids, or gases. Semiconductors have properties that are intermediate between the metallic and electrolytic types. *See* ELECTROCHEMISTRY; ELECTROMOTIVE FORCE (CELLS).

Conductances are usually reported as specific conductances κ, which are the reciprocals of the resistances of cubes of the materials, 1 cm (0.39 in.) in each dimension, placed between electrodes 1 cm square, on opposite sides. These units are sometimes called mhos, that is, ohm spelled backward. Conductances of solutions are usually measured by a method in which a Wheatstone bridge is employed. *See* WHEATSTONE BRIDGE. [H.A.L.]

Electromagnet A soft-iron core that is magnetized by passing a current through a coil of wire wound on the core. Electromagnets are used to lift heavy masses of magnetic material and to attract movable magnetic parts of electric devices, such as solenoids, relays, and clutches.

The difference between cores of an electromagnet and a permanent magnet is in the retentivity of the material used. Permanent magnets, initially magnetized by placing them in a coil through which current is passed, are made of retentive (magnetically "hard") materials which maintain the magnetic properties for a long period of time after being removed from the coil. Electromagnets are meant to be devices in which the magnetism in the cores can be turned on or off. Therefore, the core material is nonretentive (magnetically "soft") material which maintains the magnetic properties only while current flows in the coil. All magnetic materials have some retentivity, called residual magnetism; the difference is one of degree. *See* MAGNETIZATION.

In an engineering sense the word electromagnet does not refer to the electromagnetic forces incidentally set up in all devices in which an electric current exists, but only to those devices in which the current is primarily designed to produce this force, as in solenoids, relay coils, electromagnetic brakes and clutches, and in tractive and lifting or holding magnets and magnetic chucks.

Electromagnets may be divided into two classes: traction magnets, in which the pull is to be exerted over a distance and work is done by reducing the air gap; and lifting or holding magnets, in which the material is initially placed in contact with the magnet. Examples of the latter type are magnetic chucks and circular lifting magnets. For examples of the first type. *See* BRAKE; CLUTCH; RELAY; SOLENOID (ELECTRICITY). [J.Mei.]

Electromagnetic compatibility The situation in which electrical and electronic devices and systems work as intended, both within themselves and in their electromagnetic environment.

Electromagnetic interference (EMI) is said to exist when unwanted voltages or currents are present so that they adversely affect the performance of a device or system. Such voltages or currents may reach the victim circuit or device by conduction or by nonionizing radiation. In all cases, electromagnetic interference arises because of a combination of three factors: a source, a transmission path, and a response, at least one of which is unplanned. Electromagnetic interference control refers to the process of making design changes or adjustments of signal or noise levels in order to achieve electromagnetic compatibility (EMC).

The purpose of shielding is to confine radiated energy to a specific region, or to prevent radiated energy from entering a specific region. The most effective shield is a solid metallic enclosure, made of a permeable metal (for example, iron or steel) if frequencies below 100 kHz are to be shielded, or of any metal if higher frequencies are to be shielded. However, the solid shield does not permit light, air, water, or other substances to be passed through it, so shields with holes, including screens, braids, and honeycomb arrangements, as well as conductive glass may be needed. The widespread use of plastic enclosures has made thin film shields vital in achieving the needed shielding effectiveness in the use of such enclosures. *See* ELECTRICAL SHIELDING; MAGNETIC MATERIALS.

An electrical filter offers relatively little opposition to the passage of certain frequencies or direct current (dc) while blocking the passage of other frequencies. Accordingly, filters play a significant role in reducing conducted interference to the extent that such interference has a spectral content different from that of the desired signals.

A filter may be either reflective or lossy. Reflective filters present an impedance mismatch to unwanted frequencies, thereby returning them to the input, whereas lossy filters absorb unwanted frequencies. A filter may be designed on a time-domain basis as well as on a frequency-domain basis. *See* ELECTRIC FILTER; IMPEDANCE MATCHING.

Digital systems, such as computers, tend to interfere with analog systems, such as voice and video communications, more readily than analog systems interfere with digital systems. Therefore, data streams to be transmitted over analog voice circuits are converted to a quasianalog tone form first. Computer clocks also may have to be shielded and their output circuits may have to be filtered to prevent interference to communication equipment. In addition, personal computers must be connected to television receivers so that the video output of the personal computer does not reach the television receiving antenna, which then would radiate such signals. *See* ELECTRICAL NOISE. [B.E.K.]

Electromagnetic field A changing magnetic field always produces an electric field, and conversely, a changing electric field always produces a magnetic field. This interaction of electric and magnetic forces gives rise to a condition in space known as an electromagnetic field. The characteristics of an electromagnetic field are expressed mathematically by Maxwell's equation. *See* ELECTRIC FIELD; ELECTROMAGNETIC RADIATION; ELECTROMAGNETIC WAVE. [J.Be.]

Electromagnetic induction The production of an electromotive force either by motion of a conductor through a magnetic field in such a manner as to cut across the magnetic flux or by a change in the magnetic flux that threads a conductor. *See* ELECTROMOTIVE FORCE (EMF).

If the flux threading a coil is produced by a current in the coil, any change in that current will cause a change in flux, and thus there will be an induced emf while the current is changing. This process is called self-induction. The emf of self-induction is proportional to the rate of change of current.

The process by which an emf is induced in one circuit by a change of current in a neighboring circuit is called mutual induction. Flux produced by a current in a circuit *A* threads or links circuit *B*. When there is a change of current in circuit *A*, there is a change in the flux linking coil *B*, and an emf is induced in circuit *B* while the change is taking place. Transformers operate on the principle of mutual induction. *See* TRANSFORMER.

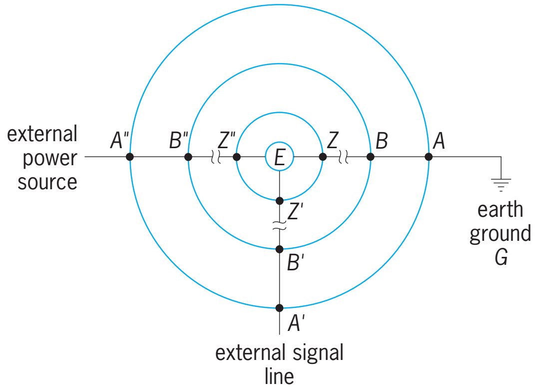
The phenomenon of electromagnetic induction has a great many important applications in modern technology. *See* COUPLED CIRCUITS; GENERATOR; INDUCTION HEATING; MICROPHONE; MOTOR; SERVOMECHANISM. [K.V.M.]

Electromagnetic pulse (EMP) A transient electromagnetic signal produced by a nuclear explosion in or above the Earth's atmosphere. Though not considered dangerous to people, the electromagnetic pulse (EMP) is a potential threat to many electronic systems.

In a typical nuclear detonation, parts of the shell casing and other materials are rapidly reduced to a very hot, compressed gas, which upon expansion gives rise to enormous amounts of mechanical and thermal energy. At the same time the nuclear reactions release tremendous amounts of energy as initial nuclear radiation (INR). This INR is in the form of rapidly moving neutrons and high-energy electromagnetic radiation, called x-rays and prompt gamma rays. About a minute after detonation, the radioactive decay of the fission products gives rise to additional gamma rays and electrons (or beta particles), known as residual nuclear radiation (RNR). The distribution of the total explosive energy of a hypothetical fission detonation in the atmosphere below an altitude of 6 mi (10 km) is 50% blast, 35% thermal, 10% RNR, 5% INR. At higher altitudes where the air is less dense, the thermal energy increases and the blast energy decreases proportionately. *See* BETA PARTICLES; GAMMA RAYS; NUCLEAR FISSION; NUCLEAR REACTION; RADIOACTIVITY.

EMP is associated with the INR output, which is a small percentage of the total explosive energy. Nevertheless, EMP is still capable of transferring something of the order of 0.1–0.9 joule/m^2 (0.007–0.06 ft-lbf/ft^2) onto a collector, more than enough to cause upset or damage to normal semiconductor devices.

As the prompt gammas move away from a high-altitude nuclear detonation, those gamma rays moving toward the Earth penetrate a more dense region of the atmosphere called the source or deposition region. In this 6-mi thick (10-km) region, approximately 15–21 mi (25–35 km) above the Earth, the highly energetic gamma rays interact with the air molecules to form Compton electrons (with energies starting at 1 MeV) and less energetic gamma rays, which then proceed in the same general direction as the original gamma rays. The fast Compton electrons eventually slow down by stripping other electrons from air molecules to form secondary electron-ion pairs. (Though these secondary electrons and ions do not contribute to the generation of the EMP, they do cause the region to become highly conductive, and therefore play an important role in determining the EMP wave shape and amplitude.) While slowing down, the very intense, short-duration flux of Compton electrons is also deflected by the Earth's geomagnetic field. The Compton electrons then spiral about the geomagnetic lines, radiating electromagnetic energy in the form of EMP until they eventually recombine with local, positively charged ions. *See* COMPTON EFFECT; SYNCHROTRON RADIATION.



Typical system protection scheme.

It is also possible for INR (both x-rays and gamma rays) to directly interact with systems, causing EMP signals internal to structures. This phenomenon has been called internal or system-generated EMP and is potentially a serious problem for satellites in orbit and for electronics in metallic enclosures on or near the ground. These forms of EMP are generated by x-rays interacting with satellites and gamma rays impinging on ground-based enclosures, producing currents of Compton electrons internally that then produce internal electromagnetic waves. They are very dependent upon the nuclear detonation, the system topology, and the relative position of one to the other.

An estimate of about 1 joule (0.7 ft-lbf) of EMP-coupled energy is considered reasonable for many systems. Even if the coupling onto circuits is inefficient, as little as 10^{-13} J can upset some semiconductor devices and 10^{-6} J can cause damage. The potential for such upset and damage in critical electronic circuits has led to the incorporation of EMP protection in many system designs. This protection is most prevalent in communications systems whose disruption by EMP is considered an important civil and military vulnerability.

The most common form of protection incorporated in system designs is a combination of shielding and penetration control. The illustration shows a protection scheme in which a system's electronics *E* is isolated from the external environment by one or more nested, shielded enclosures (often called Faraday cages). Penetration control is then maintained by minimizing the number of shield penetrations (in this case, a power line, a signal line, and a ground wire connecting *E* to earth ground *G*) and by applying terminal protection devices, such as spark gaps, high-power Zener diodes, or metal oxide varistors, at selected shield penetration points (*A*, *A*′, *A*″, *B*, *B*′, and *B*″; or *Z*, *Z*′, and *Z*″; or both). In this way, system protection can be designed not only for EMP but also for other electromagnetic transients (such as near-strike lightning and electromagnetic interference). Furthermore, cost-effective, field maintainable protection can be achieved by properly selecting off-the-shelf shielding techniques and terminal protection devices and applying them to systems. *See* ELECTRIC PROTECTIVE DEVICES; ELECTRICAL INTERFERENCE; ELECTRICAL SHIELDING; ELECTROMAGNETIC RADIATION; LIGHTNING AND SURGE PROTECTION; NUCLEAR EXPLOSION. [R.A.Pf.]

Electromagnetic pump A pump that operates on the principle that a force is exerted on a current-carrying conductor in a magnetic field. The high electrical conductivity of the liquid metals pumped (liquid metals are used as the heat-transfer media in some nuclear reactors and magnetohydrodynamic systems) allows a pumping force to be developed within the metals when they are confined in a duct or channel and subjected to a magnetic field and to an electric current. These pumps are designed principally for use in liquid-metal-cooled reactor plants where liquid lithium, sodium, potassium, or sodium-potassium alloys are pumped. Other metallic and nonmetallic liquids of sufficiently high electrical conductivity, such as mercury or molten aluminum, lead, and bismuth, may also be pumped in nonnuclear applications. The absence of moving parts within the pumped liquid eliminates the need for seals and bearings that are found in conventional mechanical pumps, thus minimizing leaks, maintenance, and repairs, and improving reliability. In liquid-metal-cooled nuclear reactor plants, electromagnetic pumps with a capacity of up to several thousand gallons per minute have operated without maintenance for decades. *See* Magnetohydrodynamics; Nuclear power; Nuclear reactor. [L.R.D.]

Electromagnetic radiation

Electromagnetic radiation Energy transmitted through space or through a material medium in the form of electromagnetic waves. The term can also refer to the emission and propagation of such energy. Whenever an electric charge oscillates or is accelerated, a disturbance characterized by the existence of electric and magnetic fields propagates outward from it. This disturbance is called an electromagnetic wave. The frequency range of such waves is tremendous, as is shown by the electromagnetic spectrum in the table. The sources given are typical, but not mutually exclusive.

Electromagnetic spectrum

Frequency, Hz	Wavelength, m	Nomenclature	Typical source
10^{23}	3×10^{-15}	Cosmic photons	Astronomical
10^{22}	3×10^{-14}	γ-rays	Radioactive nuclei
10^{21}	3×10^{-13}	γ-rays, x-rays	
10^{20}	3×10^{-12}	x-rays	Atomic inner shell
		Positron-electron annihilation	
10^{19}	3×10^{-11}	Soft x-rays	Electron impact on a solid
10^{18}	3×10^{-10}	Ultraviolet, x-rays	Atoms in sparks
10^{17}	3×10^{-9}	Ultraviolet	Atoms in sparks and arcs
10^{16}	3×10^{-8}	Ultraviolet	Atoms in sparks and arcs
10^{15}	3×10^{-7}	Visible spectrum	Atoms, hot bodies, molecules
10^{14}	3×10^{-6}	Infrared	Hot bodies, molecules
10^{13}	3×10^{-5}	Infrared	Hot bodies, molecules
10^{12}	3×10^{-4}	Far-infrared	Hot bodies, molecules
10^{11}	3×10^{-3}	Microwaves	Electronic devices
10^{10}	3×10^{-2}	Microwaves, radar	Electronic devices
10^{9}	3×10^{-1}	Radar	Electronic devices
		Interstellar hydrogen	
10^{8}	3	Television, FM radio	Electronic devices
10^{7}	30	Short-wave radio	Electronic devices
10^{6}	300	AM radio	Electronic devices
10^{5}	3000	Long-wave radio	Electronic devices
10^{4}	3×10^{4}	Induction heating	Electronic devices
10^{3}	3×10^{5}		Electronic devices
100	3×10^{6}	Power	Rotating machinery
10	3×10^{7}	Power	Rotating machinery
1	3×10^{8}		Commutated direct current
0	Infinity	Direct current	Batteries

In theory, any electromagnetic radiation can be detected by its heating effect. This method has actually been used over the range from x-rays to radio. Ionization effects measured by cloud chambers, photographic emulsions, ionization chambers, and Geiger counters have been used in the γ- and x-ray regions. Direct photography can be used from the γ-ray to the infrared region.

Fluorescence is effective in the x-ray and ultraviolet ranges. Bolometers, thermocouples, and other heat-measuring devices are used chiefly in the infrared and microwave regions. Crystal detectors, vacuum tubes, and transistors cover the microwave and radio frequency ranges. *See* Antenna (electromagnetism); Diffraction; Electromagnetic wave; Gamma rays; Heat radiation; Infrared radiation; Interference of waves; Light; Maxwell's equations; Microwave; Polarization of waves; Radiation; Radio-wave propagation; Reflection of electromagnetic radiation; Refraction of waves; Scattering of electromagnetic radiation; Transmission lines; Ultraviolet radiation; Wave motion; X-rays. [W.R.Sm.]

Electromagnetic wave

Electromagnetic wave A disturbance, produced by the acceleration or oscillation of an electric charge, which has the characteristic time and spatial relations associated with progressive wave motion. A system of electric and magnetic fields moves outward from a region where electric charges are accelerated, such as an oscillating circuit or the target of an x-ray tube. The wide wavelength range over which such waves are observed is shown by the electromagnetic spectrum. The term electric wave, or hertzian wave, is often applied to electromagnetic waves in the radar and radio range. Electromagnetic waves may be confined in tubes, such as wave guides, or guided by transmission lines. They were predicted by J. C. Maxwell in 1864 and verified experimentally by H. Hertz in 1887. *See* Electromagnetic radiation. [W.R.Sm.]

Electromagnetic wave transmission

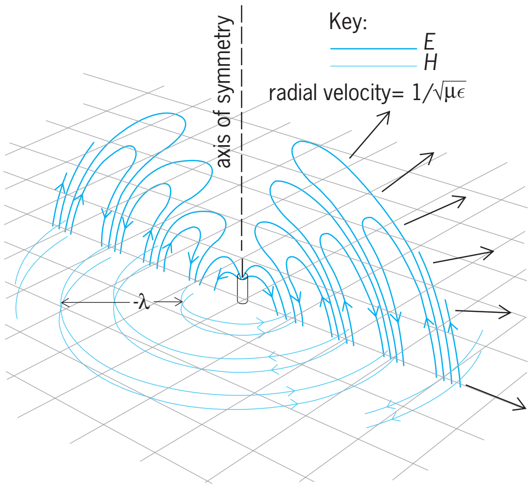
Electromagnetic wave transmission The transmission of electrical energy by wires, the broadcasting of radio signals, and the phenomenon of visible light are all examples of the propagation of electromagnetic energy. Electromagnetic energy travels in the form of a wave. Its speed of travel is approximately 3×10^8 m/s (186,000 mi/s) in a vacuum and is somewhat slower than this in liquid and solid insulators. An electromagnetic wave does not penetrate far into an electrical conductor, and a wave that is incident on the surface of a good conductor is largely reflected. *See* Electromagnetic wave.

Electromagnetic waves originate from accelerated electric charges. For example, a radio wave originates from the oscillatory acceleration of electrons in the transmitting antenna. The light that is produced within a laser originates when electrons fall from a higher energy level to a lower one.

The waves emitted from a source are oscillatory and are described in terms of frequency of oscillation. The method of generating an electromagnetic wave depends on the frequency used, as do the techniques of transmitting the energy to another location and utilizing it when it has been received. Communication of information to a distant point is generally accomplished through the use of electromagnetic energy as a carrier.

The illustration shows the configuration of the electric and magnetic fields about a short vertical antenna in which flows a sinusoidal current. The picture applies either to an antenna in free space (in which case the illustration shows only the upper half of the fields), or to an antenna projecting above the surface of a highly conducting plane surface. In the latter case the conducting plane represents to a first approximation the surface of the Earth. The fields have symmetry about the axis through the antenna. For pictorial simplicity only selected portions of the fields are shown in this illustration. The magnetic field is circular about the antenna, is perpendicular at every point to the direction of the electric field, and is proportional in intensity to the magnitude of the electric field, as in a plane wave. All parts of the wave travel radially outward from the antenna with the velocity equal to that of a plane wave in the same medium.

Often it is desired to concentrate the radiated energy into a narrow beam. This can be done either by the addition of more antenna elements or by placing a large reflector, generally parabolic in shape, behind the antenna. The production of a narrow beam requires an antenna array, or alternatively a reflector, that is large in width and height compared with a wavelength. The very narrow and concentrated beam that can be achieved by a laser is made possible by the extremely short wavelength of the radiation as compared with the cross-sectional dimensions of the radiating system.



Configuration of electric and magnetic fields about a short vertical antenna. E = electric field intensity; H = magnetic field intensity; μ = absolute permeability of the medium; ε = permittivity of the medium; γ = wavelength.

The ground is a reasonably good, but not perfect, conductor; hence, the actual propagation over the surface of the Earth will show a more rapid decrease of field strength than that for a perfect conductor. Irregularities and obstructions may interfere. In long-range transmission the spherical shape of the Earth is important. Inhomogeneities in the atmosphere refract the wave somewhat. For long-range transmission, the ionized region high in the atmosphere known as the Kennelly-Heaviside layer, or ionosphere, can act as a reflector. *See* Radio-wave propagation.

When an electromagnetic wave is introduced into the interior of a hollow metallic pipe of suitably large cross-sectional dimensions, the energy is guided along the interior of the pipe with comparatively little loss. The most common cross-sectional shapes are the rectangle and the circle. The cross-sectional dimensions of the tube must be greater than a certain fraction of the wavelength; otherwise the wave will not propagate in the tube. For this reason hollow waveguides are commonly used only at wavelengths of 10 cm or less (frequencies of 3000 MHz or higher). A dielectric rod can also be used as a waveguide. Such a rod, if of insufficient cross-sectional dimensions, can contain the electromagnetic wave by the phenomenon of total reflection at the surface. *See* Waveguide.

Electromagnetic energy can be propagated in a simple mode along two parallel conductors. Such a waveguiding system is termed a transmission line. Three common forms are the coaxial cable, two-wire line, and parallel strip line. As the wave propagates along the line, it is accompanied by currents which flow longitudinally in the conductors. These currents can be regarded as satisfying the boundary condition for the tangential field at the surface of the conductor. The conductors have a finite conductivity, and so these currents cause a transformation of electrical energy into heat. The energy lost comes from the stored energy of the wave, and so the wave, as it progresses, diminishes in amplitude. The conductors are necessarily supported by insulators which are imperfect and cause additional attenuation of the wave. *See* Coaxial cable; Transmission lines.

[W.C.Jo.]

Electromagnetism The branch of science dealing with the observations and laws relating electricity to magnetism. Electromagnetism is based upon the fundamental observations that a moving electric charge produces a magnetic field and that a charge moving in a magnetic field will experience a force. The magnetic field produced by a current is related to the current, the shape of the conductor, and the magnetic properties of the medium around it by Ampère's law. The magnetic field at any point is described in terms of the force that it exerts upon a moving charge at that point. The electrical and magnetic units are defined in terms of the ampere, which in turn is defined from the force of one current upon another. The association of electricity and magnetism is also shown by electromagnetic induction, in which a changing magnetic field sets up an electric field within a conductor and causes the charges to move in the conductor. *See* Ampère's law; Eddy current; Electricity; Electromagnet; Electromagnetic induction; Faraday's law of induction; Hall effect; Inductance; Lenz's law; Magnetic circuits; Magnetism; Reluctance.

[K.V.M.]

Electrometallurgy The branch of process metallurgy dealing with the use of electricity for smelting or refining of metals. The electrochemical effect of an electric current brings about the reduction of metallic compounds, and thereby the extraction of metals from their ores (electrowinning) or the pu-rification of the metals (electrorefining).

In other metallurgical processes, electrically produced heat is utilized in smelting, refining, or alloy manufacturing. For a discussion of electrothermics, that is, the theory and applications of electric heating to metallurgy, *See* Electric furnace; Electric heating; Electrochemical process; Steel manufacture.

[P.Du.]

Electrometer A highly sensitive instrument which measures all or some of the following variables: current, charge, voltage, and resistance. There are two classes of electrometers, mechanical and electronic. The mechanical instruments have been largely replaced by electronic types. *See* Current measurement; Electrical measurements; Voltage measurement.

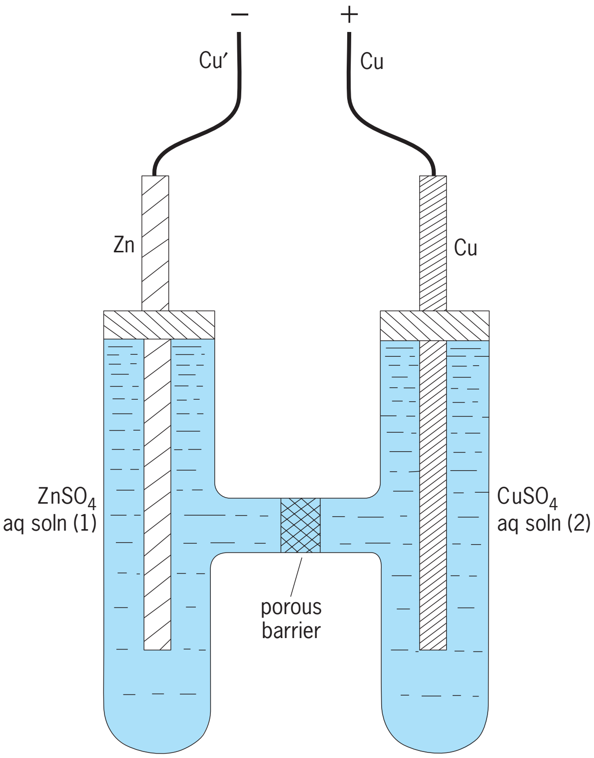
Mechanical electrometers rely for their operation on the mechanical forces associated with electrostatic fields. Attracted-disk instruments, in which the attractive force between two plates, with a potential difference between them, is measured in terms of the fundamental units of mass and length, are sometimes termed absolute electrometers. They are widely used as electrostatic voltmeters for measuring potentials greater than 1 kilovolt. *See* Electrical units and standards.

The quadrant electrometer consists of a cylindrical metal box divided into quadrants which stand on insulating pillars. Opposite quadrants are connected electrically, and a light, thin metal vane of large area is suspended by a conducting torsion fiber inside the quadrants. An unknown potential is applied across the two quadrant pairs, and electrostatic forces on the vane cause a deflection proportional to the potential. Potentials as low as 10 millivolts can be measured. Small charges and currents can also be measured if the capacitance between vane and quadrants is known. *See* Electroscope; Electrostatics; Voltmeter.

Electronic electrometers utilize some form of electronic amplifier, typically an operational amplifier with a field-effect-transistor input stage to minimize the input current. In the most sensitive applications, problems arise due to drift in the amplifier characteristics and electrical noise present in the circuit components. To obviate these effects, electrometers employing a vibrating capacitor or varactor diodes are used. The signal to be measured is converted to an alternating-current (ac) signal and subsequently amplified by an ac amplifier which is less susceptible to drift and noise. The amplified signal is finally reconverted to direct current (dc). *See* Amplifier; Electrical noise; Transistor; Varactor.

[R.W.J.B.]

Electromotive force (cells) The voltage or electric potential difference across the terminals of a cell when no current



Cross-section diagram of Daniell cell. (*After W. J. Moore, Physical Chemistry, 5th ed., Longman, 1974*)

is drawn from it. The electromotive force (emf) is the sum of the electric potential differences produced by a separation of charges (electrons or ions) that can occur at each phase boundary (or interface) in the cell. The magnitude of each potential difference depends on the chemical nature of the two contacting phases. Thus, at the interface between two different metals, some electrons will have moved from the metal with a higher free energy of electrons to the metal with a lower free energy of electrons. The resultant charge separation will produce a potential difference, just as charge separation produces a voltage across a capacitor; at equilibrium this exactly opposes further electron flow. Similarly, potential differences can be produced when electrons partition across a metal|solution interface or metal|solid interface, and when ions partition across a solution|membrane|solution interface. *See* CHEMICAL THERMODYNAMICS; ELECTROMOTIVE FORCE (EMF).

How a cell emf is composed of the sum of interfacial potential differences is shown by the Daniell cell (see illustration), where aq soln denotes an aqueous solution, a solid line indicates a phase boundary, and the broken line a porous barrier permeable to all the ions in the adjacent solutions. The copper connector to the zinc electrode is denoted Cu′. The barrier prevents physical mixing of the zinc sulfate ($ZnSO_4$) and copper sulfate ($CuSO_4$) solutions.

The cell emf is the open-circuit (that is, zero current) potential difference measured between the two Cu leads (any potential-measuring device must ultimately measure the potential difference between two chemically identical phases, in this example the Cu and Cu′ phases).

It is convenient to describe any electrochemical cell in terms of half cells. A half cell consists of an oxidant (Ox) and reductant (Red) such that $\mathrm{Ox} + ne^- \rightleftharpoons \mathrm{Red}$; species Ox and Red are commonly referred to as a redox couple. The Daniell cell, for example, comprises the two half cells $Cu^{2+} + 2e^- \rightleftharpoons Cu$ (redox couple is $Cu^{2+} \mid Cu$) and $Zn^{2+} + 2e^- \rightleftharpoons Zn$ (redox couple is $Zn^{2+} \mid Zn$) with the half-cell potentials $E_{Cu^{2+}|Cu}$ and $E_{Zn^{2+}|Zn}$ given by Eqs. (1) and (2), where F is the Faraday constant (96485.3 coulombs

$$E_{Cu^{2+}|Cu} = E^{\circ}_{Cu^{2+}|Cu} + \frac{RT}{2F} \ln a_{Cu^{2+}} \qquad (1)$$

$$E_{Zn^{2+}|Zn} = E^{\circ}_{Zn^{2+}|Zn} + \frac{RT}{2F} \ln a_{Zn^{2+}} \qquad (2)$$

for the Avogadro number of electrons), R is the gas constant (8.3144 joules/mole/degree Kelvin), T is the temperature in Kelvin, and a is the activity of the species shown. Such expressions are useful only if the standard electrode potential E° value for each half cell is known. Values of E° can be assigned to any given half cell by arbitrarily specifying that $E^{\circ}_{H^+}\ H_2$ [the E° for the standard hydrogen electrode (SHE) half cell, $H^+(aq, a = 1) + e^- \rightleftharpoons {}^1\!/_2 H_2(g, 1\ atm)$] is zero. The temperature dependence $dE^{\circ}_{H^+|H^2}/dT$ is also specified as zero. E° values versus the SHE for selected half cells are given in the table. In principle, any E° (and its temperature dependence) can be measured directly versus the SHE, or another half cell whose electrode potential and temperature dependence have been determined. Such an electrode is termed a reference electrode. The reference electrode is a half cell designed so that its potential is stable, and reproducible, and it neither contaminates nor is contaminated by the medium in which it is immersed. Two convenient reference electrodes commonly used in aqueous systems are the saturated calomel and the silver|silver chloride electrodes (see table). *See* ELECTROCHEMISTRY; OXIDATION-REDUCTION; REFERENCE ELECTRODE.

The emf produced by a single cell or a set of cells in series (a battery) is used as a dc power source for a wide array of applications, ranging from powering wristwatches to emergency power supplies. The emf of the saturated Weston cell (scheme 3;

$$\mathrm{Hg(liquid)} \mid \mathrm{Hg_2SO_4(solid)} \mid \mathrm{CdSO_4\ (sat\ aq)} \mid \mathrm{Cd(Hg)} \qquad (3)$$

sat aq = saturated aqueous solution) still serves as a high-level voltage reference for the National Institute of Standards and Technology. However, Josephson arrays are now considered the most precise voltage references, and Zener diodes are used to produce reference voltages for many laboratory and field voltage measurement devices.

There are also a few photoelectrochemical cells with possible application in solar energy conversion, such as the Grätzel cell (scheme 4; nonaq = nonaqueous solution), where the cell emf

$$\mathrm{TiO_2(solid)} \mid \mathrm{adsorbed\ Ru^{2+}\ dye} \mid \mathrm{I_2,\ I\ (nonaq)} \mid \mathrm{C} \qquad (4)$$

is produced by absorption of visible light.

Selected standard electrode potentials at 25°C

Electrode reaction	E°/V
$Li^+(aq) + e^- \rightleftharpoons Li(s)$	−3.045
$Zn^{2+}(aq) + 2e^- \rightleftharpoons Zn(s)$	−0.763
$2H^+(aq) + 2e^- \rightleftharpoons H_2(g)$	0
$Hg_2Cl_2(s) + 2e^- \rightleftharpoons 2Hg(s) + 2Cl^-$ (sat aq KCl)	0.246
$AgCl(s) + e^- \rightleftharpoons Ag(s) + Cl^-(aq)$	0.222
$Cu^{2+}(aq) + 2e^- \rightleftharpoons Cu(s)$	0.337
$Fe(CN)_6^{3-}(aq) + e^- \rightleftharpoons Fe(CN)_6^{4-}(aq)$	0.69
$O_2(g) + 4H^+(aq) + 4e^- \rightleftharpoons 2H_2O$	1.223
$F_2(g) + 2H^+ + 2e^- \rightleftharpoons 2HF(aq)$	3.06

The emf of a cell can also be used as an indicator of chemical composition. Devices that depend on the measurement of an open circuit-cell potential work well when the device is sensitive to a single analyte, but they are notoriously sensitive to interferences. An example is the so-called alkaline error that occurs when glass electrodes are used to measure very high pH values. For complex systems containing several species that can undergo electrochemical reaction, individual E° values can be determined using electroanalytical techniques that involve controlling the potential applied to a cell with measurement of the resultant current. Techniques such as polarography and cyclic voltammetry, for example, involve changing the potential of an indicator electrode and observing a wave or peak in the current at the redox potential of the species in solution; the height of the wave or peak indicates the concentration of that species. *See* BATTERY; ELECTROCHEMICAL TECHNIQUES; FUEL CELL; POLAROGRAPHIC ANALYSIS. [M.D.Ar.; S.W.F.]

Electromotive force (emf) A measure of the strength of a source of electrical energy. The term is often shortened to emf. It is not a force in the usual mechanical sense (and for this reason has sometimes been called electromotance), but it is a conveniently descriptive term for the agency which drives current through an electric circuit. In the simple case of a direct current I (measured in amperes) flowing through a resistor R (in ohms), Ohm's law states that there will be a voltage drop (or potential difference) of $V = IR$ (in volts) across the resistor. To cause this current to flow requires a source with emf (also measured in volts) $E = V$. More generally, Kirchhoff's voltage law states that the sum of the source emf's taken around any closed path in an electric circuit is equal to the sum of the voltage drops. This is equivalent to the statement that the total emf in a closed circuit is equal to the line integral of the electric field strength around the circuit. *See* ELECTRIC CURRENT; ELECTRIC FIELD; ELECTRICAL RESISTANCE; OHM'S LAW.

An emf may be steady (direct), as for a battery, or time-varying, as for a charged capacitor discharging through a resistor. Emf's may be generated by a variety of physical, chemical, and biological processes. Some of the more important are:

1. Electrochemical reactions, as used in direct-current (dc) batteries, in which the emf results from the reactions between electrolyte and electrodes. *See* BATTERY ; ELECTROCHEMISTRY; ELECTROMOTIVE FORCE (CELLS).

2. Electromagnetic induction, in which the emf results from a change in the magnetic flux linking the circuit. This finds application in alternating-current rotary generators and transformers, providing the basis for the electricity supply industry. *See* ALTERNATING-CURRENT GENERATOR; ELECTROMAGNETIC INDUCTION; FARADAY'S LAW OF INDUCTION; TRANSFORMER.

3. Thermoelectric effects, in which a temperature difference between different parts of a circuit produces an emf. The main use is for the measurement of temperature by means of thermocouples; there are some applications to electric power generation. *See* THERMOCOUPLE; THERMOELECTRIC POWER GENERATOR; THERMOELECTRICITY.

4. The photovoltaic effect, in which the absorption of light (or, more generally, electromagnetic radiation) in a semiconductor produces an emf. This is widely used for scientific purposes in radiation detectors and also, increasingly, for the generation of electric power from the Sun's radiation. *See* PHOTOVOLTAIC EFFECT; RADIOMETRY; SOLAR CELL.

5. The piezoelectric effect, in which the application of mechanical stress to certain types of crystal generates an emf. There are applications in sound recording, in ultrasonics, and in various types of measurement transducer. *See* ALTERNATING-CURRENT CIRCUIT THEORY; DIRECT-CURRENT CIRCUIT THEORY; DIRECT-CURRENT MOTOR; KIRCHHOFF'S LAWS OF ELECTRIC CIRCUITS; MICROPHONE; PIEZOELECTRICITY; TRANSDUCER; ULTRASONICS. [A.E.Ba.]

Electromyography The detection and recording of electrical activity generated by muscle fibers. The basic elements of motor control in the body are the motor units which comprise motor neurons in the brainstem or spinal cord, their axons, and from ten to several hundred muscle fibers supplied by each motor neuron. Motor units vary in the size and properties of their motoneurons, the sizes and conduction velocities of their axons, the morphology of their nerve muscle junctions, and the structure and physiological properties of the muscle fibers supplied by each motor neuron.

Impulses originating in single motoneurons in response to various command signals from the central nervous system conduct to the periphery of the unit, normally causing all the muscle fibers in the unit to discharge. The electrical activity generated by the more or less synchronous discharges of all the muscle fibers in the unit may be detected by recording electrodes on the skin surface or by needles inserted into the muscle. Such potentials reflect the electrical activity generated by the whole motor unit.

Diseases affecting motor neurons are sometimes accompanied by spontaneous discharges of the axons. Additionally, degeneration of motor axons may leave some muscle fibers deprived of their normal innervation, some of which spontaneously fire. Such single muscle-fiber discharges are called fibrillations and are readily detected for diagnostic purposes by needle electrodes inserted into the muscle.

Electromyography may also be used to study primary muscle diseases such as the muscular dystrophies, and a wide variety of other metabolic inflammatory and congenital myopathies affecting the muscle fibers rather than motor neurons or their axons. *See* BIOPOTENTIALS AND IONIC CURRENTS; ELECTRODIAGNOSIS. [W.F.Br.]

Electron An elementary particle which is the negatively charged constituent of ordinary matter. The electron is the lightest known particle which possesses an electric charge. Its rest mass is $m_e \cong 9.1 \times 10^{-28}$ g, about $^1/_{1836}$ of the mass of the proton or neutron, which are, respectively, the positively charged and neutral constituents of ordinary matter. Discovered in 1895 by J. J. Thomson in the form of cathode rays, the electron was the first elementary particle to be identified. *See* ELECTRIC CHARGE; ELEMENTARY PARTICLE; NUCLEAR STRUCTURE.

The charge of the electron is $-e \cong -4.8 \times 10^{-10}$ esu $= -1.6 \times 10^{-19}$ coulomb. The sign of the electron's charge is negative by convention, and that of the equally charged proton is positive. This is a somewhat unfortunate convention, because the flow of electrons in a conductor is thus opposite to the conventional direction of the current.

Electrons are emitted in radioactivity (as beta rays) and in many other decay processes; for instance, the ultimate decay products of all mesons are electrons, neutrinos, and photons, the meson's charge being carried away by the electrons. The electron itself is completely stable. Electrons contribute the bulk to ordinary matter; the volume of an atom is nearly all occupied by the cloud of electrons surrounding the nucleus, which occupies only about 10^{-13} of the atom's volume. The chemical properties of ordinary matter are determined by the electron cloud. *See* BETA; MESON; RADIOACTIVITY.

The electron obeys the Fermi-Dirac statistics, and for this reason is often called a fermion. One of the primary attributes of matter, impenetrability, results from the fact that the electron, being a fermion, obeys the Pauli exclusion principle; the world would be completely different if the lightest charged particle were a boson, that is, a particle that obeys Bose-Einstein statistics. *See* BOSE-EINSTEIN STATISTICS; EXCLUSION PRINCIPLE; FERMI-DIRAC STATISTICS; POSITRON. [C.J.G.]

Magnetic moment. The electron has magnetic properties by virtue of (1) its orbital motion about the nucleus of its parent atom and (2) its rotation about its own axis. The magnetic properties are best described through the magnetic dipole moment associated with 1 and 2. The classical analog of the orbital magnetic dipole moment is the dipole moment of a small current-carrying circuit. The electron spin magnetic dipole moment may be thought of as arising from the circulation of charge, that is, a current, about the electron axis; but a classical analog to this moment has much less meaning than that to the orbital magnetic dipole moment. The magnetic moments of the electrons in the atoms that make up a solid give rise to the bulk magnetism of the solid.

Spin. That property of an electron which gives rise to its angular momentum about an axis within the electron. Spin is one of the permanent and basic properties of the electron. Both the spin and the associated magnetic dipole moment of the electron were postulated by G. E. Uhlenbeck and S. Goudsmit in 1925 as necessary to allow the interpretation of many observed effects, among them the so-called anomalous Zeeman effect, the existence of doublets (pairs of closely spaced lines) in the spectra of the alkali atoms, and certain features of x-ray spectra. *See* Spin (quantum mechanics).

The spin quantum number is s, where s is always $^1/_2$. This means that the component of spin angular momentum along a preferred direction, such as the direction of a magnetic field, is $\pm\ ^1/_2\hbar$, where $\hbar$ is Planck's constant h divided by 2π. The spin angular momentum of the electron is not to be confused with the orbital angular momentum of the electron associated with its motion about the nucleus. In the latter case the maximum component of angular momentum along a preferred direction is $l\hbar$, where l is the angular momentum quantum number and may be any positive integer or zero. *See* Quantum numbers.

The electron has a magnetic dipole moment by virtue of its spin. The approximate value of the dipole moment is the Bohr magneton μ_0 which is equal to $eh/4\pi mc = 9.27 \times 10^{-21}$ erg/oersted, where e is the electron charge measured in electrostatic units, m is the mass of the electron, and c is the velocity of light. (In SI units, $\mu_0 = 9.27 \times 10^{-24}$ joule/tesla.) The orbital motion of the electron also gives rise to a magnetic dipole moment μ_l, that is equal to μ_0 when $l = 1$. [Ar.R.]

Electron affinity

The amount of energy released when an electron at rest is captured by a species M, producing the negative ion M$^-$. The electron affinity of a species M can also be thought of as the ionization potential of the negative ion M$^-$. Stated in terms of a chemical equation, the electron affinity of a species M is equal to the exothermocity of the reaction $e + \mathrm{M} \rightarrow \mathrm{M}^-$, where the negative ion M$^-$ is left in its lowest electronic, vibrational, and rotational state. *See* Ionization potential.

If the electron affinity of M is negative, the M$^-$ ion is unstable with respect to decomposition into $\mathrm{M} + e$. Most atoms have positive electron affinities, even though there is no net Coulomb attraction between the electron and the atom until the electron is close enough to be "a part of the atom." The simple rules of chemical valency provide a qualitative guide to the magnitude of electron affinities. Thus the noble gases, which have a filled outer electronic shell and are chemically inert, are not capable of binding an additional electron to form a negative ion. The largest electron affinities are possessed by the halogens, atoms which require only one additional electron to fill the valence shell. *See* Valence.

The major exception to this concept is that multiply charged negative ions—for example, O^{2-}, one of many multiply charged negative ions which are stable in solution—are not stable in the gas phase. The ability to place more than one additional electron in the valence shell of a neutral atom or molecule appears to come from the medium: the solvent shell surrounding the ion in liquid solutions and the amorphous or crystalline region surrounding the ion in solids. [W.C.L.]

Electron capture

The process in which an atom or ion passing through a material medium either loses or gains one or more orbital electrons. In the passage of charged particles (defined here as nuclei having more or less than Z atomic electrons, where Z is the atomic number) through matter, the capture (and loss) of electrons is an important process in the slowing down of the particles and therefore has a strong influence on their range. Thus a neutral hydrogen atom loses only about half as much energy per centimeter as the positively charged proton in passing through matter consisting of light elements.

For the ordinary charged particles (alpha particles and protons) the capture process is important only at low energies, when the particle velocity is of the order of electron velocities in the stopping material, and thus is important at the end of the range. For fission fragments, however, which initially have a large excess of positive charges, electron capture occurs immediately and continues throughout the slowing-down process. This fact causes the energy-loss mechanisms at the latter part of the range to be different for fission fragments and protons or α-particles. *See* Nuclear fission.

The nuclear capture of electrons (K capture) occurs by a process quite different from atomic capture and is in fact a consequence of the general beta interaction. This general interaction includes ß$^-$ decay (the oldest known beta transformation and hence the name), ß$^+$ decay (or positron decay), and K capture, the latter so called because the electron captured by the nucleus is taken from the K shell (the shell nearest the nucleus) of atomic electrons. A second-order process, called L capture, can also occur, in which (to speak pictorially and thus somewhat imprecisely) an s electron (from the K shell) is captured with the simultaneous transition of a p electron (from the L shell) to the K shell with the emission of gamma radiation. *See* Radioactivity. [McA.H.H.]

Electron configuration

The orbital arrangement of an atom's electrons. Negatively charged electrons are attracted to a positively charged nucleus to form an atom or ion. Although such bound electrons exhibit a high degree of quantum-mechanical wavelike behavior, there still remain particle aspects to their motion. Bound electrons occupy orbitals that are somewhat concentrated in spatial shells lying at different distances from the nucleus. As the set of electron energies allowed by quantum mechanics is discrete, so is the set of mean shell radii. Both these quantized physical quantities are primarily specified by integral values of the principal, or total, quantum number n. The full electron configuration of an atom is correlated with a set of values for all the quantum numbers of each and every electron. In addition to n, another important quantum number is l, an integer representing the orbital angular momentum of an electron in units of $h/2\pi$, where h is Planck's constant. The values 1, 2, 3, 4, 5, 6, 7 for n and 0, 1, 2, 3 for l together suffice to describe the electron configurations of all known normal atoms and ions, that is, those that have their lowest possible values of total electronic energy. The first seven shells are also given the letter designations K, L, M, N, O, P, and Q respectively. Electrons with l equal to 0, 1, 2, and 3 are designated s, p, d, and f, respectively. *See* Quantum mechanics; Quantum numbers.

In any configuration the number of equivalent electrons (same n and l) is indicated by an integral exponent (not a quantum number) attached to the letters s, p, d, and f. According to the Pauli exclusion principle, the maximum is s^2, p^6, d^{10}, and f^{14}. *See* Exclusion principle.

An electron configuration is categorized as having even or odd parity, according to whether the sum of p and f electrons is even or odd. Strong spectral lines result only from transitions between configurations of unlike parity. *See* Parity (quantum mechanics).

(*continued*)

Insofar as they are known from spectroscopic investigations, the electron configurations characteristic of the normal or ground states of the first 103 chemical elements are shown in the table.

In the next-to-last column of the table, the spectral term of the energy level with lowest total electronic energy is shown. The main part of the term symbol is a capital letter, *S*, *P*, *D*, *F*, and so on, that represents the total electronic orbital angular momentum. Attached to this is a superior prefix, 1, 2, 3, 4, and so on, that indicates the multiplicity, and an anterior suffix, 0, $^1/_2$, 1, $^3/_2$, 2, $^5/_2$, and so on, that shows the total angular momentum, or *J* value, of the atom in the given state. A sign ° above the *J* value signifies that the spectral term and electron configuration have odd parity.

The last column of the table presents the first ionization potential of the atom, the energy required to remove from an

atom its least firmly bound electron and transform a neutral atom into a singly charged ion. *See* ATOMIC STRUCTURE AND SPECTRA; IONIZATION POTENTIAL. [J.E.B]

Electron diffraction The phenomenon associated with interference processes that occur when electrons are scattered by atoms to form diffraction patterns. The wave character of electrons is shown most strikingly, and doubtless most conclusively, by the phenomena of interference. For this reason, the diffraction of electrons presents the most obvious confirmation of quantum mechanics. Because of the dependence of the diffraction pattern on the distances between the atoms, electron diffraction is also an important tool for the study of the structure of crystals and of free molecules, analogous to the use of x-rays for these purposes. *See* X-RAY CRYSTALLOGRAPHY; X-RAY DIFFRACTION.

According to energy $E = eV$ (where e is electron charge and V is potential difference), two major techniques of structure analysis with electron beams are distinguished: low-energy electron diffraction (LEED) [$E \simeq$ 5–500 eV] and high-energy electron diffraction (HEED) [$E \simeq$ 5–500 keV]. In addition, electrons generated in condensed matter by incident electrons or x-ray photons are diffracted (in Auger electron diffraction and photoelectron diffraction). Unlike neutrons and x-rays, electrons penetrate matter only for a very short distance before they lose energy (by inelastic scattering) or are scattered elastically (diffracted). *See* COHERENCE; DIFFRACTION; INTERFERENCE OF WAVES; MEAN FREE PATH; QUANTUM MECHANICS.

Low-energy electron diffraction. LEED is used mainly for the study of the structure of single-crystal surfaces and of processes on such surfaces that are associated with changes in the lateral periodicity of the surface. A monochromatic, nearly parallel electron beam, of 10^{-4} to 10^{-3} m (4×10^{-3} to 4×10^{-2} in.) in diameter, strikes the surface, usually at normal incidence. The elastically backscattered electrons are separated from all other electrons by a retarding field and detected with a suitable movable collector or, more frequently on a hemispherical fluorescent screen with the crystal in its center. The intensity of the diffraction spots can be measured as a function of the energy of the incident electrons to obtain so-called *I*(*V*) curves.

The most important contribution of LEED is to the understanding of chemisorption, which precedes corrosion and, in many cases, epitaxy. Here, not only the structure of many adsorption systems, mainly of gases on metals, or metals on other metals and semiconductors, has been studied, but also the kinetics of the adsorption and desorption process as well as changes in the adsorption layer upon heating. The combination of LEED with Auger electron spectroscopy (AES) and with work-function measurements has proven particularly powerful in these studies, because such methods give the coverage and information on the location of the adsorbed atoms normal to the surface. Combining LEED with other complementary techniques such as ion scattering spectroscopy, electron energy loss spectroscopy, or photoelectron spectroscopy has become increasingly popular and can enable the elimination of ambiguities in the interpretation of many LEED results. *See* ADSORPTION; AUGER EFFECT; CORROSION; ELECTRON SPECTROSCOPY; SURFACE AND INTERFACIAL CHEMISTRY; SURFACE PHYSICS.

High-energy electron diffraction. HEED is used mainly for the study of the structure of thin foils, films, and small particles (thickness or diameter of 10^{-9} to 10^{-6} m or 4×10^{-8} to 4×10^{-5} in.), of molecules, and also of the surfaces of crystalline materials. A monochromatic, usually nearly parallel, electron beam with a diameter of 10^{-3} to 10^{-8} m (4×10^{-2} to 4×10^{-7} in.) is incident on the target. The forward-scattered electrons (backscattering is negligible) are detected by means of a fluorescent screen, a photoplate, or some other current-sensitive detector, usually without the inelastically scattered electrons being eliminated.

Similar to LEED, reflection HEED (RHEED) can be used for the determination of the lateral arrangement of the atoms in the topmost layers of the surface, including the structure of adsorbed layers. Although it is more convenient to deduce the periodicity of the atomic arrangement parallel to the surface from LEED patterns than from RHEED patterns, LEED frequently becomes inapplicable when the surface is rough. This usually occurs in the later stages of corrosion or in precipitation. In such investigations RHEED is far superior to LEED because the fast electrons can penetrate the asperities and produce a transmission HEED (THEED) pattern. RHEED has become particularly important for thin-film growth monitoring via the specular beam intensity oscillations caused by monolayer-by-monolayer growth. *See* CRYSTAL GROWTH.

In scanning HEED (SHEED) the diffracted electrons are not recorded on photographic film but are directly measured electronically with sensitive detectors. By moving the detector across the diffraction pattern or by deflecting the diffracted electrons across a stationary detector (scanning), the intensity distribution in the diffraction pattern can be displayed quantitatively on an XY recorder. The main application of SHEED is in the study of processes which are accompanied by changes of the intensity distribution, such as the growth of thin films and annealing and corrosion processes.

The technological importance of thin film and interface devices has led to an upsurge of thin film growth studies by conventional transmission HEED (THEED), usually combined with transmission electron microscopy. Information obtained this way has been mainly on the orientation of the crystallites composing the film. [E.B.]

Diffraction in gases and liquids. Electron diffraction in gases and liquids is similar in principle to that in solids; the differences arise from the lack in gases and liquids of any highly regular arrangement of the component atoms. In gases the low density makes it possible to study diffraction by individual atoms and molecules. The results obtained from monatomic gases represent the density of electronic charge in the atom as a function of the distance from the nucleus. The results from gaseous polyatomic molecules represent the equilibrium distances between the atomic nuclei and the average amplitudes of vibration associated with these distances. Liquids have been studied much less thoroughly than have gases. *See* NEUTRON DIFFRACTION; SCATTERING EXPERIMENTS (ATOMS AND MOLECULES); SCATTERING EXPERIMENTS (NUCLEI). [L.O.B.]

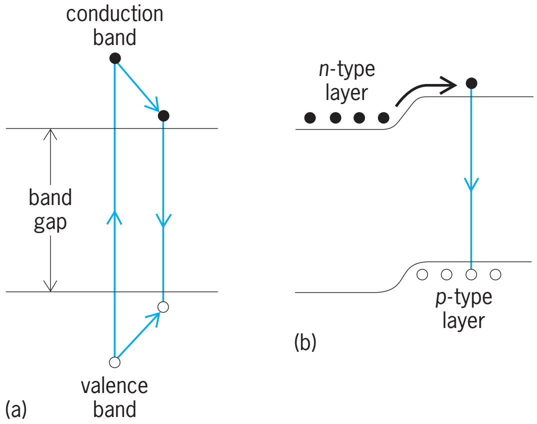
Electron emission The liberation of electrons from a substance into vacuum. Since all substances are built up of atoms and since all atoms contain electrons, any substance may emit electrons; usually, however, the term refers to emission of electrons from the surface of a solid.

The process of electron emission is analogous to that of ionization of a free atom, in which the latter parts with one or more electrons. The energy of the electrons in an atom is lower than that of an electron at rest in vacuum; consequently, in order to ionize an atom, energy must be supplied to the electrons in some way or other. By the same token, a substance does not emit electrons spontaneously, but only if some of the electrons have energies equal to, or larger than, that of an electron at rest in vacuum. This may be achieved by various means, such as by heating, irradiation with light (photoemission), bombardment with charged particles (secondary emission), or use of a strong electric field (field, or cold, emission). *See* FIELD EMISSION; PHOTOEMISSION; SECONDARY EMISSION; THERMIONIC EMISSION. [A.J.D.]

Electron-hole recombination The process in which an electron, which has been excited from the valence band to the conduction band of a semiconductor, falls back into an empty state in the valence band, which is known as a hole. *See* BAND THEORY OF SOLIDS.

Light with photon energies greater than the band gap can be absorbed by the crystal, exciting electrons from the filled valence band to the empty conduction band (illus. *a*). The state in which an electron is removed from the filled valence band is known as a hole. It is analogous to a bubble in a liquid. The hole can be thought of as being mobile and having positive charge. The excited electrons and holes rapidly lose energy (in about 10^{-12} s) by the excitation of lattice phonons (vibrational quanta). The excited electrons fall to near the bottom of the conduction band, and the holes rise to near the top of the valence band, and then on a much longer time scale (of 10^{-9} to 10^{-6} s) the electron drops across the energy gap into the empty state represented by the hole. This is known as electron-hole recombination. An energy approximately equal to the band gap is released in the process. Electron-hole recombination is radiative if the released energy is light and nonradiative if it is heat. *See* PHONON.

Electron-hole recombination requires an excited semiconductor in which both electrons and holes occupy the same volume of the crystal. This state can be produced by purely electrical



Recombination of electrons and holes generated by (*a*) optical absorption and (*b*) a forward-biased *pn* junction.

means by forward-biasing a *pn* junction. The current passing through a *pn* diode in electrons per second equals the rate of electron-hole recombination (illus. *b*). A major application of this phenomenon is the light-emitting diode. *See* LIGHT-EMITTING DIODE; LUMINESCENCE; SEMICONDUCTOR DIODE.

Efficient radiative recombination between free electrons and holes takes place only in direct-bandgap semiconductors. During an optical transition, momentum is conserved, and since the photon carries away negligible momentum, transitions take place only between conduction-band and valence-band states having the same momentum. This is easily satisfied in direct-bandgap semiconductors, because electrons and holes collect at the conduction band at minimum and the valence band at maximum, and both extrema have the same momentum. However, for indirect-bandgap semiconductors, the conduction-band minimum and valence-band maximum have very different momenta, and consequently optical transitions between free electrons and holes are forbidden. Radiative electron-hole recombination is possible in indirect-band-gap semiconductors when the transition is assisted by lattice phonons and impurities. *See* CRYSTAL.

Apart from its application in light-emitting diodes and laser operation, radiative recombination, especially at low temperatures (approximately 2 K or −456°F), has been a very important tool for studying the interaction of electrons and holes in semiconductor crystals. *See* EXCITON.

Competing with radiative recombination are the nonradiative recombination processes of multiphonon emission and Auger recombination. It is suspected that nonradiative recombination by multiphonon emission drives the movement of atoms at room temperature that are responsible for device degradation phenomena such as the climb of dislocations found in GaAs light-emitting diodes and lasers. Auger recombination has been shown to limit the performance of long-wavelength (1.3–1.6 micrometer) lasers and light-emitting diodes used in optical communication systems. *See* AUGER EFFECT; LASER; OPTICAL COMMUNICATIONS; SEMICONDUCTOR. [C.H.He.]

Electron lens An electric or magnetic field, or a combination thereof, which acts upon an electron beam in a manner analogous to that in which an optical lens acts upon a light beam. Electron lenses find application for the formation of sharply focused electron beams, as in cathode-ray tubes, and for the formation of electron images, as in infrared converter tubes, various types of television camera tubes, and electron microscopes.

Any electric or magnetic field which is symmetrical about an axis is capable of forming either a real or a virtual electron image of an object on the axis which either emits electrons or transmits electrons from another electron source. Hence, an axially symmetric electric or magnetic field is analogous to a spherical optical lens.

The lens action of an electric and magnetic field of appropriate symmetry can be derived from the fact that it is possible to define an index of refraction for electron paths in such fields. This index depends on the field distribution and the velocity and direction of the electrons.

Electron lenses differ from optical lenses both in that the index of refraction is continuously variable within them and in that it covers an enormous range. Furthermore, in the presence of a magnetic field, the index of refraction depends both on the position of the electron in space and on its direction of motion. It is not possible to shape electron lenses arbitrarily. *See* ELECTROSTATIC LENS; MAGNETIC LENS. [E.G.R.]

Electron microscope A device for forming greatly magnified images of objects by means of electrons. Electron microscopes serve primarily two purposes: the visual examination of structures too fine to be resolved with ordinary, or light, microscopes, and the study of surfaces that emit electrons. The first function made transmission electron microscopes essential research tools in biology, chemistry, and metallurgy. Beginning in the 1960s the scanning electron microscope came to play an increasingly important role in the study of the surfaces of solid objects at more moderate magnifications. Various emission electron microscopes serve more specialized research purposes. *See* FIELD-EMISSION MICROSCOPY; SCANNING ELECTRON MICROSCOPE; THERMIONIC EMISSION.

A transmission electron microscope consists in its simplest form of a source supplying a beam of electrons of uniform velocity, a condenser lens for concentrating the electrons on the specimen, a specimen stage for displacing the specimen which transmits the electron beam, an objective lens, a projector lens, and a fluorescent screen on which the final image is observed. For permanent record of the image, the fluorescent screen is replaced by a photographic plate or film.

Electrons are strongly scattered by all forms of matter, including air. Hence the entire instrument must be evacuated to about 10^{-4} mmHg (10^{-7} atm or 10^{-2} pascal). Furthermore, the lenses cannot be material in nature. Instead, they are electric or magnetic fields, symmetrical about the axis of the instrument, that have the property of bending the electron paths toward the axis, just as converging glass lenses bend light rays toward their axis. Lens strength is varied by varying the current. Most electron microscopes employ magnetic lenses of this type. These have yielded the highest resolution and magnification attained.

However, good results have also been obtained with electron microscopes employing unipotential electrostatic lenses and magnetic lenses excited by permanent magnets. *See* ELECTRON LENS; ELECTROSTATIC LENS; MAGNETIC LENS.

A microscope can, at best, permit the discrimination of two point objects greater than $0.7\lambda/\sin\theta$ apart. Here λ is the wavelength of the illuminating radiation, and θ is the aperture angle of the cone of radiation that participates in forming the image. For green light, $\lambda = 500$ nanometers. Even for ultraviolet radiation in an immersion medium of refractive index 1.5, λ is no less than 170 nm. Since light and ultraviolet microscope objectives can be designed to utilize practically all the radiation passing through the specimen, $\sin\theta \cong 1$, and the least resolvable distance for the ultraviolet microscope is about 100 nm. For 50- to 100-kV electrons, such as are commonly employed in electron microscopes, the wavelength range is 0.0053–0.0037 nm. Hence, even though a cone of radiation with an aperture angle less than 0.01 radian contributes to an image of optimum sharpness, object separations smaller than 0.3 nm have been resolved with the electron microscope. Thus the electron microscope has several hundred times the resolving power of the light microscope. Similarly, whereas the maximum useful magnification of the light microscope is about 2000, that of the electron microscope may approach 1,000,000. The maximum useful magnification is the least magnification of the image that reveals to the observer all the specimen detail that the microscope is capable of conveying.

Electrons are commonly emitted from the tip of a fine tungsten-wire hairpin filament or, to further reduce the size of the effective electron source, from a sharply pointed segment of wire welded to the filament tip. The filament is maintained at a carefully stabilized negative potential of 50–100 kV with respect to the remainder of the instrument. Electrons enter the instrument through an anode aperture. The intensity and convergence of the electron beam that is falling on the specimen are adjusted by varying the coil current of the condenser lens. Image contrasts are formed by the scattering of electrons out of the narrow cone that contributes to the formation of the image; denser or thicker portions of the specimen scatter more electrons and hence appear darker in the image. The sharpness of the image observed on the screen is adjusted by varying the objective coil current, and its magnification by varying the projector coil current. Both currents must be carefully stabilized to yield high resolution.

In addition to the standard transmission microscopes operating at 50–100 kV, a number of very high-voltage instruments have been constructed (for operation up to 1500 kV). The advantage of high-voltage electron microscopy does not lie in greater resolving power but in increased penetration, which is particularly valuable in the direct study of metal sections prepared with a microtome. [E.G.R.]

The application of the electron miscroscope to examination and investigation of the ultramicrostructure of materials has become so extensive that there is hardly an area in biological and nonbiological research where electron microscopy does not play a role. In biological and medical research the development of sectioning techniques has extended electron microscopy down to observations at the macromolecular level for delineation of the complex organization of cell components such as membranes, mitochondria, endoplasmic reticulum, and ribosomes. Other techniques have been developed for studies on the structure of virus and even individual proteins and nucleic acids. Nonbiological solid materials have also become objects of extensive and fruitful investigation. Diffraction microscopy, together with the development of adequate techniques of sectioning and thinning crystalline materials such as metals, now makes the observation of defect structure in solids an important aspect of electron microscopy. *See* ELECTRON DIFFRACTION. [B.M.Si.]

Electron paramagnetic resonance (EPR) spectroscopy The study of the resonant response to microwave- or radio-frequency radiation of paramagnetic materials placed in a magnetic field. It is sometimes referred to as electron spin resonance (ESR). Paramagnetic substances normally have an odd number of electrons or unpaired electrons, but sometimes electron paramagnetic resonance (EPR) is observed for ions or biradicals with an even number of electrons. EPR spectra are normally presented as plots of the first derivative of the energy absorbed from an oscillating magnetic field at a fixed microwave frequency versus the magnetic field strength. The dispersion may also be detected.

To overcome the intrinsic low sensitivity of the magnetic dipole transitions responsible for EPR, samples are placed in resonant cavities. Routine experiments are carried out in the steady state at a fixed microwave frequency of approximately 9 gigahertz by slowly sweeping the magnetic field through resonance. Free electrons resonate in a magnetic field of 3250 gauss (325 millitesla) at the microwave frequency of 9.1081 GHz, whereas organic free radicals resonate at slightly different magnetic fields characteristic of each particular molecule. *See* ELECTRON SPIN; MAGNETIC RESONANCE; PARAMAGNETISM.

The observation of EPR spectra depends on spin-lattice relaxation, which is the exchange of magnetic energy with the thermal motion of the crystal or molecule. For transition-metal ions and rare-earth ions, experiments often require operation at or near liquid helium temperature (4 K; −269°C; −452°F). Organic free radicals can usually be studied successfully at room temperature. *See* MAGNETIC RELAXATION.

Applications. EPR spectroscopy is used to determine the electronic structure of free radicals as well as transition-metal and rare-earth ions in a variety of substances, to study interactions between molecules, and to measure nuclear spins and magnetic moments. It is applied in the fields of physics, chemistry, biology, archeology, geology, and mineralogy. It is also used in the investigation of radiation-damaged materials and in radiation dosimetry.

The basic physics of transition-metal ions and rare-earth ions present in low concentrations in diamagnetic host crystals has provided a theoretical basis for how electronic structure is modified by the surrounding atoms. Particular applications include probing phase transitions in solids and studies of pairs and triads of magnetically interacting ions.

Applications of EPR in chemistry include characterization of free radicals, studies of organic reactions, and investigations of the electronic properties of paramagnetic inorganic molecules. Information obtained is used in the investigation of molecular structure. EPR is used widely in biology in the study of metal proteins, for nitroxide spin labeling, and in the investigation of radicals produced during reaction processes in proteins and other biomacromolecules. EPR has proved to be an important technique for interdisciplinary investigations of photosynthetic systems. By means of EPR, more than 20 proteins that function in the mitochondrial respiratory chains of mammals have been identified, and details regarding their electron transfer processes have been elucidated.

Solids. EPR spectra from single crystals clearly provide the greatest amount of information. These include crystals containing small concentrations of paramagnetic ions substituting for the regular ions in the crystal or, for organic molecules, small fractions of free radicals produced by ionizing radiation. Spectra which may contain up to several hundred lines are often highly anisotropic; that is, they change with the orientation of the magnetic field direction in the crystal. Transition-metal-ion and rare-earth-ion EPR spectra in crystals are generally much more anisotropic than free radicals due to the intrinsic anisotropy of the electron magnetic moments, and of other effects that are important when there is more than one unpaired electron.

The occurrence of many lines is due to interactions of the orbital motions of electrons with the electric potential of the local surrounding atoms, and to hyperfine interactions between the paramagnetic electrons and nuclear magnetic moments of the paramagnetic ion and surrounding atoms. In the case of free radicals, symmetric or nearly symmetric characteristic hyperfine patterns are observed. From knowledge of hyperfine interactions with nuclei whose spins and magnetic moments are known, the electron distribution throughout a molecule may be determined. Since hyperfine interactions vary as the reciprocal of the cube of the distance between the center of the free radical and the nucleus, structural information may be obtained in addition to electron densities.

Liquids and motional averaging. Spectra in solution due to free radicals are often quite simple as a result of motional averaging, and this clearly gives less information than would be obtained from a single-crystal investigation. Linewidths are very narrow (approximately 0.1 gauss or smaller). By varying the temperature above and below room temperature, EPR spectra range from the frozen solution at low temperatures, with a powderlike spectrum, to rapid motional averaging at room temperature where anisotropies are averaged out. The intermediate region can provide information about slow molecular motions, which is especially important for nitroxide spin labels selectively attached to different parts of macromolecules such as the components of natural and synthetic phospholipid membranes, liquid crystals, and proteins. Such measurements have revealed important structural and functional information. [J.R.P.]

Electron-positron pair production A process in which an electron and a positron are simultaneously created in the vicinity of a nucleus or subatomic particle. Electron-positron pair production is an example of the materialization of energy predicted by special relativity and is accurately described by quantum electrodynamics. Pair production usually refers to external pair production, in which the positron (positively charged antielectron) and electron are created from a high-energy gamma ray as it passes through matter. Electron-positron pairs are also produced from internal pair conversions in nuclei, decays of unstable subatomic particles, and collisions between charged particles. *See* QUANTUM ELECTRODYNAMICS.

In external conversion, the energy of an incoming gamma ray (a high-energy electromagnetic photon) is directly converted into the mass of the electron-positron pair. The photon energy $h\nu$ (where h is Planck's constant and ν is the photon frequency) must therefore exceed twice the rest mass of the electron $2m_0c^2$, equal to 1.022 MeV (m_0 is the electron mass, c the velocity of light). In order to conserve both energy and momentum in this process, the pair must be created near a nucleus, which recoils to balance the momentum of the incoming photon with the momenta of the created electron and positron. Because the nucleus is so much heavier than the electron, it carries away almost no energy from the pair, and the energy of the photon in excess of $2m_0c^2$ is shared unequally as kinetic energy by the positron and electron. Individually, the electron and positron each exhibit a distribution of kinetic energies ranging from zero to the maximum available energy, $E_{\max} = h\nu - 2m_0c^2$, correlated with one another so that their sum is equal to $E_{\max}$. Similarly, the positron and electron are emitted over a broad range of angles, although they exhibit a tendency to move in the same direction, which reflects the momentum of the incoming photon. For incident photon energies above 5 MeV, external pair production is the dominant mechanism by which gamma rays are absorbed in matter. *See* GAMMA-RAY DETECTORS; GAMMA RAYS; PHOTON.

Internal pair creation differs from external conversion in that the positron and electron are created directly from energy liberated by the deexcitation of an excited nucleus (produced, for example, in radioactive decay or nuclear collisions) to a state of lower energy, if the transition energy exceeds the pair mass threshold of $2m_0c^2$. Internal pair creation usually occurs only 10^{-3} times as often as deexcitation by gamma-ray emission, although the exact pair creation probability, as well as the angular correlation between the emitted positron and electron, depends on the nuclear charge and upon the energy and multipolarity of the nuclear transition. *See* RADIOACTIVITY.

Many unstable subatomic particles, such as the neutral *Z* boson and *J*/psi meson, decay into a positron-electron pair alone or with other particles. Since the decaying parent particle is massive, momentum is conserved without the presence of an additional nucleus as is required in external conversion. Decay into a single pair alone creates a positron and electron with equal and opposite momenta. [T.E.C.]

Electron-probe microanalysis A method used for determining the elemental composition of materials, based on the x-rays emitted by different elements when bombarded with high-energy electrons. It is a micro method that can detect x-ray photons emitted by the atoms within a small volume excited by an electron beam focused to 10 nanometers diameter or less. In biology electron-probe microanalysis can be used to determine the composition of cell organelles without isolating them and therefore altering the distribution of diffusible elements.

High-energy electrons can ionize atoms, ejecting an inner-shell electron. To fill the resultant vacancy, an outer-shell electron falls into the ionized shell; the atom remains in the higher-energy excited state. The emission of a characteristic x-ray by the ionized atom is one of the mechanisms for releasing its excess energy. Another mechanism is the emission of Auger electrons; the probability of ejecting an x-ray instead of an Auger electron is the fluorescence yield. In the case of electron-probe microanalysis the source of the exciting electrons is the electron gun, which, in modern electron microscopes equipped with field-emission guns, can produce a focused beam narrower than 1 nm. The x-rays emitted as the result of atomic ionization are called characteristic x-rays, because their energy is characteristic of the core shell of the ionized element and of the shell from which the electron relaxed into the vacancy. *See* AUGER EFFECT; SURFACE PHYSICS; X-RAY FLUORESCENCE ANALYSIS. [A.P.S.]

Electron spectroscopy A form of spectroscopy which deals with the emission and recording of the electrons which constitute matter—solids, liquids, or gases. The usual form of spectroscopy concerns the emission or absorption of photons (x-rays, ultraviolet rays, visible or microwave wavelengths, and so on). Electron spectra can be excited by x-rays, which is the basis for electron spectroscopy for chemical analysis (ESCA), or by ultraviolet photons, or by ions (electrons). By means of ESCA, complete sets of photoelectron lines can be excited from the internal (core) levels as well as from the external (valence) region. Also, complete sequences of the Auger electron lines are automatically obtained in this mode. *See* AUGER EFFECT.

The electron lines in an ESCA spectrum are extremely sharp and well suited for precision measurements. With a high-resolving ESCA spectrometer which has a magnetic or electrostatic focusing dispersive system, the electron lines have widths which are set by the limit caused by the uncertainty principle (the "inherent" widths of atomic levels). With a suitable choice of radiation, electron spectroscopy reproduces directly the electronic level structure from the innermost shells (core electrons) to the atomic surface (valence or conduction band). Furthermore, all elements from hydrogen to the heaviest ones can be studied even if the element occurs together with several other elements and even if the element represents only a small part of the chemical compound. *See* LINE SPECTRUM.

When applied to solid materials, ESCA is a typical surface spectroscopy with applications to problems such as chemical surface reactions, for example, corrosion or heterogeneous catalysis. ESCA also reproduces bulk matter properties such as valence electron band structures. Electron spectroscopy can supply a detailed knowledge of the valence orbital structure for all molecules which can be brought into gaseous form with pressures of 10^{-5} torr (10^{-3} pascal) or more. Under certain conditions, liquids and solutions of various compositions can be studied by ESCA techniques.

A unique feature of ESCA is that, if the exact position of the electron lines characteristic of the various elements in the molecule is measured, the area of inspection can be moved from one atomic species to another in the molecular structure. If the structure of the molecule is known, the charge distribution can be estimated in a simple way by using, for example, the electronegativity concept and assuming certain resonance structures. More sophisticated quantum-chemical treatments can also be applied. Conversely, if, by means of ESCA, the approximate charge distribution is known, conclusions concerning the structure of the molecule can be drawn. *See* ATOMIC STRUCTURE AND SPECTRA; ELECTRON CONFIGURATION; ELECTRONEGATIVITY; MOLECULAR ORBITAL THEORY; SPECTROSCOPY. [K.S.]

Electron spin That property of an electron which gives rise to its angular momentum about an axis within the electron. Spin is one of the permanent and basic properties of the electron. Both the spin and the associated magnetic dipole moment of the electron were postulated by G. E. Uhlenbeck and S. Goudsmit in 1925 as necessary to allow the interpretation of many observed effects, among them the so-called anomalous Zeeman effect, the existence of doublets (pairs of closely spaced lines) in the spectra of the alkali atoms, and certain features of x-ray spectra. *See* SPIN (QUANTUM MECHANICS).

The spin quantum number is s, which is always $^1/_2$. This means that the component of spin angular momentum along a preferred direction, such as the direction of a magnetic field, is $\pm{}^1/_2\hbar$, where $\hbar = h/2\pi$ and h is Planck's constant. The spin angular momentum of the electron is not to be confused with the orbital angular momentum of the electron associated with its motion about the nucleus. In the latter case the maximum component of angular momentum along a preferred direction is $l\hbar$, where l is the angular momentum quantum number and may be any positive integer or zero. *See* ANGULAR MOMENTUM; QUANTUM NUMBERS.

Electron magnetic moment. The electron has a magnetic dipole moment by virtue of its spin. The approximate value of the dipole moment is the Bohr magneton μ_0 which is equal, in SI units, to $eh/4\pi m = 9.27 \times 10^{-24}$ joule/tesla, where e is the electron charge measured in coulombs, and m is the mass of the electron. The orbital motion of the electron also gives rise to a magnetic dipole moment μ_l that is equal to μ_0 when $l = 1$. *See* MAGNETON.

The orbital magnetic moment of an electron can readily be deduced with the use of the classical statements of electromagnetic theory in quantum-mechanical theory; the simple classical analog of a current flowing in a loop of wire describes the magnetic effects of an electron moving in an orbit. The spin of an electron and the magnetic properties associated with it are, however, not possible to understand from a classical point of view.

In the Landé g factor, g is defined as the negative ratio of the magnetic moment, in units of μ_0, to the angular momentum, in units of $\hbar$. For the orbital motion of an electron, $g_l = 1$. For the spin of the electron the appropriate g value is $g_s \simeq 2$; that is, unit spin angular momentum produces twice the magnetic moment that unit orbital angular momentum produces. The total electronic magnetic moment of an atom depends on the state of coupling between the orbital and spin angular momenta of the electron.

Atomic beam measurements. With the development of spectroscopy by the atomic beam method, a new order of precision in the measurement of the frequencies of spectral lines became possible. By using the atomic-beam techniques, it became possible to measure g_s/g_l directly, with the result $g_s/g_l = 2(1.001168 \pm 0.000005)$. The magnetic moment of the electron therefore is not μ_0 but $1.001168\mu_0$, or equivalently the g factor of the electron departs from 2 by the so-called g factor anomaly defined as $a = (g_2 - 2)/2$ so that $\mu = (1 + a)_0$. Thus the first molecular beam work gave $a = 0.001168$. *See* Molecular beams.

Calculation of g-factor anomaly. It is not possible to give a qualitative description of the effects which give rise to the g-factor anomaly of the electron. The detailed theoretical calculation of the quantity is in the domain of quantum electrodynamics, and involves the interaction of the zero-point oscillation of the electromagnetic field with the electron. Comparison of theoretical determination of a with its experimental measurement constitutes the most accurate and direct existing test of the theory of quantum electrodynamics. *See* Atomic structure and spectra; Gyromagnetic ratio; Quantum electrodynamics; Quantum mechanics. [A.Ri.; T.Ki.]

Electron-transfer reaction A reaction in which one electron is transferred from one molecule or ion to another molecule or ion. Electron-transfer reactions are ubiquitous in nature. Some are deceptively simple [for example, reaction (1),

$$^{*}\mathrm{Fe(H_2O)_6}^{3+} + \mathrm{Fe(H_2O)_6}^{2+} \rightarrow {}^{*}\mathrm{Fe(H_2O)_6}^{2+} + \mathrm{Fe(H_2O)_6}^{3+} \qquad (1)$$

where the asterisk is used to identify a specific isotope]; others look very complicated (for example, the long-range electron transfers found in biology). The widespread occurrence of electron-transfer reactions has stimulated much theoretical and experimental work. *See* Chemiosmosis; Photosynthesis.

The simplest reactions in solution chemistry are electron self-exchange reactions (2), in which the reactants and products are

$$^{*}\mathrm{A_{ox}} + \mathrm{A_{red}} \rightarrow {}^{*}\mathrm{A_{red}} + \mathrm{A_{ox}} \qquad (2)$$

the same (the asterisk is used to identify a specific isotope). The only way to determine chemically that a reaction has taken place is to introduce an isotopic label. There is no change in the free energy ($\Delta G^\circ = 0$) for this type of reaction.

Much more common are cross reactions (3), where $\mathrm{A_{ox}}$ is the

$$\mathrm{A_{ox}} + \mathrm{B_{red}} \rightarrow \mathrm{A_{red}} + \mathrm{B_{ox}} \qquad (3)$$

oxidized reactant, $\mathrm{B_{red}}$ is the reduced reactant, $\mathrm{A_{red}}$ is the reduced product, and $\mathrm{B_{ox}}$ is the oxidized product. For these reactions, $\Delta G^\circ \neq 0$.

Both types of electron-transfer reactions (self-exchange and cross reactions) can be classified broadly as inner sphere or outer sphere. In an inner-sphere reaction, a ligand is shared between the oxidant and reductant in the transition state. An outer-sphere reaction, on the other hand, is one in which the inner coordination shells of both the oxidant and reductant remain intact in the transition state. There is no bond breaking or bond making, and no shared ligands between redox centers. Long-range electron transfers in biology are all of the outer-sphere type. *See* Oxidation-reduction.

Electron-transfer theory. The simplest electron transfer occurs in an outer-sphere reaction. The changes in oxidation states of the donor and acceptor centers result in a change in their equilibrium nuclear configurations. This process involves geometrical changes, the magnitudes of which vary from system to system. In addition, changes in the interactions of the donor and acceptor with the surrounding solvent molecules will occur. The Franck-Condon principle governs the coupling of the electron transfer to these changes in nuclear geometry: during an electronic transition, the electronic motion is so rapid that the nuclei (including metal ligands and solvent molecules) do not have time to move. Hence, electron transfer occurs at a fixed nuclear configuration. In a self-exchange reaction, the energies of the donor and acceptor orbitals (hence, the bond lengths and bond angles of the donor and acceptor) must be the same before efficient electron transfer can take place. *See* Franck-Condon principle.

Long-range electron transfer. The rate of long-range electron transfer between an electron donor ($\mathrm{B_{red}}$) and an electron acceptor ($\mathrm{A_{ox}}$) depends on both the electronic coupling between Aox and Bred (which is a function of the intersite $\mathrm{A_{ox}}//\mathrm{B_{red}}$ distance d, the nature of the intervening medium, and the relative $\mathrm{A_{ox}}//\mathrm{B_{red}}$ orientation, where // represents the protein medium that separates the donor and the acceptor) and an activation energy term. A standard theoretical rate equation (4) expresses k_{et}

$$k_{et} = \nu[\{\exp(-ß\, d)]\exp[(\lambda + \Delta G^\circ)^2/4\lambda RT]\} \qquad (4)$$

in terms of these factors; here, υ is a frequency factor, ß is a medium- and orientation-dependent quantity, d is the intersite distance, λ is the reorganization energy, ΔG° is the reaction free energy of the electron-transfer process, R is the universal gas constant, and T is the absolute temperature of the system. Experiments in several laboratories have been designed to estimate the values of λ and ß in modified metalloproteins, rigid organic molecules, and protein–protein complexes.

[B.E.Bo.; W.R.El.; H.B.Gr.; T.J.Me.]

Electron tube A device in which electrons can travel through a sealed chamber containing at least two electrodes and gas at a very low pressure. The gas pressure usually ranges from about 10^{-6} to 10^{-9} atm (10^{-1} to 10^{-4} pascal). At the low extreme of this pressure range, electron tubes are sometimes referred to as vacuum tubes, and at the high extreme as gas tubes. *See* Gas tube; Vacuum tube.

At least one of the electrodes must emit electrons, and at least one must collect electrons. The emitting electrode, the cathode, may emit electrons through one or more of four mechanisms: thermionic or primary emission, secondary emission photoelectric emission, or field emission. Electrons must acquire more energy than they have in the conduction band of a metal in order to escape from the surface of a metal. They acquire this energy, respectively, in the four mechanisms listed above, from heat, electron or ion impact, a photon impact, or an external electric field. Photoelectric emission is used in light-sensing devices, often in combination with secondary electron multiplication to amplify the current. Secondary emission, sometimes in combination with thermionic emission, plays an important role in magnetrons and in crossed-field amplifiers. Field emission is used in some experimental amplifiers, flat-panel display devices, and x-ray tubes, but by far the most common type of emitting electrode used in electron tubes is the thermionic cathode. *See* Cathode-ray tube; Field emission; Flat-panel display device; Magnetron; Photoemission; Photomultiplier; Phototube; Secondary emission; Thermionic emission; X-ray tube.

A diode is a two-electrode tube, with a cathode and a collecting electrode. A. Fleming (1904) developed the first thermionic diode using an oxide cathode. Because the collecting electrode is usually operated at a positive potential with respect to the cathode in order to collect much of the available electron current from the cathode, it is called an anode. Even so, because of the thermal energy of thermionic electrons, the anode can collect some electrons when it has a slightly negative potential. *See* DIODE.

L. DeForest (1906) added a third electrode to a diode in order to control the current flow from cathode to anode. This third electrode, the grid, took the form of a fairly open array or mesh made of wires with a diameter small compared to their spacing. In this geometry, much of the electric field from the anode terminates on the grid, and the field from the grid that terminates on the cathode exerts a primary influence on the space-charge current that flows to or through the grid. When the grid is at a negative potential with respect to the cathode, current flows due to the anode field that leaks through the grid, but the grid can collect no current. When the grid and anode are both positive, much more current flows and divides between the grid and anode.

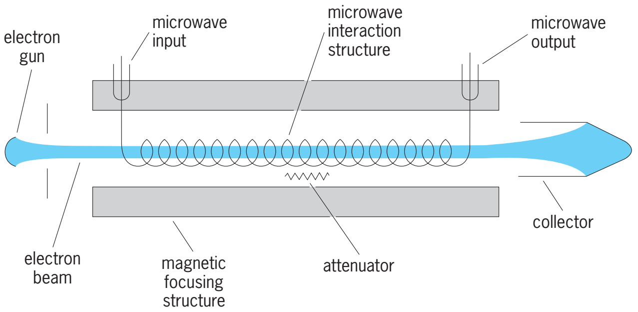
Unfortunately, in triode amplifiers at high frequencies, the capacitance between the anode and grid electrodes, in combination with typical grid circuit reactances, can cause positive feedback, regeneration, or oscillation unless circuits that provide compensating negative feedback are used. For this reason W. Schottky (1919) invented the tetrode, which has a second or screen grid between the first or control grid and the anode. This grid was operated at a constant positive potential and effectively shielded the control grid from the anode. At large signal levels, it also created a problem by collecting secondary electrons emitted from the anode as a result of primary electron impacts when the instantaneous voltage on the anode was less than the screen grid voltage. This problem was dealt with in two ways. G. Jobst and D. H. Tellegen (1926) introduced the pentode, which has a third very open suppressor grid between the screen grid and the anode. It was connected to the cathode. This created an electric field which returned secondary electrons to the anode. A more elegant solution to the secondary electron problem was provided in the beam-power tetrode. In these tetrodes the anode was placed far enough from the screen grid that the charge of the electrons traveling between the screen grid and anode actually depressed the potential in the space between the screen and anode enough to return secondary electrons to the anode.

The tubes discussed so far act as valves that control the flow of a current to a load. The potential energy of the current is derived from a direct-current power source. There is another class of electron tubes, most of which are referred to as microwave tubes, in which electrons are accelerated to a velocity at which they have a kinetic energy that is equivalent to the full voltage of the power supply that was used to accelerate them. If these electrons are bunched periodically in time, they can be made to give up their energy to the electric field in a gap or gaps in a very high frequency or microwave circuit. Microwave tubes include the inductive output tube, the klystron, traveling-wave tubes, crossed-field devices, and cyclotron-resonance devices.

In the inductive output tube, invented by A. V. Haeff (1939), an electron beam is amplitude-modulated with a grid and then accelerated through a hole in the first accelerating electrode to form the high-velocity beam of electrons that passes through a gap in the center conductor of the coaxial external cavity resonator and into the collector. Inductive output tubes are used in many television transmitters operating between 470 and 900 MHz.

The klystron, invented by R. Varian and S. Varian (1939), has a similar output cavity and collector, but has a beam which is first accelerated in a diode electron gun and then velocity-modulated in another reentrant cavity gap. Fast electrons overtake slowed electrons and yield an intensity-modulated beam by the time the electrons reach the output cavity. Additional cavities may be interposed between the input and output cavities to provide very high gain (often as high as 60 dB). *See* KLYSTRON.

In traveling-wave tubes (see illustration) invented by R. Kompfner (1946), a high-velocity electron beam is velocity-modulated by, and gives up its energy to, periodically loaded or helical waveguides which slow the electromagnetic wave to a velocity nearly equal to that of the electron beam. Again very high gain is possible. *See* TRAVELING-WAVE TUBE.



Basic elements of a typical traveling-wave tube. (*After D. Christiansen, ed., Electronic Engineers' Handbook, 4th ed., McGraw-Hill, 1996*)

Input-output tubes, klystrons, and traveling-wave tubes are used in television broadcasting, satellite communications systems, radar, scientific accelerators, medical accelerators used for cancer therapy, and military countermeasures equipment.

In magnetrons and crossed-field amplifiers, electrons circulate about a cylindrical cathode in a radial direct-current electric field and an axial magnetic field. Concentric with, and outside, the cathode is a periodically loaded transmission line that propagates a wave having components that travel in synchronism with the rotating electron cloud. The electrons follow orbits that allow them to take energy from the radial direct-current electric field and transfer it to the circumferential radio-frequency electric field of the wave on the circuit. Magnetrons are used in huge quantities in household microwave ovens. They and crossed-field amplifiers are also used in ground-based, shipboard, and airborne radars.

Cyclotron-resonance devices including gyrotrons, gyroklystrons, and gyro-traveling-wave tubes again employ electrons that have been accelerated to the full energy provided by the electrical power supply. The beam is formed in a magnetic field so that it has a great deal of momentum perpendicular to the magnetic field, and the electrons follow helical paths. A radio-frequency electric field perpendicular to the axis of the electron trajectories will modulate the energy of the electrons and hence the relativistic mass and the cyclotron frequency. This azimuthal velocity modulation causes the electrons to draw into rodlike bunches that can give up their energy to a circuit supporting either the same alternating electric field that bunched them (in a gyrotron), or to an alternating electric field in another circuit (in a gyroklystron). Cyclotron-resonance devices can be built using very long circuits producing very weak electric fields, and as a result, having very low losses at very high frequencies. Efficient gyrotrons have been built at frequencies as high as several hundred gigahertz and have produced continuous power of hundreds of kilowatts. *See* GYROTRON; MICROWAVE TUBE. [R.S.Sy.]

Electron wake The pattern of electron density fluctuation and electromagnetic disturbance set up by the passage of a swift ion through condensed matter. In dense media that can sustain well-defined resonance oscillations at a frequency ω_0, wakes of periodic character will form behind swift charged particles having speed v. The periodicity in space, λ, the distance between troughs of the wake, is given by Eq (1). The oscillations trail behind the ion, move with the ion velocity, and have the frequency ω_0. In addition, close collisions between the ion and electrons of the medium cause electrons to recoil to form

$$\lambda = \frac{2\pi v}{\omega_0} \tag{1}$$

the analog of a bow wave ahead of the ion. *See* RESONANCE (QUANTUM MECHANICS).

The wake at the position of the guiding ion is of special significance. The electric field there times the ion charge represents the reaction of the medium to the ion and yields the stopping power of the medium for the ion, that is, the energy loss per unit path length.

When molecular ions are injected into a solid with speeds greater than $v_0 = 2.2 \times 10^6$ m/s, the so called Bohr speed (the speed of an electron in the ground state of hydrogen according to the Bohr model), the valence electrons are stripped, leaving atomic ions to propagate as clusters of correlated charged particles through the medium. A dicluster is composed of two atomic ions travelling close together at nearly the same velocity. A wake is formed given by a (generally nonlinear) superposition of wakes due to the individual ions of the cluster. The dynamically modified Coulomb repulsion between its constituents causes the cluster, in effect, to explode. A pair of ions traveling with the same initial velocity, and created exactly abreast of one another, will recede rapidly from one another because of the Coulomb force acting on them. In typical experiments, the cluster-particle interaction probes the slope of the cluster wake potential near the origin, because the foils used in most experiments are so thin that the separation of the ions after traveling through the foil does not greatly exceed their initial separation. An important effect of the wake interaction is to cause the cluster to lose energy at a faster rate than would its isolated constituents traveling at the same speed, because the wake field of a given ion in a cluster acts, in most experiments, to retard the other ions of the cluster.

Measurements of the angular deflections and energy losses of protons resulting from diclusters formed from swift $(HeH)^+$ or $(OH)^+$ ions bombarding thin foils yield angular distributions that have a circular character due to the action of a Coulomb explosion. Such distributions generally have a large peaked region on the perimeter due to the trailing protons that are focused by the wake of the other ion in the Coulomb explosion. There is also a much smaller peak due to protons that lead the ion. Such experiments have been important in establishing the structure of molecular ions that were formerly not well known.

In other work with diclusters, the oscillatory character of the wake is vividly displayed in a two-foil experiment. A cluster enters the first foil and, after passing through a vacuum separating the carbon foils, enters the second one. The trailing ion experiences the wake force of the leading one. The dependence of the yield of secondary electrons from a final target on the distance between carbon foils shows the characteristic oscillatory behavior. *See* CHARGED PARTICLE BEAMS; COULOMB EXPLOSION. [R.H.Ri.]

Electronegativity According to L. Pauling, "the power of an atom in a molecule to attract electrons to itself." Quantitative definitions and scales of electronegativity have been based not on electron distribution itself but on properties which were assumed to reflect electronegativity.

The electronegativity of an element depends upon its valence state and thus is not an invariant atomic property. As an example, the electron-withdrawing ability of an sp^n hybrid orbital centered on carbon and directed toward hydrogen increases as the percentage of *s* character in the orbital increases in the series ethane < ethylene < acetylene. Thus, according to this concept of orbital electronegativity, each element exhibits a range of electronegativity values.

The original scale, proposed by Pauling in 1932, is based upon the difference between the energy of the A-B bond in the compound AB_n and the mean of the energies of the homopolar bonds A-A and B-B (see table). R. S. Mulliken proposed that the electronegativity of an element is given by the average of the valence-state ionization potential and electron affinity. The Mulliken approach is consistent with Pauling's original definition and gives orbital electronegativities, not invariant atomic electronegativities. Electronegativity was defined by A. L. Allred and E. G. Rochow as the force of attraction between a nucleus and an electron from a bonded atom. A quantum-defect electronegativity scale has been developed from potentials based on atomic spectral data, and a nonempirical scale has been calculated by an ab initio method using floating gaussian orbitals.

Average electronegativities from thermochemical data

Element	Value	Element	Value
H	2.20	Al	1.61
Li	0.98	Ga	1.81
Na	0.93	In	1.78
K	0.82	Tl	2.04
Rb	0.82	C	2.55
Cs	0.79	Si	1.90
Be	1.57	Ge	2.01
Mg	1.31	Sn	1.96
Ca	1.00	Pb	2.33

Cr	1.66	O	3.44
Mn	1.55	S	2.58
Fe	1.83	Se	2.55
Co	1.88	F	3.98
Ni	1.91	Cl	3.16
Cu	1.90	Br	2.96
Zn	1.65	I	2.66
B	2.04		

Other methods for calculating electronegativities utilize such observables as bond-stretching force constants, electrostatic potentials, spectra, and covalent radii. The measurement of electronegativities involves observations of properties dependent upon electron distribution. Close agreement of electronegativity values obtained from measurements of several diverse properties lends confidence and utility to the concept. [A.L.A.]

Electronic display An electronic component used to convert electrical signals into visual imagery in real time suitable for direct interpretation by a human operator. It serves as the visual interface between human and machine. The visual imagery is processed, composed, and optimized for easy interpretation and minimum reading error. The electronic display is dynamic in that it presents information within a fraction of a second from the time received and continuously holds that information, using refresh or memory techniques, until new information is received. The image is created by electronically making a pattern from a visual contrast in luminance between (1) individual electrically alterable picture elements (pixels) in a matrix array of pixels in flat-panel displays (FPDs) or (2) electrically excited and nonexcited areas in a phosphor film in cathode-ray tubes (CRTs). High-information-content (HIC) displays are those displays that have a sufficient number of pixels (75,000 to 2,000,000) to show standard or high-definition television images, or comparable computer images.

The use of electronic displays for presentation of graphs, symbols, alphanumerics, and still and video pictures has doubled every several years, in parallel with the rapid expansion of microelectronics. Electronic displays have largely replaced traditional mechanical devices, counters, galvanometers, and, to a degree, hardcopy (paper) means for presenting information. This change is due to the increased use of computers, microprocessors, inexpensive large-scale integration (LSI) electronics, and digital mass memories. The success of the digital watch, hand-held calculator, and personal computer is directly attributable to the availability of inexpensive LSI electronics and electronic displays. *See* CALCULATORS; COMPUTER; COMPUTER GRAPHICS; COMPUTER STORAGE TECHNOLOGY; INTEGRATED CIRCUITS; MICROCOMPUTER; MICROPROCESSOR; WATCH.

Electronic display spectrum of applications

Classification	Characteristics	Applications	Electronic technologies
Pseudoanalog	Dedicated arrangement of discrete pixels used to present analog or qualitative information	Meterlike presentations, go/no-go messages, legends and alerts, analog-like (watch) dial	Gas discharge, light-emitting diodes, liquid crystal, incandescent lamps
Alphanumeric	Dedicated alphanumeric pixel font of normally less than 480 characters; most common is 4- and 8-character numeric displays	Digital watches, calculators, digital multimeters, message terminals, games	Liquid crystal, light-emitting diodes, vacuum fluorescent, gas discharge, incandescent lamps
Vectorgraphic	Large orthogonal uniform array of pixels which are addressable at medium to high speeds; normally, monochromatic with no gray scale; may have memory; normally, over 480 characters and simple graphics	Computer terminals, TWX terminals, arrivals and departures, scheduling terminals, weather radar, air-traffic control, games	Cathode-ray tube, plasma panels, gas discharge, vacuum fluorescent, electroluminescence, PMLCD, LED
Video	Large orthogonal array of pixels which are addressed at video rates (30 frames per second); monochromatic with gray scale or full color; standardized raster scan addressing interface, arrays of pixels approximately 240 rows by 320 columns and larger	Entertainment television, graphic arts, earth resources, video repeater, medical electronics, aircraft flight instruments, computer terminals, command and control, games	Cathode-ray tube, plasma panels, electroluminescence, AMLCD, LED

The major electronic display application is in home color television. The computer terminal using a CRT or FPD is the most important industrial application of electronic displays. With advances in high-information-content FPD technology, the electronic display industry went through a dramatic change in the early 1990s. This was primarily due to breakthroughs and manufacturing advances in liquid-crystal displays (LCDs). Color active-matrix LCDs (AMLCDs) have better performance than color CRTs for video and computer graphics and are thin and portable. However, the AMLCDs are several times more expensive than CRTs, so their use remains restricted to applications such as personal computers and television receivers where the CRT will not fit. *See* LIQUID CRYSTALS.

The primary applications of the CRT are in home entertainment television, computer monitors, scientific and electrical engineering oscilloscopes, radar display, and alphanumeric and graphic electronic displays. *See* OSCILLOSCOPE; RADAR; TELEVISION.

Because of the depth dimension of the CRT, there has been a concentrated effort to develop FPDs. A primary motivating factor has been to achieve a flat high-information-content display which could be hung on a wall or carried in a briefcase. Over the years, the electrical phenomena most extensively developed for FPDs have been gas discharge (plasma), electroluminescence, light-emitting diode, cathodoluminescence, and liquid crystallinity. The cost of FPDs is higher than CRTs on a character-per basis for HIC displays. *See* CATHODOLUMINESCENCE; ELECTROLUMINESCENCE; LIGHT-EMITTING DIODE.

Before the 1990s, cost and performance limitations restricted the use of FPDs to specialized applications. With the advent of two major breakthroughs in the 1980s, LCDs emerged as the leading FPD. These two breakthroughs were the invention of the supertwisted nematic (STN) LCD, often referred to as passive-matrix LCD (PMLCD), and the evolution of a manufacturable AMLCD. The STN inventions improve LCDs so that they can be made as a HIC FPD because of improvements in the matrix addressing capability. Both of these types are made in monochrome and full color. The AMLCD is fast enough for video and for multimedia displays, comparable to a CRT. The PMLCD is fast enough for computer use but not video; however, PMLCDs are about half the cost of AMLCDs.

Applications of LCDs include portable computing devices and memory aids; electronic games; moving map devices in conjunction with global positioning satellites (GPS) for navigation of boats, aircraft, and motored vehicles; educational devices and video for portable handheld devices; and displays for television, entertainment, education, and information dissemination. LCDs are also used in helmet displays and virtual-reality displays. *See* SATELLITE NAVIGATION SYSTEMS; VIDEO GAMES.

The smaller AMLCDs are used in camcorder viewfinders, helmet displays, and projectors. The medium-size displays are used in all the applications that are viewed directly, such as portable computers or television receivers.

PMLCDs are used with the STN configuration of LCD in devices where some reduction in performance is acceptable, such as portable computer displays that do not require video imagery. PMLCDs in the basic twisted nematic (TN) mode are used in inexpensive toys, automotive panels, meter displays, and watches.

Electronic displays can be categorized into four classifications; as shown in the table. Each classification is defined by natural technical boundaries and cost considerations. The categorization is useful in visualizing the extent to which electronic displays are used.

Color can be created on a CRT equipped with a shadow mask duplicating quite closely all colors that occur in nature. This is done in the CRT by using three different electron guns and three phosphors in a triad of red, green, and blue on the screen at each pixel. The shadow mask is a metal screen with one hole for each triad of phosphor dots (pixel). It is precisely located and aligned with the phosphor screen. Electron beams from each of three guns are constrained by each shadow mask hole to hit each respective phosphor dot.

Penetration phosphors are also used to create color on CRT displays to eliminate the need for the shadow mask and extra guns. However, the color is limited and the brightness is low. Normally, two phosphors are placed on the screen in two layers or in microspheres of two layers. The gun and CRT anode are operated in two energy states to produce either a high-energy or a low-energy electron beam switchable in time.

Monochromatic as well as full color is readily produced by FPD technologies. Full color is produced by using a triad of red, green, and blue for each pixel, or sequential flashing at 180 Hz of red, green, or blue at each pixel area. Full color is very important for entertainment television displays. Most industrial electronic displays do not necessarily need full color, but full color has been used more frequently as color display costs have decreased. In these applications, the color display instrument is usually a CRT using the shadow-mask color technique.

The essence of electronic displays is based upon the ability to turn on and off individual pixels (Fig. 1). A typical HIC display will have a quarter million pixels in an orthogonal array, each under individual control by the electronics. The pixel resolution is normally just at or below the resolving power of the eye at one minute of arc. Thus, a good-quality picture can be created from a pattern of activated pixels. The pixel concept for electronic displays has evolved from the modern FPD technologies and digital electronics.

With flat-panel and CRT digital display techniques, alphanumeric character fonts are created by turning on the appropriate pixels in an array. One standard size is a 5 × 7 array with two pixels between characters and two pixels between rows (Fig. 1). All the letters and numbers can be created on this common

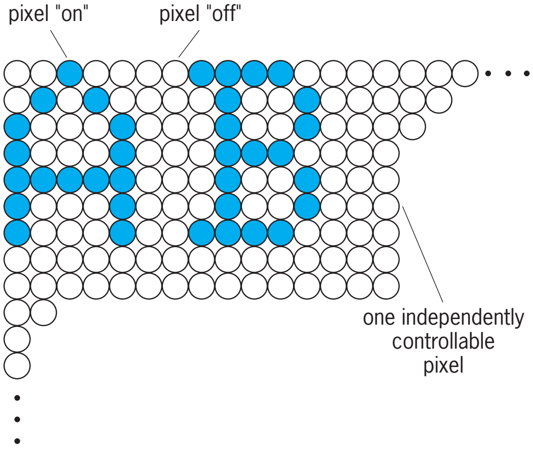

Fig. 1. Pixel array used for creating electronic display images.

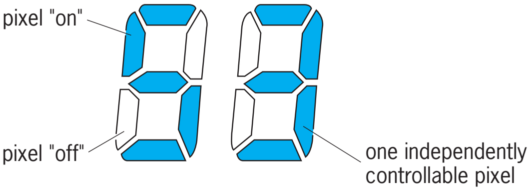

Fig. 2. Seven-bar numeric font.

array format. A very efficient and elegant array has evolved for portraying numeric characters and many letters of the alphabet, called the seven-bar font (Fig. 2). Each bar is a pixel by definition. This font was initially considered crude when compared to the Leroy font and other more esthetic printer fonts. It is now universally accepted. A similar 14 bar font is sometimes used for alphanumeric characters. [L.E.T.]

Electronic listening devices

Devices which are used to capture the sound waves of conversation originating in an ostensibly private setting in a form, usually as a magnetic tape recording, which can be used against the target by adverse interests.

There are two kinds of electronic listening devices. One takes advantage of equipment already present on the target's premises, such as a telephone, radio, phonograph, television set, public-address loudspeaker, or tape recorder, to act as a microphone, transmitter, or power supply. The other does not. In the former case, the target's equipment is said to have been compromised.

Compromise of the target's own equipment takes advantage of the fact that any loudspeaker is capable of functioning just as well as a microphone, that convenient sources of dc power are available within the equipment, or that the equipment is connected to power or signal lines that can transmit the intercepted conversation to some place where recording can conveniently be accomplished. The equipment most frequently compromised is the telephone handset.

Eavesdropping devices that can stand alone are known commonly as "bugs." They take advantage of many developments of modern technology, such as microcircuits, miniature ceramic microphones, and miniature batteries. Electronically a bug is often just a two-stage frequency-modulated transmitter: an audio amplifier and a variable-frequency radio-frequency (rf) oscillator. Bugs may operate on any frequency from 20 to 1000 MHz, but usually they snuggle up beside a powerful local FM or vhf television station. *See* AMPLIFIER; OSCILLATOR; RADIO TRANSMITTER.

A popular hybrid between a compromise device and a bug is the telephone drop-in. In this design, an FM transmitter is made in the form of a telephone microphone. The eavesdropper can casually unscrew the mouthpiece of his target's telephone handset and substitute the drop-in for the original microphone. The range of this device is about 240 ft (75 m). It has the added advantage of drawing its dc power from the telephone company central battery. [J.M.C.]

Electronic mail

The asynchronous transmission of messages by using computers and data-communication networks. Historically, electronic mail (or e-mail) referred to any of a number of technologies that allowed people to send documents to one another through electronic means. It was frequently used to describe both wirephoto [the precursor of the facsimile (fax) machine] and telegraphy. Subsequently, usage of the term focused upon the narrower sense given above. *See* FACSIMILE; TELEGRAPHY.

The use of electronic mail grew continuously until the late 1980s but never achieved widespread use outside of work groups or corporations. The limiting factor was the complicated addressing that had to be worked out before a message could be successfully transmitted.

There were two proposed methods to solve the problem of mail-system identification and routing. The Organization for International Standardization (ISO) formulated the X.400 standard, and the Internet community developed an extended use of the domain name system (DNS). Many impediments to the spread of X.400, such as high software costs and delays in standardization, caused the freely available DNS solution to become the de facto standard.

The DNS describes a worldwide distributed database in which each site maintains its own information about how to route messages to a computer within its administrative domain. A computer wishing to send a message to another asks the DNS for the routing information and uses the information returned to make the connection. This allows a person on virtually any online networking service to send mail to another person by giving only the personal identification and the e-mail system name of the recipient. *See* DISTRIBUTED SYSTEMS (COMPUTERS).

From the time the usage of the term narrowed to exclude facsimile until the early 1990s, generally only coded textual information could be transferred via e-mail. The transmission of nontextual data required special preprocessing, postprocessing, and prior arrangements between the sending and receiving parties. It was very difficult to make these kinds of transfers if the sending and receiving computers were different types.

This restriction was lifted with the adoption of the MIME (Multimedia Internet Mail Enhancements) standard. It described a way of encoding an arbitrary list of media types within a normal textual message in an operating-system-independent manner. Finally, different types of systems could send executable, sound, picture, movie, and other kinds of files to each other via e-mail. *See* MULTIMEDIA TECHNOLOGY.

The spread of electronic mail was also hampered by its lack of security. As mail was passed from one site to another closer to its destination, system administrators at each intermediate site could read messages. Also, the source of an e-mail message may be fairly easily forged to make it either untraceable or appear to come from another person. This limited the use of e-mail to so-called friendly applications. Public-key cryptography has been applied to e-mail messaging, notably in PEM (Privacy Enhanced Mail), in response to these security concerns. *See* COMPUTER SECURITY; CRYPTOGRAPHY.

Since the communications speeds required for e-mail are quite modest, messages are sometimes transmitted by wireless means. Cell phones and personal digital assistants can send and receive e-mail through Earth-satellite relay. *See* INTERNET; WORLD WIDE WEB. [E.Kro.]

Electronic navigation systems

Systems that provide a variety of navigational parameters through the application of the electronic sciences. Typical parameters are distance and bearing from a vehicle to a known point, and the present position of the vehicle in a particular coordinate system. From the knowledge of present position, the course and distance to a destination can be calculated. Most systems are based on the use of electromagnetic (radio) waves, and those described here are used by aircraft, ships, land vehicles, and space vehicles.

The use of radio waves has been found to be attractive because of their known, and nearly constant, velocity of propagation, namely, the speed of light (c), which is about 1.86×10^5 mi/s (3×10^8 m/s). Thus, if the time (t) of travel of the radio signal between two points is accurately measured, the distance or range (d) between the points can be accurately determined from the equation $d = ct$. Ships also use systems based on underwater sound waves, with due allowance for the much slower speed of sound in water. Also, electromagnetic waves in the visible (optical) or near-visible spectrum can be used in a similar manner for distance measurement. *See* ELECTROMAGNETIC RADIATION; LIGHT; SONAR; UNDERWATER NAVIGATION; UNDERWATER SOUND.

From an electronic viewpoint, all systems can be classified as either cooperative or self-contained. From a navigational viewpoint, systems are frequently classified as positioning or dead-reckoning systems. Most positioning systems are cooperative systems, while most dead-reckoning systems are self contained. Many modern systems combine the data from cooperative and self-contained sensors to obtain a more accurate solution. Such systems have been called multisensor, integrated, or hybrid systems. *See* DEAD RECKONING.

Cooperative systems. The two general categories of cooperative radio systems are point-source systems and multiple-source systems. Point-source systems typically determine position in a relative coordinate system by measuring the distance and bearing to a transmitting source at a known location. *See* RHO-THETA SYSTEM.

Perhaps the earliest form of a point-source radio system is the direction finder, in which the signal from a single transmitter source is received at two known points or elements. The direction from the vehicle to the source is determined by measuring the differential distance (or phase) of the signals received at the two points or elements. For operational convenience (size), it is desirable to have the two receiving points close together and to use common circuitry at both measuring points. A loop antenna fulfills both of these requirements. The loop is rotated until the currents in the two vertical arms of the loop are equal in amplitude and phase so that the output of the receiver is zero. The transmitter source is then located 90° from the plane of the loop. In simple loops, there is a 180° ambiguity, but this is typically resolved by temporarily connecting an omnidirectional antenna to the receiver input. *See* DIRECTION-FINDING EQUIPMENT.

The angular measurement errors, particularly on aircraft and ships, can be quite large (3° or more). However, direction finders are still used, particularly for backup navigation and emergency homing.

Another class of point-source angle-measuring systems is based on the use of rotating or scanning antenna beams at the transmitter source and reception (or reflection) of the transmitted signal by the user vehicle receiver. For example, if a ground transmitter generates a rotating cardioid amplitude pattern at a fixed rate plus an omnidirectional reference signal, the user receiver can measure the relative phase difference between these two signals and thereby determine the bearing to the transmitter source. The very high frequency (VHF) omnidirectional range (VOR), used worldwide for short-distance aircraft navigation, is based on this principle. *See* VOR (VHF OMNIDIRECTIONAL RANGE).

Another point-source technique for bearing measurement is based on using a radiated dual-lobe structure, with the carrier in each lobe being modulated at different frequency tones and phases. The user receiver can then detect when the vehicle is operating at the intersection of the two beams. The instrument landing system (ILS), which is used worldwide for aircraft approach and landing, is based on that principle. *See* INSTRUMENT LANDING SYSTEM (ILS).

Theoretically, there are two possible types of point-source systems for distance determination. One is based on the two-way (round-trip) ranging principle. The interrogator, which may be located on the navigating vehicle, transmits a signal, typically a pulse or pair of pulses, at a known time, which is stored in the equipment. The signal is received at a transponder and, after a fixed, known delay, is retransmitted toward the interrogator. When received by the interrogator's receiver, it becomes an input to the ranging circuit. This circuit measures the time difference between the original transmission time and the time of reception (less the known fixed delay), which (when multiplied by the speed of light) is a direct measure of the two-way distance. Such a system is the basis of the distance-measuring equipment (DME), used for short-range navigation worldwide, and also of the Air-Traffic Control Radar Beacon System (ATCRBS), used for air-traffic control surveillance on a global basis. *See* AIR-TRAFFIC CONTROL; DISTANCE-MEASURING EQUIPMENT.

A second possible technique for point-source distance determination is one-way signal-delay (time-of-arrival) measurement between a transmitter source at a known location and a user receiver. In this case, a successful measurement is possible only if the transmitter oscillator (clock) and the user receiver oscillator (clock) are precisely time synchronized. Since this synchronization is frequently impossible at reasonable equipment cost, no practical point-source distance measurement system based on such synchronization has been developed, but several modern multisensor systems (discussed below) have modes that employ this principle.

Multiple-source radio systems employ multiple transmitter sources, and user vehicle equipment typically consisting of a receiver or a receiver-transmitter. The four major categories of such systems (with some implementations using combinations of these) are hyperbolic systems, pseudoranging systems, one-way synchronous ranging (direct-ranging) systems, and two-way (round-trip) ranging systems.

Hyperbolic systems were the first to be developed, but they are still in widespread use. Three or more transmitter sources transmit time-synchronized continuous-wave or pulsed signals. The user receiver measures time differences of signals from pairs of stations. Loci of constant time differences, or (equivalently) constant differences in distance, from two stations form hyperbolic lines of position (LOPs). The point where two lines of position cross is the position of the user vehicle. The Loran C system is based on this hyperbolic principle. *See* DECCA; HYPERBOLIC NAVIGATION SYSTEM; LORAN.

Pseudoranging has some similarity in configuration to hyperbolic systems, but does not use time differences. Several transmitter sources (for example, space vehicles or terrestrial stations), whose positions are made known to the user, transmit highly time-synchronized signals based on an established system time. With the periodic times of transmission epochs of the signals from the sources provided or known to the user, the user measures the time of arrival (TOA) of each signal with respect to the user's own clock time, which normally has some offset from system time. This range measurement is called pseudorange, since it differs from the true range as a result of the offset of the user's clock relative to the system (transmitter) time. From successive or simultaneous time-of-arrival (pseudorange) measurements from four (or more) sources, the user receiver then calculates the three-dimensional position coordinates and its own clock offset (from system time). This is accomplished by solving four simultaneous quadratic equations (usually the computations are linearized), involving the three known position coordinates of the sources and the four unknowns, namely, the three user position coordinates and the user's clock offset. Thus, such a system accurately determines not only the user's three-dimensional position but also system time, which is easily related to Universal Time Coordinated (UTC). The pseudoranging concept is the basis of operation of two major satellite navigation systems for worldwide use, the U.S. Global Positioning System (GPS) and the Russian Global Navigation Satellite System. *See* SATELLITE NAVIGATION SYSTEMS.

The implementation of one-way synchronous ranging between one of the transmitter sources and the user receiver was discussed above. In order for a true one-way range measurement to be made, the clock of the user receiver must first be synchronized to that of the transmitter source. In some systems, this is accomplished by an independent means, for example, in the JTIDS-RelNav system and in the Position Location Reporting System (PLRS). The concept is also used in one mode of certain hyperbolic systems, notably Loran C. Two implementations are possible, the rho-rho method or the multiple-rho method. The rho-rho method requires only two source transmitters, but also requires a highly stable user receiver oscillator (clock) and precise knowledge of the time of transmission from the source stations. The multiple-rho method requires at least three stations. Using three lines of position permits clock oscillator self-calibration, much as the previously discussed pseudoranging concept, and therefore leads to a much less stringent clock oscillator requirement.

Two-way (round-trip) ranging involves multiple two-way distance measurements of the type discussed above. To obtain a completely unambiguous horizontal position fix, three such two-way ranges are required; however, two are usually sufficient. The major disadvantage of this concept is that the user requires a transmitter as well as a receiver. A typical application of this concept is DME-DME or multiple-DME operation for civil aviation navigation.

Self-contained systems. These systems can be classified as radiating or nonradiating. Radiating systems may be subject to jamming and to homing by radiation-seeking missiles, although the effects of jamming are typically small. Radiating systems include the radar altimeter, airborne mapping radar, map matching, and Doppler radar. *See* AIRBORNE RADAR; ALTIMETER; DOPPLER RADAR; ELECTRONIC WARFARE; HOMING; JAMMING.

Nonradiating systems, such as inertial, offer essentially complete protection against jamming. Inertial navigation systems, consisting of accelerometers, gyroscopes, and computers, continuously determine position, velocity, acceleration, direction, and vehicle attitude (pitch and roll), based on Newton's second law. *See* ACCELEROMETER; GYROSCOPE; INERTIAL GUIDANCE SYSTEM.

[W.R.Fr.; R.Gr.]

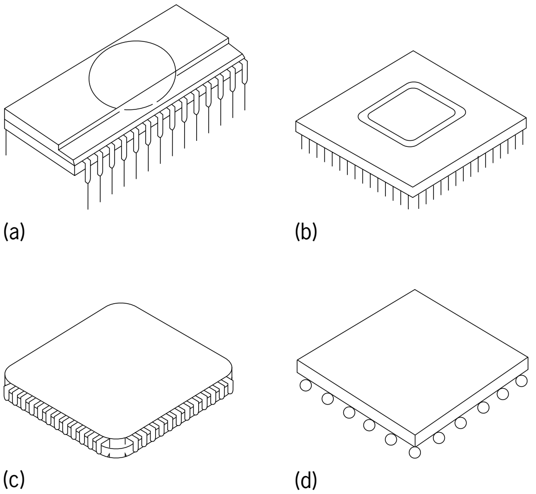
Electronic packaging

The technology relating to the establishment of electrical interconnections and appropriate housing for electrical circuitry. Electronic packages provide four major functions: interconnection of electrical signals, mechanical protection of circuits, distribution of electrical energy (that is, power) for circuit function, and dissipation of heat generated by circuit function.

Printed circuitry. As solid-state transistors started to replace vacuum-tube technology, it became possible for electronic components, such as resistors, capacitors, and diodes, to be mounted directly by their leads into printed circuit boards or cards, thus establishing a fundamental building block or level of packaging that is still in use. *See* PRINTED CIRCUIT.

Packaging hierarchy. Complex electronic functions often require more individual components than can be interconnected on a single printed circuit card. Multilayer card capability was accompanied by development of three-dimensional packaging of daughter cards onto multilayer mother boards.

Integrated circuitry allows many of the discrete circuit elements such as resistors and diodes to be embedded into individual, relatively small components known as integrated circuit chips or dies. In spite of incredible circuit integration, however, more than one packaging level is typically required, in part because of the technology of integrated circuits itself.



Typical first-level packages. (*a*) Dual in-line package. (*b*) Pin grid array. (*c*) Leadless chip carrier. (*d*) Ball grid array.

Integrated circuit chips are quite fragile, with extremely small terminals. First-level packaging achieves the major functions of mechanically protecting, cooling, and providing capability for electrical connections to the delicate integrated circuit. At least one additional packaging level, such as a printed circuit card, is utilized, as some components (high-power resistors, mechanical switches, capacitors) are not readily integrated onto a chip. For very complex applications, such as mainframe computers, a hierarchy of multiple packaging levels is required. *See* INTEGRATED CIRCUITS.

First-level packaging. Chip-to-package interconnection is typically achieved by one of three techniques: wire bond, tape-automated bond, and solder-ball flip chip. The wire bond is the most widely used first-level interconnection; it employs ultrasonic energy to weld very fine wires mechanically from metallized terminal pads along the periphery of the integrated circuit chip to corresponding bonding pads on the surface of the substrate. In the tape-automated bond, photolithographically defined gold-plated copper leads are formed on a polymide carrier that is usually handled like 35mm photographic roll film, with perforated edges to reel the film or tape. Solder-ball flip-chip technique involves the formation of solder bump contacts on the terminals of the integrated chips and reflowing the solder with the chip flipped in such a way that the bump contacts touch and wet to matching pads on the substrate.

Substrates for first-level packages are quite varied. A major classification is whether the package supports a single integrated circuit chip (single-chip module) or more than one chip (multichip module). The former is by far the most common. Substrate insulator materials for multichip and single-chip modules are selected from one of two broad groups of materials, organics and ceramics.

Means for interconnecting to the second-level package often dictate the general form of the first-level package (see illustration). *See* ELECTRONICS.

[P.J.Br.]

Electronic power supply

A source of electric power (voltage and current) to operate electronic circuits. Active electronic circuits contain such devices as transistors or vacuum tubes and require external power to amplify, filter, modify, or create electrical signals. The most common source of energy for electronic circuits is obtained by converting the electrical energy available in the conventional alternating-current (ac) electric power mains to an appropriate voltage or current. These converters, or electronic power supplies, can be implemented with a wide variety of circuits. Other power sources include batteries, mechanically driven generators, photovoltaic (solar) cells, and fuel cells. *See* Alternating current; Converter.

Most electronic circuits require a direct-current (dc) or constant voltage. If ac power is required, an oscillator or a simple transformer is used. Although some dc-to-dc converters are used, most dc power supplies convert the alternating power from the ac main to dc power. These ac-to-dc power supplies are classified according to the type of circuits used to realize the conversion: rectification, filtering, and regulation. Simple battery chargers are examples of power supplies that do not require filtering or regulation.

Rectification. An essential step in the conversion of ac to dc is a process called rectification. Rectification converts ac voltage to a waveform with average or dc value by passing only one polarity (half-wave) or by generating the magnitude or absolute value (full-wave). Three types of rectifier (diode) circuits are commonly used. Only one diode is required to obtain half-wave rectification. Full-wave rectification can be obtained with four diodes connected in a bridge configuration or with two diodes and a center-tapped transformer. Transformers are normally used at the input of the rectifiers to increase or decrease the voltage and isolate the dc output from the ac input for safety purposes. *See* Diode; Rectifier; Transformer.

Filtering. For most applications the ac or alternating portion of the rectified output is unwanted and may cause undesirable results, such as an annoying hum in audio systems. A capacitor can be used to reduce or filter the ac portion of the rectified waveform. The capacitor is charged through the diodes to the peak ac voltage minus the diode forward voltage. Some of the charge stored on the capacitor is delivered to the load each cycle, but the next voltage peak recharges the capacitor. *See* Capacitor; Electric filter.

Regulation. Regulators are often used to make the power supply output insensitive to input voltage amplitude variations and further reduce the ripple voltage. The regulator may also be used to adjust or change the dc output voltage and limit the amount of current delivered by the power supply. Regulators are a form of dc-to-dc converter.

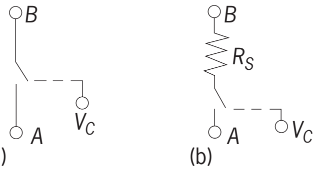
The oldest and simplest type of regulator is the linear regulator. A simple linear regulator is the shunt type. It consists of a Zener diode and a current-limiting resistor. The Zener diode establishes a fixed, or reference, voltage if it is properly reverse biased. Another common type of linear regulator is the series-pass regulator. *See* Transistor; Zener diode.

More modern power supplies have switching regulators, and are informally called switchers. There are more than a dozen different topologies (basic block diagrams) for switching regulators, but they all use one or more transistors acting as switches; either ON or OFF. In addition to the solid-state (transistor) switches, a typical switching regulator uses capacitors and inductors to store energy and diodes to direct the current.

Other common types of switching regulators are called buck-boost (or flyback) and push-pull or (buck-derived). Switching regulators can be used to generate multiple outputs at different voltage levels. The improved efficiency of switching regulators is due to the fact that energy is stored very efficiently in inductors and capacitors. The remaining losses in the control circuitry, switches, and the diodes are small compared to linear regulators. *See* Inductor; Voltage regulator.

Ferroresonant transformer-based power supplies. These have some advantages for high-current applications such as battery chargers. Ferroresonant power supplies use nonlinear magnetic properties and a resonant circuit to regulate the output voltage, and they have efficiencies similar to switching power supplies. Power supplies driven by three-, six-, or twelve-phase ac are easier to filter, and they generate much lower harmonic distortion of the current in the ac power system. [N.G.Di.]

Electronic switch An electronic device in which one or more input signals can be routed to one or more outputs by the application of the appropriate electrical control signals. The term is most often applied when analog signals are involved, but the terminology is occasionally used when digital signals are involved.



Switching devices. (*a*) Symbol for electronic switch. (*b*) Simple model of electronic switch.

Conceptually, an electronic switch can be visualized as a group of one or more mechanical electrical switches (such as light switches used in commercial wiring or toggle switches used in many electronic control panels) in which, instead of mechanically opening or closing the contacts, the physical opening and closing is achieved by applying appropriate electrical control signals to separate terminals on the switch in much the same way that a relay performs. The electronic switch does not contain mechanical contacts but semiconductor devices such as bipolar junction transistors or field-effect transistors. The basic electronic switch is depicted in illus. *a*. *A* and *B* are the terminals of the switch. When a control signal is applied to V_C, the switch closes. When the electronic switch is closed, a small residual resistance R_s remains between the terminals as depicted in the simple model of illus. *b*. The value of this resistance is termed the on resistance. In most applications the nonzero on resistance does not prove problematic, but the user needs to be aware of this limitation. The electronic switch is typically bidirectional in the sense that the terminals *A* and *B* are interchangeable. *See* Electric switch; Relay; Transistor.

Electronic switches can be very small, allowing a large number of these devices to be placed in a small area they can be very fast, with on and off response times which are orders of magnitude faster than can be achieved with mechanical counterparts; and they are considerably more reliable over a large number of cycles than their mechanical counterparts. [R.L.Ge.]

Electronic test equipment Apparatus used for the evaluation of electronic components, subassemblies, and systems.

The galvanometer was an early electromechanical instrument that converted current into angular rotation of a needle pointer across the face of a scale. The instrument consisted of a fine wire coil mechanically connected to a pivoting element. The coil was located in the field of a permanent magnet so that when current flowed through the coil the induced magnetic field rotated the element, causing the needle to move across the scale. This instrument could be used as a voltmeter, since a higher voltage induces a larger current flow through the coil. The advent of the cathode-ray tube (CRT) enabled the development of another widely used instrument, the oscilloscope. The CRT translates voltage into the deflection of an electron beam, which visibly activates a luminescent phosphor inside the face of the tube. When a voltage is connected to the vertical plates, the visual representation on the CRT face has the amplitude and polarity of the voltage displayed as a function of time. *See* Ammeter; Cathode-ray tube; Galvanometer; Oscilloscope; Voltmeter.

An important advance in electronic test equipment was the incorporation of circuits that directly converted the analog signal to be measured into a digital reading. The most significant impact of these converters was to enable a computer interface to the equipment to be set up allowing direct computer monitoring and control of the instrument. Other equipments were designed with embedded computers, which provided very sophisticated analysis of the data within the instrument itself.

See ANALOG-TO-DIGITAL CONVERTER; DIGITAL-TO-ANALOG CONVERTER; EMBEDDED SYSTEMS.

The best example of this enhancement is with spectrum analyzers. Digital signal processing (DSP) electronics have been included in these instruments which provide a frequency spectral analysis of the input signal. These instruments are widely used in the evaluation of radio communication signals, acoustic signal processing, and the analysis of mechanical forces and vibration. *See* SPECTRUM ANALYZER.

The complexity and sophistication of electronic components and subassemblies became more complicated. Multiple test instruments were integrated to form rack-and-stack automatic test equipment, where the individual instruments were connected to a control computer by a common bus. These computer-controlled testers were very efficient at providing the input stimulus to the unit under test and monitoring the output response. *See* ELECTRONICS; INTEGRATED CIRCUITS; LOGIC CIRCUITS; MICROPROCESSOR; SIGNAL GENERATOR.

The ability of automatic test equipment to sort out good from bad units is only the first requirement of modern production test equipment. Since the repair of defective units can be costly, the design and program development of test equipment frequently must include special provisions to provide failure-mode analysis. Information such as the probable defective component on a printed circuit board or the probable defective board in a system is of great value in efficient repair. Some test systems include fault dictionaries, supplemental tests after first failure, or even artificial-intelligence features to assist in repair. [W.R.Ma.]

Electronic warfare Use of techniques, devices, and equipment by an adversary to deny or counteract the enemy's use of radar, communications, guidance, or other radio-wave devices. Because of the use of optical and infrared techniques for communications, guidance, detection, and control, electronic warfare techniques are sometimes called electromagnetic, rather than electronic, to convey more adequately the idea that countermeasures are not confined to the portion of the spectrum where electronic techniques alone are applicable but may be used throughout the electromagnetic spectrum.

Traditionally, electronic warfare equipment and techniques are categorized as active and passive, depending on whether or not they radiate their own energy. The passive category includes reconnaissance or surveillance equipment that detects and analyzes electromagnetic radiation from radar and communications transmitters in a potential enemy's aircraft, missiles, ships, satellites, and ground installations. The reconnaissance devices may be used to identify and map the location of emitters without in any way altering the nature of the signals they receive. Other types of passive electronic warfare equipment do seek to enhance or change the nature of the energy reflected back to enemy radars, but they do not generate their own energy.

Active electronic warfare equipment generates energy, either in the form of noise to confuse an enemy's electromagnetic sensors or by generating false or time-delayed signals to deceive radio or radar equipment and their operators. *See* ELECTRICAL NOISE.

Passive systems. Reconnaissance or surveillance electronic warfare systems are carried by Earth-orbiting satellites, aircraft, ships, uncrewed (drone) aircraft, and automotive vehicles. Some are located on the ground. A few systems are small enough to be carried by a person. Reconnaissance systems are interchangeably called ferret or electronic intelligence (elint) systems. They consist of sensitive receivers electromechanically or electronically tuned over desired portions of the spectrum in search of transmissions of interest. Bearing to an intercepted signal can be determined by direction-finding techniques. Once secured, the signals can be displayed for analysis by an operator or stored on tape or other storage media for subsequent analysis.

Warning-receiver systems, which came into widespread use on United States tactical and transport aircraft during the Vietnamese war, are a more limited form of the elint system. Unlike the latter, which is intended to search for signals over a broad range of the spectrum, the warning receiver is programmed to alert a pilot when the aircraft is being illuminated by a specific radar signal above predetermined power thresholds anticipated by elint systems. When the pilot has been alerted, the aircraft can be maneuvered to evade the threat or initiate counteraction with onboard electronic warfare capability.

One of the oldest passive electronic warfare techniques, made famous by a Royal Air force raid on Hamburg in 1943, is the use of chaff. These are metallic strips cut to lengths resonant at the defense radar frequency so that they return spurious radar echoes to enemy radar. Chaff can confuse an enemy by generating false targets, or noise, forcing the enemy to take time to analyze the returns and sort real from false targets. Chaff can screen or mask aircraft or higher-speed ships so that the enemy is unable to determine their presence, or chaff can help an aircraft break track once it is alerted by its warning receiver that it is being tracked by radar.

Other passive electronic warfare techniques include the use of special radar-absorbing materials, such as ceramics or ferrites, which reduce reflection coefficients so that the amount of radar energy returned to the illuminating radar is reduced; the special shaping of bodies, specifically in missile reentry systems, that reduces the vehicle's radar cross section; the use of corner reflectors, or Luneberg lenses, which concentrate the energy they reflect back to the radar.

Active systems. The many active electronic warfare techniques can be classified broadly either as noise or deception jamming. The former is the oldest, simplest, and most straightforward, but requires higher average power levels and is more expensive. Deception jamming is the more artful and sophisticated technique, operating on the characteristics of the pulse train generated by threat radars.

Deception-jamming techniques are predicated on the idea of operating on pulses received from the enemy so that the signal reradiated from the target deceives the enemy radar or its operators. For instance, the deception set may receive an enemy radar pulse, circulate it through a delay line, amplify it, and reradiate it back toward the enemy. Because the enemy determines the position of the target by the round-trip transit time of the radar energy, the radar decision circuitry will conclude that the target is at a greater distance than it actually is because of the deceptive pulse delay inserted in that round-trip period by the active set. Similarly, the deception set may operate on the radar pulse train, returning many pulses instead of one, in an effort to deceive the enemy into believing there are many targets spaced at different positions. [B.Mi.]

Electronics Technology involving the manipulation of voltages and electric currents through the use of various devices for the purpose of performing some useful action. This large field is generally divided into two primary areas, analog electronics and digital electronics.

Analog electronics. Historically, analog electronics was used in large part because of the ease with which circuits could be implemented with analog devices. However, as signals have become more complex, and the ability to fabricate extremely complex digital circuits has increased, the disadvantages of analog electronics have increased in importance, while the importance of simplicity has declined.

In analog electronics, the signals to be manipulated take the form of continuous currents or voltages. The information in the signal is carried by the value of the current or voltage at a particular time t. Some examples of analog electronic signals are amplitude-modulated (AM) and frequency-modulated (FM) radio broadcast signals, thermocouple temperature data signals, and standard audio cassette recording signals. In each of these cases, analog electronic devices and circuits can be used to render the signals intelligible.

Commonly required manipulations include amplification, rectification, and conversion to a nonelectronic signal. Amplification is required when the strength of a signal of interest is not sufficient to perform the task that the signal is required to do. However, the amplification process suffers from the two primary disadvantages of analog electronics: (1) susceptibility to replication errors due to nonlinearities in the amplification process and (2) susceptibility to signal degradation due to the addition, during the amplification process, of noise originating from the analog devices composing the amplifier. These two disadvantages compete with the primary advantage of analog electronics, the ease of implementing any desired electronic signal manipulation. *See* AMPLIFIER; DISTORTION (ELECTRONIC CIRCUITS); ELECTRICAL NOISE.

Digital electronics. The advent of the transistor in the 1940s made it possible to design simple, inexpensive digital electronic circuits and initiated the explosive growth of digital electronics. Digital signals are represented by a finite set of states rather than a continuum, as is the case for the analog signal. Typically, a digital signal takes on the value 0 or 1; such a signal is called a binary signal. Because digital signals have only a finite set of states, they are amenable to error-correction techniques; this feature gives digital electronics its principal advantage over analog electronics. *See* ELECTRON TUBE; TRANSISTOR.

In common two-level digital electronics, signals are manipulated mathematically. These mathematical operations are known as boolean algebra. The operations permissible in boolean algebra are NOT, AND, OR, and XOR, plus various combinations of these elemental operations. *See* BOOLEAN ALGEBRA.

Electronic circuits are composed of various electronic devices, such as transistors, resistors, and capacitors. In circuits built from discrete components, the components are typically soldered together on a fiberglass board known as a printed circuit board. On one or more surfaces of the printed circuit board are layers of conductive material which has been patterned to form the interconnections between the different components in the circuit. In some cases, the circuits necessary for a particular application are far too complex to build from individual discrete components, and integrated-circuit technology must be employed. Integrated circuits are fabricated entirely from a single piece of semiconductor substrate. It is possible in some cases to put several million electronic devices inside the same integrated circuit. Many integrated circuits can be fabricated on a single wafer of silicon at one time, and at the end of the fabrication process the wafer is sawed into individual integrated circuits. These small pieces, or chips as they are popularly known, are then packaged appropriately for their intended application. *See* CAPACITOR; INTEGRATED CIRCUITS; PRINTED CIRCUIT; RESISTOR.

The microprocessor is the most important integrated circuit to arise from the field of electronics. This circuit consists of a set of subcircuits that can perform the tasks necessary for computation and are the heart of modern computers. Microprocessors that understand large numbers of instructions are called complete instruction set computers (CISCs), and microprocessors that have only a very limited instruction set are called reduced instruction set computers (RISCs). *See* DIGITAL COMPUTER; MICROPROCESSOR.

Other circuit designs have been standardized and reduced to integrated-circuit form as well. An example of this process is seen in the telephone modem. Modulation techniques have been standardized to permit the largest possible data-transfer rates in a given amount of bandwidth, and standardized modem chips are available for use in circuit design. *See* MODEM.

The memory chip is another important integrated electronic circuit. This circuit consists of a large array of memory cells composed of a transistor and some other circuitry. As the storage capacity of the memory chip has increased, significant miniaturization has taken place. *See* CIRCUIT (ELECTRONICS); SEMICONDUCTOR MEMORIES. [D.R.A.]

Electronvolt

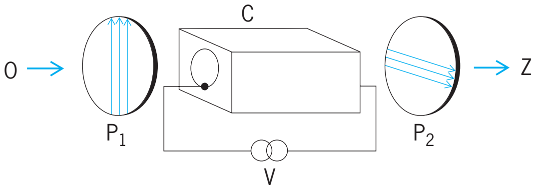
A unit of energy used for convenience in atomic systems. Specifically, it is the change in energy of an electron, or of any particle having a charge numerically equal to that of an electron, when it is moved through a difference of potential of 1 mks volt. Its value (in mks units) is obtained from the equation $W = qV$, where W is energy in joules, q the charge in coulombs, and V the potential difference in volts. For a potential difference of 1 volt and the electronic charge of 1.602×10^{-19} coulomb, the electronvolt is 1.602×10^{-19} joule. *See* ELECTRON; IONIZATION POTENTIAL. [G.H.M.]

Electrooptics

The branch of physics which deals with the influence of an electric field on the optical properties of matter, especially in its crystalline form. These properties include transmission, emission, and absorption of light.

An electric field applied to a transparent crystal can change its refractive indexes and, therefore, alter the state of polarization of light propagating through it. When the refractive-index changes are directly proportional to the applied field, the phenomenon is termed the Pockels effect. When they are proportional to the square of the applied field, it is called the Kerr effect. *See* KERR EFFECT; POLARIZED LIGHT; REFRACTION OF WAVES.

The Pockels effect is used in a light modulator called the Pockels cell. This device (see illustration) consists of a crystal C (usually potassium dihydrogen phosphate, or KDP) placed between two polarizers P_1 and P_2 whose axes are crossed. Ring electrodes bonded to two crystal faces allow an electronic driver V to apply an electric field parallel to the axis OZ along which a light beam (for example, a laser beam) is made to propagate. Pockels cells can be switched on and off in well under 1 nanosecond. *See* LASER; OPTICAL MODULATORS.



Pockels cell light modulator. The bold arrows represent a light beam.

The linearity and high-speed response of the Pockels effect within an electrooptic crystal make possible a unique optical technique for measuring the amplitude of repetitive high-frequency (greater than 1 GHz) electric signals that cannot be measured by conventional means. The technique, known as electrooptic sampling, employs a special traveling-wave Pockels cell between crossed polarizers. It is used to analyze ultrafast electric signals such as those generated by high-speed transistors and optical detectors. [M.A.D.; J.A.V.]

A self-electrooptic-effect device (SEED) is a combination of a quantum-well electrooptic modulator with a photodetector which, when light shines on it, changes the voltage on the modulator. Although the device relies internally on an electrooptic effect, the output from the modulator is controlled by the light shining on the photodetector, giving an optically controlled device with an optical output. Most of these devices rely on the quantum-confined Stark effect in semiconductor quantum-well heterostructures as the electrooptic mechanism and utilize the changes in optical absorption resulting from this mechanism. *See* SEMICONDUCTOR HETEROSTRUCTURES; STARK EFFECT. [D.A.B.M.]

Electrophilic and nucleophilic reagents

Electrophilic reagents are chemical species which, in the course of chemical reactions, acquire electrons, or a share in electrons, from other molecules or ions. Although this definition embraces all oxidizing agents and all Lewis acids, electrophilic reagents are ordinarily thought of as cationic species, such as H^+, $NO_2{}^+$, Br^+, or SO_3 (or carriers of these species such as HCl, CH_3,$COONO_2$, or Br_2), which can form stable covalent bonds with carbon atoms. Electrophilic reagents frequently are positively charged ions (cations). *See* ACID AND BASE.

Nucleophilic reagents are the opposite of electrophilic reagents. Nucleophilic reagents give up electrons, or a share in electrons, to other molecules or ions in the course of chemical reactions. Nucleophilic reagents frequently are negatively charged ions (anions). Typical nucleophilic reagents are hydroxide ion (OH^-), halide ions (F^-, Cl^-, Br^-, and I^-), cyanide ion (CN^-), ammonia (NH_3), amines, alkoxide ions (such as CH_3O^-), and mercaptide ions (such as $C_6H_5S^-$). *See* SUBSTITUTION REACTION. [J.F.B.]

Electrophoresis The migration of electrically charged particles in solution or suspension in the presence of an applied electric field. Each particle moves toward the electrode of opposite electrical polarity. For a given set of solution conditions, the velocity with which a particle moves divided by the magnitude of the electric field is a characteristic number called the electrophoretic mobility. The electrophoretic mobility is directly proportional to the magnitude of the charge on the particle, and is inversely proportional to the size of the particle. An electrophoresis experiment may be either analytical, in which case the objective is to measure the magnitude of the electrophoretic mobility, or preparative, in which case the objective is to separate various species which differ in their electrophoretic mobilities under the experimental solution conditions.

Gel techniques. Electrophoresis was first employed as an experimental technique by Arne Tiselius in 1937. The apparatus of Tiselius detected electrophoretic motion by the moving-boundary method, in which a boundary is created between the solution of particles to be examined and a sample of pure solvent. As the particles migrate in an electric field, the boundary between solution and solvent can be observed to move, and if there are a number of species in the solution with different electrophoretic mobilities, a series of boundaries of various shapes and magnitudes can be detected. The moving-boundary method was used for three decades to separate complex mixtures of charged macromolecules in solution and to study the physical characteristics of solutions of proteins and other macromolecules of biological and industrial importance.

The resolving power of electrophoresis was greatly improved by the introduction of the use of gel supporting media. The gel matrix prevents thermal convection caused by the heat which results from the passage of electric current through the sample. The absence of convection reduces greatly the mixing of the various parts of the sample, and therefore allows for more stable separation. The dimensions of the cross-links of the gel may also provide a molecular sieving effect, which increases the resolving power of the electrophoretic separation of molecules of different size. In addition, the gel media may support a gradient of a separate reagent, which assists in the separation of macromolecules. Gradients of pH and of reagents of various types may be combined in two-dimensional arrays for even greater resolving power. A very successful derivative of the gel technique is the determination of the molecular weights of protein molecules by electrophoresis of the molecules in a gel medium which contains substantial amounts of detergent. The detergent denatures the protein molecules, changing them from globular, compact structures to long, flexible polymers which are coated with detergent molecules. These polymers move in the electric field through the gel medium with a velocity which is determined by the length of the polymer, and therefore by the molecular weight of the protein unit. This method is the most common technique for the determination of molecular weights of proteins in biochemical studies. *See* GEL; PH; PROTEIN.

Isoelectric focusing. An important variation of the electrophoresis technique is isoelectric focusing. In this technique the medium supports a pH gradient which includes the isoelectric pH of the species being studied. Many charged macromolecules have both positive and negative charges on their surfaces, and the electrophoretic mobility is related to the net excess of charge of one type or the other. As the pH becomes more acidic, the number of positive charges increases, and as the pH becomes more basic, the number of negative charges increases. For each molecule of this type, there is one pH at which the net charge on the surface is zero, so that the molecule does not move when an electric field is applied and thus has an electrophoretic mobility of zero. This pH is called the isoelectric pH. If the molecule is introduced into a pH gradient which includes its isoelectric pH, it will migrate to the position of the isoelectric pH and then become stationary. In this way, all molecules of a given isoelectric pH will migrate to the same region—hence the term isoelectric focusing. The method of isoelectric focusing is particularly good for the analysis of microheterogeneity of protein species and other species which may differ slightly in their chemical content. *See* ISOELECTRIC POINT.

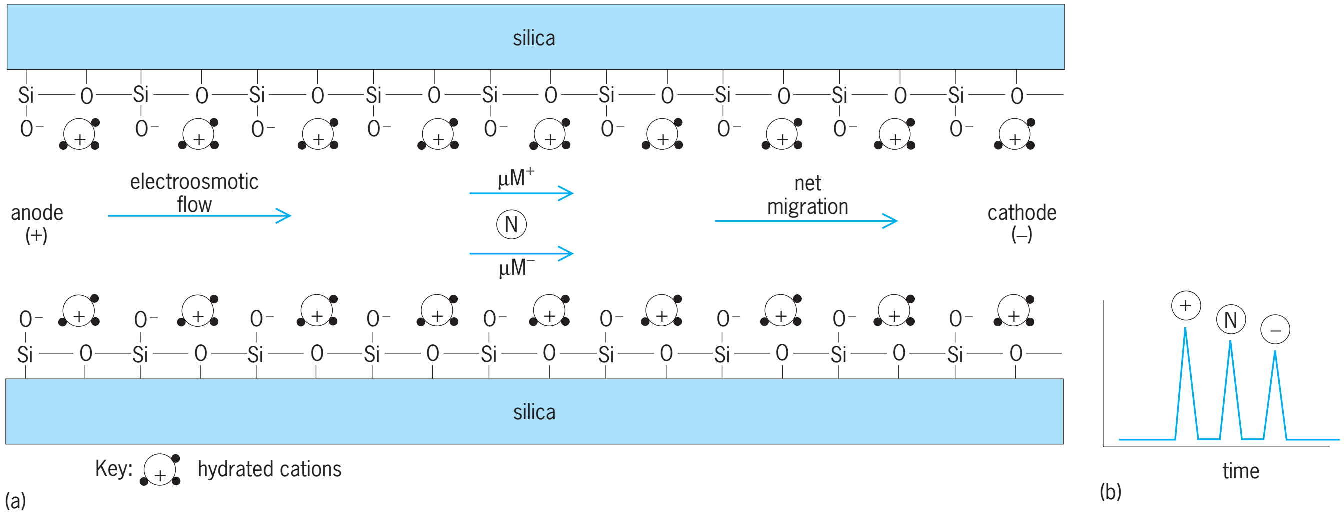
Laser applications. Application of the optical laser to electrophoretic detection resulted in the development of a technique which can be used for analytical electrophoresis experiments on particles of all sizes. The basic principle is that the highly monochromatic (single-frequency) laser light impinges upon the particles and is scattered from the particles in all directions. When observing the laser light which has been scattered from a moving particle, one can detect that there is a slight shift in the frequency of the light as a result of the motion of the particle. The application of the laser Doppler principle to electrophoresis experiments, often called electrophoretic light scattering (ELS), is an important method for the rapid determination of electrophoretic velocities. Electrophoretic light scattering has been used for the study of many types of living cells, cell organelles, viruses, proteins, nucleic acids, and synthetic polymers. *See* DOPPLER EFFECT; ELECTROLYTIC CONDUCTANCE; LASER; SCATTERING OF ELECTROMAGNETIC RADIATION. [B.R.W.]

Capillary electrophoresis. Electrophoresis can be performed in a capillary format. A typical system consists of two reservoirs and a capillary filled with a buffer solution. A high voltage is applied across the capillary by using a high-voltage power supply. The very small diameter capillaries (typically 5–100 micrometers) employed in this technique allow for efficient heat dissipation. Therefore, much higher voltages can be employed than those used in slab gel electrophoresis, leading to faster, more efficient separations. Compounds are separated on the basis of their net electrophoretic mobilities.

Most often, the detector is placed on line and analytes are detected as they flow past the detector. Spectroscopic detection (ultraviolet and laser-based fluorescence) is usually performed in this manner by using the capillary itself as the optical cell. Alternatively, detectors can be placed off line (after the column). In this case, the detector is isolated from the applied electric field through the use of a grounding joint. Electrochemical detection and mass spectroscopic detection are generally accomplished in this manner, since the electric field can interfere with the performance of these detectors.

Capillary zone electrophoresis is the simplest and most widely used form of capillary electrophoresis. The capillary is filled with a homogeneous buffer, and compounds are separated on the basis of their relative charge and size. Most often, fused silica capillaries are employed. In this case, an electrical double layer is produced at the capillary surface due to the attraction of positively charged cations in the buffer to the ionized silanol groups on the capillary wall. In the presence of an electric field, the cations in the diffuse portion of this double layer move toward the cathode and drag the solvent with them, producing an electroosmotic flow. The resulting flow profile is flat rather than the parabolic shape characteristic of liquid chromatography. This flat flow profile causes analytes to migrate in very narrow bands and leads to highly efficient separations. The electroosmotic flow is also pH dependent, and it is highest at alkaline pH values.

In most cases, the electroosmotic flow is the strongest driving force in the separation, and all analytes, regardless of charge,



Capillary zone electrophoresis. (*a*) Separation mechanism showing electrophoretic mobility of the positive ion (μM^+) and negative ion (μM^-); N is a neutral molecule. (*b*) Migration order of the ions.

migrate toward the cathode. Therefore, it is possible to separate and detect positive, negative, and neutral molecules in the same electrophoretic run, if the detector is placed at the cathodic end. Negatively charged compounds are attracted to the anode but are swept up by the electroosmotic flow and elute last. Neutral molecules, which are not separated from each other in capillary zone electrophoresis, elute as a single band with the same velocity as the electroosmotic flow. Positive compounds have positive electrophoretic mobilities in the same direction as the electroosmotic flow, and they elute first (see illustration). Capillary zone electrophoresis is generally employed for the separation of small molecules, including amino acids, peptides, and small ions, and for the separation of drugs, their metabolites, and degradation products.

All capillary electrophoresis methods have the advantage of the ability to analyze small volumes (typical injection volumes are 1–50 nanoliters). This makes it possible to analyze very small samples or to use the same sample for several different analyses. One unique application of this technique is the determination of amino acids and neutrotransmitters in single cells. [S.Lu.]

Alternating-field electrophoresis. Alternating-field agarose gel electrophoresis is a technique for separating very large molecules of deoxyribonucleic acid (DNA); fragments of DNA ranging in size from 30 to 10,000 kilobasepairs (kb) can be resolved. For the molecular biologist, this is a considerable advance over conventional agarose gel electrophoresis, which is limited to the resolution of less than 50 kb.

Conventional gel electrophoresis employs a single pair of electrodes to generate an electric field that is constant in both time and direction and that is uniform across the gel. DNA molecules are negatively charged with a uniform charge-to-mass ratio and thus migrate steadily toward the positive electrode. Although DNA is a linear molecule, in solution it tends to collapse into a random coil configuration. Agarose is a porous material that acts like a sieve, retarding the movement of the DNA; the larger the molecule, the more the retardation, and thus the molecules separate on the basis of size. However, above approximately 50 kb, the dimensions of the random coil are larger than the pore size of the agarose. The DNA can no longer be sieved through the gel, and resolution is lost.

Contrary to conventional electrophoresis, alternating-field electrophoresis does not use a constant electric field but one which regularly alternates in direction. With each change in field direction, the DNA molecules attempt to reorient themselves. When this happens, an end or a small loop of the molecule, which has dimensions much smaller than those of the random coil of the entire molecule, may find itself positioned by a pore in the agarose. The electric field can then pull the DNA by the end through the hole. When the field regularly alternates from one direction to another, the DNA regularly reorients and is pulled through an adjacent hole.

Not all molecules in the system will make equal progress under these conditions, because not all molecules can reorient themselves with equal speed. The larger the molecule, the more time it requires in a given field strength (determined by the applied voltage) to change directions and the less time it has left to move. [K.Ga.]

Electroplating of metals The process of electrodepositing metallic coatings to alter the existing surface properties or the dimensions of an object. Electroplated coatings are applied for decorative purposes, to improve resistance to corrosion or abrasion, or to impart desirable electrical or magnetic properties. Plating is also used to increase the dimensions of worn or undersized parts. An example of a decorative coating is that of nickel and chromium on automobile bumpers. However, in this application, corrosion and abrasion resistance are also important. An example of electrodeposition used primarily for corrosion protection is zinc plating on such steel articles as nuts, bolts, and fasteners. Since zinc is more readily attacked by most atmospheric corrosive agents, it provides galvanic or sacrificial protection for steel. An electrolytic cell is formed in which zinc, the less noble metal, is the anode, and steel, the more noble one, the cathode. The anode corrodes, and the cathode is protected. *See* Electrochemistry.

The electroplating process consists essentially of connecting the parts to be plated to the negative terminal of a direct-current source and another piece of metal to the positive pole, and immersing both in a solution containing ions of the metal to be deposited. The part connected to the negative terminal becomes the cathode, and the other piece the anode. In general, the anode is a piece of the same metal that is to be plated. Metal dissolves at the anode and is plated at the cathode. *See* Electrolysis.

Most plating solutions are of the aqueous type. There is a limited use of fused salts or organic liquids as solvents. Nonaqueous solutions are employed for the deposition of metal with lower hydrogen overvoltages; that is, hydrogen rather than the metal is reduced at the cathode in the presence of water.

In order for adherent coatings to be deposited, the surface to be plated must be clean, that is, free from all foreign substances such as oils and greases, as well as oxides or sulfides. The two essential steps are cleaning and pickling.

Three principal cleaning methods are employed to remove grease and attached solids. (1) In solvent cleaning, the articles undergo vapor degreasing, in which a solvent such as tri- or tetrachloroethylene is boiled in a closed system, and its vapors are condensed on the metal surfaces. (2) In emulsion cleaning, the metal parts are immersed in a warm mixture of kerosine, a wetting agent, and an alkaline solution. (3) In electrolytic cleaning, the articles are immersed in an alkaline solution, and a direct current is passed between them and the other electrode, which is usually steel. Ultrasonic cleaning is also used extensively, especially for blind holes or gears packed with soils. Ultrasonic waves introduced into a cleaning solution facilitate and accelerate the detachment of solid particles embedded in crevices and small holes.

In the pickling process, oxides are removed from the surface of the basis metal. For steel, warm, dilute sulfuric acid is used in large-scale operations because it is inexpensive; but room-temperature, dilute hydrochloric acid is also used for pickling because it is fast-acting. Hydrogen embrittlement may be caused by the diffusion of hydrogen in steel (especially high-carbon steel) during pickling and also in certain plating operations. *See* EMBRITTLEMENT.

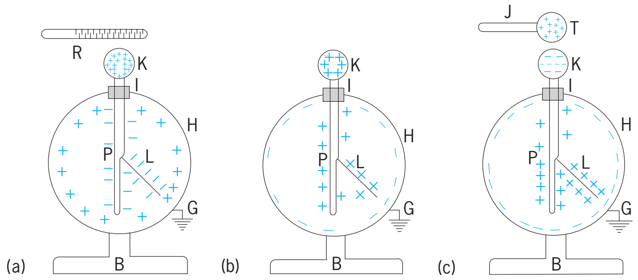
Electropolishing is used when a thin, bright deposit is to be produced. In this case, the substrate surface contours are essentially copied by the deposit. The substrate surface therefore must have a bright finish which can be attained by electropolishing. *See* ELECTROPOLISHING.

Special processes, such as electroforming and anodizing, are required for certain applications. Electroforming is a special type of plating in which thick deposits are subsequently removed from the substrate, which acts as a mold. The process is particularly suitable for forming parts which require intricate designs on inside surfaces. Important applications of electro-forming are in the production of phonograph record masters, printing plates, and some musical instruments and fountain pen caps as well in waveguides. In anodizing, a process related to plating, an oxide is deposited on a metal which is the anode in a suitable solution. The process is primarily used with aluminum, but it can be applied to beryllium, magnesium, tantalum, and titanium. Colored coatings can be produced by the incorporation of dyes. *See* METAL COATINGS. [R.W.]

Electropolishing A method of polishing metal surfaces by applying an electric current through an electrolytic bath in a process that is the reverse of plating. The metal to be polished is made the anode in an electric circuit. Anodic dissolution of protuberant burrs and sharp edges occurs at a faster rate than over the flat surfaces and crevices, possibly because of locally higher current densities. The result produces an exceedingly flat, smooth, brilliant surface.

Electropolishing is used for many purposes. The brilliance of the polished surface makes an attractive finish. Because the polished surface has the same structural properties as the base metal, it serves as an excellent surface for plating. Electropolishing avoids causing differential surface stresses, one of the requirements for the formation of galvanic cells which cause corrosion. Because no mechanical rubbing is involved, work hardening is avoided. Contaminants, which often are associated with the use of abrasives and polishing compounds, are also avoided. The surface is left clean and may require little or no preparation for subsequent treatment or use. Electropolishing also minimizes loss of high-temperature creep-rupture strength. *See* ELECTROPLATING OF METALS. [W.W.Sn.]

Electroscope An instrument for detecting the presence and sign of an electric charge. It is the simplest type of ionization chamber. *See* IONIZATION CHAMBER.



Electroscope. (P is a metal support terminating in knob K; B is the base; I is an insulator; and H is a cylindrical metal housing with flat ends and windows.) (*a*) Being charged by induction by negative charge on hard-rubber rod R. (*b*) Positive charge left on its leaf after induction process is complete. (*c*) Testing the sign of an unknown charge on test ball T.

The illustration shows a common type of simple gold-leaf electroscope. Gold leaf (L) is used because it is an extremely thin conducting foil which has low mass per unit area and is very flexible. Hence, it responds quickly and vigorously to small electrostatic forces. In the illustration H serves as a grounded electrostatic shield, as well as a shield against air currents. The hard-rubber rod R (illus. *a*) with its negative charge has set up the charge distribution by the process of electrostatic induction. The response shown is a test for the fact that R has a charge. *See* ELECTROSTATICS.

To leave the electroscope with a net charge, a grounded conductor is touched to K so that the surplus electrons on P and L go off to ground, leaving the bound positive charge on K. The ground connection is then broken and R is removed. At this stage (illus. *b*) the electroscope is said to have a positive charge because there is a positive charge on its leaf system.

If an electroscope has a charge of known sign, as in illus. *b*, it can be used to test the sign of an unknown charge, as in illus. *c*, where the metal test ball (T), with its insulating handle (J), has the unknown charge. In the situation pictured, L moves farther away from P as T is brought slowly up toward K, showing that T has a positive charge. If T had a negative charge, L would move toward P, as T slowly approaches K. The converse situation, if the leaf system in illustration *c* had a negative charge initially, can be readily visualized.

Although electroscopes have been built with a wide variety of geometries, the principle of operation is essentially the same for all. If an electroscope has a scale, permitting quantitative measurements, it is called an electrometer or electrostatic voltmeter. For information on electrometers *see* VOLTMETER [R.P.Wi.]

Electrostatic lens An electrostatic field with axial or plane symmetry which acts upon beams of charged particles of uniform velocity as glass lenses act on light beams. The action of electrostatic fields with axial symmetry is analogous to that of spherical glass lenses, whereas the action of electrostatic fields with plane symmetry is analogous to that of cylindrical glass lenses. Plane symmetry as used here signifies that the electrostatic potential is constant along any normal to a family of parallel planes.

The action of an electrostatic lens on the paths of charged particles passing through it is most readily visualized with the aid of an equipotential plot of the fields in a plane of symmetry of the lens. The equipotential lines in the plot indicate the intersection with the plane of the drawing of surfaces on which the electrostatic potential is a constant. The paths of charged particles in the electrostatic field are bent toward the normals of the equipotentials as the particles are accelerated, and away from the normals as the particles are decelerated.

Axially symmetric lenses are generally formed at or between circular apertures and cylinders maintained at suitable potentials. For any of these it is possible to define focal points, principal planes, and focal lengths in the same manner as for light lenses and to determine with their aid image magnification for any object position.

Lenses of plane symmetry, analogous to cylindrical glass lenses, are formed between parallel planes and at slits, replacing the circular cylinders and apertures of lenses with axial symmetry. [E.G.R.]

Electrostatic precipitator

A device used to remove liquid droplets or solid particles from a gas in which they are suspended. The process depends on two steps. In the first step the suspension passes through an electric discharge (corona discharge) area where ionization of the gas occurs. The ions produced collide with the suspended particles and confer on them an electric charge. The charged particles drift toward an electrode of opposite sign and are deposited on the electrode where their electric charge is neutralized. The phenomenon would be more correctly designated as electrodeposition from the gas phase.

The use of electrostatic precipitators has become common in numerous industrial applications. Among the advantages of the electrostatic precipitator are its ability to handle large volumes of gas, at elevated temperatures if necessary, with a reasonably small pressure drop, and the removal of particles in the micrometer range. Some of the usual applications are: (1) removal of dirt from flue gases in steam plants; (2) cleaning of air to remove fungi and bacteria in establishments producing antibiotics and other drugs, and in operating rooms; (3) cleaning of air in ventilation and air conditioning systems; (4) removal of oil mists in machine shops and acid mists in chemical process plants; (5) cleaning of blast furnace gases; (6) recovery of valuable materials such as oxides of copper, lead, and tin; and (7) separation of rutile from zirconium sand. [G.S.M.; W.O.M.]

Electrostatics

The class of phenomena recognized by the presence of electrical charges, either stationary or moving, and the interaction of these charges, this interaction being solely by reason of the charges and their positions and not by reason of their motion. *See* ELECTRIC CHARGE.

At least 90% of the topics that are normally classified as electrostatics are concerned with the manipulation of charged particles by electric fields. When a particle becomes charged by rubbing or other means, it has either a surplus or a deficit of electrons. A body with a surplus of electrons is said to be negatively charged; a body with a deficiency, positively charged. The amount or quantity of charge on a body is expressed in coulombs (positive or negative). A coulomb is an enormous amount of charge, and in most electrostatic situations charge levels of a small fraction of a coulomb give rise to significant effects. Electrostatic forces always exist between charged bodies. Bodies with like charge experience repulsive forces, while oppositely charged bodies experience attraction.

Principles. If two bodies are charged to Q_1 and Q_2 coulombs and are separated in vacuum by a distance of r meters, the force F in newtons between them is given by Coulomb's law, Eq. (1).

$$F = \frac{Q_1 Q_2}{4\pi\epsilon_0 r^2} \qquad (1)$$

In electrical science, ϵ_0 is an important constant known as the permittivity or dielectric constant of free space, and is also sometimes called the primary electric constant. It has the value $\epsilon_0 = 8.85416 \times 10^{-12}$ farad per meter. *See* COULOMB'S LAW; PERMITTIVITY.

Coulomb's law shows that a body charged to Q_1 experiences a force due to the presence of another body charged to Q_2. Q_2 may be considered to influence the whole of space surrounding it, because if Q_1 were to be positioned anywhere it would experience a force due to the presence of Q_2. The property of a charge to influence the whole of space can be modeled by a three-dimensional force field permeating the whole of the space surrounding the charge Q_2. This field is called the electric field. When there are many charged bodies present in an environment, the force that would be exerted on a charged particle at any location can be found by calculating the field at the location due to the presence of each charged body separately, and the net field is obtained by adding up the individual components. *See* ELECTRIC FIELD.

A system of charged particles or bodies is unstable unless the particles are prevented from moving, since the like-charged particles will repel each other until they are infinitely far apart, and oppositely charged bodies will attract one another and come together. The system has potential energy. The potential energy of two charged particles separated by a distance r can be shown to be given by Eq. (2). *See* ENERGY; POTENTIALS.

$$\text{Potential energy} = \frac{Q_1 Q_2}{4\pi\epsilon_0 r} \quad \text{joules} \qquad (2)$$

Charging methods. The three principal methods of applying electric charge to objects are corona charging, induction charging, and tribocharging. *See* ENERGY.

The corona-charging method relies upon the impact of charged atoms or molecules (ions) on charged bodies. Copious quantities of ions may be generated by a corona discharge, which is a region in which an intense electric field acts upon air molecules and ionizes them so that free ions are produced. A sharply pointed electrode maintained at a high positive or negative potential induces a stream of positive or negative ions which may be used for charging surfaces. The stream of ions from a corona point is usually so intense that neutral air molecules become entrained in the flow to produce a corona wind which can deflect a candle flame. Ions from a corona discharge may be used to charge isolated bodies, insulating surfaces or particles by simply directing a corona wind onto the surface to be charged. In the case of particles, it is normally sufficient for them to pass through a corona discharge region to receive a significant charge from ion-particle collisions. *See* CORONA DISCHARGE.

Surfaces may be charged by exposure to an electrostatic field. If the surface is a liquid and it is disrupted into droplets, they will be electrically charged. Induction charging of equipment and personnel may occur when they are exposed to an electric field. Personnel charged in this way may generate electrostatic discharges when approaching grounded surfaces. Sensitive microelectronic devices can be damaged and computer data can be corrupted by such discharges.

Applications. Electrostatics is put to good use in a wide variety of applications. For examples, the electrostatic precipitator enables smoke emissions from power-station chimneys, smelting plants, and other industrial plants to be reduced to relatively low, acceptable levels. On a smaller scale, efficient filters exist for removing dust from the air in offices, public places, and the home. In some filters, dust particles undergo corona charging as they are sucked by a fan through a duct, and are then collected on grounded electrodes; in others, permanently electrified filter material is used, made from thin plastic sheets which have been treated by surface bombardment from a corona ion source. *See* AIR FILTER; ELECTROSTATIC PRECIPITATOR.

In several applications which utilize electrostatics, solid or liquid particles are charged and sprayed onto grounded objects. Dry powder coating is used in many industries in preference to the wet-paint-spraying process. Crop spraying is another important application in which electrostatic forces help to efficiently apply herbicides or insecticides. Research into electrospraying, sometimes called electrohydrodynamic atomization, is leading to new applications for the deposition of ceramic, glass, and polymer films and for powder particle production of special materials. The electrospraying of materials is also used for analysis by means of mass spectrometry, as the electrospray process is gentle and does not disrupt delicate complex molecules.

In electrophotography an optical system is used to project the image to be copied onto a light-sensitive semiconducting surface precharged by a corona source. Exposure of the surface to light reduces the electrical conductivity of the material and allows surface charge to leak away to a back plate in proportion to the intensity of the light, so that bright parts of the image are regions that have lost most of the original charge while dark zones remain fully charged. A mixture of very fine black toner particles and coarser carrier particles is then brought into contact with the charged surface. Transfer of only charged toner particles onto the latent charged surface occurs. A sheet of paper is then laid over the toner-covered surface, and transfer of toner to paper occurs so that an image remains on the paper when it is peeled off the surface. Some ink-jet printers also utilize electrostatic principles; by ensuring that ink drops are formed in the presence of an electrostatic field, they become charged and may be deflected electrostatically to a printing surface. *See* PHOTOCOPYING PROCESSES; PRINTING.

Another development being commercially exploited is the production of metallic ion or droplet beams using electrostatic forces acting upon a liquid-metal surface. Considerable success has been achieved with many molten metals including gold and silver. Either ion or charged droplet beams may be formed depending on the operating conditions of the source. The beams so formed may be very well defined and directed with great accuracy onto targets where they can be used for ion implantation or for the formation of conducting tracks in the fabrication of microelectronic circuits. *See* INTEGRATED CIRCUITS; ION IMPLANTATION.

Electrostatic treators using electric fields have been used to separate water droplets from crude oil as well as move and deposit inorganic particles of sand, mud, and clay and organic particles.

Ion engines which produce thrust by electrostatically accelerating mercury or cesium ions have been successfully operated in space. Colloid thrusters, operating on exactly the same principles as electrostatic paint or crop sprayers, have also been developed. In these a propellant such as glycerol is atomized and accelerated from a nozzle by an electrostatic field. *See* ION PROPULSION. [A.G.B.]

Electrostriction A form of elastic deformation of a dielectric induced by an electric field; specifically, the term applies to those components of strain which are independent of reversal of the field direction. Electrostriction is a property of all dielectrics and is thus distinguished from the converse piezoelectric effect, a field-induced strain which changes sign upon field reversal and which occurs only in piezoelectric materials. *See* DIELECTRIC MATERIALS; PIEZOELECTRICITY.

The electrostrictive effect in certain ceramics is employed for commercial purposes in electromechanical transducers for sonic and ultrasonic applications. *See* MICROPHONE. [R.D.W.]

Electrotherapy The use of electric current to treat disease. Electrotherapy is based on principles developed during the nineteenth and twentieth centuries following the first demonstration of “animal electricity” by Luigi Galvani in the eighteenth century. *See* ELECTROCONVULSIVE THERAPY.

Low-frequency electrotherapy. Low-frequency electrotherapy uses relatively weak alternating electric currents. They are delivered by electrodes that are placed under or on the surface of the body and are connected to pulse-shaping circuits that are located inside or outside the body.

Electrodes that stimulate electrically excitable cells, such as those in muscle and nerve tissues, are usually placed directly in or on the tissue by surgery or are inserted through a vein by catheterization. There are many applications for electrode stimulation: irregular heart rhythms can be controlled by pacemakers; muscles, such as those of the diaphragm and urinary bladder, that become paralyzed can be made to contract electrically; and long-term pain can be relieved by implanting electrodes in the spinal canal. Surface electrodes are widely used for temporary relief of pain; for preventing muscle atrophy after injury or immobilization; and for treatment of curvature of the spine, or scoliosis. *See* CARDIAC ELECTROPHYSIOLOGY; MUSCLE; PAIN.

A wide variety—if not all—of the body’s nonexcitable cells alter their function in specific ways and at specific times in response to appropriate, very weak electrical stimuli. Much of the progress in electrotherapy has evolved from the observation that both hard and soft tissues, such as bone and arteries, become electrically charged when they are cyclically deformed by mechanical or hydrodynamic forces. By establishing the patterns and values of those stress-generated voltages in bone, researchers have been able to develop three methods of influencing the behavior of nonexcitable cells that are involved in the repair of nonunited fractures. The first clinical method for treating nonunited fractures employed surgically implanted electrodes. Unfortunately, surgical methods carry a risk of infection, and direct currents can result in adverse electrochemical reactions around the electrodes. Two noninvasive electrical methods have proved effective in altering cellular behavior. The first involves the placement of dynamically charged, insulated plates outside tissue-culture vessels or the fractured limbs of animals. The second method uses one or more coils of wire coupled to a pulse generator to create a weak time-varying magnetic field that penetrates the body, much as radio waves enter a closed building. As the understanding of their mechanisms of action at the cellular and subcellular levels has increased, pulsed electromagnetic fields have been used successfully to treat other problems of bone and its surrounding soft tissue. [C.A.L.B.]

Diathermy. Therapy for afflicted deep tissues that do not respond to conventional methods, such as infrared heating or heating pads, can often be achieved with diathermy. Heating results from the electrical resistance of tissue to high-frequency or microwave currents. Increasing the tissue temperature to a range of 106–113°F (41–45°C) increases the physiologic response and therapeutic benefit, which includes increased extensibility of collagen tissues in joint contractures, decreased joint stiffness in rheumatoid arthritis, and pain relief and reduction of muscle spasms through the local action of heat on nerve endings and receptors. Warming can also resolve inflammatory infiltrates, edema, and exudates and increase blood flow in diseased or damaged tissue. Heating has been used in cancer therapy under proper temperature control.

Hyperthermia. Hyperthermia is an experimental method of treating malignant tumors that uses heat alone, heat in combination with ionizing (x-ray) radiation, or heat with chemotherapy. One form of heating involves the application of radio-frequency energy by using methods similar to—but more sophisticated and more carefully controlled than—those in diathermy treatment. The effective temperature range of hyperthermia is very narrow, 108–111°F (42.5–44°C); the benefits are minimal at lower temperatures, and damage to normal cells is probable at higher temperatures. Several mechanisms are thought to account for the selective destruction of tumor cells: (1) selective heating caused by the lower rate of blood flow in tumor tissues; (2) greater sensitivity of tumor cells to heat due to their hypoxic, acidic, and poor nutritional state; (3) synergism of ionizing radiation and hyperthermia due to thermal killing of cells that are hypoxic and are at those critical stages of growth when they are most resistant to radiation; and (4) increase in cell membrane permeability and sensitivity to chemotherapeutic drugs. *See* THERMOTHERAPY. [A.W.G.]

Electrothermal propulsion Vehicular propulsion that involves electrical heating to raise the energy level of the propellant. In contrast, chemical rockets use the chemical energy of one or more propellants to heat and accelerate the decomposition products (monopropellants) or combustion products (bipropellants) for thrusting purposes. In both instances, the high-energy propellant gases are exhausted through a nozzle where they are accelerated to a high velocity, and thrust is produced by reaction. By decoupling the heating or energy addition process from the restraints of propellant chemistry considerations, electrothermal devices can be operated on a wide variety of materials, many of which would not otherwise be considered to be propellants. Water and space station liquid-waste streams are two examples of such propellants being considered for electrothermal propulsion purposes. *See* ROCKET PROPULSION.

Practical electrothermal thrusters come in two forms, resistojets and arcjets. In resistojets, which are now flying in a station keeping role on many communications satellites, the electrical energy is first deposited in a heater or resistive element and then transferred to the propellant. The need to first heat a material limits the maximum operating temperature and the maximum enthalpy of the propellant. As a consequence, the essential simplicity of the device is balanced by well-defined limitations on exhaust velocity or specific impulse. Arcjets circumvent this limitation by using the propellant as the heater element. An electric arc discharge passes directly through the propellant. High temperatures and specific-impulse values can be achieved but only at the price of design complexity. *See* ARC DISCHARGE; SPECIFIC IMPULSE.

One further and fundamental distinction is that electrical thrusters are power-limited whereas chemical thrusters are energy-limited. By definition, electrical propulsion systems must have an associated power supply for operation. Solar panels or nuclear power supplies can supply well-defined power to the thruster for essentially unlimited time. Consequently, although the power level is well constrained, the total energy available is virtually boundless. Chemical systems are exactly opposite. In this case, the total energy available for propulsion is well defined by the propellant volume. However, the rate at which this propellant is used, the rate of energy usage per unit time, or the power can be exceedingly high. Chemical thrusters are ideal for escaping the Earth's gravity well; electrical thrusters are ideal for moving payloads in low-acceleration conditions removed from gravity wells, that is, for the more ambitious missions far removed from low Earth orbit. *See* SPACECRAFT PROPULSION. [G.W.Bu.]

Electroweak interaction One of the three basic forces of nature, along with the strong nuclear interaction and the gravitational interaction. The terms "force" and "interaction between particles" are used interchangeably in this context. All of the known forces, such as atomic, nuclear, chemical, or mechanical forces, are manifestations of one of the three basic interactions.

Until the early 1970s, it was believed that there were four fundamental forces: strong nuclear, electromagnetic, weak nuclear, and gravity. It was by the work of S. Glashow, S. Weinberg, and A. Salam that the electromagnetic and the weak nuclear forces were unified and understood as a single interaction, called the electroweak interaction. This unification was a major step in understanding nature, similar to the achievement of J. C. Maxwell and others a century earlier in unifying the electric forces and magnetic forces into the electromagnetic interactions. A goal of theoretical physics is to achieve a further simplification in understanding nature and describe the presently known three basic interactions in a unified way, usually referred to as the grand unified theory (GUT). Whether this is possible remains to be seen. *See* ELECTROMAGNETISM; FUNDAMENTAL INTERACTIONS; GRAVITATION; MAXWELL'S EQUATIONS; STRONG NUCLEAR INTERACTIONS; WEAK NUCLEAR INTERACTIONS.

Some of the properties of the basic interactions are summarized in the table. The strong nuclear forces are the strongest, electroweak is intermediate, and gravity the most feeble by a huge factor. The ranges, that is, the distances over which the forces act, also differ greatly. The strong nuclear and the weak interactions have a very short range, while electromagnetism and gravity act over very large distances. Thus, at very short subatomic distances the strong nuclear force, which holds the atomic nucleus together and governs many interactions of the subnuclear particles, dominates. At larger distances the electromagnetic forces dominate, and hold the atom together and govern chemical and most mechanical forces in everyday life. At even larger scales, objects such as planets, stars, and galaxies are electrically neutral (have an exact balance of positive and negative electric charges) so that the electromagnetic forces between them are negligible, and thus the gravitational forces dominate in astronomical and cosmological situations.

Each of the basic forces acts on, or depends on, different properties of matter. Gravity acts on mass, and electromagnetic forces act on electric charges that come in two kinds, positive and negative. The strong nuclear forces act on a much less well-known property, called color charge, which come in three kinds, r, b, and g (often called red, blue, and green). The weak nuclear forces act on equally esoteric properties called weak isospin t and hypercharge y. While the mass and the electric charge are properties that are recognized in everyday situations, the color charge and the weak isospin and hypercharge have no correspondence in the large-scale everyday world. *See* COLOR (QUANTUM MECHANICS); ELECTRIC CHARGE; HYPERCHARGE; I-SPIN; MASS.

All known forms of matter are made of molecules and atoms, which are made up of the nucleus (protons and neutrons) and orbital electrons. These in turn can be understood to be made up of the fundamental constituents, the quarks and the leptons. Each of these comes in six kinds. All of the quarks and leptons have gravitational and weak interactions since they have nonzero values of mass and weak isospin and hypercharge. The particles with zero electric charge have no electromagnetic interactions, and the leptons have no strong nuclear interactions since they carry no color charge. *See* LEPTON; QUARKS.

The present understanding is that the basic forces are not contact forces but act over distances larger than the sizes of the particles (action at a distance). In this picture, based on field theory, the forces are carried or mediated by intermediate particles that are called gauge bosons. For example, the electromagnetic force between an electron and a proton is carried by the quantum of the electromagnetic field called the photon (γ). The strong nuclear force is carried by the gluon (g), and the gravitational force is carried by the graviton (G). The weak nuclear force comes in two categories: the charge-changing (charged-current, for short) mediated by the $W^{\pm}$ bosons, and the neutral-current weak interactions mediated by the Z^0 boson. *See* GLUONS; GRAVITON; INTERMEDIATE VECTOR BOSON; PHOTON.

All of the fundamental constituents, the quarks and the leptons, carry one-half unit of angular momentum (spin = 1/2) as if they were spinning around their own axis. (Such particles are called fermions.) By the rules of quantum mechanics, the direction of this spin is quantized to be either parallel or antiparallel to the direction of motion of the particle. Particles with spin direction parallel to their direction of motion have helicity $+1$ and are called right-handed, and particles with antiparallel spin have helicity -1 and are called left-handed. One of the symmetries of nature is called parity, which is a symmetry between right-handed and left-handed coordinate systems. If parity symmetry holds, left-handed and right-handed particles must have the same interactions. In 1956 T. D. Lee and C. N. Yang proposed that parity symmetry is violated in the weak interactions, and this proposal was soon verified experimentally. It was found that the left-handed and the right-handed particles have different weak interactions. In particular, the right-handed particles have no weak isospin, and thus only the left-handed particles participate in the charged-current weak interactions. *See* ANGULAR MOMENTUM; HELICITY (QUANTUM MECHANICS); PARITY (QUANTUM MECHANICS); SPIN (QUANTUM MECHANICS).

Until the early 1970s, the electromagnetic and the weak interactions were believed to be separate basic interactions. At that time the Weinberg-Salam-Glashow model was proposed to understand these two interactions in a unified way. In its original form, this model, based on an unbroken gauge symmetry, led to some physically unacceptable features such as zero masses for all the constituent particles and predictions of infinities for

Basic forces in nature

Interaction		Relative strength	Property acted on	Force carrier	Range
Strong nuclear		1	Color charge (r, g, b)	Gluon (g)	10^{-13} cm
Electroweak	Electromagnetic	10^{-2}	Electric charge (q)	Photon (γ)	∞
	Weak nuclear	10^{-6}	Weak charges (t_3, y)	Bosons ($W^{\pm}$, Z^0)	10^{-16} cm
Gravity		10^{-40}	Mass (m)	Graviton (G)	∞

some measurable quantities. Through the pioneering work of G. 'tHooft, M. Veltman, and others, it was shown that the theory can be made renormalizable, removing the infinities and providing masses to the particles, by spontaneous breaking of the gauge symmetry and the introduction of one new particle, the Higgs boson. *See* Gauge theory; Higgs boson; Renormalization; Symmetry breaking.

The neutral gauge bosons, the W^0 and B^0, form a quantum-mechanical mixture, which produces the two physically observable gauge bosons, the γ and the Z^0, as given by Eqs. (1). The γ is

$$\begin{aligned} \gamma &= \sin\theta\ W^0 + \cos\theta\ B^0 \\ Z^0 &= \cos\theta\ W^0 - \sin\theta\ B^0 \end{aligned} \tag{1}$$

the well-known photon that mediates the electromagnetic interactions. The Z^0 mediates the neutral-current weak interactions, and the $W^{\pm}$ mediate the charged-current weak interactions. In this way, all of these interactions are described by a common unified theory. The mixing angle θ in Eqs. (1), forming the γ and the Z^0, is called the weak mixing angle and is the fundamental parameter of the theory. The strength and nature of the interactions of the particles are determined by the vector and axial vector coupling constants g_v and g_A. In the electroweak model all of these couplings are given in terms of the single parameter of the theory, the weak mixing angle, and the properties of the leptons and quarks. The model also gives a relationship between the electric charge q and the weak charges t_3 and y, Eq. (2).

$$q = t_3 + 1/2y \tag{2}$$

See Nonrelativistic quantum theory; Quantum mechanics.

The coupling constants that govern the electroweak interactions of all of the particles can be summarized as:

1. Electromagnetic interactions: $g_v = q$, $g_A = 0$
2. Charged current weak interactions: $g_v = -\ g_A = t$
3. Neutral current weak interactions: $g_v = t_3 - 2q \sin^2\theta$, $g_A = -t_3$

In the above expressions, t stands for the magnitude of the weak isospin, and t_3 is its projection along an axis of quantization.

The electroweak theory has great predictive power. Its first and most striking prediction was the existence of neutral-current weak interactions mediated by the Z^0 boson. Until the time of this prediction, the weak interactions were believed to be of charged-current nature only, with no neutral-current component.

A second major triumph for the electroweak theory was the discovery of the W and Z bosons in 1983 at the proton-antiproton collider at the CERN Laboratory in Geneva, Switzerland, with masses very close to the values predicted by the theory. At this time the validity of the theory was considered to be firmly established. *See* Particle accelerator.

The successful electroweak theory, combined with quantum chromodynamics (QCD), the theory describing the strong nuclear interactions, forms the so-called standard model of particle physics. This standard model has been brilliantly successful in accurately predicting and describing all experimental results over a huge energy range, varying from the electronvolt energies of atomic physics to the 100-GeV energy range of the largest existing particle colliders. As such, it represents a landmark achievement of both experimental and theoretical physics. *See* Quantum chromodynamics; Standard model.

In spite of these great successes, two major problems remain to be solved in this field. The first one is that the standard model in its present form cannot explain the masses of the fundamental constituents, the quarks and leptons. These masses vary over a large range, from a few electronvolts to 174 GeV. The basic gauge symmetry on which the standard model is based would indicate that these masses should all be the same. There must therefore be an additional piece of the puzzle, usually referred to as the source of the electroweak symmetry breaking, that remains to be found. Hypothetical ideas about this missing element of the model range from the prediction of a single additional particle, the Higgs boson, to complicated models such as supersymmetry that predict dozens of new elementary particles. *See* Higgs boson; Supersymmetry; Symmetry breaking.

The second outstanding problem is the search for a theory that not only describes the strong nuclear and the electroweak interactions but includes gravity as well. The standard model is based on the principles of quantum mechanics, while the current understanding of the gravitational forces is based on Einstein's theory of general relativity. No one so far has been able to combine these two theories; that is, a quantum theory of gravity does not, as yet, exist. The search for such a grand unified theory is a major focus of activity in theoretical physics. *See* Elementary particle; Quantum gravitation; Relativity. [C.B.]

Element (chemistry) An element is a substance made up of atoms with the same atomic number. Some common elements are oxygen, hydrogen, iron, copper, gold, silver, nitrogen, chlorine, and uranium. Approximately 75% of the elements are metals and the others are nonmetals. Most of the elements are solids at room temperature, two of them (mercury and bromine) are liquids, and the rest are gases.

A few of the elements are found in nature in the free (uncombined) state. Some of these are oxygen, nitrogen, the noble gases (helium, neon, argon, krypton, xenon, and radon), sulfur, copper, silver, and gold. Most of the elements in nature are combined with other elements in the form of compounds. The most abundant element on the Earth is oxygen; the next most abundant is silicon. The most abundant element in the universe is hydrogen and the next most abundant is helium. *See* Elements, geochemical distribution of.

The elements are classified in families or groups in the periodic table. Elements are also frequently classified as metals and nonmetals. A metallic element is one whose atoms form positive ions in solution, and a nonmetallic element is one whose atoms form negative ions in solution. *See* Periodic table.

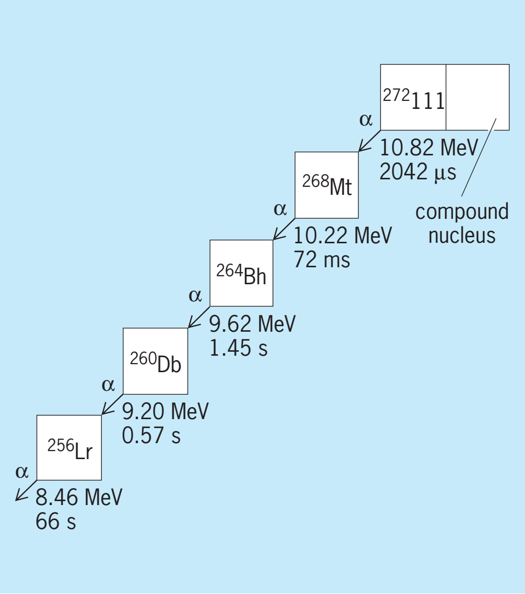
Atoms of a given element have the same atomic number, but may not all have the same atomic weight. Atoms with identical atomic numbers but different atomic weights are called isotopes. Oxygen, for example, is made up of atoms whose atomic weights are 16, 17, and 18. Hydrogen is made up of isotopes 1, 2, and 3; the isotopes of masses 2 and 3 are called deuterium and tritium, respectively. Carbon is made up of isotopes 11, 12, 13, and 14. Carbon-14 is radioactive and is used as a tracer in many chemical experiments.

All the elements have isotopes, although in certain cases only synthetic isotopes are known. Thus, fluorine exists in nature as ^{19}F, but the artificial radioactive isotope ^{18}F can be prepared. Many of the isotopes of the different elements are unstable, or radioactive, and hence they disintegrate to form stable atoms either of that element or of some other element. *See* Atomic mass; Radioactivity.

The origin of the chemical elements is believed to be the result of the synthesis by fusion processes at very high temperatures (in the order of 100,000,000°C or 180,000,000°F and higher) of the simple nuclear particles (protons and neutrons) first to heavier atomic nuclei such as those of helium and then on to the heavier and more complex nuclei of the light elements (lithium, boron, and so on). The helium atoms bombard the atoms of the light elements and produce neutrons. The neutrons are captured by the nuclei of elements and produce heavier elements. *See* Nucleosynthesis.

A number of elements that are found in only very slight traces or not at all in nature, such as technetium, promethium, astatine, francium, and all the elements with atomic numbers above 92, have been synthesized by a variety of nuclear reactions that involve transmuting atoms of one element into atoms of another by bombarding that element with neutrons or fast-moving particles (protons, deuterons, and alpha particles) which will change the atomic number to that of the new element. *See* Atomic structure and spectra; Transuranium elements. [A.B.G.]

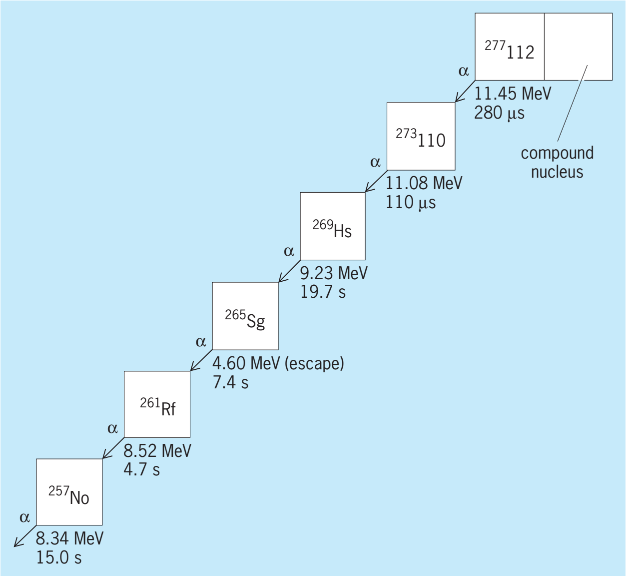
Element 111 Element 111 was discovered in late 1994. It should be a homolog of the elements gold, silver, and copper. It is expected to be the ninth element in the 6*d* shell, but the half-life of 1.5 ms of the only isotope known today is too short to allow chemical studies. *See* Copper; Gold; Half-life; Radioisotope; Silver.



Sequence of decay chains that document the discovery of element 111. Numbers below boxes are alpha energies and correlation times. Element 111 is produced in the reaction ^{64}Ni + ^{209}Bi → ^{272}111 + 1*n*.

The element was discovered on December 17, 1994, at GSI (Gesellschaft für Schwerionenforschung), Darmstadt, Germany, by detection of the isotope ^{272}111 (the isotope of element 111 with mass number 272), which was produced by fusion of a nickel-64 projectile and a bismuth-209 target nucleus after the fused system was cooled by emission of one neutron. Sequential alpha decays to meitnerium-268, bohrium-264, dubnium-260, and lawrencium-256 allowed identification from the known decay properties of ^{260}Db and ^{256}Lr. In the decay chain (see illustration), the first three members are new isotopes. The isotope ^{272}111 has a half-life of 1.5 ms, and is produced with a cross section of 3.5×10^{-36} cm^2. Altogether, three chains were observed. The new isotopes meitnerium-268 and bohrium-264 are the heaviest isotopes of these elements currently known. Their half-lives of 70 ms and 0.4 s, respectively, are longer than those of the previously known isotopes of these elements. *See* Alpha particles; Neutron; Nuclear reaction. [P.Ar.]

Element 112 Element 112 was discovered in 1996. It should be a heavy homolog of the elements mercury, cadmium, and zinc. It is expected to be the last element in the 6*d* shell. No chemistry is possible in the near future as all cross sections are in the range of 10^{-36} cm^2 and the half-lives are short. *See* Cadmium; Half-life; Mercury (element); Zinc.



Sequence of decay chains that document the discovery of element 112. Numbers below boxes are alpha energies and correlation times. Element 112 is produced in the reaction ^{70}Zn + ^{208}Pb → ^{277}112 + 1*n*.

Element 112 was discovered on February 9, 1996, at GSI (Gesellschaft für Schwerionenforschung), Darmstadt, Germany, by detection of the isotope ^{277}112, which was produced by fusion of a zinc-70 projectile and a lead-208 target nucleus following the cooling down of the fused system by emission of a single neutron. Sequential alpha decays to ^{273}110, hassium-269, seaborgium-265, rutherfordium-261, and nobelium-257 allowed unambiguous identification by using the known decay properties of the last three members of the chain. In the decay chain (see illustration), the first three members are new isotopes. Isotope ^{277}112 has a half-life of 0.24 ms, and it is produced with a cross section of 1.0×10^{-36} cm^2 (the smallest observed in the production of heavy elements). The new isotopes of darmstadtium and hassium are of special interest. Their half-lives and alpha energies are very different, as is characteristic of a closed-shell crossing. At the neutron number $N = 162$, a closed shell was theoretically predicted, and this closed shell is verified in the decay chain observed. Isotope ^{269}Hs has a half-life of 9 s, which is long enough to allow studies on the chemistry of this element. The crossing of the neutron shell at $N = 162$ is an important achievement in the field of research on superheavy elements. The stabilization of superheavy elements is based on high fission barriers, which are due to corrections in the binding energies found near closed shells. The shell at $N = 162$ is the first such shell predicted, and is now verified. *See* Alpha particles; Element 111; Hassium; Lead; Neutron; Nobelium; Nuclear structure; Radioisotope; Rutherfordium; Seaborgium. [P.Ar.]

Elementary particle A particle that is not a compound of other particles. At one time the elementary particles of matter were the atoms of the chemical elements, but the atoms are now known to be compounds of the electron, proton, and neutron. In turn, the proton and neutron, and likewise all the other hadrons (strongly interacting particles), are now known to be compounds of quarks. It is convenient, however, to continue to call hadrons elementary particles to distinguish them from their compounds (atomic nuclei, for instance); this usage is also justified by the fact that quarks are not strictly particles, because, as far as is known, they cannot be isolated. The term fundamental particle can be used to denote particles that are truly fundamental constituents of matter and are not compounds in any sense. *See* Electron; Hadron; Neutron; Proton; Quarks.

The known fundamental particles (see table) fall into two categories: the gauge bosons, comprising the photon, gluon, and weak bosons; and the fermions, comprising the quarks and leptons. The graviton, the quantum of the gravitational field, has been omitted from table since it plays no role in high-energy particle physics: it is firmly predicted by theory, but the prospect of direct observation is exceedingly remote. Of the gauge bosons, the photon has been known since the beginning of quantum mechanics. The heavy gauge bosons $W^{\pm}$ and Z^0 were observed in 1983; their properties had been deduced from the weak interactions, for which they are responsible. The lightest (and stable) lepton, the electron (e), is the first known fundamental particle. The next found was the muon (μ, originally called the mu meson). The fundamental fermions are grouped into three families. Gluons and quarks are never seen as free particles; this phenomenon is known as confinement. Particles that are composed of quarks and gluons are called hadrons; essentially, mesons are composed of a quark-antiquark pair $q\bar{q}$, and baryons are three quarks qqq, bound together by the exchange of gluons. *See* Baryon; Gluons; Graviton; Intermediate vector boson; Lepton; Meson; Photon.

Particles with the properties of the quarks of the quark model (charges $\pm\frac{2}{3}e$ or $\pm\frac{1}{3}e$ and masses less than 300 MeV) have never been observed. Direct evidence both for quarks and for their confinement is given by the phenomenon of hadronic jets. For example, in high-energy deep-inelastic electron-proton scattering, in which the electron loses a sizable fraction of its energy, the observed cross section shows that the charge of the proton is carried by pointlike (radius less than 10^{-1} femtometer) particles of small mass. However, no such particles are seen in the final state of this process, or indeed of any other high-energy collision. What is seen is a narrow shower of hadrons. The interpretation is that the electron scatters off one of the quarks in the proton and gives it a large energy and momentum, the quark responding as though it were a free particle of mass much less than 100 MeV, consistent with the masses of the u and d quarks (see table). Later, through the production of quark-antiquark pairs, the energy and momentum of the struck quark is divided among a number of hadrons, mostly pions, a process called hadronization or fragmentation of the quark, which is to be distinguished from the decay of a free particle. The resulting shower of hadrons, whose total momentum vector is roughly that of the original quark, is called a hadronic jet (like a jet of water which breaks up into a spray of droplets). Such jets are also seen in other high-energy reactions, such as e^+e^- annihilation into hadrons, and also in pp collisions; they are the closest available phenomenon to the actual observation of a quark as a free particle.

To each kind of particle there corresponds an antiparticle, or conjugate particle, which has the same mass and spin, belongs to the conjugate representation (multiplet) of internal symmetry, and has opposite values of charge, I_3, strangeness, and so forth (quantum numbers which are conserved additively). The product of the space parities of a particle and its antiparticle is $+1$ if the particle is a boson, -1 if a fermion. For instance, the electron e and its antiparticle, the positron e^-, have the same masses and spins, and opposite charges and lepton number, and an S-wave state of e and e^- has parity -1. Particles for which the antiparticle is the same as the particle are called self-conjugate; examples are the photon γ and the neutral pion π^0. The equality of masses implies the equality of lifetimes of particle and antiparticle. Thus the positron is stable; however, in the presence of ordinary matter it soon annihilates with an electron, and thus is not a component of ordinary matter. *See* Antimatter; Positron.

The interactions of particles are responsible for their scattering and transformations (decays and reactions). Because of interactions, an isolated particle may decay into other particles. Two particles passing near each other may transform, perhaps into the same particles but with changed momenta (elastic scattering) or into other particles (inelastic scattering). The rates or cross sections of these transformations, and so also the interactions responsible for them, fall into three groups: strong (typical decay rates of 10^{21}–10^{23} s^{-1}), electromagnetic (10^{16}–10^{19} s^{-1}), and weak ($<10^{15}$ s^{-1}). Strong interactions occur only between hadrons. Electromagnetic interactions result from the coupling of charge to the electromagnetic field. Weak interactions are usually unobservable in competition with strong or electromagnetic interactions. They are observable only when they do something which those much stronger interactions cannot do (forbidden by the selection rules); for instance, by changing flavors they can make a particle decay which would otherwise be stable, and by making parity-violating transition amplitudes they can produce an otherwise absent asymmetry in the angular distribution of a reaction. *See* Selection rules (physics).

Most particles are unstable and decay into smaller-mass particles. The only particles which appear to be stable are the massless particles (graviton, photon), the neutrinos (possibly massless), the electron, the proton, and the ground states of stable nuclei, atoms, and molecules. It is speculated that some or all of the neutrinos may be massive and unstable and that the proton (and therefore all nuclei) may be unstable. The present view is that the only massive particles which are strictly stable are the electron and the lightest neutrino(s). The electron is the lightest charged particle; its decay would be into neutral particles and could not conserve charge. Likewise, the lightest neutrino is the lightest fermion; its decay would be into bosons and could not conserve angular momentum. *See* Neutrino.

The unstable elementary particles must be studied within a short time of their creation, which occurs in the collision of a fast (high-energy) particle with another particle. Such fast particles exist in nature, namely the cosmic rays, but their flux is small; thus most elementary particle research is based on high-energy particle accelerators. *See* Cosmic rays; Nuclear reaction; Particle accelerator; Particle detector.

Hadrons can be divided into the quasistable (or hadronically stable) and the unstable. The quasistable hadrons are simply those that are too light to decay into other hadrons by way of the strong interactions, such decays being restricted by the requirement that isobaric spin I and flavors be conserved.

The unstable hadrons are also called particle resonances. Their lifetimes, of the order of 10^{-23} s, are much too short to be observed directly. Instead they appear, through the uncertainty principle, as spreads in the masses of the particles—that is, in their widths—just as in the case of nuclear resonances. *See* Uncertainty principle.

A characteristic of the hadrons is that they are grouped into i-spin multiplets (for example, n, p; π^-, π^0, π^+); the masses of the particles in each multiplet differ by only a few megaelectronvolts (MeV). The i-spin multiplets of hadrons themselves form groups (called supermultiplets) which were recognized in 1961 as multiplets (representations) of the group SU_3 (now referred to as SU_3^{flavor} to distinguish this physical symmetry from SU_3^{color}). For instance, the lightest mesons (η, K, $\bar{K}$, π) and baryons (Λ, N, Ξ, Σ) are each a set of eight particles having i-spins $I = (0, \frac{1}{2}, \frac{1}{2}, 1)$ and hypercharges $Y = (0,1,-1,0)$ respectively; this pattern is that of the octet, $\{8\}$, representation of the group SU_3. Again, the lowest-mass $J^P = {}^3\!/_2{}^+$ baryons (Δ, Σ^*, Ξ^*, Ω), ten particles with

The fundamental particles[a]

Gauge bosons $J_C^P = 1_-^-$ Self-conjugate except $\overline{W^+} = W^-$.

Name	Symbol	Charge[b]	Mass and width, GeV	Couplings
Photon	γ	0	0	$A \Rightarrow \gamma A$
Gluon[c]	g	0	0	$A \Rightarrow gA'$
Weak bosons				
Charged	$W^\pm$	±1	80.4, 2.1	$U \Rightarrow W^+D$
Neutral	Z^0	0	91.2, 2.5	$A \Rightarrow Z^0A$

Fermions $J = {}^1\!/_2$ All have distinct antiparticles, except perhaps the neutrinos.

Name	Charge[b]	Symbol and mass, GeV	Symbol and mass, GeV	Symbol and mass, GeV

Up type	$^2\!/_3$	u .005	c 1.4	t 178[g]
Down type	$-^1\!/_3$	d .01	s .15	b 4.8

[a] The graviton, with $J_C^P = 2_+^+$, has been omitted, since it plays no role in high-energy particle physics.
[b] In units of the proton charge.
[c] The gluon is a color SU_3 octet (8); each quark is a color triplet (3). These colored particles are confined constituents of hadrons; they do not appear as free particles.
[e] The three known families (generations) of fermions are displayed in three columns.
[f] The μ and τ leptons are unstable, with mean lives of 2.2×10^{-6} s and 2.9×10^{-13} s respectively.
[g] The t quark has a width ≈2 GeV, with dominant decay to Wb.

$I = ({}^3\!/_2, 1, \frac{1}{2}, 0)$ and $Y = (1, 0, -1, -2)$, form a decuplet, $\{10\}$, representation of SU_3. The spread of the masses in these groups is about a hundred times greater than in the *i*-spin multiplets, a few hundred MeV compared to a few MeV. According to the quark model, this SU_3 symmetry and the pattern of charges in the SU_3 multiplets result simply from the existence of a third kind (flavor) of quark, the *s* (strange) quark, with charge the same as the *d* quark, namely $\frac{1}{3}$, together with the flavor independence of the glue force; that is, all three quarks *u*, *d*, and *s* have the same interaction with the glue field. The resulting flavor SU_3 symmetry is broken by the relatively large mass of the *s*, approximately 150 MeV. The three quarks make up the fundamental triplet, $\{3\}$, representation of SU_3.

Hadrons are known which contain yet more massive quarks, the *c* and the *b* (see the table). The resulting symmetry is badly broken, and the supermultiplets hardly recognizable.

It appears that the "glue" field which binds quarks together to make hadrons is a Yang-Mills (that is, a non-abelian) gauge field of an SU_3 symmetry group, SU_3^{color}. This is an exact symmetry of nature. The quanta of the field are called gluons, and its quantum theory is called quantum chromodynamics (QCD). The gluon field resembles the electromagnetic field, but has an internal symmetry index (octet index) which runs over eight values; that is, there are really eight fields, corresponding to the eight parameters needed to specify an SU_3 transformation. Just as the electromagnetic field is coupled to (that is, photons are emitted and absorbed by) the density and current of a conserved quantity, charge, the gluon field is coupled to color. The coupling of the gluon to a particle is fixed by the color of the particle (that is, what member of what color multiplet) and just one universal coupling constant *g*, analogous to the electronic unit of charge *e*. (The analogy breaks down in quantum theory, as discussed below; the quantity *g* is no longer constant but it is still universal.) *See* GAUGE THEORY.

Since the long-range forces observed between hadrons are no different than those between other particles, hadrons must be colorless, that is, color singlet combinations of quarks, their colored constituents. The two simplest combinations of quarks which can be colorless are $\bar{q}_1q_2$ and $q_1q_2q_3$; these are found in nature as the basic structure of mesons and baryons, respectively. The exchange of gluons between any of the quarks in these colorless combinations gives rise to an attractive force, which binds them together.

Gluons are not colorless, and therefore they are coupled to themselves. This situation is very different from electromagnetism, where the photon does not carry charge. The consequence of this self-coupling of massless particles is a severe infrared (small momentum transfer or large distance) divergence of perturbation theory. In particular, the interaction between two colored particles through the gluon field, which in lowest order is an inverse-square Coulomb force, proportional to g^2/r^2 (where *r* is the distance between the particles), becomes stronger than this inverse-square force at larger *r*. A way of describing this is to say that the coupling constant *g* is effectively larger at larger *r*; this defines the so-called running coupling constant $g(r)$. According to the first-order radiative correction, $g(r)$ becomes infinite at a certain distance, the so-called scale parameter r_c.

A specific form for the gluonic force between two colored particles, at large *r*, namely that it falls to a nonzero constant value λ, of the order of $\hbar c r_c^{-2}$ (where $\hbar$ is Planck's constant divided by 2π, and *c* is the speed of light), is suggested by a model, the superconductor analogy. This force is confining.

The conjecture is that the vacuum is like a superconductor with respect to color, with the interchange, however, of electric and magnetic quantities. That is, the vacuum acts like a color magnetic superconductor which confines color flux into bundles which have a diameter of order r_c and an energy per unit length equal to λ of order $\hbar c r_c^{-2}$. The color flux bundles run between colored particles; they can also form closed loops. These flux bundles are often idealized as having vanishing diameter and are then called strings. This idealization is obviously good only if the flux bundles are long compared to r_c, and if their local radius of curvature is always much larger than r_c.

According to the so-called naive quark model, hadrons are bound states of nonrelativistic (slowly moving) quarks, analogous to nuclei as bound states of nucleons. The interactions between the quarks are taken qualitatively from QCD, namely a confining central potential and (exactly analogous to electrodynamic interactions) spin-spin (hyperfine) and spin-orbit potentials; quantitatively, these potentials are adjusted to make the energy levels of the model system fit the observed hadron masses. This model should be valid for hadrons composed of heavy quarks but not for hadrons containing light quarks (u, d, s), but in fact it succeeds in giving a good description of many properties of all hadrons. One reason is that many of these properties follow from so-called angular physics, that is, symmetry-based physical principles that transcend the specific model. A meson is a bound state of a quark and an antiquark, q_1q_2. A baryon is a bound state of three quarks, $q_1q_2q_3$.

The known heavy quarks are the c (charm), b (bottom), and t (top) quarks, whose masses are larger than the natural energy scale of QCD, ≈1 GeV. But because the width of the t is also larger than 1 GeV, the t quark decays before the QCD force acts on it, and thus before any well-defined hadron forms. So in the present context "heavy quarks" mean only c and b. A hadron which contains a single heavy quark resembles an atom; the heavy quark sits nearly at rest at the center, and is a static source of the color field, just as the atomic nucleus is a static source of the electric field. Just as an atom is changed very little (except in mass) if its nucleus is replaced by another of the same charge (an isotope), a heavy-quark hadron is changed very little (except in mass) if its heavy quark is replaced by another of the same color. This is called heavy-quark symmetry. So, for example, the D, D^*, B, and B^* mesons are similar, except in mass. This plays an important role in the quantitative analysis of their weak decays.

If a hadron contains two heavy quarks, then in a not too highly excited state the heavy quarks move slowly, compared to the speed of light c, and so the effect of the exchange of gluons between the quarks can be approximated (up to radiative corrections) by a potential energy which depends only on the positions of the quarks (local static potential); further, the wave function of the system satisfies the ordinary nonrelativistic Schrödinger equation. Consequently, the properties of hadrons composed of heavy quarks are rather easily calculated.

Mesons with the composition $c\bar{c}$ and $b\bar{b}$ are called charmonium and bottomonium, respectively. These names are based on the model of positronium, ee^-; the generic name for flavorless mesons, $q\bar{q}$, is quarkonium. Since both heavy quarkonium and positronium are systems of a fermion bound to its antifermion by a central force, they are qualitatively very similar.

The electroweak theory, starting from the observation that both the electromagnetic and weak interactions result from the exchange of vector (spin-1) bosons, has unified these interactions into a spontaneously broken gauge theory. Similarly, the observation that the strong (hadronic) interactions are also due to the exchange of vector bosons (gluons) suggests that all these vector bosons (the photon, the three weak bosons, and the eight gluons) are quanta of the components of the gauge field of a large symmetry group, SU_5 or larger. Such theories are called grand unification theories (GUTs). The large symmetry group of the grand unification theory must be spontaneously broken, making all the gauge bosons massive except the gluon octet and the photon, leaving $SU_3 \times U_1$ (color × electromagnetism) as the apparent gauge symmetry of the world. *See* GRAND UNIFICATION THEORIES.

In these theories, the leptons and quarks occur together in multiplets of the large symmetry group. These multiplets are called families (or generations). The known fundamental fermions do seem to fall into three families (see table). Each family consists of a weak i-spin doublet of leptons (neutrino [charge 0] and charged lepton [charge $+e$]), and a color triplet of weak i-spin doublets of quarks (up-type [charge $\frac{2}{3}e$] and down-type [charge $-\frac{1}{3}e$]). [C.J.G.]

Elements, cosmic abundance of The average chemical and isotopic composition of the solar system is appropriately referred to as cosmic, since this elemental abundance distribution is found to be nearly the same for interstellar gas and for young stars associated with gas and dust in the spiral arms of galaxies. The Sun makes up more than 99.9% of the mass of the solar system, so the bulk chemical composition of the solar system is essentially the same as that of the Sun. The cosmic abundances of the nonvolatile elements are determined from chemical analyses of a type of meteorite known as CI chondrites, whereas the relative abundances of the volatile elements are determined from quantitative measurements of the intensities of elemental emission lines from the Sun's photosphere. In most silicate-rich meteorites and the Earth, Moon, Venus, and Mars, the most abundant elements are oxygen, magnesium, silicon, iron, aluminum, and calcium. Average solar-system composition consists of 70.7 wt % hydrogen, 27.4 wt % helium, and only 1.9 wt % of all remaining elements, lithium to uranium. Cosmic abundances are now widely referred to as standard abundances in the astrophysical literature. *See* ASTRONOMICAL SPECTROSCOPY; ELEMENT (CHEMISTRY); ELEMENTS, GEOCHEMICAL DISTRIBUTION OF.

Cosmic abundances of elements have several important uses. First, by comparing cosmic abundances to chemical analyses of various types of meteorites, inferences can be made about chemical fractionation processes that occurred in the primitive solar nebula, such as condensation and vaporization. Also, by comparing them to rock compositions, inferences can be made about processes that occurred early in the history of rocky planets, such as separation of a metallic core and differentiation of silicates into mantle and crust. Second, cosmic abundances serve as a standard of comparison for spectroscopic measurements of elemental abundances of the photospheres of other stars and for measurements of elemental and isotopic abundances in cosmic rays. Finally, nucleosynthesis occurs in many different stellar environments. Explanations of nucleosynthesis must account for how elements and isotopes from various astrophysical sources are made and then mixed to form the solar system's average chemical and isotopic composition. *See* NUCLEOSYNTHESIS; SOLAR SYSTEM. [A.M.D.]

Elements, geochemical distribution of The distribution of the chemical elements within the Earth in space and time. Knowledge of the geochemical distribution of the elements in the Earth, particularly in the Earth's crust, and of the processes that lead to the observed distributions make it possible to locate and use efficiently essential elements and minerals and to predict their dispersal patterns when they reenter the natural environment after use.

To understand the present-day distribution of the elements in the Earth, it is necessary to go back to the time of Earth formation approximately 4.5 billion years ago. It is generally believed that the Earth and the other planets in the solar system formed by agglomeration of smaller fragments of solid material orbiting around the Sun. This material had precipitated from a cooling hot gas cloud (the solar nebula), with the most refractory materials condensing out first, the most volatile last. The distribution of elements in the solar system in this early phase thus had much to do with volatility, and the solid material that aggregated to form the planets was a mix of volatile and nonvolatile materials. *See* COSMOCHEMISTRY; ELEMENTS, COSMIC ABUNDANCE OF; SOLAR SYSTEM.

Although the Earth may have been an approximately homogeneous mixture of accreted materials at the time of its formation, it is now made of many chemically distinct parts. At the fundamental level, these are the core, the mantle, and the crust. While chemical fractionation in the solar nebula depended upon volatility, chemical differentiation within the Earth took place by the separation of molten material from unmelted residue under the influence of gravity. Because large amounts of energy were released from accreting fragments, the early Earth was very hot, and during the accretion stage itself, temperatures in some parts exceeded the melting point of iron metal. Pools of dense molten iron, with dissolved nickel and other elements, aggregated and sank through the Earth under gravity to form the core, leav-

Element distribution among some of the major subdivisions of the Earth[*]

Element	Continental crust	Oceanic crust	Upper mantle	Core[†]
Oxygen	45.3	43.6	44.2	—
Silicon	26.7	23.1	21.0	—
Aluminium	8.39	8.47	1.75	—
Iron	7.04	8.16	6.22	85.5
Calcium	5.27	8.08	1.86	—
Magnesium	3.19	4.64	24.0	—
Sodium	2.29	2.08	0.25	—
Potassium	0.91	0.13	0.02	—
Titanium	0.68	1.12	0.11	—
Nickel	0.011	0.014	0.20	5.5
Sulfur	NA	NA	NA	9.0

[*] Estimates of element abundances are in percent by weight and are arranged in order of decreasing abundance in the continental crust. Sulfur contents are not well known and are designated "not applicable."

[†] The estimate for the core is just one of several models. Others substitute light elements such as oxygen, carbon, or silicon for some or most of the sulfur shown here.

ing behind a mantle of silicate and oxide minerals. The present core constitutes about 32.4% of the Earth's mass. The distinct parts of the Earth possess unique overall compositions (see table).
