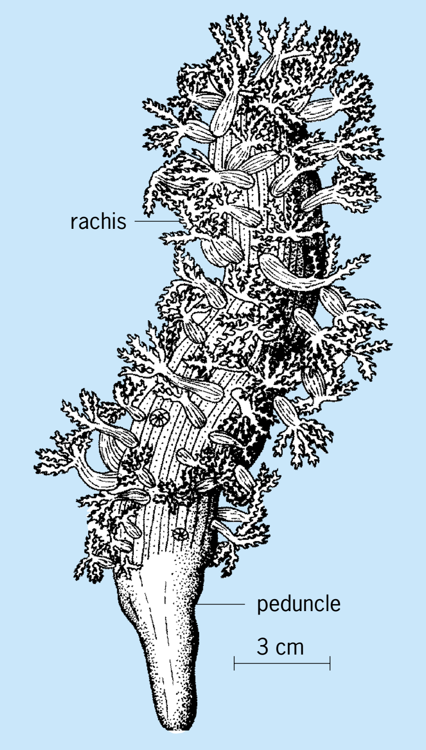
Erection of the penis is caused by nervous stimulation resulting in engorgement of the spiral helicine arteries and the plentiful venous sinuses of the organ. In most mammals other than Primates the penis is retracted into a sheath when not in use.

In submammalian forms the penis is not as well developed. Crocodilians, turtles, and some birds have a penis basically like that of mammals, lying in the floor of the cloaca. When erected, it protrudes from the cloaca and functions in copulation. Other vertebrates lack a penis, although various functionally comparable organs may be developed such as the claspers on the pelvic fins of sharks and the gonopodia on the anal fins of certain teleost fishes. *See* COPULATORY ORGAN. [T.S.P.]

Pennatulacea An order of the subclass Alcyonaria, commonly called the sea pens. These animals lack stolons and live with their bases embedded in the soft substratum of the sea. The colony consists of a distal rachis bearing many polyps and a polypless proximal peduncle, whose terminal end sometimes expands to form a bladder. The colony of *Pennatula* looks like a feather being formed of numerous secondary polyps which arise from leaf-shaped lateral expansions of the very elongated primary axial or terminal polyp. In the other form of colony the polyps arise directly from the primary one, as in *Veretillum* (see illustration) and *Renilla* and *Cavenularia*. The colony has a horny unbranched axial skeleton composed of pennatulin and some calcium carbonate and phosphate, but *Cauenularia*, including the luminous species, has a rudimentary one and *Renilla* lacks a skeleton. *See* ALCYONARIA. [K.At.]



Veretillum cynomorium.

Pennsylvanian A major division of late Paleozoic time, considered either as an independent period or as the younger subperiod of the Carboniferous. In North America, the Pennsylvanian has been widely recognized as a geologic period and derives its name from a thick succession of mostly nonmarine, coal-bearing strata in Pennsylvania. Radiometric ages place the beginning of the period at approximately 320 million years ago and its end at about 290 million years ago. In northwestern Europe, strata of nearly equivalent age are commonly designated as Upper Carboniferous and in eastern Europe as Middle and Upper Carboniferous. *See* CARBONIFEROUS.

In North America, the Pennsylvanian Period was characterized by the progressive growth and enlargement of the Alleghenian-Ouachita-Marathon orogenic belt, which formed as the northwestern parts of the large continent Gondwana (mainly northwestern Africa, the area that is now Florida, and northern South America) collided against and deformed the eastern and southern parts of the North American continent. *See* OROGENY.

Much of North America remained a stable, low-lying cratonic platform during the Pennsylvanian and was covered by a relatively thin veneer of shallow-water marine carbonates and marine and nonmarine clastic sediments. These were deposited as sea level repeatedly rose and fell as the polar glaciers of southern Gondwana contracted and expanded. In Pennsylvania and along the western part of the present Allegheny Plateau, Pennsylvanian strata are predominantly nonmarine deposits made up of channel sandstones, floodplain shales, siltstones, sandstones, and coals. *See* CARBONATE MINERALS; COAL; CRATON; MARINE SEDIMENTS.

During Pennsylvanian time, the paleoequator extended across North America from southern California to Newfoundland, through northwestern Europe into the Ukrainian region of eastern Europe, and across parts of northern China. This was a time of extensive coal deposition in a tropical belt that appears to have included areas from 15 to 20° north and south of the paleoequator. Coal of this age is abundant and relatively widespread and has great economic importance.

Petroleum is commonly trapped in nearshore marine deposits of Pennsylvanian age, particularly in carbonate banks near the edge of shelves, in longshore bars and beaches, in reefs and mounds, and at unconformities associated with transgressive-regressive shore lines. Many of these traps contribute significantly to petroleum production. *See* PETROLEUM.

Pennsylvanian paleogeography changed significantly during the period as the supercontinent Pangaea gradually was formed by the joining together of Gondwana and Laurasia. North America and northern Europe, which had been combined into the continent Laurasia since the late Silurian, and South America and northwestern Africa, which formed the northern part of the continent of Gondwana, came together along the Ouachita–Southern Appalachian–Hercynian geosyncline. The result was an extensive orogeny, or mountain-building episode, which supplied the vast amounts of sediments that make up most of the Pennsylvanian strata in the eastern and midwestern parts of the United States. *See* PALEOGEOGRAPHY.

Evidence in the form of well-developed tree rings, less diverse fossil floras and faunas, and glacial deposits indicates that temperate and glacial conditions were common in nonequatorial climatic belts during Pennsylvanian time. Climatic fluctuations during the period caused significant increases and decreases in the amount of water that was temporarily stored in the glaciers in Gondwana and contributed to eustatic changes of sea level. *See* PALEOCLIMATOLOGY. [C.A.R.; J.R.P.R.]

Pentamerida An extinct order of brachiopods that lived from Middle Cambrian to Late Devonian (520 to 390 million years ago) with a peak during the Silurian Period. Pentamerides are among the largest brachiopods, with adults ranging 1–15 cm (0.4–6 in.) in length. The two valves, always composed of calcite ($CaCO_3$), are both convex, with a larger ventral (pedicle) valve and a smaller dorsal (brachial) valve. Externally, most pentamerides are smooth except for concentric growth-line increments, but a proportion have radial ribs (costae) which may be sinuous or sharp-crested in cross section. Internally, the valve space is divided by variably developed walls (septa), with one median septum in the ventral valve dividing it into two, and two septa in the dorsal valve, dividing it into three, for a total of five divisions. The septa in the dorsal valve unite to form a platform termed the spondylium, which was used as an attachment area for the muscles which opened and closed the valves. The form and disposition of the soft parts are not well known.

Within the order Pentamerida there are currently 215 genera, which have been described from Paleozoic rocks in all continents. The order is subdivided into the rather smaller suborder Syntrophidina, with 90 genera ranging in age from the Middle Cambrian to the Early Devonian, and the suborder Pentameridina, which ranged from the Middle Ordovician to the Late Devonian. *See* BRACHIOPODA. [L.R.M.C.]

Pentastomida A class of bloodsucking arthropods, parasitic in the respiratory organs of vertebrates, that frequently are referred to as the Linguatulida or tongue worms. The adults are vermiform, with a short cephalothorax and an elongate, annulate abdomen that may be cylindrical or flattened.

The class is divided into two orders: the Cephalobaenida, a more primitive group, and the Porocephalida, a more specialized one. The first has six-legged larvae and the other, four-legged larvae. The mitelike form of the larvae, with short stumpy legs, demonstrates relationship to the arthropods. Characteristic arthropod features include the presence of (1) jointed appendages in the larvae; (2) stigmata or breathing pores in the body wall; (3) specialized reproductive organs, especially those of the male; and (4) ecdysis or molting of larvae and nymphs. More than 50 species have been described.

Human infection occurs frequently in Africa and the Orient, where humans are an accidental intermediate host of the nymphal form. The liver is a common site of infection, and large numbers of larvae may produce serious and even fatal effects. *See* ARTHROPODA; CEPHALOBAENIDA; POROCEPHALIDA. [H.W.S.]

Pentlandite A mineral having composition $(Fe,Ni)_9S_8$. Pentlandite is the major ore of nickel. It is usually massive, showing a well-defined octahedral parting. The hardness is 3.5–4 (Mohs scale) and the specific gravity varies from 4.6 to 5.0, depending on the ratio of iron to nickel; greater amounts of iron cause an increase in the specific gravity. The luster is metallic and the color yellowish bronze. Pentlandite is found at many localities in small amounts, but its chief occurrence is at Sudbury, Ontario, where it is mined on a large scale. *See* NICKEL. [C.S.Hu.]

Pepper The garden pepper, *Capsicum annuum* (family Solanaceae), is a warm-season crop originally domesticated in Mexico. It is usually grown as an annual, although in warm climates it may be perennial. This species includes all peppers grown in the United States except for the “Tabasco” pepper (*C. frutescens*), grown in Louisiana. Other cultivated species, *C. chinense*, *C. baccatum*, and *C. pubescens*, are grown primarily in South America. Some 10–12 strictly wild species also occur in South America. Peppers are grown worldwide, especially in the more tropical areas, where the pepper is an important condiment.

Sweet (nonpungent) peppers, harvested fully developed but still green, are widely used in salads or cooked with other foods. Perfection pimento, harvested red ripe, is used for canning. Paprika is made from ripe red pods of several distinct varieties; the pods are dried and ground. *See* PAPRIKA; PIMENTO.

The ripe color of most varieties is red, a few varieties are orange-yellow, and in Latin America brown-fruited varieties are common. Nutritionally, the mature pepper fruit has three to four times the vitamin C content of an orange, and is an excellent source of vitamin A. *See* ASCORBIC ACID; VITAMIN A. [P.G.S.]

Peppermint The mint species *Mentha piperita* (family Lamiaceae), a sterile interspecific hybrid believed to have occurred in nature from the hybridization of fertile *M. spicata*. Peppermint oil is obtained by steam distillation from the partially dried hay. The main uses of peppermint oil are to flavor chewing gum, confectionery products, toothpaste, mouthwashes, medicines, and as a carminative in certain medical preparations for the alleviation of digestive disturbances. [M.J.M.]

Pepsin A proteolytic enzyme found in the gastric juice of mammals, birds, reptiles, and fish. It is formed from a precursor, pepsinogen, which is found in the stomach mucosa. Pepsinogen is converted to pepsin either by hydrochloric acid, naturally present in the stomach, or by pepsin itself. *See* ENZYME.

Pepsin is prepared commercially from the glandular layer of fresh hog stomachs. It is a part of the crude preparation known as rennet, which is used to curdle milk in preparation for cheese manufacture. Pepsin is also used for a variety of other applications in food manufacturing; to modify soy protein and gelatin, thereby providing whipping qualities; to modify vegetable proteins for use in nondairy snack items; to make precooked cereals into instant hot cereals; and to prepare animal and vegetable protein hydrolysates for use in flavoring foods and beverages. [M.So.]

Peptide A compound that is made up of two or more amino acids joined by covalent bonds which are formed by the elimination of a molecule of H_2O from the amino group of one amino acid and the carboxyl group of the next amino acid. Peptides larger than about 50 amino acid residues are usually classified as proteins. Glutathione is the most abundant peptide in mammalian tissue. Hormones such as oxytociri (8), vasopressin (8), glucagon (29), and adrenocorticotropic hormone (39) are peptides whose structures have been deduced; in parentheses are the numbers of amino acid residues for each peptide.

For each step in the biological synthesis of a peptide or protein there is a specific enzyme or enzyme complex that catalyzes each reaction in an ordered fashion along the biosynthetic route. However, it is noteworthy that, although the biological synthesis of proteins is directed by messenger RNA on cellular structures called ribosomes, the biological synthesis of peptides does not require either messenger RNA or ribosomes. *See* AMINO ACIDS; PROTEIN; RIBONUCLEIC ACID (RNA); RIBOSOMES. [J.M.M.]

Peracarida A superorder of the superclass Crustacea, subclass Eumalacostraca. The Peracarida includes the orders Amphipoda, Cumacea, Isopoda, Mictacea, Mysidacea, Spelaeogriphacea, Thermosbaenacea, and Tanaidacea. In these orders the young develop within the mother's ventral thoracic marsupium, which they leave at an advanced stage of development. The marsupium is formed by one to seven pairs of membranous oostegites that extend inward from the coxae of the thoracic legs. The eggs or developing young lie free in the space between the ventral surface of the thorax and the overlapping oostegites. The other basic feature of the Peracarida is an accessory incisor process (lacinia mobilis) in the adult that is known elsewhere only in the primitive class Remipedia. The lacinia mobilis, on the left mandible or both mandibles, is formed from modification of the anterior spine of the spine-row. Besides aiding in cutting, the lacinia mobilis helps align the incisor processes for occlusion.

As with other Malacostraca, the thorax consists of eight somites, the first of which is fused with the head. A carapace is present except in the Amphipoda, Isopoda, and Mictacea; in the last, small carapace folds cover the bases of the mouthparts posterior to the mandibles. When present, the carapace does not coalesce with more than four thoracic somites. The thorax is followed by an abdomen of six segments bearing up to five pairs of biramous swimming legs or pleopods. The sixth segment has a pair of uropods, which, together with the telson, forms a tail fan. Pleopods are absent in all female and some male Cumacea, may be reduced or absent in female Tanaidacea, and may be rudimentary in female Mysidacea. The embryo in the Amphipoda is ventrally concave and lies with the dorsal side toward the outside of the egg. The position is reversed in the other orders. Mysidacea and Amphipoda leave the egg with a full complement of appendages; hatchlings in the other orders lack the eighth thoracic leg. *See* CRUSTACEA; EUMALACOSTRACA. [T.E.B.]

Percent A ratio comparison of two quantities expressed by using 100 equal parts, or hundredths; symbolized %. There are three major uses of percent: part of a whole, rate, and comparison of any two quantities.

Part of a whole. The basic idea of percent is as a ratio that shows a part of a whole. The technical name for the whole is base.

If 89 out of 100 problems are correct, the part-whole comparison shows 89/100 or 89% correct. If the whole is not already divided into equal parts, an equivalent ratio to 100 is found.

Certain ratios are easy to express as hundredths. When 3 baskets are made in basketball out of 10 attempts, an equivalent ratio using 100 is found from which the percent is obvious: $3/10 = 30/100 = 30\%$.

For 35 hits out of 126 times at bat, the ratio 35/126 is not easily expressed as a ratio using 100. Hundredths will be more obvious by dividing 35 by 126, and then reading the number of hundredths to find the percent: $35 \div 126 \approx 0.278$ or 27.8%. The percent is obtained by moving the decimal point two places to the right.

Rate. While percent always means a comparison to 100, percent can show a rate of so many per 100, not so many out of 100. A sales tax of 6% means a rate of 6 cents for each dollar, and this 6 cents is in addition to the dollar. The tax amount can often be calculated mentally by multiplying the 6% rate by the number of dollars.

Interest paid or interest received is done by using rates. Simple interest at a rate of 6% means $6 per $100 for a full year. If interest is calculated monthly on the unpaid balance and the yearly rate is 18%, the monthly rate is approximately $18\% \div 12$ or about 1.5%.

With compound interest, the amount of interest is added each compounding period, and this total amount is subject to compounding for the next period. For example, $1.00 invested at 8% will be worth 108% of $1.00 at the end of one year, or $1.08. The worth at the end of the second year is 108% of $1.08, or $(1.08)^2$. At this same rate, after 10 years the compounded value is $(1.08)^{10} = 2.1589247$, or $2.15, using 1.08 as a factor for 10 times.

Comparing any two quantities. Percent is used to compare any two quantities, but special care must be given to the base for the comparison. Comparison of city A with a population of 42,000 people and city B with 67,000 people will depend on the base. A compared to B is 42,000/67,000, 62.7%; A is 62.7% of B. B compared to A is 67,000/42,000, 1.595, or 159.5%; B is 159.5% of A. *See* ARITHMETIC. [J.N.P.]

Perception Those subjective experiences of objects or events that ordinarily result from stimulation of the receptor organs of the body. This stimulation is transformed or encoded into neural activity (by specialized receptor mechanisms) and is relayed to more central regions of the nervous system where further neural processing occurs. Most likely, it is the final neural processing in the brain that underlies or causes perceptual experience, and so perceptionlike experiences can sometimes occur without external stimulation of the receptor organs, as in dreams.

In contemporary psychology, interest generally focuses on perception or the apprehension of objects or events, rather than simply on sensation or sensory process. While no sharp line of demarcation between these topics exists, it is fair to say that sensory qualities are generally explicable on the basis of mechanisms within the receptor organ, whereas object and event perception entails higher-level activity of the brain. *See* HEARING (HUMAN); SENSATION; VISION.

Since objects or events are not experienced only through vision, the term perception obviously applies to other sense modalities as well. Certainly things and their movement may be experienced through the sense of touch. Such experiences derive from receptors in the skin (tactile perception), but more importantly, from the positioning of the fingers with respect to one another when an object is grasped, the latter information arising from receptors in the muscles and joints (haptic or tactual perception). The position of the parts of the body are also perceived with respect to one another whether they are stationary (proprioception) or in motion (kinesthesis), and the position of the body is experienced with respect to the environment through receptors sensitive to gravity such as those in the vestibular apparatus in the inner ear. Auditory perception yields recognition of the location of sound sources and of structures such as melodies and speech. Other sense modalities such as taste (gustation), smell (olfaction), pain, and temperature provide sensory qualities but not perceptual structures as do vision, audition, and touch, and thus are usually dealt with as sensory processes. *See* OLFACTION; PAIN; PROPRIOCEPTION.

Constancy. By and large, these perceptual properties of objects remain remarkably constant despite variations in distance, slant, and retinal locus caused by movements of the observer. This fact, referred to as perceptual constancy, is perhaps the hallmark of perception and more than any other, serves to characterize the field of perception.

Examples of perceptual constancy are: size (except at very great distances, an object appears the same size whether seen nearby or far away, although the size of its image on the retina can be very different); shape (a circle seen from the side is perceived as a circle, although it appears as an ellipse on the retina); orientation (objects appear to keep the same orientation in space, independently of the orientation of the observer's head); and position (a fixed object remains perceived as stationary even when its image on the retina moves because of eye or head movements).

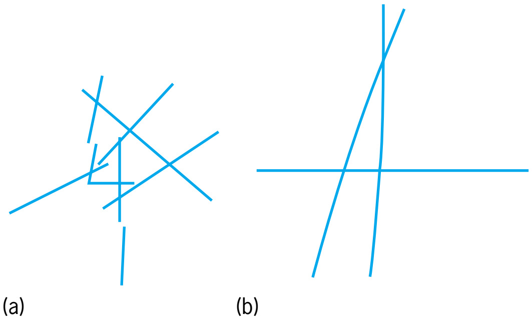
Motion perception. Perceived movement cannot simply be explained by the motion of an object's retinal image since image motion caused by observer or eye movement does not lead to perceived object movement. Moreover, an object tracked by smooth-pursuit eye movements will appear to move, although in that case there is essentially no motion of the object's image over the retina. Similarly, an afterimage will appear to move during eye movement even in a completely darkened room. Where ordinarily the movement of the retinal image caused by the moving eye is computed to signify "no object motion," thus yielding position constancy (since the image motion and eye motion are equal in magnitude), the same computational rule must signify "object motion" in the case of the afterimage.

Form perception. Form perception means the experience of a shaped region in the field. Recognition means the experience that the shape is familiar. Identification means that the function or meaning or category of the shape is known. For those who have never seen the shape before, it will be perceived but not recognized or identified. For those who have, it will be perceived as a certain familiar shape and also identified. Recognition and identification obviously must be based on past experience, which means that through certain unknown processes, memory contributes to the immediate experience that one has, giving the qualities of familiarity and meaning.

The figure of a 4 in Fig. 1*a* is seen as one unit, separate from other units in the field, even if these units overlap. This means that the parts of the figure are grouped together by the perceptual system into a whole, and these parts are not grouped with the parts of other objects. This effect is called perceptional organization. There are other problems about form perception that remain to be unraveled. For example, the size of a figure can vary, as can its locus on the retina or even its color or type of contour, without affecting its perceived shape (Fig. 2).

A further fact about form perception is that it is dependent upon orientation. It is a commonplace observation that printed or written words are difficult to read when inverted, and faces look very odd or become unrecognizable when upside down. Simple figures also look different when their orientation is changed: a square looks like a diamond when tilted by 45°.

Geometrical illusions. Related to the topic of form perception is the misperception of the size or direction of parts of figures that constitutes many of the geometric illusions. In an illusion figure, one particular part is perceived to be either longer or shorter than another part, although they are objectively equal (Fig. 3*a*); or the direction of a contour is perceived to be different from that of another contour although they are the same (Fig. 3*b*). For reasons still not understood, the background or context of the rest of the figure affects these parts.



(a) (b)

Fig. 1. Perceptual organization, (*a*) The figure of a four is immediately and spontaneously perceived despite the presence of other overlapping and adjacent lines, (*b*) The four, although physically present, is not spontaneously perceived and is even difficult to see when one knows it is there.

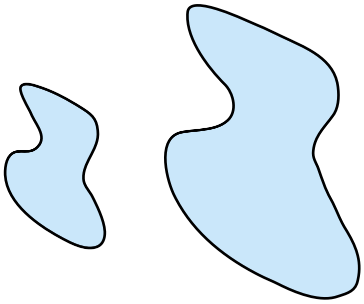


Fig. 2. Transposition of form; the two shapes clearly look the same despite the difference in size.

(a) (b)

Fig. 3. Geometrical illusions, (*a*) The Ponzo illusion in which the two horizontal lines of equal length appear unequal, (*b*) The Poggendorff illusion in which the two oblique line segments are aligned with one another (that is, are collinear) but appear to be misaligned.

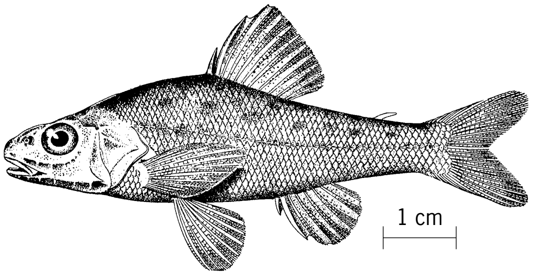
Innate or learned? A central problem is whether the perception of properties such as form and depth or the achievement of veridical perception as in the constancies is innately determined or is based on past experience. By "innate" it is meant that the perception is the result of evolutionary adaptation and thus is present at birth or when the necessary neural maturation has occurred. By "past experience" it is meant that the perception in question is the end result of prior exposure to certain relevant patterns or conditions, a kind of learning process. Despite centuries of discussion of this problem, and considerable experimental work, there is still no final answer to the question. It now seems clear that certain kinds of perception are innate, but equally clear that past experience also is a determining factor. *See* INTELLIGENCE. [I.R.]

Perciformes

The typical spiny-rayed fishes, also known by the ordinal names Acanthopteri and Percomorphi. This is the largest order of vertebrates; the approximately 7500 species include 41% of all fishes. Perciformes include a diversity of structural types and sizes. The characters of the Perciformes include fin spines, usually present; a pelvic fin which, if present, is usually thoracic or jugular in position; the pelvic girdle usually attached to the cleithra, sometimes connected by ligaments; the pelvic fin usually with a spine and 5 soft rays, the latter occasionally reduced; the pectoral fin base more or less vertical, usually placed well up on the side; a swim bladder without a duct; scales usually ctenoid, sometimes secondarily cycloid, absent, or variously modified; and the caudal fin with 17 principal rays (15 branched) or fewer.

Perciform fishes dominate the modern vertebrate life of the oceans and have done so throughout the Cenozoic. The group first appeared in the Upper Cretaceous, after which it underwent a rapid adaptive radiation; many of the basic structural types, as well as most major perciform derivatives such as the Pleuronectiformes and Tetraodontiformes, were present in the Eocene, A few families of perciforms have been notably successful in fresh water. Other families have effectively adapted to life in the deep seas, and still others have become specialized for pelagic existence. It is in the shore areas, the offshore banks, the coral reefs, the coastal beaches and lagoons, and the intertidal zone, however, that the perciforms have attained their ultimate achievement. Here the enormous variety attests to the adaptive effectiveness of the group. *See* ACTINOPTERYGII; OSTEICHTHYES. [R.M.B.]

Percopsiformes A small order of actinopterygian fishes that is also known as the Salmopercae and Amblyopsiformes. The order is thought to be remotely related to the codfishes (Gadiformes) and toadfishes (Batrachoidiformes). The characters (see illustration) include single, ray-supported dorsal and anal fins, each usually with one to four anterior spines; pelvic fin, if present, subabdominal in position, with three to eight soft rays; pelvic girdle, if present, attached to the postcleithra; swim bladder without a duct; and body covered with cycloid or ctenoid scales. *See* BATRACHOIDIFORMES; GADIFORMES.



Sand roller (*Percopsis transmontana*). (*After D. S. Jordan and B. W. Evermann, The Fishes of North and Middle America, U.S. Nat. Mos. Bull. 47, 1900*)

The order comprises three families, five genera, and eight Recent species of North American fresh-water fishes. *See* ACTINOPTERYGII; TELEOSTEI. [R.M.B.]

Performance rating A procedure for determining the value for a factor which will adjust the measured time for an observed task performance to a task time that one would expect of a trained operator performing the task, utilizing the approved method and performing at normal pace under specified workplace conditions. Normal time (ultimately subjectively based) is the time that a trained worker requires to perform the specified task under defined workplace conditions, employing the assumed philosophy of "a fair day's work for a fair day's pay."

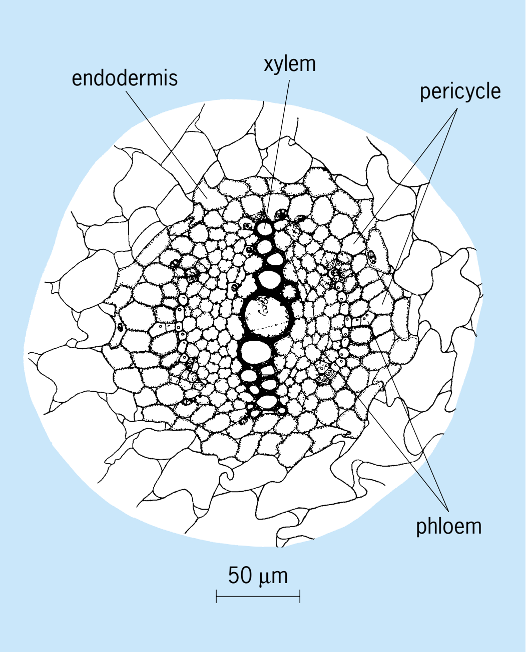
The performance rating process is concerned with determining normal pace during the work portion of an average day and must, therefore, consider the fatigue recovery aspects of allowance (nonwork) times occurring during the day. The following two equations relate factors in determining how much time a worker will be allowed per unit of output:

$$\text{Standard time} = \text{normal time} \times \text{allowances}$$
$$\text{Normal time} = \text{observed time} \times \text{rating factor}$$

If the observed time for a task is adjusted by the performance rating factor to determine normal time, and allowance time is added for nonwork time, the standard time will represent the allowed time per unit of production.

The most commonly employed rating technique throughout the history of stopwatch time study, including the present, is referred to as pace rating. A properly trained employee of average skill is time-studied while performing the approved task method under specified work conditions. Rating consists only of determining the relative pace (speed) of the operator in relation to the observer's concept of what normal pace should be for the observed task, including consideration of expected allowances to be applied to the standard. *See* HUMAN-FACTORS ENGINEERING; METHODS ENGINEERING; WORK MEASUREMENT. [P.E.H.]

Pericycle As commonly defined, the outer boundary of the stele of plants. Originally it was interpreted as a band of cells between the phloem and the innermost layer (endodermis) of the cortex. Such pericycle is commonly found in roots and, in lower vascular plants, also in stems. In higher vascular plants, however, a distinct layer of cells may not be present between the phloem and the cortex. The pericycle, if present, may be composed of parenchyma or sclerenchyma cells with relatively thin or heavily thickened walls. It may be one to several layers in radial dimensions.



Transection of central part of sugarbeet. (*From K. Esau, Hilgardia, 9(8), 1935*)

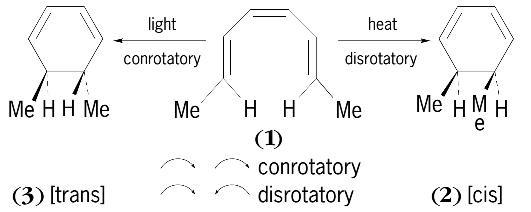
Primordia of branch roots commonly arise in the pericycle in seed plants, most frequently outside the xylem ridges (see illustration). The first cork cambium may also arise in the pericycle of those roots that have secondary vascular tissues. In roots, a part of the vascular cambium itself (that outside the primary xylem ridges) originates from pericycle cells. *See* CORTEX (PLANT); ENDODERMIS; LATERAL MERISTEM; PARENCHYMA; PHLOEM; ROOT (BOTANY); SCLERENCHYMA; STEM; XYLEM. [V.I.C.]

Pericyclic reaction Concerted (single-step) processes in which bond making and bond breaking occur simultaneously (but not necessarily synchronously) via a cyclic (closed-curve) transition state. Although a given reaction may appear formally to be pericyclic, it cannot be assumed to be a concerted process. In each case, the detailed mechanism of the reaction must be established experimentally. Pericyclic reactions can be promoted either by heat or by light; the stereochemistry of the reaction is determined by the mode of activation employed and the number of electrons that are delocalized in the transition state. *See* CHEMICAL BONDING; PHYSICAL ORGANIC CHEMISTRY; STEREOCHEMISTRY.

Four types of pericyclic reactions that are frequently encountered in organic chemistry are electrocyclic processes, cycloadditions, sigmatropic shifts, and cheletropic reactions.

Electrocyclic processes are reactions that involve their cyclization across the termini of a conjugated π-system with concomitant formation of a new σ-bond or the microscopic reverse. The sequence of steps involved in the forward reaction must be the same, in the reverse order, as that in the reverse direction when the forward and reverse reactions are carried out under identical conditions. This statement is known as the principle of microscopic reversibility.

The effect of the mode of activation upon the stereochemistry of an electrocyclic process is shown in the reaction (1), where



(1)

Me = methyl, for the hexatrienecyclohexadiene interconversion (a six-electron electrocyclic process). Thus, when *trans*,*cis*,*trans*-2,4,6-octatriene [structure (**1**)] is heated, disrotatory motion of the two terminal 2*p* orbitals occurs; that is, they rotate in opposite directions thereby resulting in exclusive formation of *cis*-5,6-dimethylcyclohexa-l,3-diene (**2**). The corresponding photochemical process results in conrotatory motion of the termini in structure (**1**); that is, the two terminal 2*p* orbitals rotate in the same direction thereby yielding *trans*-5,6-dimethylcyclohexa-l,3-diene (**3**) exclusively.

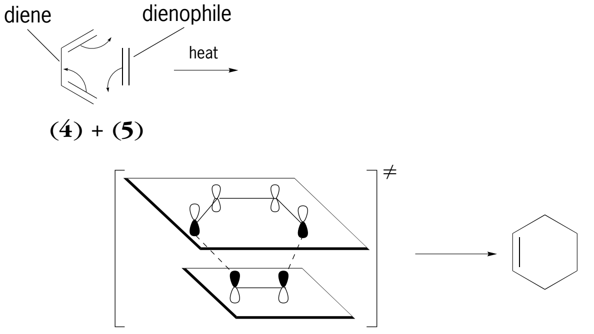
Cycloadditions occur when two (or more) π-electron systems react under the influence of heat or light to form a cyclic compound with concomitant formation of two new σ-bonds that join the termini of the original π-systems. The stereochemistry of this reaction is classified with respect to the two molecular planes of the reactants. Thus, if σ-bond formation occurs from the same face of the molecular plane across the termini of one of the component π-systems, the reaction is said to be suprafacial on that component. If instead σ-bond formation occurs from opposite faces of the molecular plane, the reaction is said to be antarafacial on that component. This distinction is illustrated in reaction (2) for two thermal processes, where the symbol $\neq$ indicates the structure of the transition state. Reaction (2*a*) shows the Diels-Alder [4 + 2] cycloaddition of butadiene (**4**) to ethylene (**5**), a six-electron pericyclic reaction in which additions across the termini of the diene (four-electron component) and dienophile (two-electron component) both occur suprafacially. Reaction (2*b*) shows a [14 + 2] cycloaddition in which σ-bond formation occurs suprafacially on the two-electron component [tetracyanoethylene (**6**)] and antarafacially on the fourteen-electron component [heptafulvalene (**7**)].

Sigmatropic shifts involve migration of a σ-bond that is flanked at either (or both) ends by conjugated π-systems. Either one or both ends of the σ-bond may migrate to a new location within the one or more flanking π-systems.

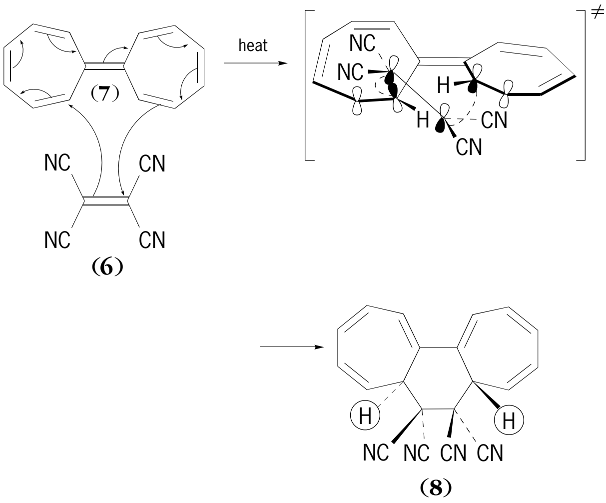
Cheletropic reactions involve extrusion of a fragment via concerted cleavage of two σ-bonds that terminate at a single atom or the reverse process. Cheletropic fragmentations may be either linear or nonlinear [reaction 3].

R. B. Woodward and R. Hoffmann introduced an application of molecular orbital theory that permits prediction of rates and products of pericyclic reactions. They utilized symmetry properties of molecular orbitals to estimate relative energies of diastereoisomeric transition states for structurally similar pericyclic reactions.

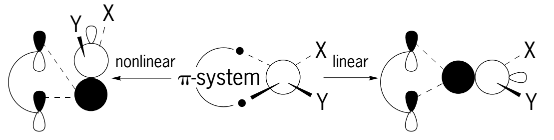
In an alternative theoretical approach to understanding pericyclic reactions, the transition state is examined directly, and



(2*a*)



(2*b*)



(3)

attempts to estimate the degree of electronic stabilization (allowedness) or destabilization (forbiddenness) inherent in that transition state are made. One such approach emphasizes the importance of frontier orbitals (highest-occupied-lowest-unoccupied molecular orbitals) in determining the course of a pericyclic reaction. *See* DELOCALIZATION; DIELS-ALDER REACTION; ELECTRON CONFIGURATION; MOLECULAR ORBITAL THEORY; ORGANIC REACTION MECHANISM; WOODWARD-HOFFMANN RULE. [A.P.M.]

Periderm A group of tissues which replaces the epidermis in the plant body. Its main function is to protect the underlying tissues from desiccation, freezing, heat injury, mechanical destruction, and disease. Although periderm may develop in leaves and fruits, its main function is to protect stems and roots. The fundamental tissues which compose the periderm are the phellogen, phelloderm, and phellem.

The phellogen is the meristematic portion of the periderm and consists of one layer of initials. These exhibit little variation in form, appearing rectangular and somewhat flat in cross and radial sections, and polygonal in tangential sections.

The phelloderm cells are phellogen derivatives formed inward. The number of phelloderm layers varies with species, season, and age of the periderm. In some species, the periderm lacks the phelloderm altogether. The phelloderm consists of living cells with photosynthesizing chloroplasts and cellulosic walls.

The phellem, or cork, cells are phellogen derivatives formed outward. These cells are arranged in tiers with almost no intercellular spaces except in the lenticel regions. After completion of their differentiation, the phellem cells die and their protoplasts disintegrate. The cell lumens remain empty, excluding a few species in which various crystals can be found. The remarkable impermeability of the suberized cell walls is largely due to their impregnation with waxes, tannins, cerin, friedelin, and phellonic and phellogenic acids.

Lenticels are loose-structured openings that develop usually beneath the stomata and that facilitate gas transport through the otherwise impermeable layers of phellem. *See* BARK; SCLERENCHYMA. [Y.W.; H.Wi.]

Peridotite A rock consisting of more than 90% of millimeter-to-centimeter-sized crystals of olivine, pyroxene, and hornblende, with more than 40% olivine. Other minerals are mainly plagioclase, chromite, and garnet. Much of the volume of the Earth's mantle probably is peridotite.

Peridotites have three principal modes of occurrence corresponding approximately to their textures: (1) Peridotites with well-formed olivine crystals occur mainly as layers in gabbroic complexes. (2) Peridotite nodules in alkaline basalts and diamond pipes generally have equigranular textures, but some have irregular grains. (3) Peridotite also occurs on the walls of rifts in the deep sea floor and as hills on the sea floor, some of which reach the surface. *See* GABBRO.

Peridotites are rich in magnesium, reflecting the high proportions of magnesium-rich olivine. The compositions of peridotites from layered igneous complexes vary widely, reflecting the relative proportions of pyroxenes, chromite, plagioclase, and amphibole.

Peridotite is an important rock economically. Where granites have intruded peridotite, asbestos and talc are common. Pure olivine rock (dunite) is quarried for use as refractory foundry sand and refractory bricks used in steelmaking. Serpentinized peridotite is locally quarried for ornamental stone. Tropical soils developed on peridotite are locally ores of nickel. The sulfides associated with peridotites are common ores of nickel and platinoid metals. The chromite bands commonly associated with peridotites are the world's major ores of chromium. *See* IGNEOUS ROCKS. [A.T.A.]

Period doubling A scenario for the transition of a natural process from regular motion to chaos. Various natural processes develop in time in a way that depends upon prevailing environmental details. A quantity that specifies the particular state of the environment of a process is called a parameter, and is taken as a fixed value over the course of development of the process.

It is a frequent natural occurrence for a process to have a regular and easily describable motion for some range of parameters, but to have complex, irregular, and difficult-to-describe motions for other ranges of parameters. In the context of fluid flow, the latter circumstance is termed turbulence. In a more general context it is called chaos (which includes fluid turbulence but presages an underlying generality). *See* FLUID FLOW; TURBULENT FLOW.

Sometimes, as the environmental parameters are varied, a process may systematically exhibit more irregular motions, turning over into chaotic motion beyond some parameter value. In analogy to the phenomenology of phase transitions, this circumstance is termed a transition to chaos. There are a variety of qualitatively different transitions to chaos, each termed a scenario. Period doubling is one frequently encountered scenario leading to chaos for which a full theoretical account exists. Since it occurs in a wide variety of processes of significantly divergent physical characters (for example, fluid-flow, chemical reactions, and electronic devices), it is sensible to consider it as a phenomenon in its own right. *See* PHASE TRANSITIONS.

In order to observe this scenario, it is sufficient that all but one parameter is held fixed. Over some range of this varied parameter (it shall be defined to increase over the range of investigation) the motion is observed to be periodic. Above a certain value of the parameter the motion grows more complicated (a bifurcation has occurred): after the amount of time T for which the motion exactly repeated itself just prior to the bifurcation, the motion now slightly fails to do so, exactly repeating, however, after another T seconds. That is, the period has doubled from T to $2T$. As the parameter is further increased, the error to repeat after the first half of the new period systematically increases. A still further increase of parameter produces another bifurcation resulting in a new doubling of the period: the motion slightly fails to repeat after two roughly periodic cycles, exactly doing so after four. As the parameter is further increased, there are successive period-doubling bifurcations, more and more closely spaced in parameter value until at a critical value the doubling has occurred an infinite number of times, so that the motion is now no longer periodic and hence of a more complex character than had yet been encountered. Unpredictably complex motions occur for values of the parameter above its critical value, although ranges of parameter still exist for which the system exhibits new periodic motions. Indeed any period-doubling system exhibits the same sequence of truly chaotic motion and interspersed periodicities as its parameter increases. Thus there is a strong degree of qualitatively universal behavior for all systems experiencing this scenario.

However, there is also a precise quantitative universality. That is, without knowing the system (or its equations) essentially all measurable quantities can be predicted: By looking at the data alone, it would not be possible to guess the physical system responsible for that data. Thus, reminiscent of thermodynamics, questions can be posed and answered in a general manner that bypasses the specific mechanisms governing any particular system. [M.J.F.]

Periodic motion Any motion that repeats itself identically at regular intervals. If $x(t)$ represents the displacement of any coordinate of the system at time t, a periodic motion has the property defined by the following equation for every value of the

$$x(t + T) = x(t)$$

variable time t. The fixed time interval T between repetitions, or the duration of a cycle, is known as the period of the motion.

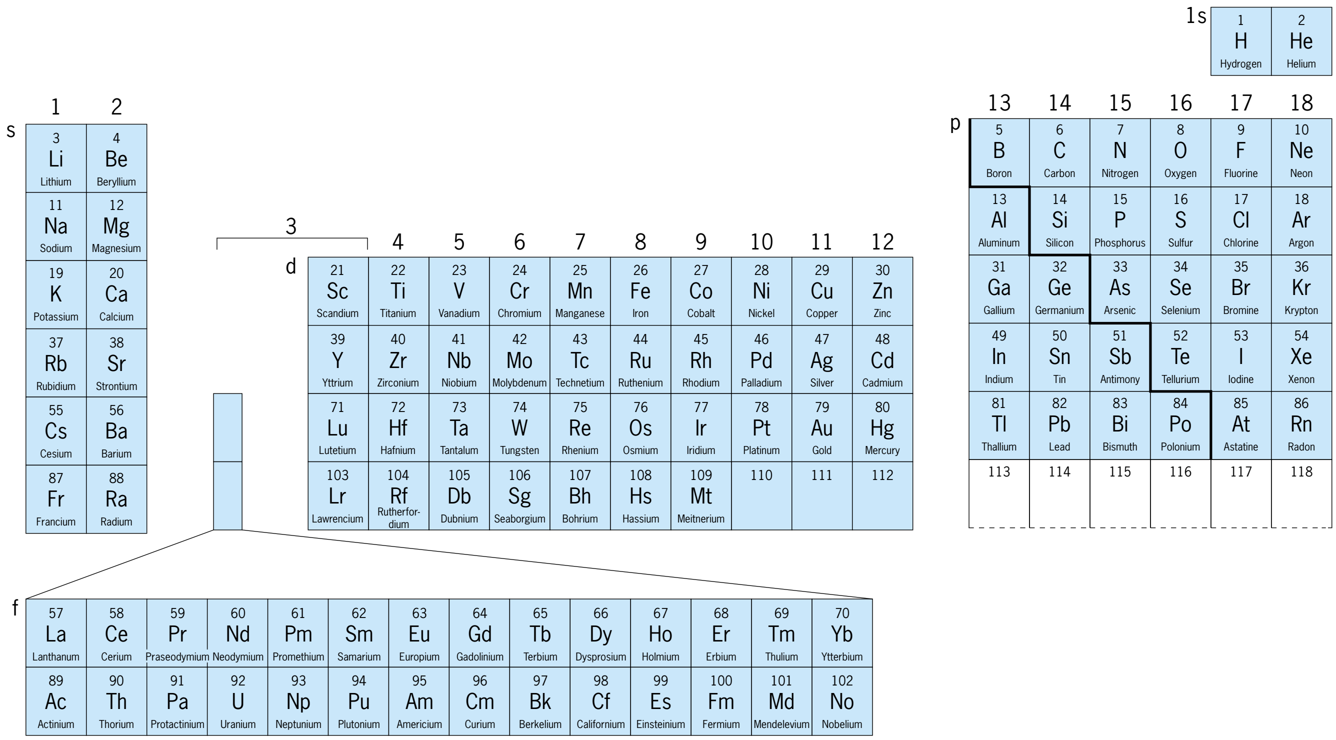
The motion of the escapement mechanism of a watch, the motion of the Earth about the Sun, and the more complicated motion of the crankshaft, piston rods, and pistons in an engine running at uniform speed are all examples of periodic motion.

The vibration of a piano string after it is struck is a damped periodic motion, not strictly periodic according to the definition. Although the motion very nearly repeats itself, and with a fixed repetition time, each successive cycle has a slightly smaller amplitude. *See* DAMPING; HARMONIC MOTION; VIBRATION; WAVE MOTION. [J.M.Ke.]

Periodic table A list of elements (atoms) ordered along horizontal rows according to atomic number (the number of electrons in an atom and also the charge on its nucleus). In the periodic table (see illustration), the rows are arranged so that elements with nearly the same chemical properties occur in the same column (group), and each row ends with a noble gas (closed-shell element that is generally inert). For chemists, the position of atoms in the periodic table provides the most powerful guide for classifying the expected properties of molecules and solids made from these particular atoms. *See* INERT GASES.

The origin of the periodic table was explained in the 1920s in terms of the basic physical laws (quantum mechanics) obeyed by the electrons of an atom. Thus, the rows in the periodic table correspond to the shell number, n, and groups correspond to a particular electronic configuration designated by the number and type of electrons in the outermost shell. These electrons govern chemical properties and are known as valence electrons. *See* ELECTRON CONFIGURATION; QUANTUM MECHANICS; VALENCE.

Additional information from the physical laws of atoms can be incorporated into the periodic table and can greatly enhance its organizing capability. For example, configuration energy adds a



Periodic table. The atomic numbers are listed above the symbols identifying the elements. The heavy line separates metals from nonmetals.

third dimension to the periodic table. The configuration energy is defined in terms of the ionization energy (*I*), the energy required to remove an electron from an atom.

Besides enhancing the organizing capability of the periodic table, the concept of configuration energy explains many longstanding puzzles about the table itself. It explains the existence of the metalloid band of elements (configuration energy is nearly constant in this band) and why these elements divide the metals from the nonmetals. Elements possessing configuration energies with magnitudes greater than those of the metalloids are nonmetals; those with lower configuration energies are metals. *See* METAL; NONMETAL.

The lack of numerical or analytic connection between the traditional two-dimensional periodic table and methods used to predict the structure and reactivity of molecules and solids has long reduced the table's usefulness. However, configuration energy, introduced as a new dimension of the periodic table, is just the average atomic energy level, and simultaneously the average density of states, for the atoms out of which the molecular-orbit–energy-level diagrams and energy bands in solids are constructed, thereby tying the periodic table directly to present-day research techniques. *See* BAND THEORY OF SOLIDS; ENERGY LEVEL (QUANTUM MECHANICS); MOLECULAR ORBITAL THEORY; MOLECULAR STRUCTURE AND SPECTRA. [L.C.A.]

Periodontal disease An inflammatory lesion caused by bacteria affecting the tissues housing the roots of the teeth. The disease, sometimes called pyorrhea, increases in prevalence and severity with increasing age, and it is the principal cause of tooth loss in adult humans throughout the world. When only the gum tissue or gingiva is affected, the disease is called gingivitis, but when the process extends into the deeper structures it is known as periodontitis. The diseased tissues appear abnormally red and slightly swollen, and they tend to bleed, sometimes profusely, when the teeth are brushed. In some cases the gums may become thickened and scarred, and they may recede, exposing the root surface. As the disease advances, the attachment of the gum to the tooth is lost, creating a periodontal pocket, a large portion of the gum is destroyed, and the bone surrounding the roots is resorbed. The teeth become loose, abscesses form, and extraction is required.

Both gingivitis and periodontitis are caused by bacteria that form plaques on the surfaces of the teeth at the gingival sulcus or pocket. These plaques may contain 250 or more separate microbial species. Plaques of any microbial composition can cause gingivitis, but specific bacteria appear to be necessary for induction of periodontitis. Among the bacteria involved in periodontitis are various species of *Porphyromonas*, *Bacteroides*, *Actinobacillus*, *Eikenella*, *Fusobacterium*, *Wolinella*, and other less well-characterized species. Spirochetes are present in active lesions, but their role remains unclear. The bacteria extend apically along the interface between the tooth root and the gingival tissue and causes periodontal pockets to form.

The principal features of the pathogenesis of periodontitis have been described. The lesions begin as an acute inflammatory response followed by a dense accumulation of lymphoid cells. There is a net loss of collagen in the area nearest the junctional epithelium and periodontal pocket, with scarring and fibrosis of the connective tissues at more distant sites. The junctional epithelium is converted into an ulcerated pocket epithelium, the alveolar bone housing the tooth roots is resorbed, and the periodontal ligament is destroyed. Products released by infiltrating leukocytes, including prostaglandins, interleukins and collagenase, and other hydrolytic enzymes, are involved in tissue destruction.

Bacterial colonization and extension activate several host defense mechanisms. The most effective of these is the accumulation of functional neutrophilic granulocytes between the surface of the plaque and the gingival tissue. These cells tend to counter and limit microbial extension. The bacteria appear to invade the periodontal connective tissues, where they induce immunopathologic and other destructive inflammatory reactions in the host, and these lead, in major part, to the observed tissue destruction. Periodontal destruction is episodic, with periods of exacerbation characterized by highly acute inflammation, followed by periods of quiescence.

Although bacteria are essential for induction of the disease, predisposing factors are also important, though their elucidation is not complete. Individuals who manifest functionally abnormal neutrophilic granulocytes or monocytes are unusually susceptible to the severe early onset forms of periodontitis. The leukocyte abnormality appears to be genetically transmitted. The early-onset forms have been designated as prepubertal, juvenile, and rapidly progressive periodontitis; adult periodontitis has a later onset and does not seem to be related to leukocyte abnormalities. Some persons with acquired immune deficiency syndrome (AIDS) manifest a highly destructive, unique form of periodontitis. Other predisposing conditions include unusually stressful situations and periods of hormone imbalance occurring at puberty, during pregnancy, and in some women taking birth control drugs.

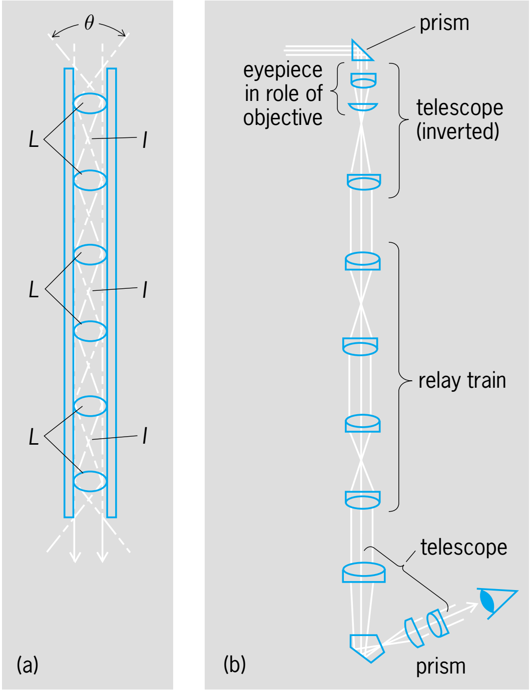
Good daily oral hygiene practices, including vigorous brushing of the exposed surfaces of the teeth and use of dental floss, interproximal brushes, and other devices to clean between the teeth, constitute the most effective measures to prevent periodontal disease. Basic ingredients of treatment of existing disease include bringing the infection under control and establishing conditions which preclude reinfection. All of the microbial deposits must be removed from the crown and root surfaces. In individuals with severe forms of periodontitis, these procedures may be supplemented by use of antibiotics either systematically or directly into the pocket. These procedures usually lead to reduction of the inflammation and to some shrinkage in the gums, but the periodontal pockets remain. Based on the traditional view that treated pockets may become reinfected and the disease may continue to spread, surgical treatment may be performed with the aim of reducing pocket depth and restoring normal tissue contours. Alternatively, regenerative procedures use various grafting materials, including freeze-dried decalcified bone or bone substitutes and guided tissue regeneration. To perform guided tissue regeneration, flaps are opened in the gingival tissue and the root surfaces are thoroughly cleaned; a porous membrane is placed around the tooth, covering the bone defect with or without placing grafts, and flaps covering the membranes are sutured into place. The membrane permits the wound site to become populated with cells having the capacity to generate new bone, cementum, and periodontal attachment. *See* TOOTH DISORDERS. [R.C.P.]

Perischoechinoidea A subclass of Echinoidea lacking stability in the number of columns of plates that make up the ambulacra and interambulacra. The ambulacral columns vary from 2 to 20, the interambulacral from 1 to 14. Of the four included orders, three are exclusively Paleozoic; the other, Cidaroida, includes both Paleozoic and extant members and is probably ancestral to all other surviving echinoids. *See* ECHINOIDEA. [H.B.F.]

Periscope An optical instrument that permits viewing along a displaced or deflected axis, providing an observer with the view from a position which may be inaccessible or dangerous. Periscopes range in complexity from the simple unit-power tank periscope to the complex multielement submarine periscope.

The tank periscope, intended to protect the user from bullets, employs a pair of plane, parallel, reflecting surfaces (either mirrors or prisms), so arranged in a mount that the path of light through the instalment forms a crude letter *Z*. If powers greater than unity are desired or if the periscope is to be used for sighting, a terrestrial telescope can be added to the periscope. *See* TELESCOPE.

In the submarine periscope, it is necessary to employ a telescope system having a wide field of view and uniform illumination across a field which can be fitted into a long, narrow tube whose length-to-diameter ratio may be 50 or greater. This is achieved by utilizing a plurality of lenses so spaced along the length of the tube as to cause the incoming principal rays from the edge of the field to be deviated from side to side within the tube (see illustration). In general, the greater the number of lenses, the wider the field of view.



Periscopic relay train, (*a*) Showing lenses *L*, inversions *i*, and angle of view *θ*. (*b*) Between a pair of facing telescopes in a submarine periscope.

Various modifications of the basic optical systems described here are employed as viewing periscopes in military aircraft and as viewing devices in particle accelerators and nuclear reactors. The cystoscope and endoscope are slender, sometimes mechanically flexible periscopes used for visual examination and photography of body cavities inaccessible to direct observation; an entirely different basis for the design of such instruments is in the use of bundles of optical fibers. *See* OPTICAL FIBERS. [E.K.K.]

Perissodactyla An order of herbivorous, odd-toed, hoofed mammals, including the living horses, zebras, asses, tapirs, rhinoceroses, and their extinct relatives. They are defined by a number of unique specializations, but the most diagnostic feature is their feet. Most perissodactyls have either one or three toes on each foot, and the axis of symmetry of the foot runs through the middle digit.

The perissodactyls are divided into three groups: the Hippomorpha (horses and their extinct relatives); the Titanotheriomorpha (the extinct brontotheres); and the Moropomorpha (tapirs, rhinoceroses, and their extinct relatives). *See* RHINOCEROS; TAPIR.

Perissodactyls originated in Asia some time before 57 million years ago (Ma). By 55 Ma, the major groups of perissodactyls had differentiated, and migrated to Europe and North America. Before 34 Ma, the brontotheres and the archaic tapirs were the largest and most abundant hoofed mammals in Eurasia and North America. After these groups became extinct, horses and rhinoceroses were the most common perissodactyls, with a great diversity of species and body forms. Both groups were decimated during another mass extinction about 5 Ma, and today only five species of rhinoceros, four species of tapir, and a few species of horses, zebras, and asses cling to survival in the wild. The niches of large hoofed herbivores have been taken over by the ruminant artiodactyls, such as cattle, antelopes, deer, and their relatives.

Most extinct horses were browsers and ate soft, leafy vegetation, but all living horses are grazers, using their sharp incisors and mobile lips to crop low-growing grasses. The only common wild horse, the plains zebra, lives in large herds (up to 100 individuals) and migrates over large areas of grasslands in search of food. However, desert-dwelling asses and Grevy's zebra live in small herds, with a stallion guarding a small harem of mares. Most species of wild horses, including the Grevy's and mountain zebras, all species of onagers and asses, and Przewalski's horse (an ancestor of domesticated horses), are nearly extinct in the wild.

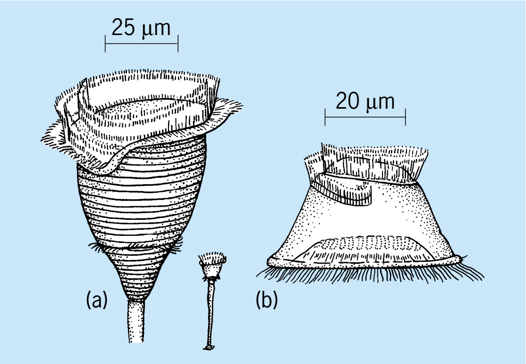
The earliest moropomorphs, such as *Homogalax*, from strata about 55 million years old, are virtually indistiguishable from the earliest horses. From this unspecialized ancestry, a variety of archaic tapirlike animals diverged. Most retained the simple leaf-cutting teeth characteristic of tapirs and, like brontotheres, died out about Ma when their forest habitats shrank. Only the modern tapirs, with their distinctive long proboscis, survive in the jungles of Central and South America (three species), and southeast Asia (one species). All are stocky, piglike beasts with short stout legs, oval hooves, and a short tail. They have no natural defenses against large predators (such as jaguars or tigers), so they are expert at fleeing through dense brush and swimming to make their escape.

Rhinoceroses have been highly diverse and successful throughout the past 50 million years. They have occupied nearly every niche available to a large herbivore, from dog-sized running animals, to several hippolike forms, to the largest land mammal that ever lived—the 18-ft-tall (6-m), 44,000-lb (20,000-kg) *Paraceratherium*. Between 20 and 5 Ma, rhinos diversified into several browsing (leaf-eating) lineages, and hippolike grazing lineages, and browser-grazer pairs of rhinos were found all over the grasslands of Eurasia, Africa, and North America. The mass extinction event that occurred about 5 Ma wiped out North American rhinos and decimated most of the archaic rhino lineages in the Old World. During the ice ages, woolly rhinos and their relatives were common all over Eurasia. Their only surviving descendant is the endangered Sumatran rhinoceros. Only a few hundred individuals still live in the mountainous jungles of Sumatra. Four other species of rhino survive in Asia and Africa, but all are on the brink of extinction because of heavy poaching for their horns. *See* Mammalia. [D.R.Pr.]

Peritoneum The membranous lining of the coelomic, especially the abdominal, cavity, which surrounds most of the organs. It is composed mainly of flattened epithelial cells that produce a small amount of watery, or serous, fluid. In the embryo the coelomic wall is lined by this membrane, which continues over the developing viscera so that they are suspended and supported by the reflected peritoneum, principally from the dorsal body wall, but also from the ventral body wall in the region of the liver. *See* Epithelium; Fetal membrane. [T.S.P.]

Peritonitis Inflammation of the peritoneum. The condition may be caused by infectious organisms or foreign substances introduced into the abdominal cavity. The small amount of serous fluid normally present as a lubricant acts as an excellent culture medium for bacterial growth and also as a means of spreading invading materials. The source of such substances or organisms is commonly a gastrointestinal inflammation, especially if perforation has occurred. Appendicitis, peptic ulcer, cancer of the bowel, gallbladder disease, and dysentery are common sources of infection that may produce peritonitis, as well as blood-borne forms of tuberculosis and pneumonia. *See* Peritoneum. [E.G.St./N.K.M.]

Peritrichia A specialized subclass of the class Ciliatea composed of a large group of unusual-looking ciliate protozoans. Many are sessile and stalked, while some form colonies which may reach a large size. A number are attached as ectocommensals to a variety of animals and plants. A free-swimming stage in the life cycle, indispensable for distribution, is known as the telotroch. It is a small, mouthless form equipped with a single girdle of posteriorly located locomotor cilia. This is quite unlike the morphology of the mature, sedentary form, which is an inverted bell form atop a long stalk.



Peritrichida. (*a*) *Vorticella*, a stalked peritrich, (*b*) a mobile peritrich.

Vorticella (illustration *a*) and *Epistylis* are probably the best-known stalked forms. The former is a solitary ciliate, the latter a colony builder. *Trichodina* (illustration *b*) belongs to the group of mobile peritrichs. *See* Ciliatea; Hymenostomatida; Thigmotrichida. [J.O.C.]

Permafrost Perennially frozen ground, occurring wherever the temperature remains below 32°F (0°C) for several years, whether the ground is actually consolidated by ice or not and regardless of the nature of the rock and soil particles of which the earth is composed. Perhaps 25% of the total land area of the Earth contains permafrost; it is continuous in the polar regions and becomes discontinuous and sporadic toward the Equator. During glacial times permafrost extended hundreds of miles south of its present limits in the Northern Hemisphere.

Temperature of permafrost at the depth of no annual change, about 30–100 ft (10–30 m), crudely approximates mean annual air temperature. It is below 23°F (−5°C) in the continuous zone, between 23–30°F (−5 and −1°C) in the discontinuous zone, and above 30°F (−1°C) in the sporadic zone. Temperature gradients vary horizontally and vertically from place to place and from time to time.

Ice is one of the most important components of permafrost, being especially important where it exceeds pore space. Physical properties of permafrost vary widely from those of ice to those of normal rock types and soil. The cold reserve, that is, the number of calories required to bring the material to the melting point and melt the contained ice, is determined largely by moisture content.

Permafrost develops today where the net heat balance of the surface of the Earth is negative for several years. Much permafrost was formed thousands of years ago but remains in equilibrium with present climates. Permafrost eliminates most groundwater movement, preserves organic remains, restricts or inhibits plant growth, and aids frost action. It is one of the primary factors in engineering and transportation in the polar regions. [R.F.B.]

Permeance The reciprocal of reluctance in a magnetic circuit. It is the analog of conductance (the reciprocal of resistance) in an electric circuit, and is given by Eq. (1), where **B** is the

$$P_m = \frac{\text{magnetic flux}}{\text{magnetomotive force}} = \frac{\iint \mathbf{B} \cdot d\mathbf{S}}{\oint \mathbf{H} \cdot d\mathbf{l}} \tag{1}$$

magnetic flux density, **H** is the magnetic field strength, and the integrals are respectively over a cross section of the circuit and around a path within it. *See* Conductance.

From Eq. (1), it can be shown that Eq. (2) is valid, where A is

$$P_m = \mu A/l \qquad (2)$$

the cross-sectional area of the magnetic circuit, l its length, and μ the permeability. If the material is ferromagnetic, as is often the case, then μ is not constant but varies with the flux density and the complete magnetization curve of B against H may have to be used to determine the permeance. *See* MAGNETIC MATERIALS; RELUCTANCE. [A.E.Ba.]

Permian The name applied to the last period of geologic time in the Paleozoic Era and to the corresponding system of rock formations that originated during that period. The Permian Period commenced approximately 290 million years ago and ceased about 250 million years ago. The system of rocks that originated during this interval of time is widely distributed on all the continents of the world. The Permian Period was a time of variable and changing climates, and during much of this time latitudinal climatic belts were well developed. During the latter half of Permian time, many long-established lineages of marine invertebrates became extinct and were not immediately replaced by new fossil-forming lineages. Rocks of Permian age contain many resources, including petroleum, coal, salts, and metallic ores. *See* LIVING FOSSILS.

During the Permian Period, several important changes took place in the paleogeography of the world. The joining of Gondwana to western Laurasia, which had started during the Carboniferous, was completed during Wolfcampian time (earliest Permian). The addition of eastern Laurasia (Angara) to the eastern edge of western Laurasia finished during Artinskian time (middle to latest early Permian) and completed the assembly of the supercontinent Pangaea. The climatic effects of these changes were dramatic. Instead of having a circumequatorial tropical ocean, such as during the middle Paleozoic, a large landmass with several high chains of mountains extended from the South Pole across the southern temperate, the tropical, and into the north temperate climatic belts. One very large world ocean, Panthalassa and its western tropical branch, the Tethys, occupied the remaining 75% of the Earth's surface, with a few much smaller cratonic blocks, island arcs, and atolls. *See* CONTINENTAL DRIFT; CONTINENTS, EVOLUTION OF; PALEOGEOGRAPHY.

Most marine invertebrates of the Early Permian were continuations of well-established phylogenetic lines of middle and late Carboniferous ancestry. During early Permian time, these faunas were dominated by brachiopods, bryozoans, conodonts, corals, fusulinaceans, and ammonoids. The Siberian traps, an extensive outflow of very late Permian basalts and other basic igneous rocks (dated at about 250 million years ago), are considered by many geologists as contributing to climatic stress that resulted in major extinctions of many animal groups, particularly the shallow-water marine invertebrates. The end of the Permian is also associated with unusually sharp excursions in values of the carbon-12 isotope (^{12}C) in organic material trapped in marine sediments, suggesting major disruption of the ocean chemistry system.

Terrestrial faunas included insects which showed great advances over those of the Carboniferous Coal Measures. Several modern orders emerged, among them the Mecoptera, Odonata, Hemiptera, Trichoptera, Hymenoptera, and Coleoptera. *See* INSECTA.

Of the vertebrates, labyrinthodont amphibians were common and varied; however, reptiles showed the greatest evolutionary radiation and the most significant advances. Reptiles are found in abundance in the lower half of the system in Texas and throughout most of the upper part of the system in Russia and also are common in Gondwana sediments. Of the several Permian reptilian orders, the most significant was the Theriodonta. These reptiles carried their bodies off the ground and walked or ran like mammals. Unlike most reptiles, their teeth were varied—incisors, canines, and jaw teeth as in the mammals—and all the elements of the lower jaw except the mandibles showed progressive reduction. Most of the known theriodonts are from South Africa and Russia. *See* PALEOZOIC; REPTILIA; THERAPSIDA. [C.A.R.; J.R.P.R.]

Permittivity A property of a dielectric medium that determines the forces that electric charges placed in the medium exert on each other. If two charges of q_1 and q_2 coulombs in free space are separated by a distance r meters, the electrostatic force F newtons acting upon each of them is proportional to the product of the charges and inversely proportional to the square of the distance between them. Thus, F is given by Eq. (1), where

$$F = \frac{q_1 q_2}{4\pi\epsilon_0 r^2} \qquad \text{newtons} \qquad (1)$$

$1/(4\pi\epsilon_0)$ is the constant of proportionality, having the magnitude and dimensions necessary to satisfy Eq. (1). This condition leads to a value for ϵ_0, termed the permittivity of free space, given by Eq. (2), where c is the velocity of light in vacuum.

$$\epsilon_0 = \frac{1}{4\pi 10^{-7} c^2} \simeq 8.8542 \times 10^{-12} \qquad \text{farads/meter} \qquad (2)$$

If now the charges are placed in a dielectric medium that is homogeneous and isotropic, the force on each of them is reduced by a factor ϵ_r, where ϵ_r is greater than 1. This dimensionless scalar quantity is termed the relative permittivity of the medium, and the product $\epsilon_0\epsilon_r$ is termed the absolute permittivity ϵ of the medium.

A consequence is that if two equal charges of opposite sign are placed on two separate conductors, then the potential difference between the conductors will be reduced by a factor ϵ_r when the conductors are immersed in a dielectric medium compared to the potential difference when they are in vacuum. Hence a capacitor filled with a dielectric material has a capacitance ϵ_r times greater than a capacitor with the same electrodes in vacuum would have. Except for exceedingly high applied fields, unlikely normally to be reached, ϵ_r is independent of the magnitude of the applied electric field for all dielectric materials used in practice, excluding ferroelectrics. *See* CAPACITANCE; CAPACITOR; FERROELECTRICS. [J.H.Ca.]

Perovskite A minor accessory mineral, formula $CaTiO_3$, occurring in basic rocks. Perovskite has given its name to a large family of materials, synthetic and natural, crystallizing in similar structures. The crystal structure is ideally cubic, with a framework of corner-sharing octahedra, containing titanium (Ti) or other relatively small cations surrounded by six oxygen (O) or fluorine (F) anions. Within this framework are placed calcium (Ca) or other large cations, surrounded by twelve anions. Tilting of the octahedra and other distortions often lower the symmetry from cubic, giving the materials important ferroelectric properties and decreasing the coordination of the central cation. This flexibility gives the structure the ability to incorporate ions of different sizes and charges. Substitution of niobium (Nb), cerium (Ce), and other rare-earth elements in natural calcium titanate ($CaTiO_3$) is common and can make perovskite an ore for these elements. *See* COORDINATION CHEMISTRY; CRYSTAL STRUCTURE; RARE-EARTH ELEMENTS.

A number of synthetic perovskites are of major technological importance. Barium titanate ($BaTiO_3$) and lead zirconate-titanate (PZT) ceramics form the basis of a sizable industry in ferroelectric and piezoelectric materials crucial to transducers, capacitors, and electronics. Lanthanum chromate ($LaCrO_3$) and related materials find applications in fuel cells and high-temperature electric heaters. *See* CERAMICS; FUEL CELL; SOLID-STATE CHEMISTRY. [A.Na.]

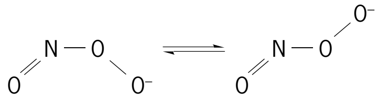
Peroxide A chemical compound which contains the peroxy (—O—O—) group, which may be considered to be a derivative of hydrogen peroxide (HOOH). An organic (or inorganic) peroxide is one in which some organic (or inorganic) substituent has replaced one or both hydrogens. Peroxides are used in such diverse reactions as oxidation, synthesis, polymerization, and oxygen generation. Inorganic peroxides include persulfates, hydrogen peroxide (H_2O_2), sodium peroxide, bivalent metal peroxides, and H_2O_2 addition compounds. Organic peroxides include peroxyacetic acid, dibenzoyl peroxide, and cumene peroxide. *See* Hydrogen peroxide; Oxidizing agent; Oxygen. [S.S.N.]

Peroxisome An intracellular organelle found in all eukaryotes except the archezoa (original lifeforms). In electron micrographs, peroxisomes appear round with a diameter of 0.1–1.0 micrometer, although there is evidence that in some mammalian tissues peroxisomes form an extensive reticulum (network). They contain more than 50 characterized enzymes and perform many biochemical functions, including detoxification. *See* Cell organization; Enzyme.

Peroxisomes are important for lipid metabolism. In humans, the β-oxidation of fatty acids greater than 18 carbons in length occurs in peroxisomes. In yeast, all fatty acid β-oxidation occurs in peroxisomes. Peroxisomes contain the first two enzymes required for the synthesis of plasmalogens. Peroxisomes also play important roles in cholesterol and bile acid synthesis, purine and polyamine catabolism, and prostaglandin metabolism. In plants, peroxisomes are required for photorespiration. *See* Lipid metabolism; Photorespiration.

A number of recessively inherited peroxisomal disorders have been described and grouped into three categories. Group I is the most severe and is characterized by a general loss of peroxisomal function. Many of the enzymes normally localized to the peroxisome are instead found in the cytosol. Among the diseases found in group I are Zellweger syndrome, neonatal adrenoleukodystrophy, and infantile Refsum disease. Patients with these disorders usually die within the first years after birth and exhibit neurological and hepatic (liver) dysfunction, along with craniofacial dysmorphism (malformation of the cranium and the face). Groups II and III peroxisomal disorders are characterized by a loss of peroxisomal function less severe than in group I. [R.A.Ra.]

Peroxynitrite A nitrogen oxyanion containing an O—O peroxo bond that is a structural isomer of the nitrate ion. These species are generally distinguished as $ONOO^-$ and NO_3^-, respectively. Other names for peroxynitrite include pernitrite and peroxonitrite; the systematic name recommended by the International Union of Pure and Applied Chemistry (IUPAC) is oxoperoxonitrate (1−). Energy calculations indicate that there are two stable conformations of $ONOO^-$, for which all of the atoms lie in a plane with the peroxo O—O and N=O bonds forming dihedral angles of approximately 0° (cis isomer) or 180° (trans isomer) [notation (1)].



(1)

(cis) (trans)

See Chemical bonding.

Peroxynitrite is formed in nitrate salts or nitrate-containing solutions when exposed to ionizing radiation or ultraviolet light. Solutions can also be prepared by a variety of chemical reactions, including the reaction of hydrogen peroxide with nitrous acid (2); reaction of the hydroperoxide anion with organic and inorganic nitrosating agents (3); reaction of ozone with the azide ion (4); or, apparently, reaction of O_2 with compounds capable of generating the nitroxyl anion (NO^-) [5]. These preparations invariably contain unreacted materials or decomposition products, particularly nitrite ion, which can significantly modulate the peroxynitrite chemical reactivity. Peroxynitrite is also formed in radical-radical coupling reactions, notably superoxide ($\cdot O_2^-$) with nitric oxide ($\cdot NO$) [reaction (6)], and hydroxyl radical with nitrogen dioxide [reaction (7)].

$$HOOH + HNO_2 \rightarrow ONOOH + H_2O \tag{2}$$

$$HOO^- + RONO \rightarrow ROH + ONOO^- \tag{3}$$

$$2O_3 + N_3^- \rightarrow ONOO^- + N_2O + O_2 \tag{4}$$

$$2O_2 + NH_2OH + 2OH^- \rightarrow ONOO^- + HO_2^- + 2H_2O \tag{5}$$

$$\cdot NO + \cdot O_2^- \rightarrow ONOO^- \tag{6}$$

$$\cdot OH + \cdot NO_2 \rightarrow ONOOH \tag{7}$$

See Superoxide chemistry.

Peroxynitrite has been isolated as the tetramethylammonium salt by carrying out reaction (6) in liquid ammonia. Formation of peroxynitrite in both solids and solutions is indicated by the appearance of yellow coloration, which is due to tailing of intense near-ultraviolet absorption bands into the visible region.

Peroxynitrite is a powerful oxidant that has been shown to react with a wide variety of inorganic and organic reductants. Interest in these reactions has been greatly stimulated by recognition that $\cdot NO$ and $\cdot O_2^-$ radicals are generated in the bloodstream, neuronal tissues, and phagocytic cells of animals in sufficient quantities to form peroxynitrite [reaction (6)]. Correspondingly, major roles for this powerful oxidant have been proposed both in diseases and tissue damage associated with oxidative stress, and in natural cellular defense mechanisms against microbial infection. *See* Bioinorganic chemistry. [J.K.Hu.]

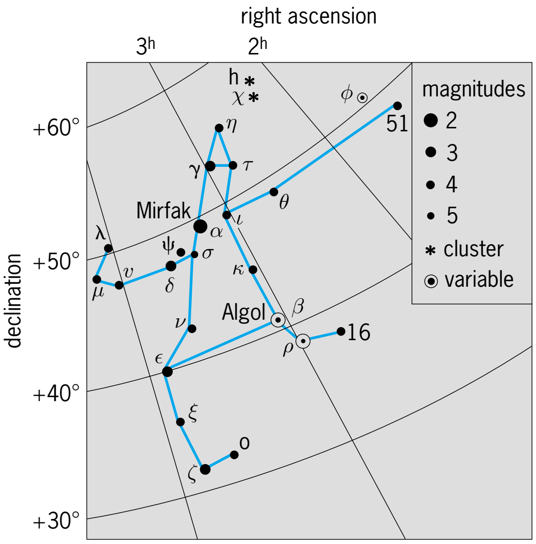
Perpetual motion The expression perpetual motion, or perpetuum mobile, arose historically in connection with the quest for a mechanism which, once set in motion, would continue to do useful work without an external source of energy or which would produce more energy than it absorbed in a cycle of operation. This type of motion, now called perpetual motion of the first kind, involves only one of the three distinct concepts presently associated with the idea of perpetual motion.

Perpetual motion of the first kind refers to a mechanism whose efficiency exceeds 100%. Clearly such a mechanism violates the now firmly established principle of conservation of energy, in particular that statement of the principle of conservation of energy embodied in the first law of thermodynamics. (Indeed, the first law of thermodynamics is sometimes stated as "A perpetuum mobile of the first kind cannot exist."). *See* Conservation of energy.

Perpetual motion of the second kind refers to a device that extracts heat from a source and then converts this heat completely into other forms of energy, a process which satisfies the principle of conservation of energy. A dramatic scheme of this type would be an ocean liner, which extracts heat from the nearly limitless oceanic source and then uses this heat for propulsion. This type of perpetual motion is, however, precluded by the second law of thermodynamics which is sometimes stated as "A perpetuum mobile of the second kind cannot exist."

The third type of perpetual motion is, in contrast to the two types described above wherein useful output was the goal, merely a device which can continue moving forever. It could result in actual systems if all mechanisms by which energy is dissipated could be eliminated. Since experience indicates that dissipative effects in mechanical systems can be reduced, by lubrication in the case of friction, for example, but not eliminated, mechanical perpetual motion of the third kind can be approximated but never achieved. An example of a genuine case of this kind occurs in a superconductor. If a direct current is caused to flow in a superconducting ring, this current will continue to flow undiminished in time without application of any external force. *See* Superconductivity; Thermodynamic principles. [K.L.K.]

Perseus A compact circumpolar constellation of the northern sky, like its neighbor, Cassiopeia, on the east. Both constellations lie in a brilliant part of the Milky Way. The prominent stars



Line pattern of the constellation Perseus. The grid lines in the chart represent the coordinates of the sky. The apparent brightness, or magnitude, of the stars is shown by the size of the dots, which are graded by appropriate numbers as indicated.

in Perseus form the capital script letter *A* (see illustration). This group is represented by the figure of the hero Perseus. Mirfak, a navigational star, lies in the right shoulder. The constellation is noted for its clusters of stars. Just above the head are the famous double clusters *h* and *x* in Perseus. Algol, the Demon Star, which is an eclipsing variable, is located in this constellation. *See* CASSIOPEIA; CONSTELLATION. [C.-S.Y.]

Persian melon A long-season cultivar of muskmelon, *Cucumis melo*, of the gourd family, Cucurbitaceae. The fruit is round and without sutures; it has dark-green skin and thin, abundant netting. The flesh is deep orange, very thick and firm, and distinctly sweet in flavor. The flesh is very rich in potassium, vitamin A, and vitamin C. *See* MUSKMELON; VIOLALES. [O.A.L.]

Persimmon A deciduous fruit tree species, *Diospyros kaki.* Persimmons originated in the subtropical regions of China but were cultivated more extensively in Japan, the current leader in world production. Persimmons have been introduced to a number of temperate zone countries; however, they have not attained substantial popularity, and only small commercial plantings exist in the United States (primarily in California), Italy, Brazil, and Israel. Persimmon cultivars adapt to a wide climatic range. Although they have a low chilling requirement, they can tolerate temperatures as low as 5°F (−15°C) if they are dormant. However, areas with late spring and early fall temperatures below 27°F (−3°C) should be avoided, as young growth and maturing fruit will be damaged. Mean annual temperatures averaging 57–59°F (14–15°C) are required for good growth and quality. Multiple, selective harvests are done in late fall to ensure that the fruits achieve the desirable deep orange-red color.

Persimmons are clonally propagated by budding onto seedling rootstocks. Seed extracted from mature fruits of *D. lotus*, *D. kaki*, and *D. virgiana* are germinated in the greenhouse in the fall. Seedlings are transplanted in outdoor nursery rows when temperatures are over 55°F (13°C). For horticultural purposes, persimmons are classified as astringent or nonastringent. Astringent persimmons have water-soluble tannins in the flesh that decrease as the fruit softens to ripeness. They are conical in shape. Nonastringent persimmons are firm when ripe, as their soluble tannins decrease with pollination. They have an oblate shape. Astringent cultivars produce best in cool climates, whereas nonastringent types require hot, dry climates for good quality. *See* FRUIT, TREE. [L.Fe.]

Personality theory A branch of psychology concerned with developing a scientifically defensible model or view of human nature—in the modern parlance, a general theory of behavior.

Most personality theories can be classified in terms of two broad categories, depending on their underlying assumptions about human nature. On the one hand, there are a group of theories that see human nature as fixed, unchanging, deeply perverse, and self-defeating. These theories emphasize self-understanding and resignation; in the cases of Freudian psychoanalysis and existentialism, they also reflect a distinctly tragic view of life—the sources of human misery are so various that the best that can be hoped for is to control some of the causes of suffering. On the other hand, there are a group of theories that see human nature as plastic, flexible, and always capable of growth, change, and development. Human nature is basically benevolent; therefore bad societies are the source of personal misery. Social reform will produce human happiness if not actual perfection. These theories emphasize self-expression and self-actualization—in the cases of Carl Rogers and Abraham Maslow, they reflect a distinctly optimistic and romantic view of life. [R.Hog.]

PERT An acronym for program evaluation and review technique; a planning, scheduling, and control procedure based upon the use of time-oriented networks which reflect the interrelationships and dependencies among the project tasks (activities). The major objectives of PERT are to give management improved ability to develop a project plan and to properly allocate resources within overall program time and cost limitations, to control the time and cost performance of the project, and to replan when significant departures from budget occur.

The basic requirements of PERT, in its time or schedule form of application, are:

1. All individual tasks required to complete a given program must be visualized in a clear enough manner to be put down in a network composed of events and activities. An event denotes a specified program accomplishment at a particular instant in time. An activity represents the time and resources that are necessary to progress from one event to the next.
2. Events and activities must be sequenced on the network under a logical set of ground rules.
3. Time estimates can be made for each activity of the network on a three-way basis. Optimistic (minimum), most likely (modal), and pessimistic (maximum) performance time figures are estimated by the person or persons most familiar with the activity involved. The three-time estimates are used as a measure of uncertainty of the eventual activity duration.
4. Finally, critical path and slack times are computed. The critical path is that sequence of activities and events on the network that will require the greatest expected time to accomplish. Slack time is the difference between the earliest time that an activity may start (or finish) and its latest allowable start (or finish) time, as required to complete the project on schedule.
5. The difference between the pessimistic (b) and optimistic (a) activity performance times is used to compute the standard deviation ($\hat{\sigma}$) of the hypothetical distribution of activity performance times [$\hat{\sigma} = (b - a)/6$]. The PERT procedure employs these expected times and standard deviations (σ^2 is called variance) to compute the probability that an event will be on schedule, that is, will occur on or before its scheduled occurrence time.

In the actual utilization of PERT, review and action by responsible managers is required, generally on a biweekly basis, concentrating on important critical path activities. A major advantage of PERT is the kind of planning required to create an initial network. Network development and critical path analysis reveal interdependencies and problem areas before the program begins that are often not obvious or well defined by conventional planning methods. [J.J.M.]

Perthite Any of the oriented intergrowths of potassium- and sodium-rich feldspars, (K,Na)$AlSi_3O_8$, whose proportions are determined in part by the initial composition of the alkali feldspar from which they exsolved and whose physical properties are thus somewhat variable. The early stages of perthite formation from homogeneous, usually monoclinic (K,Na)$AlSi_3O_8$ may be observed experimentally by high-magnification electron microscopy.

If the final K- and Na-rich lamellae or particles are submicroscopic, the composite feldspar is called cryptoperthite. If the particles are small enough and the feldspar relatively clear, Rayleigh-type scattering of light may occur, giving rise to the beautiful blue-to-whitish luster of the semiprecious gem called moonstone. If coarsening has progressed to the micrometer scale and can be seen on a polarizing microscope, the composite is called microperthite; and if the two feldspars are visible to the eye in hand specimen, it is called perthite or macroperthite. Often the albite phase will appear as white veins or blotchy patches against a colored K-rich phase, which may be green to blue microcline (amazonite) or dull pink to orange-brown orthoclase. *See* ALBITE; ANORTHITE; ANORTHOCLASE; FELDSPAR; MICROCLINE; ORTHOCLASE. [P.H.R.]

Perturbation (astronomy) Departure of a celestial body from the trajectory it would follow if moving only under the action of a single central force. Perturbations may be caused by either gravitational or nongravitational forces.

Planetary orbits are subject to two classes of disturbances: secular, or long-term, perturbations; and periodic, or relatively short-term, perturbations. Secular perturbations, so called because they are either progressive or have excessively long periods, arise because of the relative orientation of the orbits in space. They cause slow oscillatory changes of eccentricities and inclinations about their mean values with accompanying changes in the motions of the nodes and perihelia. Periodic perturbations arise from the relative positions of the planets in their orbits. When the disturbed and disturbing planets are aligned on the same side of the Sun, the perturbation reaches a maximum, and reduces to minimum when alignment is reached on opposite sides of the Sun.

The motions of planetary satellites, natural and artificial, reflect both gravitational and nongravitational perturbations. The centrifugal force arising from the rotation of a planet causes a deformation or oblateness of figure. In such a case the central mass does not attract as if it were concentrated at its center. For a close satellite the principal perturbation arises from the attraction of this equatorial bulge. [R.L.Du.]

Perturbation (mathematics) A modification in the mathematical structure of a problem changing the problem from one that can be solved exactly, the unperturbed problem, to one, the perturbed problem, for which it is usually possible to obtain only an approximate solution. The methods employed for this purpose form perturbation theory. These methods attempt to express the solution of the perturbed problem in terms of the properties of the solutions of the unperturbed problem.

Examples of perturbation problems can be found in nearly every branch of mathematics and physics, and in astronomy. The simplest case occurs in ordinary algebra. Suppose that the roots of the equation $f(x) = 0$ are known (the unperturbed problem), and that the roots of the equation $f(x) + \epsilon g(x) = 0$ are to be found (the perturbed problem). The parameter ϵ measures the size of the perturbation. Another set of examples occurs in linear differential equations and in particle dynamics. Possible perturbations include changes in the forces considered to be acting on the particle as well as changes in initial conditions. *See* PERTURBATION (ASTRONOMY).

Several examples occur in partial differential equations. One physical realization occurs in the theory of wave propagation where the perturbations can be changes in the index of refraction, changes in initial conditions, or changes in the nature or shape of the surfaces encountered by the waves. All of these changes can occur separately or concurrently. The first of these changes is called a volume perturbation, the second a perturbation of initial conditions, and the third a perturbation of boundary conditions. Similar examples can be taken from quantum mechanics, where the volume perturbation corresponds to a change in the hamiltonian, and perturbation of initial conditions to quantum mechanical time-dependent perturbation theory. Other partial differential equations of physics, such as the Laplace equation, the diffusion equation, and the equations of hydrodynamics, furnish further examples. *See* PERTURBATION (QUANTUM MECHANICS).

All of these problems are linear and can therefore be cast into an equation of the form $A\psi = \lambda\psi$, where ψ is the unknown quantity, λ is a constant, and A is an operator involving among other possibilities differentiation and integration. The quantity σ may be a scalar, a vector, or more generally a matrix quantity. When solutions can be obtained for only special values of λ, the eigenvalues, the equation is called the eigenvalue equation, and the associated problem is called the eigenvalue problem. The operator A contains the perturbation: that is, A equals $A_0 + \epsilon A_1$, where A_0 is the unperturbed operator and ϵA_1, the perturbing term. [H.F.]

Perturbation (quantum mechanics) An expansion technique useful for solving complicated quantum-mechanical problems in terms of solutions for simple problems. Perturbation theory in quantum mechanics provides an approximation scheme whereby the physical properties of a system, modeled mathematically by a quantum-mechanical description, can be estimated to a required degree of accuracy. Such a scheme is useful because very few problems occurring in quantum mechanics can be solved analytically. Consequently an approximation technique must be employed in order to give an approximate analytic solution or to provide suitable algorithms for a numerical solution. Even for problems which admit an exact analytic solution, the exact solution may be of such mathematical complexity that its physical interpretation is not apparent. For these situations, perturbation techniques are also desirable.

Here the discussion of the application of perturbation techniques to quantum mechanics is limited to the domain of nonrelativistic quantum theory. Applications of a similar but mathematically more intricate nature have also been made in quantum electrodynamics and quantum field theory. *See* QUANTUM ELECTRODYNAMICS; QUANTUM FIELD THEORY; QUANTUM MECHANICS.

Perturbation theory is applied to the Schrödinger equation, $H\Psi = (H_0 + \lambda V)\Psi = i\hbar(\partial/\partial t)\Psi$ [where $\hbar$ is Planck's constant h divided by 2π, and $(\partial/\partial t)$ represents partial differentiation with respect to the time variable t], for which the exact hamiltonian H is split into two parts: the approximate (unperturbed) time-independent hamiltonian H_0 whose solutions of the corresponding Schrödinger equation are known analytically, and the perturbing potential λV. The basic idea is to expand the exact solution Ψ in terms of the solution set of the unperturbed hamiltonian H_0 by means of a power series in the coupling constant λ. Such a procedure is expected to be successful if the system characterized by the unperturbed hamiltonian closely resembles that characterized by the exact hamiltonian. Supposedly the differences are not singular in character, but change as a continuous function of the parameter λ.

Perturbation theory is used in two contexts to provide information about the state of the system, which in quantum mechanics is determined by the wave function Ψ. If λV is time-independent, an objective may be to find the stationary states of the system Ψ_n whose time dependence is given by $\exp(-iE_nt/\hbar)$, where $i = \sqrt{-1}$ and E_n represents the energy of the stationary state labeled by n. If λV is either time-independent or time-dependent, an objective may be to find the time evolution of a state which at some specified time was a stationary state of the unperturbed hamiltonian. The perturbing potential is then considered as causing transitions from the original state to other states of the unperturbed hamiltonian, and application of time-dependent perturbation theory provides the probability of such transitions. *See* PERTURBATION (MATHEMATICS). [D.M.Fr.]

Pesticide A material useful for the mitigation, control, or elimination of plants or animals detrimental to human health or economy. Algicides, defoliants, desiccants, herbicides, plant growth regulators, and fungicides are used to regulate populations of undesirable plants which compete with or parasitize crop or ornamental plants. Attractants, insecticides, miticides, acaricides, molluscicides, nematocides, repellants, and rodenticides are used principally to reduce parasitism and disease transmission in domestic animals, the loss of crop plants, the destruction of processed food, textile, and wood products, and parasitism and disease transmission in humans.

Some pesticides are obtained from plants and minerals. Examples include the insecticides cryolite, a mineral, and nicotine, rotenone, and the pyrethrins which are extracted from plants. A few pesticides are obtained by the mass culture of microorganisms. Two examples are the toxin produced by *Bacillus thuringiensis*, which is active against moth and butterfly larvae, and the so-called milky disease of the Japanese beetle produced by the spores of *B. popilliae*. Most pesticides, however, are products which are chemically manufactured. Two outstanding examples are the insecticide DDT and the herbicide 2,4-D.

Concern over the undesirable effects of pesticides on nonpest organisms culminated in laws to prevent exposure of either humans or the environment to unreasonable hazard from pesticides through rigorous registration procedures. The purpose of regulations are to classify pesticides for general or restricted use as a function of acute toxicity, to certify the qualifications of users of restricted pesticides, to identify accurately and label pesticide products, and to ensure proper and safe use of pesticides. Recommendations as to the product and method of choice for control of any pest problem—weed, insect, or varmint—are best obtained from county or state agricultural extension specialists. [G.F.L.]

Sophisticated methods of pest control are continually being developed. Highly specific synthetic insect hormones are being developed. In an increasing number of pest situations, a natural predator of an insect has been introduced, or conditions are maintained that favor the propagation of the predator. The numbers of the potential pest species are thereby maintained below a critical threshold. An insect control program in which use of insecticides is only one aspect of a strategy based on ecologically sound measures is known as integrated pest management. *See* AGRICULTURAL CHEMISTRY; CHEMICAL ECOLOGY; FUNGISTAT AND FUNGICIDE; HERBICIDE; INSECT CONTROL, BIOLOGICAL; INSECTICIDE. [R.W.Ri.]

Petalite A rare pegmatitic mineral with composition $LiAlSi_4O_{10}$. Its economic significance is markedly disproportionate to the number of its occurrences. It is the only basic raw material suitable for production of a group of materials known as crystallized glass ceramics (melt-formed ceramics). These extremely fine-grained substances are based on a keatite-type structure (stuffed silica derivative). Among the desirable properties of such submicroscopic aggregates are their exceedingly low thermal expansion and high strength, making them suitable for use in cooking utensils and telescopic mirror blanks.

The color is white, pink, pale green, or gray to black. Hardness is $6^1/_2$ on Mohs scale. Petalite is mined from a large lithium-rich pegmatite at Bikita, Zimbabwe, the only major world source. [E.W.H.]

Petrifaction A mechanism by which the remains of extinct organisms are preserved in the fossil record. In petrifactions (though chiefly in plants rather than animals) the original shape and topography of the tissues, and occasionally even minute cytological details, are retained relatively undeformed.

The term petrifaction was adopted as a scientific term before knowledge existed of the geochemical mechanism or processes involved. It was formerly widely believed that in the formation of a petrifaction the organic matter of the organism or tissue was replaced molecule by molecule with mineral material entering in solution in percolating groundwater. It is now evident that what actually happens is that the mineral fills cell lumena and the intermicellar interstices of cell walls with insoluble salts depositing from solution. Petrifaction is hence a form of mineral emplacement or embedding, by which the organic residues are filled with solid substance which infiltrates in solution. The most common substances involved in petrifactions are silica, SiO_2, and calcium carbonate, $CaCO_3$ (calcite). Occasionally phosphate minerals, pyrite, hematite, and other less common minerals make up all or part of the petrifaction matrix. *See* FOSSIL; PALEOBOTANY; PETRIFIED FORESTS. [E.S.B.]

Petrified forests Exposures containing appreciable numbers of petrified tree trunks, either standing upright or lying prostrate in the enclosing sedimentary rocks; sometimes called fossil forests. The best-known examples are the Petrified Forest of Arizona, and the fossil forests near Cairo, Egypt; near Calistoga, California; near Vantage Bridge, Washington; and in Yellowstone National Park, Wyoming. *See* PALEOBOTANY; PETRIFACTION. [E.Do.]

Petrochemical Any of the chemicals derived from petroleum or natural gas. The definition of petrochemicals has been broadened to include the whole range of aliphatic, aromatic, and naphthenic organic chemicals, as well as carbon black and such inorganic materials as sulfur and ammonia.

Petrochemicals are made or recovered from the entire range of petroleum fractions, but the bulk of petrochemical products are formed from the lighter (C_1–C_4) hydrocarbon gases as raw materials. These materials generally occur in natural gas, but they are also recovered from the gas streams produced during refinery operations, especially cracking. Refinery gases are particularly valuable because they contain substantial amounts of olefins that, because of their double bonds, are much more reactive then the saturated (paraffin) hydrocarbons. Also important as raw materials are the aromatic hydrocarbons (benzene, toluene, and xylene) that are obtained from various refinery product streams. For example, catalytic reforming processes convert nonaromatic hydrocarbons to aromatic hydrocarbons by dehydrogenation and cyclization. *See* PETROLEUM; PETROLEUM PRODUCTS.

Thermal cracking processes (such as coking) are focused primarily on increasing the quantity and quality of gasoline and other liquid fuels, but also produce gases, including lower-molecular-weight olefins such as ethylene ($CH_2{=}CH_2$), propylene ($CH_3CH{=}CH_2$), and butylenes (butenes, $CH_3CH{=}CHCH_3$ and $CH_3CH_2CH{=}CH_2$). Catalytic cracking is a valuable source of propylene and butylene, but it is not a major source of ethylene, the most important of the petrochemical building blocks. *See* CRACKING; ETHYLENE.

The starting materials for the petrochemical industry are obtained from crude petroleum in one of two ways. They may be present in the raw crude oil and are isolated by physical methods, such as distillation or solvent extraction; or they are synthesized during the refining operations. Unsaturated (olefin) hydrocarbons, which are not usually present in natural petroleum, are nearly always manufactured as intermediates during the refining sequences. *See* Distillation; Petroleum processing and refining; Solvent extraction.

The main objective in producing chemicals from petroleum is the formation of a variety of well-defined chemical compounds, including (1) chemicals from aliphatic compounds; (2) chemicals from olefins; (3) chemicals from aromatic compounds; (4) chemicals from natural gas; (5) chemicals from synthesis gas (carbon monoxide and hydrogen); and (6) inorganic petrochemicals.

A significant proportion of the basic petrochemicals are converted into plastics, synthetic rubbers, and synthetic fibers. These materials, known as polymers, are high-molecular-weight compounds made up of repeated structural units. The major polymer products are polyethylene, polyvinyl chloride, and polystyrene, all derived from ethylene, and polypropylene, derived from propylene. Major raw material sources for synthetic rubbers include butadiene, ethylene, benzene, and propylene. Among synthetic fibers the polyesters, which are a combination of ethylene glycol and terephthalic acid (made from xylene), are the most widely used. They account for about one-half of all synthetic fibers. The second major synthetic fiber is nylon, its most important raw material being benzene. Acrylic fibers, in which the major raw material is the propylene derivative acrylonitrile, make up most of the remainder of the synthetic fibers. *See* Manufactured fiber; Polyacrylate resin; Polyamide resins; Polyester resins; Polymer; Polymerization; Polyolefin resins; Polyurethane resins; Polyvinyl resins; Rubber.

An inorganic petrochemical is one that does not contain carbon atoms; typical examples are sulfur (S), ammonium sulfate [$(NH_4)_2SO_4$], ammonium nitrate (NH_4NO_3), and nitric acid (HNO_3). Of the inorganic petrochemicals, ammonia is by far the most common. Ammonia is produced by the direct reaction of hydrogen with nitrogen, with air being the source of nitrogen. Refinery gases, steam reforming of natural gas (methane) and naphtha streams, and partial oxidation of hydrocarbons or higher-molecular-weight refinery residual materials (residua, asphalt) are the sources of hydrogen. The ammonia is used predominantly for the production of ammonium nitrate (NH_4NO_3) as well as other ammonium salts and urea (H_2HCONH_2) that are major constituents of fertilizers. *See* Ammonia; Ammonium salt; Fertilizer; Urea. [J.G.S.]

Petrofabric analysis The systematic study of the fabrics of rocks, generally involving statistical study of the orientations and distribution of large numbers of fabric elements. The term fabric denotes collectively all the structural or spatial characteristics of a rock mass. The fabric elements are classified into two groups: (1) megascopic features, including bedding, schistosity, foliation, cleavage, faults, joints, folds, and mineral lineations; and (2) microscopic features, including the shapes, orientations, and mutual arrangement of the constituent mineral crystals (texture) and of internal structures (twin lamellae, deformation bands, and so on) inside the crystals.

The aim of fabric analysis is to obtain as complete and accurate a description as possible of the structural makeup of the rock mass with a view to elucidating its kinematic history. The fabric of a sedimentary rock, for example, may retain evidence of the mode of transport, deposition, and compaction of the sediment in the size, shape, and disposition of the particles; similarly, that of an igneous rock may reflect the nature of the flow or of gravitational segregation of crystals and melt during crystallization. The fabrics of deformed metamorphic rocks (tectonites) have been most extensively studied by petrofabric techniques with the objective of determining the details of the history of deformation and recrystallization. *See* Structural geology; Structural petrology. [J.M.Ch.]

Petrography The description of rocks with goals of classification and interpretation of origin. Most schemes for the classification of rocks are based on the size of grains and the proportions of various minerals. Interpretations of origin rely on field relations, structure, texture, and chemical composition as well as sizes and proportions of different kinds of grains. The names of rocks are based on the sizes and relative proportions of different minerals; boundaries between the names are arbitrary. The conditions of formation of a rock can be estimated from the types and textures of its constituent minerals.

The description of rocks begins in the field with observation of the shape and structure of bodies of rock at the scale of centimeters to kilometers. The geometrical relations between and structures within mappable rock units are generally the domain of field geology, but are simply rock descriptions at a reduced scale.

A petrographer can correctly name most rocks in which most crystals are larger than about 0.04 in. (1 mm) simply by examining the rock with a 10-power magnifying lens. Rocks with smaller grains require either microscopical examination or chemical analysis for proper classification.

Sizes, shapes, and orientations of grains and voids are the most important features of a rock relevant to its origin. The same features also affect density, porosity, permeability, strength, and magnetic behavior. It is also essential to know the identity, abundance, and compositions of minerals constituting the grains in order to name a rock and infer its conditions of formation.

Petrographers study organic as well as inorganic objects, and petrographic analyses are useful to both paleontologists and petroleum geologists. The quality of coal is revealed with polarizing and reflecting light microscopes. Inclusions of petroleum and brine in crystals of silicates and salt in rocks help scientists infer how petroleum formation is connected with cementation and other modifications of buried sediments. *See* Paleontology; Petroleum geology.

Petrographers also study synthetic objects. The textures of metals and alloys are scrutinized by petrographers in order to understand what makes these materials strong and resistant to corrosion. Flaws in glasses and ceramics are revealed by microscopical and polarizing techniques. Fragments of minerals and rocks in some pottery can help point to its source and help trace prehistoric routes of trade. The industrial, agricultural, and natural sources of particles in the air and water may be established from petrographic study. *See* Mineralogy; Petrology. [A.T.A.]

Petrolatum A smooth, semisolid blend of mineral oil with waxes crystallized from the residual type of petroleum lubricating oil. The wax molecules are microneedles and hold a large amount of oil in a gel. Petrolatums are useful because they cling, lubricate, and resist both moisture and oxidation. They serve as lubricants in baking and candymaking; as carriers in polishes, cosmetics, and ointments; as rust preventives; as waterproofing agents for paper; and in other uses calling for an inert greaselike material. [J.K.R.]

Petroleum Unrefined, or crude, oil is found underground and under the sea floor, in the interstices between grains of sandstone and limestone or dolomite (not in caves). Petroleum is a mixture of liquids varying in color from nearly colorless to jet black, in viscosity from thinner than water to thicker than molasses, and in density from light gases to asphalts heavier than water. It can be separated by distillation into fractions that range from light color, low density, and low viscosity to the opposite extreme. In places where it has oozed from the ground, its volatile fractions have vaporized, leaving the dense, black parts of the oil as a pool of tar or asphalt (such as the Brea Tar Pits in California). Much of the world's crude oil is today produced from drilled wells. *See* Petroleum engineering.

Petroleum consists mostly of hydrocarbon molecules. The four main classes of hydrocarbons are paraffins (also called alkanes), olefins (alkenes), cycloparaffins (cycloalkanes), and aromatics. Olefins are absent in crude oil but can be formed in certain refining processes. The simplest hydrocarbon is one carbon atom bonded to four hydrogen atoms (chemical formula CH_4), and is called methane. *See* ALKANE; PARAFFIN.

Petroleum usually contains all of the possible hydrocarbon structures except alkenes, with the number of carbon atoms per molecule going up to a hundred or more. These fractions include compounds that contain sulfur, nitrogen, oxygen, and metal atoms. The proportion of compounds containing these atoms increases with increasing size of the molecule.

Asphaltic molecules contain many cyclic compounds in which the rings contain sulfur, nitrogen, or oxygen atoms; these are called heterocyclic compounds. An example is pyridine. *See* ASPHALT AND ASPHALTITE.

It is generally agreed that petroleum formed by processes similar to those which yielded coal, but was derived from small animals rather than from plants. Dead organisms have been buried in mud over millions of years. Further layers deposited over these mud layers have in some cases reached a thickness of thousands of feet, and compacted the layers beneath them, until the mud has become shale rock. The mud layers were heated and compressed by the layers above. The bodies of the organisms in the mud were decomposed and converted into fatty liquids and solids. Heating these fatty materials over a very long time caused their molecules to break into smaller fragments and combine into larger ones, so the original range of molecular size was spread greatly into the range found in crude oil. Bacteria were usually present, and helped remove oxygen from the molecules and turned them into hydrocarbon compounds. The great pressure of the overlying rock layers helped to force the oil out of the compacted mud (shale) layers into less compacted limestone, dolomite, or sandstone layers next to the shale layers. *See* DOLOMITE; LIMESTONE; ORGANIC GEOCHEMISTRY; PETROLEUM GEOLOGY; SANDSTONE; SEDIMENTOLOGY; SHALE.

At depths greater than about 25,000 ft (7620 m), the temperature is so high that the oil conversion processes go all the way to natural gas and soot. Natural gas formed by the conversion processes is now also found over a variety of depths which do not indicate the depth and temperature of their origin. *See* NATURAL GAS.

The oil formed by the natural thermal and bacterial processes was squeezed out of the compacting mud layers into sandstone or limestone layers and migrated upward in tilted layers. Tectonic processes caused such uptilting and bulging of layers to form ridges and domes. When the ridges and domes were covered by shale already formed, the pores of the shale were too tiny to let the oil through, so the shale acted as a sealing cap. When the oil could not rise farther, it was trapped. Porous rock in such a structure that contains oil or gas is called an oil or gas reservoir.

The recovery from typical reservoirs is not as high as might be thought. Multiple-layer reservoirs will typically contain oil-bearing layers with a wide range of permeability. When recovery from the highest-permeability layers is as complete as it can be, the low-permeability layers will usually have been only slightly depleted, despite all efforts to improve the recovery. Despite recovery efforts, half or more of the oil originally present in oil reservoirs is still in them. *See* PETROLEUM ENHANCED RECOVERY; PETROLEUM RESERVES; PETROLEUM RESERVOIR ENGINEERING. [E.L.Cl.]

Heavy oil and tar sand oil (bitumen) are petroleum hydrocarbons found in sedimentary rocks. They are formed by the oxidation and biodegradation of crude oil, and occur in the liquid or semiliquid state in limestones, sandstones, or sands. *See* BITUMEN.

These oils are characterized by their viscosity; however, density (or API gravity) is also used when viscosity measurements are not available. Heavy oils contain 3 wt % or more sulfur and as much as 200 ppm vanadium. Titanium, zinc, zirconium, magnesium, manganese, copper, iron, and aluminum are other trace elements that can be found in these deposits. Their high naphthenic acid content makes refinery processing equipment vulnerable to corrosion. *See* OIL AND GAS FIELD EXPLOITATION. [E.Ok.]

Petroleum engineering The technologies used for the exploitation of crude oil and natural gas reservoirs. It is usually subdivided into the branches of petrophysical, geological, reservoir drilling, production, and construction engineering. After an oil or gas accumulation is discovered, technical supervision of the reservoir is transferred to the petroleum engineering group, although in the exploration phase the drilling and petrophysical engineers have played a role in the completion and evaluation of the discovery.

By the use of down-hole logging tools and of laboratory analysis of cores made during the drilling operation, the petrophysical engineer estimates the porosity, permeability, and oil content of the reservoir rock that has been sampled at the drill site. *See* WELL LOGGING.

The geological engineer, using the petrophysical data, the seismic surveys conducted during the exploration operations, and an analysis of the regional and environmental geology, develops inferences concerning the lateral continuity and extent of the reservoir. *See* PETROLEUM GEOLOGY.

The reservoir engineer, using the initial studies of the petrophysicist and geological engineers together with the early performance of the wells drilled into the reservoir, attempts to assess the producing rates (barrels of oil or millions of cubic feet of gas per day) that individual wells and the entire reservoir are capable of sustaining. One of the major assignments of the reservoir engineer is to estimate the ultimate production that can be anticipated from both primary and enhanced recovery from the reservoir. *See* PETROLEUM ENHANCED RECOVERY; PETROLEUM RESERVES; PETROLEUM RESERVOIR ENGINEERING.

The drilling engineer has the responsibility for the efficient penetration of the earth by a well bore, and for cementing of the steel casing from the surface to a depth usually just above the target reservoir. The drilling engineer or another specialist, the mud engineer, is in charge of the fluid that is continuously circulated through the drill pipe and back up to surface in the annulus between the drill pipe and the bore hole.

The production engineer, upon consultation with the petrophysical and reservoir engineers, plans the completion procedure for the well. This involves a choice of setting a liner across the formation or perforating a casing that has been extended and cemented across the reservoir, selecting appropriate pumping techniques, and choosing the surface collection, dehydration, and storage facilities. *See* OIL AND GAS WELL COMPLETION.

Major construction projects, such as the design and erection of offshore platforms, require the addition of civil engineers to the staff of petroleum engineering departments, and the design and implementation of natural gasoline and gas processing plants require the addition of chemical engineers. *See* OIL AND GAS, OFFSHORE; PETROLEUM. [T.M.D.]

Relational databases and advanced computer graphics are used in petroleum exploration. There is a heavy emphasis on facile gathering of data and extraction of selected items to provide effective displays and interpretations. In general, petroleum computing can be viewed on three levels: geological computing, geophysical computing, and engineering applications. Geological computing trends have focused on database and spatial system configurations, with specialty applications such as cross-section balancing or geochemical modeling. Geophysical computing tends to be computer-intensive; interpretive installations are, like all interactive workstation environments, driven by graphics. Engineering applications are also computer-intensive; they are generally classified as either simulation or process types. [B.R.S.]

Petroleum enhanced recovery Technology to increase oil recovery from a porous formation beyond that obtained by conventional means. Conventional oil recovery technologies produce an average of about one-third of the original oil in place in a formation. Conventional technologies are primary or secondary. Primary technologies rely on native energy, in the form of fluid and rock compressibility and natural aquifers, to produce oil from the formation to wells. Secondary technologies supplement the native energy to drive oil to producing wells by injecting water or low-pressure gas at injection wells. The target of enhanced recovery technologies is that large portion of oil that is not recovered by primary and secondary means. *See* PETROLEUM ENGINEERING.

Many of the challenges encountered by secondary technologies are identical to those encountered by enhanced recovery technologies. Those challenges include reducing residual oil saturation, improving sweep efficiency, fitting the technology to the reservoir heterogeneities, and minimizing up-front and operating costs.

Residual oil remains trapped in a porous rock after the rock has been swept with water, gas, or any other recovery fluid. The residual oil saturation is the percentage of the pore space occupied by the residual oil. The residual oil saturation depends on the pore size distribution and connectivity, the interfacial tension between a recovery agent and the oil, the relative wettability of the rock surfaces with respect to the recovery agent and the oil, the viscosity of the fluids, and the rate at which the fluids are moving through the rock.

The sweep efficiency specifies that portion of a reservoir that is contacted by a recovery fluid. Sweep efficiency increases with volume of injected fluid. It also depends on the pattern of injection and production wells in a formation, on the mobility of the oil and the recovery fluid, and on heterogeneities in the formation.

A wide variety of processes have been considered for enhancing oil recovery: thermal processes, high-pressure gas processes, and chemical processes. Specifically, low residual oil saturation can be obtained by selecting a recovery fluid that provides a very low interfacial tension between the oil and the fluid. With very low interfacial tension, the capillary number is large. And high sweep efficiency can be obtained by selecting a recovery agent with low mobility or by increasing the mobility of the oil. [R.L.Chr.]

Petroleum geology The practice of utilizing geological principles and applying geological concepts to the discovery and recovery of petroleum. Related fields in petroleum discovery include geochemistry and geophysics. The related areas in petroleum recovery are petroleum and chemical engineering. *See* CHEMICAL ENGINEERING; GEOCHEMISTRY; GEOPHYSICS.

Petroleum occurs in a liquid phase as crude oil and condensate, and in a gaseous phase as natural gas. The phase is dependent on the kind of source rock from which the petroleum was formed and the physical and thermal environment in which it exists. Most petroleum occurs at varying depths below the ground surface, but generally petroleum existing as a liquid (crude oil) is found at depths of less than 20,000 ft (6100 m) while natural gas is found both at shallow depths and at depths exceeding 30,000 ft (9200 m). In some cases, oil may seep to the surface, forming massive deposits of oil or tar sands. Natural gas also seeps to the surface but escapes into the atmosphere, leaving little or no surface trace. *See* NATURAL GAS; OIL SAND; PETROLEUM.

Most petroleum is found in sedimentary basins in sedimentary rocks, although many of the 700 or so sedimentary basins of the world contain no known significant accumulations. Several conditions must exist for the accumulation of petroleum: (1) There must be a source rock, usually high in organic matter, from which petroleum can be generated. (2) There must be a mechanism for the petroleum to move, or migrate. (3) A reservoir rock with voids to hold petroleum fluids must exist. (4) The reservoir must be in a configuration to constitute a trap and be covered by a seal—any kind of low-permeability or dense rock formation that prevents further migration. If any of these conditions do not exist, petroleum either will not form or will not accumulate in commercially extractable form. *See* BASIN; SEDIMENTARY ROCKS.

The aim of petroleum geologists is to find traps or accumulations of petroleum. The trap not only must be defined but must exist where other conditions such as source and reservoir rocks occur.

To locate these traps, the geologist must rely on subsurface information and data gathered by drilling exploratory wells and data obtained by geophysical surveying. These data, once interpreted, are used to construct maps, cross sections, and models that are used to infer or to actually depict subsurface configurations that might contain petroleum. Such depictions are prospects for drilling. *See* GEOPHYSICAL EXPLORATION; OIL AND GAS WELL DRILLING.

Oil and gas must be trapped in an individual reservoir in sufficient quantities to be commercially producible. Worldwide, 25% of all oil discovered so far is contained in only ten fields, seven of which are in the Middle East. Fifty percent of all oil discovered to date is found in only 50 fields.

Most of the large and fairly obvious fields in the United States have been discovered, except those possibly existing in frontier or lightly explored areas such as Alaska and the deep waters offshore. Few areas of the world remain entirely untested, but many areas outside the United States are only partly explored, and advanced techniques have yet to be deployed in the recovery of oil and gas found so far. *See* PETROLEUM RESERVES.

Greater efforts in petroleum geology along with petroleum engineering are being made to increase recovery from existing fields. Of all oil discovered so far, it is estimated that there will be recovery of only 35% on the average. Recovering some part of this huge oil resource will require geological reconstruction of reservoirs, a kind of very detailed and small-scale exploration. These reconstructions and models have allowed additional recovery of oil that is naturally movable in the reservoir. If the remaining oil is immobile because it is too viscous or because it is locked in very small pores or is held by capillary forces, techniques must be used by the petroleum geologist and the petroleum engineer to render the oil movable. [W.L.Fi.]

Petroleum microbiology Those aspects of microbiology in which crude oil, refined petroleum products, or pure hydrocarbons serve as nutrients for the growth of microorganisms or are altered as a result of their activities. Applications of petroleum microbiology include oil pollution control, enhanced oil recovery, microbial contamination of petroleum fuels and oil emulsions, and conversion of petroleum hydrocarbons into microbial products.

Many species of bacteria, fungi, and algae have the enzymatic capability to use petroleum hydrocarbons as food. Biodegradation of petroleum requires an appropriate mixture of microorganisms, contact with oxygen gas, and large quantities of utilizable nitrogen and phosphorus compounds and smaller amounts of other elements essential for the growth of all microorganisms. Part of the hydrocarbons are converted into carbon dioxide and water and part into cellular materials, such as proteins and nucleic acids. The requirement for a mixture of different microorganisms arises from the fact that petroleum is composed of a wide variety of different groups of hydrocarbons, whereas any specific microorganism is highly specialized with regard to the type of hydrocarbon it can digest. The bacterial genera that contain the most frequently isolated hydrocarbon degraders are *Pseudomonas*, *Acinetobacter*, *Flavobacterium*, *Brevibacterium*, *Corynebacterium*, *Arthrobacter*, *Mycobacterium*, and *Nocardia*. The fungal genera that contain oil utilizers include *Candida*, *Cladosporium*, *Rhodotorula*, *Torulopsis*, and *Trichosporium*. *See* BIODEGRADATION.

Oil pollution results from natural hydrocarbon seeps, accidental spills, and intentional discharge of oily materials into the environment. Once the oil is released and comes into contact with water, air, and the necessary salts, microorganisms present in the environment begin the natural process of petroleum biodegradation. If this process did not occur, the world's oceans would soon become completely covered with a layer of oil. The reason that oil spills become a pollution problem is that the natural microbial systems for degrading the oil become temporarily overwhelmed. *See* Water pollution.

The largest potential application of petroleum microbiology is in the field of enhanced oil recovery. Microbial products, as well as viable microorganisms, have been used as stimulation agents to enhance oil recovery from petroleum reservoirs. Xanthan, a polysaccharide produced by *Xanthomonas campestris*, is used as a waterflood thickening agent in oil recovery. Emulsan, a lipopolysaccharide produced by a strain of *Acinetobacter calcoaceticus*, stabilizes oil-in-water emulsions. A number of other microbial products are being tested for potential application in enhanced oil recovery processes. Field tests have indicated that injection of viable microorganisms with their nutrients into petroleum reservoirs can lead to enhanced oil recovery, presumably due to production of carbon dioxide gas, acids, and surfactants. *See* Petroleum enhanced recovery.

A variety of valuable materials, such as amino acids, carbohydrates, nucleotides, vitamins, enzymes, antibiotics, citric acid, long-chain dicarboxylic acids, and biomass, can be produced by microbial processes using petroleum hydrocarbons as substrates. The main advantage of using hydrocarbons as substrates is their lower cost. Also, certain products, such as tetradecane-1,14-dicarboxylic acid, a raw material for preparing perfumes, are synthesized in higher yields on hydrocarbon than on carbohydrate substrates.

The most active area of research and development in petroleum microbiology since the mid-1960s has been in the large-scale production and concentration of microorganisms for animal feed and human food. Dried microbial cells are collectively referred to as single-cell protein. In spite of its advantages, single-cell protein has not yet played a significant role in providing protein for animal feed or human consumption. However, many scientists are optimistic about its potential. The ability of microorganisms to utilize petroleum also has its detrimental aspects, particularly with respect to the deterioration of petroleum fuels, asphalt coatings, and oil emulsions used with cutting machinery. All hydrocarbons become contaminated if they come into contact with water during storage. *See* Bacterial physiology and metabolism; Corrosion; Industrial microbiology.

[E.Ros.]

Petroleum processing and refining The separation of petroleum into fractions and the treating of these fractions to yield marketable products. Petroleum is a mixture of gaseous, liquid, and solid hydrocarbon compounds that occurs in sedimentary rock deposits throughout the world. In the crude state, petroleum has little value but, when refined, it provides liquid fuels (gasoline, diesel fuel, aviation fuel), solvents, heating oil, lubricants, and the distillation residuum asphalt, which is used for highway surfaces and roofing materials. *See* Petroleum; Petroleum products.

Crude petroleum (oil) is a mixture of compounds with different boiling temperatures that can be separated into a variety of fractions (see table). Since there is a wide variation in the composition of crude petroleum, the proportions in which the different fractions occur vary with origin. Some crude oils have higher proportions of lower-boiling components, while others have higher proportions of residuum (asphaltic components).

Petroleum processing and refining involves a series of steps by which the original crude oil is converted into products with desired qualities in the amounts dictated by the market. In fact, a refinery is essentially a group of manufacturing plants that vary in number with the variety of products in the mix. Refinery processes must be selected and products manufactured to give a balanced operation; that is, crude oil must be converted into products according to the demand for each. For example, the manufacture of products from the lower-boiling portion of petroleum automatically produces a certain amount of higher-boiling components. If the latter cannot be sold as, say, heavy fuel oil, these products will accumulate until refinery storage facilities are full. To prevent such a situation, the refinery must be flexible and able to change operations as needed. This usually means more processes, such as thermal processes to change excess heavy fuel oil into gasoline with coke as the residual product, or vacuum distillation processes to separate heavy oil into lubricating oil stocks and asphalt.

Petroleum fractions and their uses*

Fraction	Boiling range °C	Boiling range °F	Uses
Fuel gas	−160 to −40	−260 to −40	Refinery fuel
Propane	−40	−40	Liquefied petroleum gas (LPG)
Butane(s)	−12 to −1	11–30	Increases volatility of gasoline, advantageous in cold climates
Light naphtha	−1 to 150	30–300	Gasoline components, may be (with heavy naphtha) reformer feedstock
Heavy naphtha	150–205	300–400	Reformer feedstock, with light gas oil, jet fuels
Gasoline	−1 to 180	30–355	Motor fuel
Kerosine	205–260	400–500	Fuel oil
Stove oil	205–290	400–550	Fuel oil
Light gas oil	260–315	500–600	Furnace and diesel fuel components
Heavy gas oil	315–425	600–800	Feedstock for catalytic cracker
Lubricating oil	>400	>750	Lubrication
Vacuum gas oil	425–600	800–1100	Feedstock for catalytic cracker
Residuum	>600	>1100	Heavy fuel oil, asphalts

*From J. G. Speight (ed.), *The Chemistry and Technology of Petroleum*, 3d ed., Marcel Dekker, New York, 1999.

Distillation. In a petroleum distillation unit, a tower is used for fractionation. The feedstock of crude oil flows through one or more pipes arranged within a large furnace where it is heated to a temperature at which a predetermined portion of the feed changes into vapor. The heated feed is introduced into a fractional distillation tower where the nonvolatiles or liquid portions pass downward to the bottom of the tower and are pumped away, while the vapors pass upward through the tower and are fractionated into gas oils, kerosine, and naphthas.

Vacuum distillation is used in petroleum refining to separate the less volatile products, such as lubricating oils, from petroleum without subjecting the high-boiling products to cracking conditions. Operating pressure for vacuum distillation is usually 50–100 mm of mercury (6.7–13.3 kilopascals) [atmospheric pressure = 760 mm of mercury]. By this means, a heavy gas oil that has a boiling range in excess of 315°C (600°F) at atmospheric pressure may be obtained at temperatures of around 150°C (300°F); and lubricating oil, having a boiling range in excess of 370°C (700°F) at atmospheric pressure may be obtained at temperatures of 250–350°C (480–660°F). Atmospheric and vacuum distillation are major parts of refinery operations, and no doubt will continue to be used as the primary refining operation.

Thermal processes. One of the earliest conversion processes used in the petroleum industry was the thermal decomposition of higher-boiling materials into lower-boiling products. This process is known as thermal cracking. The majority of the thermal cracking processes use temperatures of 455–540°C (850–1005°F) and pressures of 100–1000 psi (690–6895 kPa). For example, the feedstock (reduced crude) is preheated by direct exchange with the cracking products in the fractionating columns. Cracked gasoline and heating oil are removed from the upper section of the column. Light and heavy distillate fractions are removed from the lower section and are pumped to separate heaters. Higher temperatures are used to crack the more stable light distillate fraction. The streams from the heaters are combined and sent to a soaking chamber where additional time is provided to complete the cracking reactions. The cracked products are then separated in a low-pressure flash chamber where a heavy fuel oil is removed as bottoms. The remaining cracked products are sent to fractionating columns. The thermal cracking of higher-boiling petroleum fractions to produce gasoline is now virtually obsolete. The antiknock requirements of modern automobile engines together with the different nature of crude oils (compared to those of 50 years ago) has reduced the ability of the thermal cracking process to produce gasoline on an economic basis. *See* Distillation column.

Visbreaking (viscosity breaking) is a mild thermal cracking operation that can be used to reduce the viscosity of residua to allow the products to meet fuel oil specifications. Alternatively, the visbroken residua can be blended with lighter product oils to produce fuel oils of acceptable viscosity. By reducing the viscosity of the residuum, visbreaking reduces the amount of light heating oil that is required for blending to meet fuel oil specifications.

Delayed coking is a thermal process for converting residua into lower-boiling products, such as gases, naphtha, fuel oil, gas oil, and coke. It is a semicontinuous process in which the heated charge is transferred to large soaking (or coking) drums, which provide the long residence time needed to allow the cracking reactions to proceed to completion. The feedstock is introduced into a product fractionator where it is heated and the lighter fractions are removed as a side streams. Gas oil, often the major product of a coking operation, serves primarily as a feedstock for catalytic cracking units. The coke obtained is typically used as fuel; but specialty uses, such as electrode manufacture, and production of chemicals and metallurgical coke are also possible, increasing the value of the coke. For these uses, the coke may require treatment to remove sulfur and metal impurities. *See* Coke; Cracking; Fuel oil; Naphtha.

Catalytic cracking is basically the same as thermal cracking, but differs by the use of a catalyst, which directs the course of the cracking reactions to produce more of the desired higher-octane hydrocarbon products. Catalytic cracking is regarded as the modern method for converting high-boiling petroleum fractions, such as gas oil, into gasoline and other low-boiling fractions. The usual commercial process involves contacting a gas oil faction with an active catalyst at a suitable temperature, pressure, and residence time so that a substantial part (>50%) of the gas oil is converted into gasoline and lower-boiling products, usually in a single-pass operation. *See* Gasoline; Octane number.

Hydroprocesses. The use of hydrogen in thermal processes was perhaps the single most significant advance in refining technology during the twentieth century. The process uses the principle that the presence of hydrogen during a thermal reaction of a petroleum feedstock will terminate many of the coke-forming reactions and enhance the yields of the lower-boiling components, such as gasoline, kerosine, and jet fuel. *See* Hydrogenation.

Destructive hydrogenation (hydrogenolysis or hydrocracking) is characterized by the conversion of the higher-molecular-weight constituents in a feedstock to lower-boiling products. Such treatment requires severe processing conditions and the use of high hydrogen pressures to minimize the polymerization and condensation reactions that lead to coke formation. *See* Hydrocracking.

Nondestructive hydrogenation is used for improving product quality without appreciable alteration of the boiling range. Nitrogen, sulfur, and oxygen compounds undergo reaction with the hydrogen, forming ammonia, hydrogen sulfide, and water, respectively. Unstable compounds that might lead to the formation of gums or insoluble materials are converted to more stable compounds. [J.G.S.]

Petroleum products Petroleum products are those fractions derived from petroleum that have commercial value as a bulk product. Petrochemicals, in contrast, are individual chemicals, derived from bulk fractions, that are used as the basic building blocks of the chemical industry. Gases and liquid fuels are currently the main products of the petroleum industry (see table). However, other products, such as lubricating oils, waxes, and asphalt, have also added to the value of petroleum resources. *See* Petrochemical; Petroleum.

Petroleum products are hydrocarbon compounds, containing combinations of hydrogen and carbon with various molecular forms. Many compounds occur naturally. Other compounds are created by commercial processes for altering one combination to form another. Each combination has its unique set of chemical and physical properties. Specifications for petroleum products are based on properties such as density and boiling range to assure that a petroleum product can perform its intended task. *See* Petroleum processing and refining.

Natural gas is predominantly methane (CH_4), which has the lowest boiling point and least complex structure of all hydrocarbons. Natural gas from an underground reservoir, when brought to the surface, may contain other, higher-boiling-point hydrocarbons, and is often referred to as wet gas. Wet gas is processed to remove the entrained hydrocarbons that are higher-boiling than methane. The high-boiling hydrocarbons that are isolated and liquefied are called natural gas condensates. *See* Methane; Natural gas.

Gasoline (motor fuel) is a complex mixture of hydrocarbons that boils below 200°C (390°F) and is intended for most spark-ignition engines (such as those used in passenger cars, light-duty trucks, motorcycles, and motorboats). The properties of gasoline are intended to satisfy the requirements of smooth and clean burning, easy ignition in cold weather, minimal evaporation in hot weather, and stability during long storage periods. *See* Gasoline; Internal combustion engine.

Petroleum naphtha is a generic term applied to refined, partly refined, or unrefined petroleum products. Naphthas are prepared by several methods, including (1) fractionation of distillates or crude petroleum, (2) solvent extraction, (3) hydrogenation of distillates, (4) polymerization of unsaturated (olefinic) compounds, and (5) alkylation processes. The naphtha may also be a combination of product streams from more than one process. The main uses of petroleum naphthas fall into the general areas of (1) solvents (diluents) for paints, (2) dry-cleaning solvents, (3) solvents for cutback asphalts, (4) solvents in rubber industry, and (5) solvents for industrial extraction processes. Turpentine, the traditional solvent for paints, has been almost completely replaced by the cheaper and more abundant petroleum naphthas. *See* Naphtha; Solvent.

Kerosine is essentially a distillation fraction of petroleum. The quantity and quality of the kerosine vary with the type of crude

Commercial names and uses for major petroleum products

Crude oil cuts	Refinery blends	Consumer products
Gases	Still gases	Fuel gas
	Propane/butane	Liquefied petroleum gas (LPG)
Light/heavy naphtha	Motor fuel	Gasoline
	Aviation turbine, Jet-B	Jet fuel (naphtha type)
Kerosine	Aviation turbine, Jet-A	Jet fuel (kerosine type)
	No. 1 fuel oil	Kerosine (range oil)
Light gas oil	Diesel	Auto and tractor diesel
	No. 2 fuel oil	Home heating oil
Heavy gas oil	No. 4 fuel oil	Commercial heating oil
	No. 5 fuel oil	Industrial heating oil
	Bright stock	Lubricants
Residuals	No. 6 fuel oil	Bunker C oil
	Heavy residual	Asphalt
	Coke	Coke

oil; some crude oils yield excellent kerosine, while others produce kerosine that requires substantial refining. Kerosine is a very stable product, and additives are not required to improve the quality. Apart from the removal of excessive quantities of aromatics, kerosine fractions may need only a lye (alkali) wash if hydrogen sulfide is present. Kerosine is used as a fuel for heating and cooking, jet engines, and lamps, for weed burning, and as a base for insecticides. *See* KEROSINE.

Diesel fuel is a distillate product that has a higher boiling point than gasoline (or naphtha) but that also must self-ignite easily. This is determined through the cetane rating, derived from the reference fuel *n*-cetane. Cetane number is a measure of the tendency of a diesel fuel to knock in a diesel engine. The scale is based upon the ignition characteristics of two hydrocarbons, *n*-hexadecane (cetane) and 2,3,4,5,6,7,8-heptamethylnonane. Diesel fuel oil is essentially the same as furnace fuel oil, but the proportion of cracked gas oil is usually less since the high aromatic content of the cracked gas oil reduces the cetane value of the diesel fuel. *See* CETANE NUMBER; DIESEL ENGINE; DIESEL FUEL.

Domestic fuel oil is used primarily in the home, and includes kerosine, stove oil, and furnace fuel oil. Stove oil is a straight-run (distilled) fraction from crude oil, whereas other fuel oils are usually blends of two or more fractions. The straight-run fractions available for blending into fuel oils are heavy naphtha, light and heavy gas oil, and residua. Cracked fractions such as light and heavy gas oil from catalytic cracking, cracking coal tar, and fractionator bottoms from catalytic cracking may also be used as blends to meet the specifications of the different fuel oils.

Heavy fuel oil includes a variety of oils, ranging from distillates to residual oils that must be heated to 260°C (500°F) or higher before they can be used. In general, heavy fuel oil consists of residual oil blended to suit specific needs and to meet designed specifications.

Heavy fuel oil usually contains residuum that is mixed (cut back) to a specified viscosity with gas oils and fractionator bottoms. For some industrial purposes where flames or flue gases contact the product (ceramics, glass, heat treating, open hearth furnaces), the fuel oil must be blended to have a minimum specified sulfur content. *See* FUEL OIL.

Asphalt is a residuum that cannot be distilled even under the highest vacuum since the temperatures required to volatilize the residuum promote the formation of coke. Asphalts have complex chemical and physical compositions that usually vary with the source of the crude oil. *See* ASPHALT AND ASPHALTITE.

Petroleum coke is the residue left by the noncatalytic destructive distillation (thermal decomposition with simultaneous removal of distillate) of petroleum residua. The coke formed in catalytic cracking operations is usually nonrecoverable because it adheres to the catalyst employed as fuel for the process. The composition of the coke varies with the source of the crude oil, but in general, large amounts of high-molecular-weight complex hydrocarbons (rich in carbon but correspondingly poor in hydrogen) make up a high proportion. Petroleum coke is employed for a number of purposes, but the major use is in the manufacture of carbon electrodes for aluminum refining, which requires a high-purity carbon (that is, low in ash and sulfur-free). In addition, petroleum coke is employed in the manufacture of carbon brushes, silicon carbide abrasives, and structural carbon (such as pipes and Rashig rings), as well as in the manufacture of calcium carbide (CaC_2) from which acetylene is produced. *See* COKE. [J.G.S.]

Petroleum reserves Proved reserves are the estimated quantities of crude oil liquids which with reasonable certainty can be recovered in future years from delineated reservoirs under existing economic and operating conditions. Thus, estimates of crude oil reserves do not include synthetic liquids which at some time in the future may be produced by converting coal or oil shale, nor do reserves include fluids which may be recovered following the future implementation of a supplementary or enhanced recovery scheme.

Indicated reserves are those quantities of petroleum which are believed to be recoverable by already implemented but unproved enhanced oil recovery processes or by the application of enhanced recovery processes to reservoirs similar to those in which such recovery processes have been proved to increase recovery.

Thus, crude oil reserves can be called upon in the future with a high degree of certainty, subject of course to the limitations placed on production rate by fluid flow within the reservoir and the capacity of the individual producing wells and surface facilities to handle the produced fluids. It is important to bear in the mind the distinction between resources and reserves. The former term refers to the total amount of oil that has been discovered in the subsurface, whereas the latter refers to the amount of oil that can be economically recovered in the future. The ratio of the ultimate recovery (the sum of currently proved reserves and past production) to the resource or original oil in place is the anticipated recovery efficiency. *See* NATURAL GAS; PETROLEUM; PETROLEUM ENHANCED RECOVERY. [T.M.D.]

Petroleum reservoir engineering The technology concerned with the prediction of the optimum economic recovery of oil or gas from hydrocarbon-bearing reservoirs. It is an eclectic technology requiring coordinated application of many disciplines: physics, chemistry, mathematics, geology, and chemical engineering. Originally, the role of reservoir engineering was exclusively that of counting oil and natural gas reserves. The reserves—the amount of oil or gas that can be economically recovered from the reservoir—are a measure of the wealth available to the owner and operator. It is also necessary to know the reserves in order to make proper decisions concerning the viability of downstream pipeline, refining, and marketing facilities that will rely on the production as feedstocks.

The scope of reservoir engineering has broadened to include the analysis of optimum ways for recovering oil and natural gas, and the study and implementation of enhanced recovery techniques for increasing the recovery above that which can be expected from the use of conventional technology.

The amount of oil in a reservoir can be estimated volumetrically or by material balance techniques. A reservoir is sampled only at the points at which wells penetrate it. By using logging techniques and core analysis, the porosity and net feet of pay (oil-saturated interval) and the average oil saturation for the interval can be estimated in the immediate vicinity of the well. The oil-saturated interval observed at one location is not identical to that at another because of the inherent heterogeneity of a sedimentary layer. It is therefore necessary to use statistical averaging techniques in order to define the average oil content of the reservoir (usually expressed in barrels per net acre-foot) and the average net pay. The areal extent of the reservoir is inferred from the extrapolation of geology and fluid content as well as the drilling of dry holes beyond the productive limits of the reservoir. The definition of reservoir boundaries can be heightened by study of seismic surveys, particularly 3-D surveys, and analysis of pressure buildups in wells after they have been brought on production. *See* PETROLEUM GEOLOGY; WELL LOGGING.

The overall recovery of crude oil from a reservoir is a function of the production mechanism, the reservoir and fluid parameters, and the implementation of supplementary recovery techniques. In general, recovery efficiency is not dependent upon the rate of production except for those reservoirs where gravity segregation is sufficient to permit segregation of the gas, oil, and water. Where gravity drainage is the producing mechanism, which occurs when the oil column in the reservoir is quite thick and the vertical permeability is high and a gas cap is initially present or is developed on producing, the reservoir will also show a significant effect of rate on the production efficiency. Reservoir engineering expertise, together with geological and petrophysical engineering expertise, is being used to make very detailed studies of the production performance of crude oil reservoirs in an effort to delineate the distribution of residual oil and gas in the reservoir, and to develop the necessary technology to enhance the recovery. *See* PETROLEUM ENHANCED RECOVERY. [T.M.D.]

Well testing broadly refers to the diagnostic tests run on wells in petroleum reservoirs to determine well and reservoir properties. The most important well tests are called pressure transient tests and are conducted by changing the rate of a well in a prescribed way and recording the resulting change in pressure with time.

The information obtained from pressure transient tests includes estimates of (1) unaltered formation permeability to the fluid(s) produced in the well; (2) altered (usually reduced) permeability near the well caused by drilling and completion practices; (3) altered (increased) permeability near the well created by deliberately stimulating the well by injecting either an acid that dissolves some of the formation or a high-pressure fluid that creates fractures in the formation; (4) distances to flow barriers located in the area drained by the well; and (5) average pressure in the area drained by the well. In addition, some testing programs may confirm hypothesized models of the reservoir, including important variations of formation properties with distance or location of gas/oil, oil/water, or other fluid/fluid contacts.

Pressure transient tests are usually interpreted by comparing the observed pressure-time response to the predicted response by a mathematical model of the well/reservoir system. Graphical techniques are used to calculate permeability. More sophisticated graphical techniques involve matching changes in pressure to preplotted analytical solutions (type-curve matching). Regression analysis is used to match observed pressure-time data to mathematical models. Although analytical solutions are being found for more and more complex reservoir models each year, many reservoirs are still so complex that their behavior cannot be described accurately by analytical solutions. In such cases, finite-difference approximations to the governing flow equations can be used in commercial reservoir simulators, the reservoir properties treated as unknowns, and properties found that fit the observed data well. [W.J.Le.]

Reservoir behavior can be simulated using models that have been constructed to have properties similar either to an ideal geometric shape of constant properties or to the shape and varying properties of a real (nonideal) oil or gas reservoir. *See* MODEL THEORY; SIMULATION.

For application to petroleum reservoirs, it is necessary to predict the simultaneous flow behavior of more than one fluid phase having different properties (water, gas, and crude oil). The permeability, the relative permeability, and the density and viscosity of each phase constitute its transport properties for calculating its flow. The relative permeability is a factor for each phase (oil, water, gas) which, when multiplied by the permeability for a single phase such as water, will give the permeability for the given phase. It varies with the volume fraction of the pore space occupied by the phase, called the saturation of the given phase. Generally, the relative permeability of the water phase depends only on its own saturation, and likewise for the gas phase. The relative permeability of the oil phase is a function of the saturations of both gas and water phases. *See* FLUID FLOW; FLUID-FLOW PRINCIPLES; FLUID MECHANICS. [E.L.Cl.]

Petrology The study of rocks, their occurrence, composition, and origin. Petrography is concerned primarily with the detailed description and classification of rocks, whereas petrology deals primarily with rock formation, or petrogenesis. A petrological description includes definition of the unit in which the rock occurs, its attitude and structure, its mineralogy and chemical composition, and conclusions regarding its origin. *See* MINERALOGY; PETROGRAPHY; ROCK. [W.I.R.]

One aim of mineralogy and petrology is to decipher the history of igneous and metamorphic rocks. Detailed study of the field geology, the structures, the petrography, the mineralogy, and the geochemistry of the rocks is used as a basis for hypotheses of origin. The conditions at depth within the Earth's crust and mantle, the processes occurring at depth, and the whole history of rocks once deeply buried are deduced from the study of rocks now exposed at the Earth's surface. One approach used to test hypotheses so developed is experimental petrology; the term experimental minerals refers to similar studies involving minerals rather than rocks (mineral aggregates). *See* IGNEOUS ROCKS; METAMORPHIC ROCKS.

The experimental petrologist reproduces in the laboratory the conditions of high pressure and high temperature encountered at various depths within the Earth's crust and mantle where the minerals and rocks were formed. By suitable selection of materials the petrologist studies the chemical reactions that actually occur under these conditions and attempts to relate these to the processes involved in petrogenesis. [P.J.Wy.]

Petromyzontida The order comprising the lampreys, sometimes called Petromyzontiformes, which are eellike, jawless vertebrates (class Agnatha). Lampreys differ from Myxiniformes as follows: the single nasal opening is on the dorsal side of the head and ends internally as a blind sac; the mouth is surrounded by a circular oral disk and provided with a rasping tongue (both disk and tongue are set with horny teeth); seven pairs of gill pouches open separately to the exterior; two pairs of semicircular canals are present; adults have well-developed eyes; dorsal and caudal fins are separate, and both are supported by fin rays; there are separate sexes and a distinct larval stage; and they either live in fresh water or enter fresh water to breed if they live in the sea. *See* MYXINIFORMES.

After they have metamorphosed to adults, most lampreys aggressively attack other fish to which they attach themselves by suction, using their oral disks; then they rasp through skin and scales with their tongues and suck the blood and flesh of the host. This parasitic habit has resulted in serious damage to commercial fisheries. Lampreys are rarely used as food.

The Petromyzontida have a worldwide distribution and are divided into eight Recent genera, of which *Petromyzon* and *Lampetra* are well known. Two genera of fossil lampreys are currently known. Details of the structure of the four genera indicate a relationship to the Osteostraci and Anaspida, extinct ostracoderms of the Silurian and Devonian periods, from which they may be descended. *See* ANASPIDA; OSTEOSTRACI. [R.H.De.; E.C.O.]

Pewter A tarnish-resistant alloy of lead and tin always containing appreciably more than 63% tin. Other metals are sometimes used with or in place of the lead; among them are copper, antimony, and zinc. Pewter is commonly worked by spinning and it polishes to a characteristic luster. Because pewter work hardens only slightly, pewter products can be finished without intermediate annealing. Early pewter, with high lead content, darkened with age. With less than 35% lead, pewter was used for decanters, mugs, tankards, bowls, dishes, candlesticks, and canisters. The lead remained in solid solution with the tin so that the alloy was resistant to the weak acids in foods. [F.H.R.]

pH An expression for the effective concentration of hydrogen ions in solution. The activity of hydrogen ions or, more correctly, hydronium ions, which are hydrated hydrogen ions $H(H_2O)_n^+$, affects the equilibria and kinetics of a wide variety of chemical and biochemical reactions. Because these effects are activity-dependent, it is extremely important to distinguish between the hydrogen-ion concentration and activity. The concentration, or total acidity, is obtained by titration and corresponds to the total concentration of hydrogen ions available in a solution, that is, free, unbound hydrogen ions as well as hydrogen ions associated with weak acids. The hydrogen-ion activity refers to the effective concentration of unassociated hydrogen ions, the form that directly affects physicochemical reaction rates and equilibria. This activity is therefore of fundamental importance in many areas of science and technology. The relationship between hydrogen-ion activity (a_{H^+}) and concentration (C) is given by Eq. (1), where

$$a_{H^+} = \gamma C \qquad (1)$$

the activity coefficient γ is a function of the total ionic strength (concentration) of the solution and approaches unity as the ionic strength approaches zero; that is, the difference between the activity and the concentration of hydrogen ion diminishes as the solution becomes more dilute. *See* ACTIVITY (THERMODYNAMICS); CHEMICAL EQUILIBRIUM; HYDROGEN ION.

The effective concentration of hydrogen ions in solution is expressed in terms of pH, which is the negative logarithm of the hydrogen-ion activity [Eq. (2)]. Because of the negative

$$\text{pH} = -\log_{10} a_{H^+} \qquad (2)$$

logarithmic (exponential) relationship, the more acidic a solution, the smaller the pH value. The pH of a solution may have little relationship to the titratable acidity of a solution that contains weak acids or buffering substances; the pH of a solution indicates only the free hydrogen-ion activity. If total acid concentration is to be determined, an acid-base titration must be performed. *See* ACID AND BASE; BUFFERS (CHEMISTRY); TITRATION.

Two methods, electrometric and chemical indicator (optical), are used for measuring pH. The more commonly used electrometric method is based on measurement of the difference between the pH of a test solution and that of a standard solution. The pH scale is defined by a series of reference buffer solutions that are used to calibrate the pH measurement system. The instrument measures the potential difference developed between the pH electrode and a reference electrode of constant potential. The difference in potential obtained when the electrode pair is removed from the standard solution and placed in the test solution is converted to the pH value. In the indicator method, the pH value is obtained by simple visual comparison of the color of pH-sensitive dyes to standards (for example, color charts) or by use of calibrated optical readout devices (photometers), often in combination with fiber-optic sensors. *See* ELECTRODE; REFERENCE ELECTRODE. [R.A.D.]

pH regulation (biology) The processes operating in living organisms to preserve a viable acid-base state. In higher animals, much of the body substance (60–70%) consists of complex solutions of inorganic and organic solutes. For convenience, these body fluids can be subdivided into the cellular fluid (some two-thirds of the total) and the extracellular fluid. The latter includes blood plasma and interstitial fluid, the film of fluid that bathes all the cells of the body. For normal function, the distinctive compositions of these various fluids are maintained within narrow limits by a process called homeostasis. A crucial characteristic of these solutions is pH, an expression representing the concentration (or preferably the activity) of hydrogen ions, $[H^+]$, in solution. The pH is defined as $-\log [H^+]$, so that in the usual physiological pH range of 7 to 8, $[H^+]$ is exceedingly low, between 10^{-7} and 10^{-8} M. Organisms use a variety of means to keep pH under careful control, because even small deviations from normal pH can disrupt living processes. *See* HOMEOSTASIS; PH.

The most accessible and commonly studied body fluid is blood, and it, therefore, provides the most information on pH regulation. Blood pH in humans, and in mammals generally, is about 7.4. This value indicates that blood is slightly alkaline, because neutrality, the condition in which the concentration of hydrogen ions $[H^+]$ equals the concentration of hydroxyl ions $[OH^-]$, is pH 6.8 at mammalian body temperature of 98°F (37°C). The pH within cells, including the red blood cells, is typically lower by 0.2–0.6 unit, and is thus close to neutrality. In most animals other than warm-blooded mammals, blood pH deviates from the familiar value of 7.4. The major reason is that body temperature has an important influence on pH regulation. Consequently, animals that experience significant changes in body temperature have no single normal pH at which they regulate, but rather a series of values depending on body temperature.

Blood pH regulation is necessary because metabolic and ingestive processes add acidic or basic substances to the body and can displace pH from its proper value. For true regulation, active physiological mechanisms are required that can alter the acid-base composition of the blood in a controlled fashion. It is conventional to identify these control mechanisms with their effects on the principal buffer of the extracellular fluid, carbon dioxide (CO_2). Carbon dioxide is produced by cellular metabolism and distributes readily throughout the body because of its high solubility and rapid diffusion. In solution, CO_2 is hydrated to carbonic acid (H_2CO_3) which dissociates almost completely to H^+ and bicarbonate ions $[HCO_3^-]$. Dissolved CO_2 can be identified with a particular partial pressure of CO_2 (PCO_2). To regulate blood pH, organisms have mechanisms to independently control PCO_2 and $[HCO_3^-]$.

The cells, while benefitting from the stability afforded by whole body mechanisms (respiratory and ionic), also have local means for their own pH regulations. An acute acid load on a cell, whether from its intrinsic metabolism or from an external source, is dealt with first by the cell's chemical buffering capacity, a capacity that exceeds that of the blood by severalfold. Other cellular mechanisms include the conversion of organic acids to neutral compounds through metabolic transformations, and the transfer of acid equivalents from the primary cell fluid, the cytoplasm, into cellular organelles. *See* BIOPOTENTIALS AND IONIC CURRENTS; CHEMIOSMOSIS; ENZYME. [D.C.J.]

Phaeophyceae A class of plants, commonly called brown algae, in the chlorophyll *a-c* phyletic line (Chromophycota). Brown algae occur almost exclusively in marine or brackish water, where they are attached to rocks, wood, sea grasses, or other algae. Approximately 265 genera and 1500 species are recognized, arranged in about 15 orders. *See* ALGAE; CHROMOPHYCOTA.

Phaeophyceae are characterized primarily by biochemical and ultrastructural features. The cells are typically uninucleate and contain one or more chloroplasts with or without pyrenoids. Photosynthetic pigments include chlorophyll *a* and *c*, β-carotene, and several xanthophylls, principally fucoxan-thin. The simplest thallus exhibited by Phaeophyceae is generally considered to be an erect, unbranched or branched, uniseriate filament arising from a prostrate filamentous base, Many Phaeophyceae are crustose or bladelike. Complex thalli differentiated into macroscopic organs are produced by kelps and rockweeds.

The geographic distribution of Phaeophyceae is bimodal. Kelps are most abundant and diverse on surf-swept rocky shores of the North Pacific, but they form an ecologically important vegetation belt in the lower intertidal and upper sub-tidal zones on all cold-water shores except Antarctica. Rockweeds are similarly abundant on cold-water shores, forming conspicuous belts in the upper intertidal zone. They also form extensive stands in salt marshes in the Northern Hemisphere. Tropical waters support a diverse array of Dictyotales and members of the fucalean family Sargassaceae. [P.C.Si.; R.L.Moe]

Phagocytosis A mechanism by which single cells of the animal kingdom, such as smaller protozoa, engulf and carry particles into the cytoplasm. It differs from endocytosis primarily in the size of the particle rather than in the mechanism; as particles approach the dimensions and solubility of macromolecules, cells take them up by the process of endocytosis.

Cells such as the free-living amebas or the wandering cells of the metazoa often can "sense" the direction of a potential food source and move toward it (chemotaxis). If, when the cell contacts the particle, the particle has the appropriate chemical composition, or surface charge, it adheres to the cell. The cell responds by forming a hollow, conelike cytoplasmic process around the particle, eventually surrounding it completely.

Although the particle is internalized by this sequence of events, it is still enclosed in a portion of the cell's surface membrane and thus isolated from the cell's cytoplasm. The combined particle and membrane package is referred to as a food or phagocytic vacuole. *See* VACUOLE.

Ameboid cells of the metazoa also selectively remove foreign particles, bacteria, and other pathogens by phagocytosis. After the foreign particle or microorganism is trapped in a vacuole inside the macrophage, it is usually digested. To accomplish this, small packets (lysosomes) of lytic proenzymes are introduced into the phagocytic vacuole, where the enzymes are then dissolved and activated. *See* LYSOSOME. [P.W.B.]

Pharetronidia A subclass of sponges of the class Calcarea in which the skeleton is formed of quadriradite spicules cemented together into a compact network, or includes an aspiculous massive basal skeleton formed of irregular calcitic spherulites. Spicules shaped like tuning forks are characteristically present, and free triradiates, quadriradiates, and diactinal spicules may occur. *See* CALCAREA. [W.D.H.]

Pharmaceutical chemistry The chemistry of drugs and of medicinal and pharmaceutical products. The important aspects of pharmaceutical chemistry are as follows:

1. Isolation, purification, and characterization of medicinally active agents and materials from natural sources used in treatment of disease and in compounding prescriptions.
2. Synthesis of medicinal agents not known from natural sources, or the synthetic duplication, for reasons of economy, purity, or adequate supply, of substances first known from natural sources.
3. Semisynthesis of drugs, whereby natural substances are transformed by means of comparatively simple steps into products which possess more favorable therapeutic or pharmaceutical properties.
4. Determination of the derivative or form of a medicinal agent which exhibits optimum medicinal activity and at the same time lends itself to stable formulation and elegant dispensing.
5. Determination of incompatibilities, chemical and biological, between the various ingredients of a prescription.
6. Establishment of safe and practical standards, with respect to both dosage and quality, to assure uniform and therapeutically reliable forms for all medication.
7. Improvement and promotion of the use of chemical agents for prevention of illness, alleviation of pain, cure of disease, and search for new therapeutic agents, particularly where no satisfactory remedy now exists. [W.H.H.]

Pharmaceuticals testing Techniques used to determine that pharmaceuticals conform to specified standards of identity, strength, quality, and purity. Conformance to these standards assures pharmaceuticals which are safe and efficacious, of uniform potency and purity, and of acceptable color, flavor, and physical appearance. Pharmaceuticals are medicinal products which are prescribed by medical doctors and dispensed through pharmacies and hospitals. They are usually taken orally or by parenteral injection.

Standards or specifications and their attendant procedures are designed to provide desired characteristics and acceptable tolerances for all raw materials, intermediates, and finished products. These standards thus provide an objective determination of whether pharmaceuticals are properly constituted. Two components are vital to the makeup of such standards: appropriate analytical procedures to permit a comprehensive examination, and a list of specifications to define the acceptable limits for each property tested. Standards are established by the pharmaceutical manufacturer, official compendiums (*U.S. Pharmacopeia* and the *National Formulary*), and regulations promulgated by the U.S. Food and Drug Administration (FDA).

The steps in the production cycle for pharmaceuticals must be rigidly and uniformly controlled so that each phase is completely accurate. The four control phases are generally designated as raw materials, manufacturing procedures, finished product testing, and control of identity.

Raw materials are usually referred to as components and are purchased on specifications. Physical specifications include such characteristics as bulk density, mesh size, color, odor, extraneous contamination such as fibers, and homogeneity. Chemical specifications usually include such characteristics as chemical or physiological potency, melting point, boiling range, optical rotation, moisture, heavy-metals content, chemical identity, solubility, and presence of chemical contaminants. Samples are taken upon receipt of a specific batch of raw material. The samples are tested to ensure conformance to each specification. Only after the raw material has been checked against each of the specifications can it be approved for use in pharmaceuticals.

Pharmaceutical manufacturers must make products in conformance with the Good Manufacturing Practices as prescribed by the FDA. These regulations provide criteria on the following: buildings, equipment, personnel, components, master-formula and batch-production records, production and control procedures, product containers, packaging and labeling, laboratory controls, distribution records, stability, and complaint files. The quality-control system must provide regular and continuous use of all reasonable procedures, methods, and operations that are necessary to ensure uniform safety and effectiveness of the pharmaceutical.

Finished pharmaceuticals must conform to appropriate standards of identity, strength, quality, and purity. Accordingly each batch of a pharmaceutical must satisfy five requirements: conformance with (1) the label claim for potency, (2) homogeneity standards, (3) standards of pharmaceutical elegance (the physical appearance of the dosage units), (4) identity specifications, and (5) regulatory standards if they are applicable to the specific pharmaceutical.

Identity is the final requirement in pharmaceutical testing. Identity techniques guarantee proper labeling, that is, that the right product is in the right bottle with the right label. To maintain the identity of the product, extensive checks are made throughout the manufacturing operation, including the use of duplicate label tags on all bulk goods, and very rigid controls are applied to printing, storage, and application of labels on finished pharmaceuticals. *See* BIOASSAY; QUALITY CONTROL. [W.B.Fo.]

Pharmacognosy The general biology, biochemistry, and economics of nonfood natural products of value in medicine, pharmacy, and other health professions. The products studied are of biologic origin, either plant or animal. Pharmacognosy literally means knowledge of drugs, as do pharmacology and pharmacy. The center of interest in pharmacology, however, is on the mode of action of drugs. In pharmacy major attention is directed toward provision of suitable dosage forms, their production and distribution. Pharmacognosy is restricted to natural products with attention centered on sources of drugs, plant and animal, and on the biosynthesis and identity of their pharmacodynamic constituents.

Organs, or occasionally entire plants or animals, are dried or frozen for preservation and are termed crude drugs. They may be used medicinally in essentially this form or as sources of mixtures or of chemicals obtained by processes of extraction. Mixtures obtained by exudation from living plants include such drugs as opium, turpentine, and acacia. Processes of extraction are required to obtain such mixtures as peppermint oil (steam distillation), podophyllum resin (percolation), and parathyroid extract (solution).

Pure chemicals may be extracted from a crude drug (for example, the glycoside digitoxin from digitalis or the hormone insulin from pancreas), from a mixture obtained by exudation (for example, the alkaloid morphine from opium), or from an extracted mixture (for example, the terpene menthol from peppermint oil).

Vitamins as a class of natural products are within the scope of pharmacognosy, although many are obtained commercially by laboratory synthesis. Included also are antibiotics and biologicals (serums, vaccines, and diagnostic biological products).

Development of synthetic drugs related chemically to the active constituent of a natural product has frequently followed investigation of native use of the natural product as drug or poison. The objective of such development is usually to produce a drug having fewer undesirable side effects while retaining the useful therapeutic action. *See* PHARMACEUTICAL CHEMISTRY; PHARMACOLOGY; PHARMACY. [R.A.De.]

Pharmacology The science of detection and measurement of the effects of drugs or other chemicals on biological systems. The effect of chemicals may be beneficial (therapeutic) or harmful (toxic). The pure chemicals or mixtures may be of natural origin (plant, animal, or mineral) or may be synthetic compounds.

The broad area covered may be conveniently divided into a number of categories: chemotherapy, the use of chemicals to destroy invading organisms such as bacteria and molds in or on the host; pharmacotherapy, the use of drugs to restore or replace normal function in various tissue cells, organs, or integrated units; pharmacodynamics, studies on the mechanism of action of drugs which may utilize physiological, biochemical, or electrical techniques; toxicology, the study of the poisonous effects of chemicals; psychopharmacology, the study of the effects of chemicals on the behavior of humans or animals; biochemical pharmacology, the effects of chemicals on biochemical reactions in living systems, and the effects of these systems on the chemicals, that is, their metabolism; structure-activity relationship, relationship of biological activity to chemical structure and molecular properties; and clinical pharmacology, the study and evaluation of the effects of drugs in humans. *See* CHEMOTHERAPY; PATHOLOGY; TOXICOLOGY. [C.J.K.]

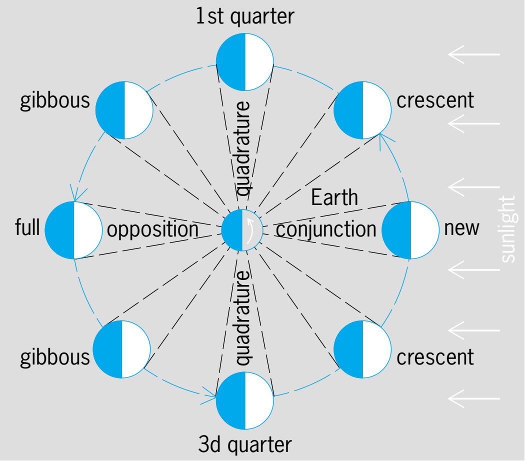
Pharmacy The health profession concerned with the discovery, development, production, and distribution of drugs. Drugs are substances (other than devices) used to diagnose, prevent, cure, or relieve the symptoms of disease. For relations to closely allied fields. *See* MEDICINE; PHARMACEUTICAL CHEMISTRY; PHARMACOGNOSY; PHARMACOLOGY.

General practice is carried on in exclusive prescription pharmacies, semiprofessional pharmacies, and drug stores. It consists of compounding and dispensing drugs on order of the physician, dentist, or veterinarian; serving as consultant on drugs to the health professions and to the public; and selling other health supplies such as antiseptics, bandages, and home remedies.

A hospital pharmacy includes special administrative features, provision of drugs for nursing stations, manufacturing of pharmaceutical preparations, teaching of nurses and medical and pharmacy interns, service to the hospital committee on pharmacy and therapeutics, preparation and revision of a hospital formulary, and monitoring the drug regimen of the individual patient (clinical pharmacy). The pharmacist may have charge of investigational drugs, radioactive pharmaceuticals, medical and surgical sterile supplies, and gaseous drugs for inhalation therapy. [R.A.De.]

Pharynx A chamber at the oral end of the vertebrate alimentary canal, leading to the esophagus. In adult humans it is divided anteriorly by the soft palate into a nasopharynx and an oropharynx, lying behind the tongue but anterior to the epiglottis; there is also a retropharyngeal compartment, posterior to both epiglottis and soft palate. The nasopharynx receives the nasal passages and communicates with the two middle ears through auditory tubes. The retropharynx leads to the esophagus and to the larynx, and the paths of breathing and swallowing cross within it. *See* ESOPHAGUS; LARYNX; PALATE. [W.W.B.]

Phase (astronomy) The changing fraction of the disk of an astronomical object that is illuminated, as seen from some particular location. The monthly phases of the Moon are a familiar example (see illustration). When the Sun is approximately on the far side of the Moon as seen from Earth (conjunction), the dark side of the Moon faces the Earth and there is a new moon. The phase waxes, beginning with crescent phases, as an increasing fraction of the illuminated face of the Moon is seen. At quadrature, when half the visible face of the Moon is illuminated, the phase is called the first-quarter moon, since the Moon is now one-quarter of the way through its cycle of phases. The waxing moon continues through its gibbous phases until it is in opposition; the entire visible face of the Moon is illuminated, the full moon. During the full moon, the Moon and the Sun are on opposite sides of the Earth, a configuration known as a syzygy. Then the Moon wanes, going through waning gibbous, third-quarter, and waning crescent phases until it is new again. The cycle of moon phases takes approximately 29.53 days and explains the origin of the word month. *See* MOON.

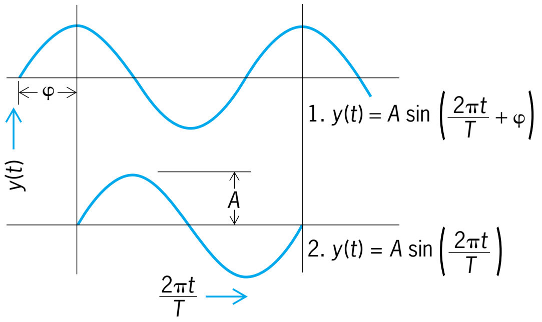


From Earth, different fractions of the illuminated half of the Moon are seen at different times as the Moon goes through a 29.53-day cycle of phases.

Galileo discovered the phases of the planet Venus when he observed the sky with his telescope in 1610. Giovanni Zupus discovered the phases of the planet Mercury in 1639. Because of the angle at which the outer planets are seen from Earth, and because of their great distance, they do not appear to go through phases as seen from Earth. [J.M.P.]

Phase (periodic phenomena) The fractional part of a period through which the time variable of a periodic quantity (alternating electric current, vibration) has moved, as measured at any point in time from an arbitrary time origin. In the case of a sinusoidally varying quantity, the time origin is usually assumed to be the last point at which the quantity passed through a zero position from a negative to a positive direction.

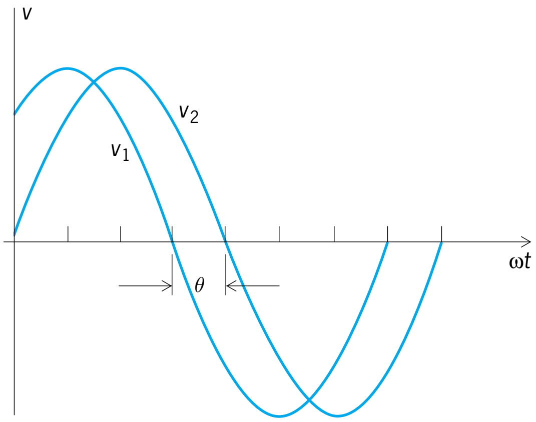
In comparing the phase relationships at a given instant between two time-varying quantities, the phase of one is usually assumed to be zero, and the phase of the other is described, with respect to the first, as the fractional part of a period through which the second quantity must vary to achieve a zero of its own (see illustration). In this case, the fractional part of the period is



An illustration of the meaning of phase for a sinusoidal wave. The difference in phase between waves 1 and 2 is φ and is called the phase angle. For each wave, *A* is the amplitude and *T* is the period.

usually expressed in terms of angular measure, with one period being equal to 360° or 2π radians. *See* PHASE-ANGLE MEASUREMENT; SINE WAVE. [W.J.G.]

Phase-angle measurement Measurement of the time delay between two periodic signals. The phase difference between two sinusoidal waveforms that have the same frequency and are free of a dc component can be conveniently described as shown in the illustration. It can be seen that the phase angle can be considered as a measure of the time delay between two periodic signals expressed as a fraction of the wave period. This fraction is normally expressed in units of angle, with a full cycle corresponding to 360°. For example, in the illustration, where the voltage v_1 passes through zero $\frac{1}{8}$ cycle before a second voltage v_2, it leads by 360°/8 or 45°. Phase angle is usually defined from the fundamental component of each waveform; therefore distortion of either or both signals can give rise to errors, the extent of which depends on the nature of the distortion and the method of measurement. *See* DISTORTION (ELECTRONIC CIRCUITS).



Phase angle θ between voltages v_1 and v_2.

The majority of modern phase-measuring devices are based on the use of zero-crossing detectors. The time at which each signal crosses the zero-voltage axis is determined, usually by means of a squaring-up circuit (for example, an overdriven amplifier) followed by a high-speed comparator. This produces, in each channel, a trigger pulse that is used to drive a bistable flip-flop. The output from the bistable is a rectangular wave, the duty cycle of which is proportional to the phase difference between the input signals. If this signal is integrated by means of a suitable filter, a dc voltage is produced that is an analog representation of the phase angle. This voltage is then displayed on a panel meter (analog or digital) suitably scaled in degrees or radians. Instrumentation using this principle is capable of measuring phase differences to approximately ±0.05° over a wide range of amplitudes and frequencies. *See* AMPLIFIER; COMPARATOR; ELECTRIC FILTER; MULTIVIBRATOR; SWITCHING CIRCUIT; WAVE-SHAPING CIRCUITS.

Conventional phase meters have an upper frequency limit of a few hundred kilohertz. This limit is imposed mainly by the ability of the arrangement consisting of a comparator and a flip-flop to maintain a clean and precise rectangular waveform under conditions of high-speed operation. In order to measure phase angle at frequencies between about 100 kHz and several gigahertz, it is necessary to down-convert the radio-frequency signals to a frequency that can be handled correctly by the phase meter. At microwave frequencies, instruments such as slotted lines, air lines, and vector network analyzers are also used for phase-angle measurements. *See* MICROWAVE MEASUREMENTS. [J.Hur.]

Phase-contrast microscope A microscope used for making visible differences in phase or optical path in transparent or reflecting specimens. It is one of the most important instruments available for studying living cells and is widely used in biological and medical research.

The essential features of a phase-contrast microscope are shown in the illustration. The practical problem is to find some way of separating the incident or direct light from that diffracted by the object. This is done by placing a diaphragm D of easily recognizable shape, such as an annulus, at the front focal plane of the substage condenser C. Light from each point of

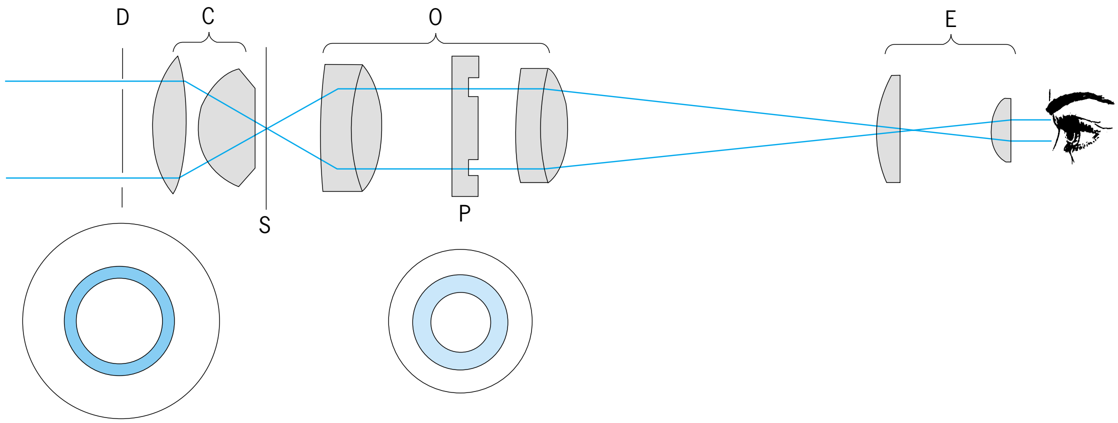


Diagram of a phase-contrast microscope.

the focal plane passes as a parallel pencil of rays through the specimen S and is brought to a focus at the rear focal plane P of the objective O. Thus, on removing the eyepiece, an image of the annulus will be seen at the back of the objective lens. This image corresponds to the incident light. In addition, when a specimen is present, some light is diffracted by it and spreads out to fill the whole of the back lens of the objective. Thus, apart from the small area of overlap over the image of the annulus, the direct and diffracted waves are essentially separated at the plane P. A phase plate is now inserted at this level. This can be a transparent disk with an annular groove of such dimensions that it coincides exactly with the image of the diaphragm D. All the direct light now passes through the groove in the phase plate, whereas the diffracted light passes mainly outside the groove. Since the diffracted light has to pass through a greater thickness of transparent material than the direct light, a phase difference, depending on the refractive index of the phase-plate material and on the thickness of the groove, is introduced between them. If this phase difference is about one-quarter of a wavelength, the basic conditions for phase contrast will have been achieved. If the phase plate is made to retard the incident wave by a quarter of a wavelength, the crests and troughs of the two waves will coincide, giving a resultant of greater amplitude. Refractile details will appear bright (negative contrast) instead of dark (positive contrast).

The phase-contrast microscope is the routine instrument for the examination of living cells because it is possible to study the cell structure under excellent optical conditions and with no loss in resolving power. The method is also useful for the study of unstained tissue sections and has found considerable use for the comparison of material in the electron and optical microscopes. *See* ELECTRON MICROSCOPE; MICROSCOPE; OPTICAL MICROSCOPE. [R.Ba.]

Phase equilibrium A general field of physical chemistry dealing with the various situations in which two or more phases (or states of aggregation) can coexist in thermodynamic equilibrium with each other, with the nature of the transitions between phases, and with the effects of temperature and pressure upon these equilibria. Many superficial aspects of the subject are largely qualitative, for example, the empirical classification of types of phase diagrams; but the basic problems always are susceptible to quantitative thermodynamic treatment, and in many cases, statistical thermodynamic methods can be applied to simple molecular models.

Thermodynamics requires that when two phases, α and β, are free to exchange heat, mechanical work, and matter (chemical species), the temperature T, the pressure P, and the chemical potential (partial molar free energy)μ_i(of each particular component *i* must be equal in both phases at equilibrium. Algebraically, equilibrium exists when $T_\alpha = T_\beta$, $P_\alpha = P_\beta$, $\mu_{i,\alpha} = \mu_{i,\beta}$, and $\mu_{j,\alpha} = \mu_{j,\beta}$.

These conditions of thermal, mechanical, and material equilibrium need not all be present if the equilibrium between phases is subject to inhibiting restrictions. Thus, for a solution of a nonvolatile solute in equilibrium with the solvent vapor, the condition of equality of solute chemical potentials $\mu_{2,\alpha} = \mu_{2,\beta}$ need not apply, since there can be no solute molecules in the vapor phase. Similarly, in osmotic equilibria, in which solvent molecules can pass through a semipermeable membrane, whereas solute molecules cannot, $\mu_{1,\alpha} = \mu_{1,\beta}$ and $T_{1,\alpha} = T_{2,\beta}$, but the solute chemical potentials μ_2 are unequal, as are the pressures on opposite sides of the membrane. *See* OSMOSIS; SOLUTION.

If a system consists of P phases and C distinguishable components, there are $C + 2$ thermodynamic variables (C chemical potentials μ_i, plus the temperature and pressure) which are interrelated by an equation for each phase. Since there are P independent equations relating the $C + 2$ variables, only $F = C + 2 - P$ variables need be fixed to define completely the state of the system at equilibrium; the other variables are then beyond control. This relation for the number of degrees of freedom F, or variance, is called the phase rule. It has proved to be a powerful tool in interpreting and classifying types of phase equilibria.

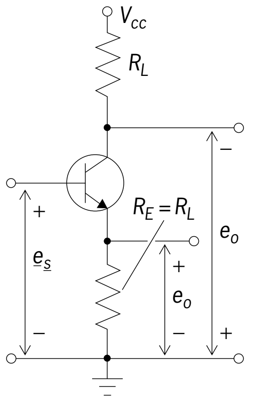
When chemical changes may occur in the system, the number of components C is the number of independent components whose amounts can be varied by the experimenter; this is equal to the total number of chemical species present less the number of independent chemical equilibria between them.

An invariant system has no degrees of freedom ($F = 0$), for which the number of phases $P = C + 2$. For a one-component system, such an invariant point is a triple point at which three phases coexist at a single temperature and pressure only; for a two-component system, a quadruple point (four phases) would be invariant. *See* TRIPLE POINT. [R.L.S.]

Phase inverter A circuit having the primary function of changing the phase of a signal by 180°. The phase inverter is most commonly employed as the input stage for a push-pull amplifier. Therefore, the phase inverter must supply two voltages of equal magnitude and 180° phase difference. A variety of circuits are available for the phase inversion. *See* PUSH-PULL AMPLIFIER.

Overall fidelity of a phase inverter and push-pull amplifier can be adversely affected by improper design of the phase inverter. The principal design requirement is that frequency response of one input channel to the push-pull amplifier be identical to the frequency response of the other channel.

The simplest form of phase-inverter circuit is a transformer with a center-tapped secondary. Careful design of the transformer assures that the secondary voltages are equal. The transformer forms a good inverter when the inverter must supply power to the input of the push-pull amplifier. The transformer inverter has several disadvantages. It usually costs more, occupies more space, and weighs more than a transistor circuit. Furthermore, some means must be found to compensate for the frequency response of the transformer, which may not be as uniform as that which can be obtained from solid-state circuits. *See* TRANSFORMER.

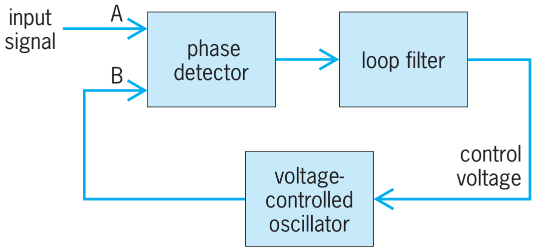


Single-transistor inverter, e_s = signal voltage; e_o = output voltage; V_{cc} = collector supply voltage; R_L = load resistance; R_E = emitter resistance.

An amplifier that provides two equal output signals 180° out of phase is called a paraphase amplifier. If coupling capacitors can be omitted, the simplest paraphase amplifier is shown in the illustration. Approximately the same current flows through R_L and R_E, and therefore if R_L and R_E are equal, the ac output voltages from the collector and from the emitter are equal in magnitude and 180° out of phase. *See* PHASE (PERIODIC PHENOMENA); PHASE-ANGLE MEASUREMENT. [H.F.K.]

Phase-locked loops Electronic circuits for locking an oscillator in phase with an arbitrary input signal. A phase-locked loop (PLL) is used in two fundamentally different ways: (1) as a demodulator, where it is employed to follow (and demodulate) frequency or phase modulation, and (2) to track a carrier or synchronizing signal which may vary in frequency with time. When operating as a demodulator, the PLL may be thought of as a matched filter operating as a coherent detector. When used to track a carrier, it may be thought of as a narrowband filter for removing noise from the signal and regenerating a clean replica of the signal. *See* DEMODULATOR; ELECTRIC FILTER.

The basic components of a phase-locked loop are shown in the illustration. The input signal is a sine or square wave of arbitrary frequency. The voltage-controlled oscillator (VCO) output signal is a sine or square wave of the same frequency as the input, but the phase angle between the two is arbitrary. The output of the phase detector consists of a direct-current (dc) term, and components of the input frequency and its harmonics. The low-pass filter removes all alternating-current (ac) components, leaving the dc component, the magnitude of which is a function of the phase angle between the VCO signal and the input signal. If the frequency of the input signal changes, a change in phase angle between these signals will produce a change in the dc control voltage in such a manner as to vary the frequency of the VCO to track the frequency of the input signal.



Phase-locked loop. R_1 and R_2 are resistors; C_1 and C_2 are capacitors.

The most widespread use of phase-locked loops is undoubtedly in television receivers. Synchronization of the horizontal oscillator to the transmitted sync pulses is universally accomplished with a PLL. The color reference oscillator is often synchronized with a phase-locked loop. Phase-locked loops are also used as frequency demodulators. They have been applied to stereo decoders made on silicon monolithic integrated circuits. High-performance amplitude demodulators may be built using phase-lock techniques. *See* AMPLITUDE-MODULATION DETECTOR. [T.B.M.]

Phase modulation A technique used in telecommunications transmission systems whereby the phase of a periodic carrier signal is changed in accordance with the characteristics of an information signal, called the modulating signal. Phase modulation (PM) is a form of angle modulation. For systems in which the modulating signal is digital, the term “phase-shift keying” (PSK) is usually employed. *See* ANGLE MODULATION.

In typical applications of phase modulation or phase-shift keying, the carrier signal is a pure sine wave of constant amplitude, represented mathematically as Eq. (1), where the constant A is

$$c(t) = A \sin \theta(t) \tag{1}$$

its amplitude, $\theta(t) = \omega t$ is its phase, which increases linearly with time, and $\omega = 2\pi f$ and f are constants that represent the carrier signal's radian and linear frequency, respectively.

Phase modulation varies the phase of the carrier signal in direct relation to the modulating signal $m(t)$, resulting in Eq. (2),

$$\theta(t) = \omega t + km(t) \tag{2}$$

where k is a constant of proportionality. The resulting transmitted signal $s(t)$ is therefore given by Eq. (3).

$$s(t) = A \sin [\omega t + km(t)] \tag{3}$$

At the receiver, $m(t)$ is reconstructed by measuring the variations in the phase of the received modulated carrier.

Phase modulation is intimately related to frequency modulation (FM) in that changing the phase of $c(t)$ in accordance with $m(t)$ is equivalent to changing the instantaneous frequency of $c(t)$ in accordance with the time derivative of $m(t)$. *See* FREQUENCY MODULATION.

Among the advantages of phase modulation are superior noise and interference rejection, enhanced immunity to signal fading, and reduced susceptibility to nonlinearities in the transmission and receiving systems. *See* DISTORTION (ELECTRONIC CIRCUITS); ELECTRICAL INTERFERENCE; ELECTRICAL NOISE.

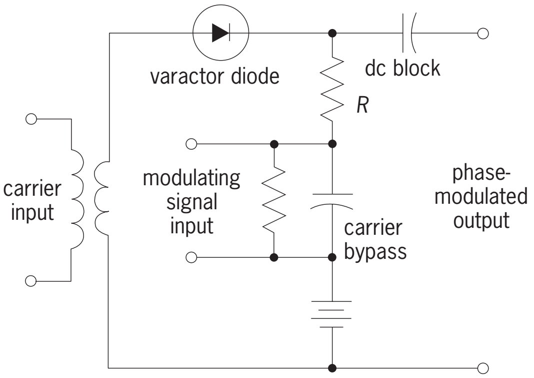
When the modulating signal $m(t)$ is digital, so that its amplitude assumes a discrete set of values, the phase of the carrier signal is “shifted” by $m(t)$ at the points in time where $m(t)$ changes its amplitude. The amount of the shift in phase is usually determined by the number of different possible amplitudes of $m(t)$. In binary phase-shift keying (BPSK), where $m(t)$ assumes only two amplitudes, the phase of the carrier differs by 180°. An example of a higher-order system is quadrature phase-shift keying (QPSK), in which four amplitudes of $m(t)$ are represented by four different phases of the carrier signal, usually at 90° intervals. *See* MODULATION. [H.J.He.]

Phase-modulation detector A device which recovers or detects the modulating signal from a phase-modulated carder. Any frequency-modulation (FM) detector with minor modifications will detect phase-modulated waves. *See* FREQUENCY-MODULATION DETECTOR; PHASE MODULATION.

The only difference between FM and phase modulation (PM) is the manner in which the modulation index varies with the modulating frequency. The modulation index is independent of the modulating frequency in PM but is inversely proportional to the modulating frequency in FM. Therefore an FM detector, when used to detect a phase-modulated wave, produces an output voltage which is proportional to the modulating frequency, assuming the original modulating signal to be of constant amplitude. Consequently, a low-pass filter with a single reactive element, such as an RC (resistance-capacitance) filter, is needed in the output of the FM detector which is used to detect a phase-modulated wave. [C.L.A.]

Phase modulator An electronic circuit that causes the phase angle of the modulated wave to vary (with respect to the unmodulated carrier) in accordance with the modulating signal. Since frequency is the rate of change of phase, a phase modulator will produce the characteristics of frequency modulation (FM) if the frequency characteristics of the modulating signal are so altered that the modulating voltage is inversely proportional to frequency. Commercial FM transmitters normally employ a phase modulator because a crystal-controlled oscillator can then be used to meet the strict carrier-frequency control requirements of the Federal Communications Commission. The chief disadvantage of phase modulators is that they generally produce insufficient frequency-deviation ratios, or modulation index, for satisfactory noise suppression. Frequency multiplication can be used, however, to increase the modulation index to the desired value, since the frequency deviation is multiplied along with the carrier frequency. *See* FREQUENCY MODULATION; PHASE MODULATION; PHASE-MODULATION DETECTOR.

Many types of phase modulators have been devised. A simple modulator is shown in the illustration. In this circuit the modulating voltage changes the capacitance of the varactor diode. The phase shift depends upon the relative magnitudes of the capacitive reactance of the varactor diode and the load resistance R. Therefore the phase shift varies with the modulating voltage and phase modulation (PM) is accomplished. However, the phase



A simple phase modulator.

shift is not linearly related to the modulating voltage if the PM exceeds a few degrees, because the phase shift is not linearly related to the capacitance and the capacitance of the varactor diode is not linearly related to the modulating voltage. *See* Varactor. [C.L.A.]

Phase rule A relationship used to determine the number of state variables F, usually chosen from among temperature, pressure, and species compositions in each phase, which must be specified to fix the thermodynamic state of a system in equilibrium. It was derived by J. Willard Gibbs. The phase rule (in the absence of electric, magnetic, and gravitational phenomena) is given by the equation below, where C is the number of chemical

$$F = C - P - M + 2$$

species present at equilibrium, P is the number of phases, and M is the number of independent chemical reactions. Here phase is used to indicate a homogeneous, mechanically separable portion of the system, and the term independent reactions refers to the smallest number of chemical reactions which, upon forming various linear combinations, includes all reactions which occur among the species present. The number of independent state variables F is referred to as the degrees of freedom or variance of the system. *See* Chemical equilibrium; Chemical thermodynamics; Phase equilibrium; Thermodynamic processes. [S.I.S.]

Phase-transfer catalysis A process in which the rate of a reaction occurring in a two-phase organic-water system is enhanced by addition of a compound that helps transfer the water soluble reactant across the interface to the organic phase.

An important factor, which contributes to the slowness of many organic reactions, is the lack of homogeneity of the reaction mixture. This is particularly the case with nucleophilic substitution reactions such as the reaction below, where RX is an organic

$$\mathrm{RX} + \mathrm{Nu}^- \rightarrow \mathrm{RNu} + \mathrm{X}^-$$

reagent and Nu^+ is the nucleophilic reagent, The nucleophilic reagent is frequently an inorganic anion, which is soluble in water in which the organic substrate is insoluble, but is insoluble in the organic phase. The encounter rate between Nu^- and RX is consequently low, as they can only meet at the interface of the heterogeneous system. The water-soluble anion is also frequently highly solvated by water molecules, which stabilize the anion and thus reduce its nucleophilic reactivity. These problems have been overcome in the past by the use of polar aprotic solvents, which will dissolve both the organic and inorganic reagents, or by the use of homogeneous mixed-solvent systems, such as water:ethanol or water:dioxan. *See* Electrophilic and nucleophilic reagents.

Phase-transfer catalysis involves the transportation of the inorganic anion, Nu^- , from the aqueous phase into the organic phase by the formation of a nonsolvated ion-pair with a cationic phase-transfer catalyst, Q^+. With highly lipophilic catalysts, the reactive ion pair $[\mathrm{Q}^+\mathrm{Nu}^-]$ is formed at the interface between the aqueous and organic phases, followed by rapid transportation into the bulk of the organic phase. The rate of the reaction is enhanced, as the encounter rate of the nucle-ophile, Nu^-, with the organic reagent, RX, in the single phase will be significantly higher than at the interface, Moreover, as the anion is transferred without water of solvation, its nucleophilic reactivity can be considerably higher in the organic phase than in the aqueous phase. Rate enhancements of greater than 10^7 have thus been observed. *See* Catalysis; Heterogeneous catalysis; Homogeneous catalysis; Quaternary ammonium salts; Stereochemistry. [R.A.J.]

Phase transitions Changes of state brought about by a change in an intensive variable (for example, temperature or pressure) of a system. Some familiar examples of phase transitions are the gas-liquid transition (condensation), the liquid-solid transition (freezing), the normal-to-superconducting transition in electrical conductors, the paramagnet-to-ferromagnet transition in magnetic materials, and the superfluid transition in liquid helium. Further examples include transitions involving amorphous or glassy structures, spin glasses, charge-density waves, and spin-density waves. *See* Amorphous solid; Charge-density wave; Metallic glasses; Spin-density wave; Spin glass; Superconductivity; Superfluidity.

Typically the phase transition is brought about by a change in the temperature of the system. The temperature at which the change of state occurs is called transition temperature (usually denoted by T_c). For example, the liquid-solid transition occurs at the freezing point.

The two phases above and below the phase transition can be distinguished from each other in terms of some ordering that takes place in the phase below the transition temperature. For example, in the liquid-solid transition, the molecules of the liquid get “ordered” in space when they form the solid phase. In a paramagnet, the magnetic moments on the individual atoms can point in any direction (in the absence of an internal magnetic field), but in the ferromagnetic phase the moments are lined up along a particular direction, which is then the direction of ordering. Thus in the phase above the transition, the degree of ordering is smaller than in the phase below the transition. One measure of the amount of disorder in a system is its entropy, which is the negative of the first derivative of the thermodynamic free energy with respect to temperature. When a system possesses more order, the entropy is lower. Thus at the transition temperature the entropy of the system changes from a higher value above the transition to some lower value below the transition. *See* Entropy; Ferromagnetism; Paramagnetism.

This change in entropy can be continuous or discontinuous at the transition temperature. In other words, the development of order in the system at the transition temperature can be gradual or abrupt. This leads to a convenient classification of phase transitions into two types, namely, discontinuous and continuous.

Discontinuous transitions involve a discontinuous change in the entropy at the transition temperature. A familiar example of this type of transition is the freezing of water into ice. As water reaches the freezing point, order develops without any change in temperature. Thus there is a discontinuous decrease in the entropy at the freezing point. This is characterized by the amount of latent heat that must be extracted from the water for it to be “ordered” into the solid phase (ice). Discontinuous transitions are also called first-order transitions.

In a continuous transition, entropy changes continuously, and hence the growth of order below T_c is also continuous. There is no latent heat involved in a continuous transition. Continuous transitions are also called second-order transitions. The paramagnet-to-ferromagnet transition in magnetic materials is an example of such a transition.

The degree of ordering in a system undergoing a phase transition can be made quantitative in terms of an order parameter.

At temperatures above the transition temperature the order parameter has a value zero, and below the transition it acquires some nonzero value. For example, in a ferromagnet the order parameter is the magnetic moment per unit volume (in the absence of an externally applied magnetic field). It is zero in the paramagnetic state since the individual magnetic moments in the solid may point in any random direction. Below the transition temperature, however, there exists a preferred direction of ordering, and as the temperature is lowered below T_c, more and more individual magnetic moments start to align along the preferred direction of ordering, leading to a continuous growth of the magnetization or the macroscopic magnetic moment per unit volume in the ferromagnetic state. Thus the order parameter changes continuously from zero above to some nonzero value below the transition temperature. In a first-order transition, the order parameter would change discontinuously at the transition temperature. [D.J.S.; S.J.]

Phase velocity The velocity of propagation of a pure sine wave of infinite extent. In one dimension, for example, the form of the disturbance for such a wave is given by $y(x, t) = A \sin [2\pi(x/\lambda - t/T)]$. Here x is the position at which the disturbance $y(x, t)$ exists at time t, λ is the wavelength, T is the period which is related to the wave frequency by $T = 1/f$, and A is the disturbance amplitude. The argument of the sine function is called the phase. The phase velocity is the speed with which a point of constant phase can be said to move. Thus $x/\lambda - ft =$ constant, so the phase velocity v_p is given by $dx/dt = v_p = \lambda f$. This is the basic relationship connecting phase velocity, wavelength, and frequency. *See* Phase (periodic phenomena); Sine wave; Wave motion.

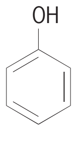
The phase velocity for waves in a medium is determined in part by intrinsic properties of the medium. For all mechanical waves in elastic media, the square of the phase velocity is proportional to the ratio of the appropriate elastic property of the medium to the appropriate inertia property. The phase velocity of electromagnetic waves depends upon the medium as well. In vacuum, the phase velocity c is given by $c^2 = 1/\epsilon_0\mu_0 \approx 9 \times 10^{16}$ m^2/s^2, where ϵ_0 and μ_0 are respectively the permittivity and permeability of the vacuum. Phase velocity may also depend upon the mode of wave propagation—in general, upon the frequency of the wave. Waves of different frequencies will travel at different speeds, resulting in a phenomenon called dispersion. *See* Electromagnetic radiation; Light; Wave equation; Young's modulus. [S.A.Wi.]

Phenocryst A relatively large crystal embedded in a finer-grained or glassy igneous rock. The presence of phe-nocrysts gives the rock a porphyritic texture. Phenocrysts are represented most commonly by feldspar, quartz, biotite, hornblende, pyroxene, and olivine. Strictly speaking, phenocrysts crystallize from molten rock material (lava or magma). They commonly represent an earlier and slower stage of crystallization than does the matrix in which they are embedded. *See* Igneous rocks; Porphyroblast. [C.A.C.]

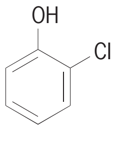
Phenol The simplest member of a class of organic compounds possessing a hydroxyl group attached to a benzene ring or to a more complex aromatic ring system. Phenol itself, C_6H_5OH, may also be called hydroxybenzene or carbolic acid. Pure phenol is a colorless solid melting at 42°C (108°F), moderately soluble in water, and weakly acidic (pK 9.9).

Phenol has broad biocidal properties, and dilute aqueous solutions have long been used as an antiseptic. At higher concentrations phenol causes severe skin burns; it is a violent systemic poison. *See* Antiseptic.

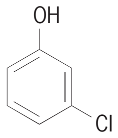
Phenol has the structure shown. Simple substituted phenols, such as the three isomeric chlorophenols, are named as indicated, using the ortho (*o*), meta (*m*), and para (*p*) prefixes. In more highly substituted phenols the positions of substitution are indicated by numbers (as in 2,4-dichlorophenol). Compounds with more than one hydroxyl group per aromatic ring are known as polyhydric phenols, and include catechol, resorcinol, hydroquinone, phloroglucinol, and pyrogallol.



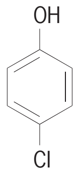
Phenol



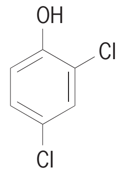
o-Chlorophenol



m-Chlorophenol



p-Chlorophenol



2,4-Dichlorophenol

Until World War I phenol was essentially a natural coal tar product. However, synthetic methods have replaced extraction from natural sources. There are many possible syntheses.

Phenol is one of the most versatile and important industrial organic chemicals. It is the starting point for many diverse products used in the home and industry. A partial list includes: nylon, epoxy resins, surface active agents, synthetic detergents, plasticizers, antioxidants, lube oil additives, phenolic resins (with formaldehyde, furfural, and so on), polyurethanes, aspirin, dyes, wood preservatives, herbicides, drugs, fungicides, gasoline additives, inhibitors, explosives, and pesticides. *See* Phenolic resin. [R.I.S.; M.St.]

Phenolic resin One of the condensation products of phenols or phenolic derivatives with aldehydes such as formaldehyde and furfural. The phenol-formaldehyde resins, developed commercially between 1905 and 1910, were the first truly synthetic polymers and have found wide usage. They are characterized by low cost, dimensional stability, high strength, and resistance to aging.

Phenolic resins can be cast from syrupy intermediates or molded from B-stage solid resins. Laminated products can be produced by impregnating fiber, cloth, wood, and other materials with the resin. An important type of phenolic resin product is rigid foam. Cured phenolic plastics are rigid, hard, and resistant to chemicals (except strong alkali) and to heat.

Some of the uses for phenolic resins are for making precisely molded articles, such as telephone parts, for manufacturing strong and durable laminated boards, or for impregnating fabrics, wood, or paper. Phenolic resins are also widely used as adhesives, as the binder for grinding wheels, as thermal insulation panels, as ion-exchange resins, and in paints and varnishes. *See* Adhesive; Ion exchange; Phenol; Plastics processing; Polymerization. [J.A.M.]

Phenylketonuria An inborn error of metabolism in which affected individuals lack the liver enzyme needed to metabolize phenylalanine, an amino acid essential for normal growth and development. If untreated, affected individuals may become severely mentally retarded, become microcephalic, have behavioral problems, develop epilepsy, or show other signs of neurological impairment. Phenylketonuria (PKU) is inherited as an autosomal recessive trait and is found in all ethnic groups but most frequently in individuals of northern European descent. Its incidence is about 1 per 14,000 births in the United States.

Newborn screening programs for phenylketonuria have been successful in identifying most cases within a few weeks of birth. A low phenylalanine diet with restriction of proteins, if initiated early in infancy, can prevent the development of severe intellectual and neurological handicaps that would otherwise occur in virtually all untreated cases. *See* PROTEIN METABOLISM. [F.delaC.]

Pheromone A substance that acts as a molecular messenger, transmitting information from one member of a species to another member of the same species. A distinction is made between releaser pheromones, which elicit a rapid, behavioral response, and primer pheromones, which elicit a slower, developmental response and may pave the way for a future behavior.

Communication via pheromones is common throughout nature, including some eukaryotic microorganisms such as fungi that exchange vital chemical signals. The cellular slime molds form large aggregations of amebas which unite to form a sorocarp made up of a long, slender stalk that supports a spore-containing fruiting body. A pheromone is responsible for the aggregation. In several species of algae, relatively simple hydrocarbons act as sperm attractants.

By far the largest number of characterized pheromones come from insect species. In social insects, such as termites and ants, there may be as many as a dozen different types of messages that are used to coordinate the complex activities which must be carried out to maintain a healthy colony. These activities might require specialized pheromones such as trail pheromones (to lead to a food source), alarm pheromones (recruiting soldiers to the site of an enemy attack), or pheromones connected with reproductive behavior. Much less is known about mammalian pheromones because mammalian behavior is more difficult to study. There are, however, a small number of well-characterized mammalian pheromones from pigs, dogs, hamsters, mice, and marmosets.

There is great potential for controlling the behavior of a given species by manipulating its natural chemical signals. For example, pheromones have been used to disrupt the reproduction of certain insect pests. This approach can lead to reduced use of pesticides as well as advances in the control of both agricultural pests and disease vectors. *See* CHEMICAL ECOLOGY; CHEMORECEPTION; INSECT CONTROL, BIOLOGICAL; SOCIAL INSECTS. [J.Mein.]

Phlebitis An inflammation of a vein. Individuals with phlebitis typically experience tenderness, redness, and hardness along the course of the vein. The cause of the inflammation may be related to injury of the vein or infection. The presence of varicose veins and the long-term use of indwelling intravenous catheters or irritating intravenous solutions place individuals at risk of developing phlebitis. In addition, those with certain diseases, including systemic lupus erythematosus, vasculitis, or malignancy, are at increased risk. Two varieties of phlebitis are recognized: phlebothrombosis and thrombophlebitis.

Phlebothrombosis is a condition in which a blood clot develops within an inflamed vein. As the clot enlarges, it may detach and travel to the lung, becoming a pulmonary embolism. Thrombophlebitis begins with an inflammatory reaction in the vein wall. When the lining of the vein is damaged, three reactions influence the development of thrombosis. Initially, damage to the lining results in adherence of white blood cells, coagulation, and a loss of the lining's nonthrombogenic characteristics. Subsequently, the deep lining of the vein is exposed, bringing it into contact with blood and allowing platelets to adhere and aggregate. Finally, the exposed lining and activated platelets result in changes in coagulation, causing more platelets to interact with deep-lining structures. These factors are influenced by the velocity of blood flow in the affected area. *See* EMBOLISM; THROMBOSIS.

Symptomatic thrombophlebitis usually results in a clot which is firmly adherent to the vein wall with a decreased risk of embolizing. Some individuals may develop symptoms suggestive of deep venous thrombosis such as pain and swelling, and should undergo noninvasive ultrasound examination of the deep veins of the leg. In the absence of deep venous thrombosis, the goal of treatment of superficial phlebitis is symptomatic relief. Analgesics, warm compresses and elevation of the affected limb may be beneficial. Late effects of phlebitis include damage to the vein wall and destruction of the venous valves or obliteration of the vein. When the deep veins of the lower extremity are involved, many individuals develop chronic venous insufficiency and its associated morbidity. *See* CIRCULATION; INFLAMMATION. [L.J.Gr.; M.C.P.]

Phloem The principal food-conducting tissue in vascular plants. Its conducting cells are known as sieve elements, but phloem may also include companion cells, parenchyma cells, fibers, sclereids, rays, and certain other cells. As a vascular tissue, phloem is spatially associated with xylem, and the two together form the vascular system. *See* XYLEM.

Sieve elements differ from phloem parenchyma cells in the structure of their walls and to some extent in the character of their protoplasts. Sieve areas, distinctive structures in sieve element walls, are specialized primary pit fields in which there may be numerous modified plasmodesmata. Plasmodesmata are strands of cytoplasm connecting the protoplasts of two contiguous cells. These strands are often surrounded by callose, a carbohydrate material, that appears to form rapidly in plants when they are placed under stress.

Typical sieve cells are long elements in which all the sieve areas are of equal specialization, though sieve areas may be more numerous in some walls than in others. In contrast, a sieve-tube member has some sieve areas more specialized than others; that is, the pores, or modified plasmodesmata, are larger in some sieve areas. Parts of the walls containing such sieve areas are called sieve plates.

Companion cells are specialized parenchyma cells that occur in close ontogenetic and physiologic association with sieve tube members. Some sieve-tube members lack companion cells. The precise functional relationship between these two kinds of cells is unknown.

Parenchyma cells in the phloem occur singly or in strands of two or more cells. They store starch, frequently contain tannins or crystals, commonly enlarge as the sieve elements become obliterated, or may be transformed into sclereids or cork cambium cells.

Phloem fibers vary greatly in length (from less than 0.04 in. or 1 mm in some plants to 20 in. or 50 cm in the ramie plant). The secondary walls are commonly thick and typically have simple pits, but may or may not be lignified. [M.A.W.]

Phlogopite A mineral with an ideal composition of $KMg_3(AlSi_3)O_{10}(OH)_2$. Phlogopite belongs to the mica mineral group. It has been occasionally called bronze mica. Phlogopite is a trioctahedral mica, where all three possible octahedral cation sites are occupied by magnesium (Mg). The magnesium octahedra, $Mg(O,OH)_6$, form a sheet by sharing edges. As in all micas, tetrahedra are located on either side of the octahedral sheet, which may be occupied by aluminum (Al) or silicon (Si). Adjacent tetrahedra share corners to form a two-dimensional network of sixfold rings, thus producing a tetrahedral sheet. Two opposing tetrahedral sheets and the included octahedral sheet form a 2:1 layer. Potassium (K) ions are located between adjacent tetrahedral sheets in the interlayer region.

Specific gravity is 2.86, hardness on the Mohs scale is 2.5–3.0, and luster is vitreous to pearly. Thin sheets are flexible. Color is yellow brown, reddish brown, or green, and thin sheets are transparent. Thermal stability varies greatly with composition, with iron or fluorine substitutions reducing or increasing stability, respectively. Weathering of phlogopite may produce vermiculite. *See* HARDNESS SCALES; VERMICULITE; WEATHERING PROCESSES.

Phlogopite occurs in marbles produced by the metamorphism of siliceous magnesium-rich limestones or dolomites and in ultrabasic rocks, such as peridotites and kimberlites. *See* DOLOMITE; LIMESTONE; PERIDOTITE.

Phlogopite is used chiefly as an insulating material and for fireproofing. It has high dielectric properties and high thermal stability. *See* Mica; Silicate minerals. [S.Gu.]

Phobia An intense irrational fear that often leads to avoidance of an object or situation. Phobias (or phobic disorders) are common (for example, fear of spiders, or arachnophobia; fear of heights, or acrophobia) and usually begin in childhood or adolescence. Psychiatric nomenclature refers to phobias of specific places, objects, or situations as specific phobias. Fear of public speaking, in very severe cases, is considered a form of social phobia. Social phobias also include other kinds of performance fears (such as playing a musical instrument in front of others; signing a check while observed) and social interactional fears (for example, talking to people in authority; asking someone out for a date; returning items to a store). Individuals who suffer from social phobia often fear a number of social situations. Although loosely regarded as a fear of open spaces, agoraphobia is actually a phobia that results when people experience panic attacks (unexpected, paroxysmal episodes of anxiety and accompanying physical sensations such as racing heart, shortness of breath).

The origin of phobias is varied and incompletely understood. Most individuals with specific phobias have never had anything bad happen to them in the past in relation to the phobia. In a minority of cases, however, some traumatic event occurred that likely led to the phobia. It is probable that some common phobias, such as a fear of snakes or a fear of heights, may actually be instinctual, or inborn. Both social phobia and agoraphobia run in families, suggesting that heredity plays a role. However, it is also possible that some phobias are passed on through learning and modeling.

Phobias occur in over 10% of the general population. Social phobia may be the most common kind, affecting approximately 7% of individuals. When persons encounter the phobic situation or phobic object, they typically experience a phobic reaction consisting of extreme fearfulness, physical symptoms (such as racing heart, shaking, hot or cold flashes, or nausea), and cognitive symptoms (particularly thoughts such as "I'm going to die" or "I'm going to make a fool of myself"). These usually subside quickly when the individual is removed from the situation. The tremendous relief that escape from the phobic situation provides is believed to reinforce the phobia and to fortify the individual's tendency to avoid the situation in the future.

Many phobias can be treated by exposure therapy: the individual is gradually encouraged to approach the feared object and to successively spend longer periods of time in proximity to it. Cognitive therapy is also used (often in conjunction with exposure therapy) to treat phobias. It involves helping individuals to recognize that their beliefs and thoughts can have a profound effect on their anxiety, that the outcome they fear will not necessarily occur, and that they have more control over the situation than they realize.

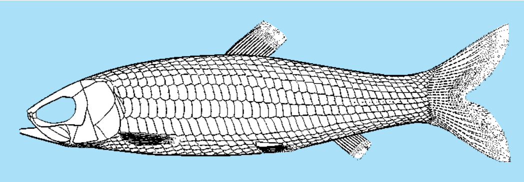
Medications are sometimes used to augment cognitive and exposure therapies. For example, beta-adrenergic blocking agents, such as propranolol, lower heart rate and reduce tremulousness, and lead to reduced anxiety. Certain kinds of antidepressants and anxiolytic medications are often helpful. It is not entirely clear how these medications exert their antiphobic effects, although it is believed that they affect levels of neurotransmitters in regions of the brain that are thought to be important in mediating emotions such as fear. *See* Neurotic disorders. [M.B.St.]

Phoenicopteriformes The flamingos, a small monotypic order of wading birds that includes the family Phoenicopteridae, which has six species found worldwide in tropical marine and fresh waters; one species lives in the high Andes. The flamingos were formally included in the Ciconiiformes and are still placed there by many researchers; others have advocated a close relationship with either the Anseriformes or the Charadriiformes. None of these classifications, however, are strongly supported by available evidence, and so it is best to place these bizarre birds in a unique order. *See* Anseriformes; Charadriiformes; Ciconiiformes.

The earliest definite flamingo fossil is *Juncitarsus*, from the middle Eocene of Wyoming; it possesses several primitive traits for the family. Beginning in the late Oligocene, modern flamingos are found in the fossil records from all areas of the world.

Flamingos are long-legged, long-necked wading birds with a thick bill which is sharply bent downward at the midpoint. The three anterior toes are webbed, possibly for walking on soft substrates. The long and broad wings enable the bird to fly well. The adult plumage is pink to light red, with black flight feathers. Flamingos are gregarious, often congregative in flocks in excess of 1 million. They breed monogamously in large colonies, and both parents incubate the one or two eggs in a nest formed of a stout pillar of mud 1 ft (0.3 m) high on a mud flat. *See* Aves. [W.J.B.]

Pholidophoriformes An extinct actinopterygian group composed of mostly small fusiform fishes of an advanced holostean level that are found in both marine and fresh-water deposits and range from the Middle Triassic to the Lower Cretaceous. The best-known representative is *Pholidophorus bechei* (see illustration), which exhibits holostean features in its enamel-covered ganoid scales, fin rays, and head bones; in the fulcra bordering all the fins with a strong series on the upper caudal lobe; and in the structure of its caudal skeleton. *See* Actinopterygii; Holostei; Teleostei. [T.M.C.]



Pholidophorus bechei **Lower Jurassic of England; length to 8 in. (20 cm). (*After D. Rayner, The structure of certain Jurassic holostean fishes with special reference to their neurocrania, Phil. Trans. Roy. Soc. London, Ser. B, no. 601, Cambridge University Press, 1948*)**

Pholidota An order of mammals comprising the living pangolins, or scaly anteaters, and their poorly known fossil predecessors. All living pangolins are assigned to the genus *Manis*. They are found in Africa south of the Sahara and in southeastern Asia, including certain islands of the East Indies.

Pangolins feed principally on termites and ants. The elongate tubular skull without teeth, long protrusive tongue, small eyes with heavy eyelids, thick skin, strong legs, five-toed feet with large claws, and large tail enable these unique animals to rip open ant nests and termite dens and devour the animals therein. The greatest peculiarity of animals in the genus Manis is a covering of all but the undersides of the body by an armor of large imbricating dermal horny scales. Living pangolins are frequently characterized as being animated pine cones. The position and number of hairs in relation to the scales are peculiar to each modern species. *See* Mammalia. [D.E.S.]

Phonetics The science that deals with the production, transmission, and perception of spoken language. At each level, phonetics overlaps with some other sciences, such as anatomy, physiology, acoustics, psychology, and linguistics. In each case, phonetics focuses on phenomena relevant to the study of spoken language.

Speech is normally produced by exhaling air from the lungs through the vocal tract. The vocal tract extends from the larynx through the pharynx and the oral cavity to the lips. If the velum (soft palate) is not raised, the air also passes through the nasal cavities. The shape and size of the oral cavity can be varied by the movement of active articulators: tongue, lips, and velum. *See* Palate.

Phoneticians usually describe speech sounds with reference to their point (or place) of articulation and their manner of articulation. The point of articulation of a sound is the place of maximum constriction within the vocal tract. The great majority of sounds are produced by moving some part of the tongue toward some region on the roof of the mouth. Exceptions are articulations involving lips and those sounds in which the vocal folds serve as articulators.

At most of these points of articulation, sounds can be produced with several manners of articulation. One way to classify manners of articulation refers to the degree of stricture employed in producing the sound. Sounds produced with complete constriction of the vocal tract are stops, or plosives. If the closure is incomplete, but the articulators are brought close enough so that the air passing between them is set into turbulent motion, the resultant sounds are fricatives or spirants. If the articulators are approximated, but the constriction remains large enough so that air can pass through without friction, the sounds are called approximants—vowellike sounds functioning as consonants. Most of these consonant sounds can be voiced or voiceless; vowels are normally voiced. The terms "voiced" and "voiceless" refer to the presence and the absence of vocal fold vibration.

Acoustic phonetics deals with the manner in which the spoken message is encoded in the sound waves. According to the generally accepted source-filter theory of speech acoustics, sound is generated at a source (which for phonated speech is constituted by the vibrating vocal folds) and passed through the vocal tract. The opening and closing of the vocal folds create a succession of condensations and rarefactions of air molecules—variations in air pressure—and transform kinetic energy into acoustic energy. The sound wave generated at the glottis can be considered, for practical purposes, a complex periodic wave, and as such it contains energy at frequencies that are multiples of the fundamental frequency (harmonics).

The vocal tract acts as a filter, transmitting more energy at those frequencies that correspond to the resonances of the vocal tract than at other frequencies. Energy concentrations at the resonance frequencies of the vocal tract are referred to as formants.

In principle, the source and filter are independent of each other; consider the fact that the same vowel can be sung at different fundamental frequencies (pitches), and different vowels can be produced at the same pitch. The sound wave can be described by specifying its fundamental frequency, amplitude, and spectrum.

The subject matter of phonetics is not limited to the production and perception of vowels and consonants; of equal importance are such prosodic and suprasegmental aspects of spoken language as duration, fundamental frequency, and intensity, as they determine such linguistically relevant phenomena as tone and intonation, stress and emphasis, and the signaling of various boundaries—boundaries of morphemes and words, phrases, clauses, and sentences. *See* Speech. [I.Le.]

Phonolite A light-colored, aphanitic (not visibly crystalline) rock of volcanic origin, composed largely of alkali feldspar, feldspathoids (nepheline, leucite, sodalite), and smaller amounts of dark-colored (mafic) minerals (biotite, soda amphibole, and soda pyroxene). Phonolite is chemically the effusive equivalent of nepheline syenite and similar rocks. Rocks in which plagioclase (oligoclase or andesine) exceeds alkali feldspar are rare and may be called feldspathoidal latite. *See* Feldspathoid; Magma.

Phonolites are rare and highly variable rocks. They occur as volcanic flows and tuffs and as small intrusive bodies (dikes and sills). They are associated with trachytes and a wide variety of feldspathoidal rocks. *See* Igneous rocks; Trachyte. [C.A.C.]

Phonon A quantum of vibrational energy in a solid or other elastic medium. This vibrational energy can be transported by elastic waves. The energy content of each wave is quantized. For a wave of frequency f, the energy is $(N + \frac{1}{2})hf$, where N is an integer and h is Planck's constant. Apart from the zero-point energy, $\frac{1}{2}hf$, there are N quanta of energy hf. In elastic or lattice waves, these quanta are called phonons. Quantization of energy is not related to the discreteness of the lattice, and also applies to waves in a continuum. *See* Quantum mechanics; Wave motion.

The concept of phonons closely parallels that of photons, quanta of electromagnetic wave energy. The indirect consequences of quantization were established for phonons just as for photons in the early days of quantum mechanics—for example, the decrease of the specific heat of solids at low temperatures. Direct evidence that the energy of vibrational modes is changed one phonon at a time came much later than that for photons—for example, the photoelectric effect—because phonons exist only within a solid, are subject to strong attenuation and scattering, and have much lower quantum energy than optical or x-ray photons. *See* Photoemission; Specific heat of solids.

Like photons, phonons can be regarded as particles, each of energy hf and momentum proportional to the wave vector of the elastic or lattice wave. Such a particle can be said to transport energy, thus moving with a velocity equal to the group velocity of the underlying wave. *See* Lattice vibrations; Photon. [P.G.Kl.]

Phonoreception The perception of sound by animals through specialized sense organs. A sense of hearing is possessed by animals belonging to two divisions of the animal kingdom: the vertebrates and the insects. The sense is mediated by the ear, a specialized organ for the reception of vibratory stimuli. Such an organ is found in all except the most primitive vertebrates, but only in some of the many species of insects. The vertebrate and insect types of ear differ in evolutionary origin and in their modes of operation, but both have attained high levels of performance in the reception and discrimination of sounds. *See* Sound.

The vertebrate ear is a part of the labyrinth, located deep in the bone or cartilage of the head, one ear on either side of the brain. A complex assembly of tubes and chambers contains a membranous structure which bears within it a number of sensory endings of different kinds. Beginning with the amphibians, which are the earliest vertebrates to spend a considerable portion of their lives on land, there appears a special mechanism, the middle ear, whose function is the transmission of aerial vibrations to the sensory endings of the inner ear. All the vertebrates above the fishes, and certain of the fishes as well, have some type of sound-facilitative mechanism. *See* Ear (vertebrate); Hearing (vertebrate).

The group of invertebrates which has received the most attention has been the insects. Other arthropods, such as certain crustaceans and spiders, have also been found to be sensitive to sound waves. The insect ear consists of a superficial membrane of thin chitin with an associated group of sensilla called scolophores. These ears are found in most species of katydids, crickets, grasshoppers, cicadas, waterboatmen, mosquitoes, and nocturnal and spinner moths. The occur in different places in the body: on the antennae of mosquitoes, on the forelegs of katydids and crickets, on the metathorax of cicadas and waterboatmen, and on the abdomen of grasshoppers. Probably these differently situated organs represent separate evolutionary developments, through the association of a thinned-out region of the body wall with sensilla that are found extensively in the bodies of insects and that by themselves seem to serve for movement perception.

The insects mentioned above are noted for their production of stridulatory sounds made by rubbing the edges of the wings together, or a leg against a wing, or by other means. These sounds are produced by the males and serve for enticing the females in mating. A striking adaptation is that shown by mosquitoes: The ear of the male mosquito is sensitive only to a narrow range of frequencies around 380 Hz, and this frequency is the one which is produced by the wings of the female in flight. If the ear of the male mosquito is made nonfunctional, the mosquito fails to find a mate. [E.G.W.]

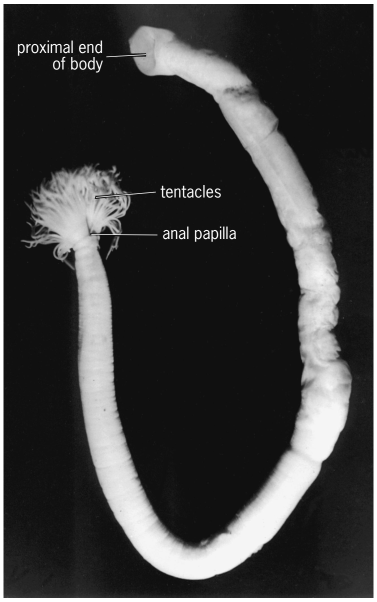
Phoresy A relationship between two different species of organisms in which the larger, or host, organism transports a smaller organism, the guest. It is regarded as a type of commensalism in which the relationship is limited to transportation of the guest. [C.B.C.]

Phoronida A small, relatively homogeneous group of animals now generally considered to constitute a separate animal phylum. Two genera, *Phoronis* and *Phoronopsis*, and about 16 species are recognized.

Phoronids may occur in vertical tubes placed just below the surface in intertidal or subtidal mud flats, or as feltlike masses of intertwined tubes attached to rocks, pilings, or old logs in shallow water. In both cases the tubes, composed basically of a secreted, parchmentlike material, are encrusted with small particles of sand or shell. A third living habit concerns those phoronids found inside channels, probably self-made, in limestone rock or the shells of dead pelecypod mollusks.

The geographical distribution of phoronids appears to be worldwide in temperate and tropical seas. There are no records of phoronids from the polar regions.

The body is more or less elongate, ranging in length from about 1.6 to 8 in. (4 to 20 cm), and bears a crown of tentacles arranged in a double row surrounding the mouth which is usually crescent-shaped (see illustration). The anus occurs at the level of the mouth and is borne on a papilla immediately outside the double row of tentacles. The digestive tract is therefore U-shaped, the mouth and anus opening close together at one end of the animal. The tentacles rest on a connective tissue base known as the lophophore. Associated with the mouth is a ciliated flap of tissue known as the epistome. *See* LOPHOPHORE.



Phoronopsis harmeri **removed from its tube.**

The phylum includes both dioecious animals and hermaphrodites. All phoronids may reproduce sexually, and in most cases the life history includes the pelagic actinotroch larva. Some species reproduce asexually by transverse fission. [J.R.M.]

Phosphate metabolism Organic phosphate compounds are present in the structural units of every animal cell, and inorganic phosphate is associated with calcium in bone and teeth. The total phosphorus in the adult human body is about 12 g/kg, with only 1.4 g/kg present in the soft tissues and the remainder in mineralized tissue in the form of apatite crystals. Blood phosphate plays an important role in regulating neutrality, and it is in equilibrium with both bone and cellular organic phosphates. The blood level is held relatively constant by regulating phosphate excretion by the kidney. This control is primarily mediated by action of parathyroid hormone. Vitamin D enhances the entry of phosphate into bone. Phosphate plays an important role in absorption of sugars from the intestine and reabsorption of glucose from the kidney. *See* PARATHYROID HORMONE; VITAMIN D.

The central role of phosphates in life processes is indicated by their occurrence in ribonucleic acid (RNA) and deoxyribonucleic acid (DNA). Through the formation of lecithins, phosphates are involved in fat metabolism. Phosphates play a major role in the conservation and transfer of energy, particularly of the energy produced in the tricarboxylic acid cycle (Krebs cycle), in glycolysis, and in the pentose shunt. They do so by participating in many phosphorylation and transphosphorylation reactions involving sugars and other organic compounds. *See* CARBOHYDRATE METABOLISM; CHROMOSOME; CITRIC ACID CYCLE; LIPID METABOLISM; NUCLEIC ACID.

In phosphorylation reactions, compounds such as phosphocreatine (PC) and adenosine triphosphate (ATP) are formed which are capable of yielding relatively large amounts of free energy (5000–11,000 cal or 21–46 kilojoules per mole) when the phosphate bonds are broken by hydrolysis. ATP and PC have a central role in energy storage and transfer in all tissues.

Phosphorus-containing coenzyme systems include the pyridine (nicotinamide) and the riboflavin nucleotide systems concerned with oxidation-reduction reactions; coenzyme A, the functional form of pantothenic acid, concerned with transacetylation, acylation, and condensation reactions; the diphosphothiamine system concerned with decarboxylation; and pyridoxal phosphate concerned with transamination. *See* BIOCHEMISTRY; BIOLOGICAL OXIDATION; COENZYME; ENERGY METABOLISM. [M.K.S.]

Phosphate minerals Any naturally occurring inorganic salts of phosphoric acid, $H_3[PO_4]$. All known phosphate minerals are orthophosphates. There are over 150 species of phosphate minerals, and their crystal chemistry is often very complicated. Phosphate mineral paragenesis can be divided into three categories: primary phosphates (crystallized directly from a melt or fluid), secondary phosphates (derived from the primary phosphates by hydrothermal activity), and rock phosphates (derived from the action of water upon buried bone material, skeletons of small organisms, and so forth). *See* MINERAL; PHOSPHATE. [P.B.M.]

Phospholipid A lipid that contains one or more phosphate groups. Phospholipids are amphipathic in nature; that is, each molecule consists of a hydrophilic (water-loving) portion and a hydrophobic (water-hating) portion. Due to the amphipathic nature and insolubility in water, phospholipids are ideal compounds for forming the biological membrane. *See* LIPID.

There are two classes of phospholipids: those that have a glycerol backbone and those that contain sphingosine. Both classes are present in the biological membrane. Phospholipids that contain a glycerol backbone are called phosphoglycerides (or glycerophospholipids), which are the most abundant class of phospholipid found in nature. The most abundant types of naturally occurring phosphoglyceride are phosphatidylcholine (lecithin), phosphatidylethanolamine, phosphatidylserine, phosphatidylinositol, phosphatidylglycerol, and cardiolipin. The structural diversity within each type of phosphoglyceride is due to the variability of the chain length and degree of saturation of the fatty acid ester groups.

Sphingomyelin is the major sphingosine-containing phospholipid. Its general structure consists of a fatty acid attached to sphingosine by an amide linkage.

A bilayer membrane is formed spontaneously when phospholipids are dispersed in an aqueous solution. In this bilayer structure, phospholipids are arranged in two leaflets with the hydrophobic tails facing each other, and the hydrophilic ends exposed to the aqueous medium. Differences in the head group, the chain length, and the degree of saturation of fatty acids in the hydrophobic end are important factors in determining the shape of the bilayer. Individual phospholipid molecules are able to move freely in the lateral plane of the bilayer but not in the transverse plane (flip-flop). Small uncharged molecules are able to diffuse through the bilayer structure, but the permeability of larger or charged molecules is restricted. The arrangement of phospholipid molecules into a bilayer in an aqueous medium follows the laws of thermodynamics and represents the structural basis for the formation of all biological membranes. *See* Cell membranes.

For a long time, phospholipids were regarded as merely building blocks for the biological membrane. It was discovered in the mid-1970s, however, that phospholipids participate in the transduction of biological signals across the membrane. For example, when the hormone vasopressin is bound to its receptor on the plasma membrane of a liver cell, the binding sets off a cascade of reactions which result in enhanced breakdown of glycogen in the liver cell, thus producing more glucose. *See* Second messengers.

A special form of phosphoglyceride, 1-alkyl-2-acetyl-glycero-3-phosphocholine, acts as a very powerful biological mediator. It causes the aggregation and degranulation of blood platelets, and is known as platelet-activating factor (PAF).

Phospholipases are responsible for the degradation of phosphoglycerides. These enzymes are found in all tissues and in the pancreatic juice. A number of toxins and venoms have very high phospholipase activity, and several pathogenic bacteria produce phospholipases that dissolve cell membrane and allow the spread of infection. There are very few inherited diseases associated with the metabolism of phosphoglycerides; presumably, such genetic defects would be lethal during the early stage of cellular development.

Sphingomyelinase, a lysosomal enzyme, hydrolytically degrades sphingomyelin. A genetic disorder caused by a defect in the production of sphingomyelinase, called Niemann-Pick disease, leaves the cell with no or limited or ability to degrade sphingomyelin. In a severe form (type A) of this disease, the liver and spleen are sites of lipid deposits and are therefore tremendously enlarged. The lipid deposits consist primarily of the sphingomyelin that cannot be degraded. *See* Lipid metabolism. [P.Ch.]

Phosphorescence A delayed luminescence, that is, a luminescence that persists after removal of the exciting source. It is sometimes called afterglow.

This original definition is rather imprecise, because the properties of the detector used will determine whether or not there is an observable persistence. There is no generally accepted rigorous definition or uniform usage of the term phosphorescence. In the literature of inorganic luminescent systems, some authors define phosphorescence as delayed luminescence whose persistence time decreases with increasing temperature. According to this usage, luminescence whose persistence time is independent of temperature is called fluorescence regardless of the length of the afterglow; a temperature-independent afterglow of long duration is called simply a slow fluorescence, which implies that the atomic or molecular transition involved is forbidden to a greater or lesser degree by the spectroscopic selection rules. The most common mechanism of phosphorescence in photoconductive inorganic systems, however, occurs when electrons or holes, set free by the excitation process and trapped at lattice defects, are expelled from their traps by the thermal energy in the system and recombine with oppositely charged carriers with the emission of light. *See* Hole states in solids; Selection rules (physics).

In the organic literature the term phosphorescence is reserved for the forbidden luminescent transition from a metastable energy state M to the ground state G, while the afterglow corresponding to the M→E→G process (where E is a higher energy state) is called delayed fluorescence. *See* Fluorescence; Light; Luminescence. [C.C.K.; J.H.S.]

Phosphorus A chemical element, P, atomic number 15, atomic weight 30.9738. Phosphorus forms the basis of a very large number of compounds, the most important class of which are the phosphates. For every form of life, phosphates play an essential role in all energy-transfer processes such as metabolism, photosynthesis, nerve function, and muscle action. The nucleic acids which among other things make up the hereditary material (the chromosomes) are phosphates, as are a number of coenzymes. Animal skeletons consist of a calcium phosphate. *See* Periodic table; Phosphate.

About three-quarters of the total phosphorus (in all of its chemical forms) used in the United States goes into fertilizers. Other important uses are as builders for detergents, nutrient supplements for animal feeds, water softeners, additives for foods and Pharmaceuticals, coating agents for metal-surface treatment, additives in metallurgy, plasticizers, insecticides, and additives for petroleum products. *See* Detergent; Water softening.

Of the nearly 200 different phosphate minerals, only one, fluorapatite, $Ca_5F(PO_4)_3$, is mined chiefly from large secondary deposits originating from the bones of dead creatures deposited on the bottom of prehistoric seas and from bird droppings on ancient rookeries. *See* Phosphate minerals.

Research in phosphorus chemistry indicates that there may be as many compounds based on phosphorus as on carbon. In organic chemistry it has been customary to group the various chemical compounds based on carbon into families which are called homologous series. This can also be done in the chemistry of phosphorus compounds, even though many phosphorus-based families are incomplete. The best known of the families of compounds based on phosphorus is the group of chain phosphates. Phosphate salts consist of cations, such as sodium, along with chain anions, such as $(P_nO_{3n+1})^{(n+2)-}$, which may have 1–1,000,000 phosphorus atoms per anion.

The phosphates are based on phosphorus atoms tetrahedrally surrounded by oxygen atoms, with the lowest member of the series being the simple PO_4^{3-} anion (the orthophosphate ion). The family of chain phosphates is based on a row of alternating phosphorus and oxygen atoms in which each phosphorus atom remains in the center of a tetrahedron of four oxygen atoms. There is also a closely related family of ring phosphates, a member of which, the trimetaphosphate, is shown in Fig. 1.

An interesting structural characteristic of many known phosphorus compounds is the formation of cagelike structures. Such cagelike molecules are exemplified by white phosphorus, P_4, and one of the phosphorus pentoxides, P_4O_{10} (Fig. 2). Network structures are also common; for example, black phosphorus crystals in which the atoms are bonded together in the form of vast, corrugated planes (Fig. 3).

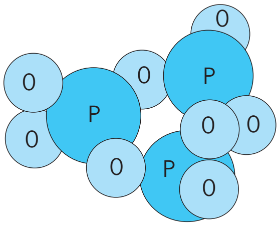


Fig. 1. Ring phosphate anion, $(P_3O_9)^{3-}$.

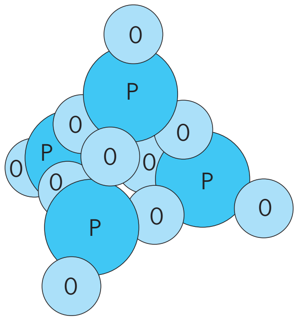

Fig. 2. Phosphorus pentoxide, P_4O_{10}, in vapor state.

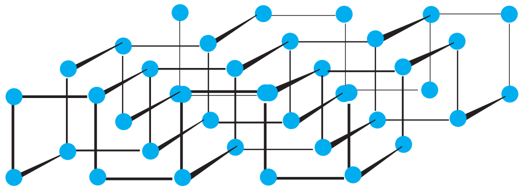

Fig. 3. Black phosphorus, P_n.

In the majority of its compounds, phosphorus is chemically bonded to four neighboring atoms. There is a large number of compounds in which one of the four neighboring atoms is absent, and in which its place is taken by an unshared pair of electrons. There are also a few compounds in which there are five or six neighboring atoms bonded to the phosphorus. These compounds are very reactive and tend to be unstable.

During the 1960s and 1970s a large number of organic-phosphorus compounds were prepared. Most of these chemical structures involve three or four neighboring atoms bonded to the phosphorus, but stable structures having two, five, or six neighboring atoms per phosphorus are also known. *See* ORGANOPHOSPHORUS COMPOUND; PHOSPHATE.

Essentially all of the phosphorus used in commerce is in the form of phosphates. The majority of phosphatic fertilizers consist of highly impure monocalcium or dicalcium orthophosphate, $Ca(H_2PO_4)_2$ and $CaHPO_4$. These phosphates are salts of orthophosphoric acid. *See* FERTILIZER.

The phosphorus compound of major biological importance is adenosine triphosphate (ATP), which is an ester of sodium tripolyphosphate, widely employed in detergents and water-softening compounds. Practically every reaction in metabolism and photosynthesis involves the hydrolysis of this tripolyphosphate to its pyrophosphate derivative, called adenosine diphosphate (ADP). [J.R.V.W.]

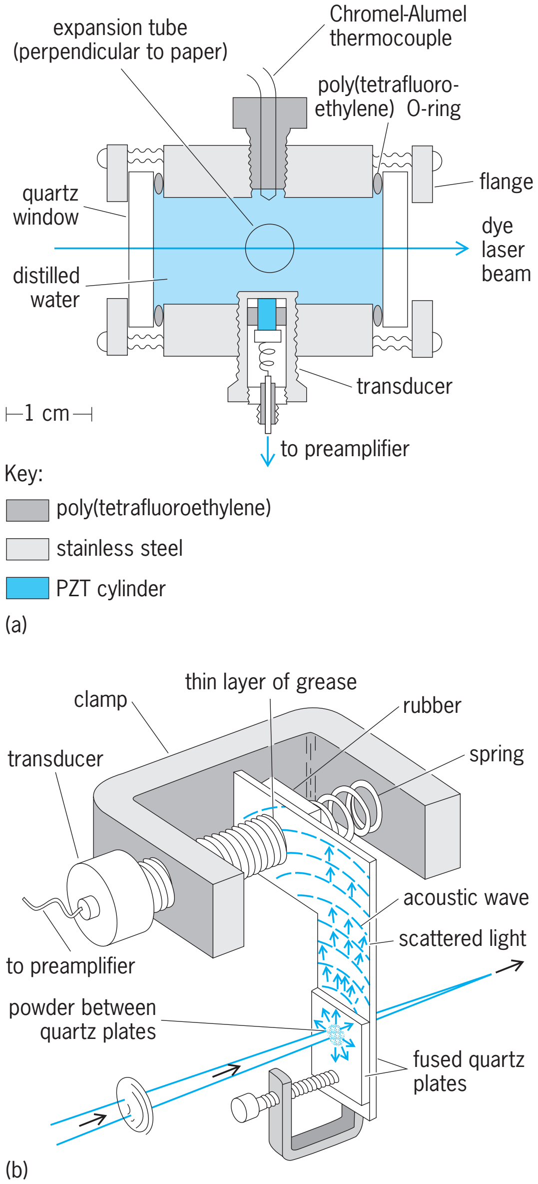
Photoacoustic spectroscopy A technique for measuring small absorption coefficients in gaseous and condensed media, involving the sensing of optical absorption by detection of sound. It is frequently called optoacoustic spectroscopy.

During the transmission of optical radiation through a sample (gas, liquid, or solid), the absorption of radiation by the sample can be measured by several techniques. The straightforward detection technique requires a measurement of the optical radiation level with and without the sample in the optical path. The transmitted power P_{out} and the incident power P_{in} are related through the equation below, where α is the absorption coefficient and l is the length of the absorber. With this technique, the minimum measurable value of αl is of the order of 10^{-4} unless special precautions have been taken to stabilize the source of radiation.

$$P_{\text{out}} = P_{\text{in}} e^{-\alpha l}$$

Optoacoustic detection is a calorimetric method where no direct detection of optical radiation is carried out but, instead, a measurement is made of the power absorbed by the medium from the incident radiation. The optoacoustic signal is proportional to the incident power and the absorption-length product αl. Thus, for given sources of noise from the detection transducers, the signal-to-noise ratio improves as the incident energy is increased.

If optical radiation is amplitude-modulated at an audio frequency, the absorption of such radiation by a gaseous medium that has been confined in a cell with appropriate optical windows for the entrance and exit of the radiation, and nonradia-tive relaxation of the medium, will cause a periodic variation in the temperature of the column of the irradiated gas. Such a periodic rise and fall in temperature gives rise to a corresponding periodic variation in the gas pressure at the audio frequency. The audio-frequency pressure fluctuations (that is, sound) are efficiently detected using a sensitive gas-phase microphone.



Arrangement for pulsed-laser (*a*) immersed and (*b*) contacted piezoelectric transducer optoacoustic spectroscopy.

The capability of measuring extremely small absorption coefficients and correspondingly small concentrations of the absorption gases has many applications, including high-resolution spectroscopy of isotopically substituted gases, excited states of molecules and forbidden transitions, and pollution detection. The pollution measurements have demonstrated that the optoacoustic spectroscopy technique in conjunction with tunable lasers can be routinely used for on-line real-time in-place detection of undesirable gaseous constituents at sub-parts-per-billion levels. *See* LASER; LASER SPECTROSCOPY.

A very sensitive calorimetric spectroscopic technique has been developed for the study of weak absorption in liquids and solids. This technique uses a pulsed tunable laser for excitation and a submerged piezoelectric transducer, in the case of a liquid, or a contacted piezoelectric transducer, in the case of a solid, for the detection of the ultrasonic signal generated due to the absorption of the radiation and its subsequent conversion into a transient ultrasonic signal (see illustration). Because of the capability of measuring very small fractional absorptions, the technique is clearly applicable to the area of monitoring water pollution, impurity detection in thin semiconductor wafers, transmission studies of ultrapure glasses (used in optical fibers for optical communications), and so forth. *See* ABSORPTION. [C.K.N.P.]

Photoaffinity labeling A process by which a macromolecule can be labeled at or near its binding or active site. The method can be applied to proteins, nucleic acids, and lipids by chemists who need to identify the parts of these molecules that are significant for particular biological functions. X-ray crystallography can frequently determine the complete structure of proteins and sometimes of nucleic acids, although the method does not necessarily highlight the reactive groups in a biomolecule. Nuclear magnetic resonance spectroscopy is increasingly useful in illuminating such structures. *See* NUCLEAR QUADRUPOLE RESONANCE; X-RAY CRYSTALLOGRAPHY.

Many important biological processes involve the formation of a complex between a biopolymer and a chemical reagent; for example, enzymes form complexes with their substrates on the way to catalysis, and antibodies form tight complexes with their antigens. Many biochemical receptors (such as hormone receptors) are complexed with lipid membranes. These complexes cannot usually be crystallized, but information about them can often be obtained by photoaffinity labeling. The idea behind photoaffinity labeling is to place in the binding site a compound that is essentially inert but can be photoactivated at will to yield a highly reactive intermediate. Preferably, this intermediate will react with almost any chemical structure.

The successful photoaffinity labeling reagents include diazirines that yield carbenes on photolysis, arylazides that are photochemically decomposed to nitrenes (highly reactive compounds that contain univalent nitrogen), and ketones that yield free radicals on irradiation. Special structural features (such as trifluromethyl substituents) can enhance the activity of the reagents.

In order to identify the products of reactions, many of which occur only in low yield, the reagent must be made radioactive. This is usually accomplished with carbon-14 (^{14}C) or tritium (^{3}H), radioactive isotopes of relatively low energy that nevertheless can easily be traced. [F.H.W.]

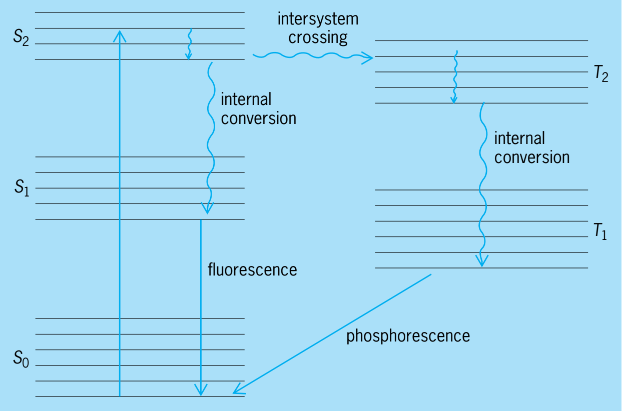
Photochemistry The study of chemical reactions of molecules in electronically excited states produced by the absorption of infrared (700–1000 nanometers), visible (400–700 nm), ultraviolet (200–400 nm), or vacuum ultraviolet (100–200 nm) light. Bond making and bond breaking as well as electron transfer and ionization are often observed in both organic and inorganic compounds as a consequence of such excitation. *See* ELECTROMAGNETIC RADIATION.

Electronic absorption. An important generalization sometimes called the first law of photochemistry is that only light that is absorbed can induce chemical change. The absorption of a photon induces an electronic transition in which an electron originally present in a molecular orbital, usually a bonding or nonbonding molecular orbital of the ground state of the absorbing molecule, is promoted to a higher-lying orbital. The excited state produced by absorption of light has a different electronic structure than its ground-state precursor and can reasonably be regarded as an isomeric species with distinct and characteristic chemical and physical properties. *See* PHOTON.

Most organic molecules exist as ground-state singlets in which all electrons are paired. Because photoexcitation causes the promotion of only a single electron, two singly occupied orbitals are produced upon excitation. If the electronic transition takes place without a spin inversion, these two electrons have opposite spins, and a singlet excited state is produced. The number of unpaired electrons in a molecule determines its multiplicity: a molecule with no unpaired spins is a singlet; one with one unpaired spin is a doublet; one with two unpaired spins is a triplet; one with three unpaired spins is a quartet, and so forth. If an electronic transition were to take place with a spin inversion, the two singly occupied orbitals would be populated by electrons with parallel spins, producing a triplet excited state. Spin restrictions forbid spin inversion during excitation, and only singlet-singlet electronic transitions are easily observed spectroscopically. After excitation, however, a change in state multiplicity can take place by a process called intersystem crossing. The facility of intersystem crossing is influenced by the magnitude of spin-orbital coupling, which can be enhanced by the presence of a heavy atom (an atom in the third row or below of the periodic table), either bound to the absorbing molecule or present externally as solvent. *See* PERIODIC TABLE; TRIPLET STATE.

Transitions. A chromophore is that part of the molecule that accounts for its absorption of light and its photochemical activity. The absorption corresponding to a particular chromophore depends on the type of transition involved in that particular excitation. The promotion of an electron from a π-bonding molecular orbital to a π-antibonding orbital is referred to as a π,π^* (read pi to pi star) transition. Such transitions are frequently encountered in alkenes, alkynes, aromatic molecules, and other unsaturated compounds. Because the spatial overlap of π and π^* orbitals is substantial, such a transition typically has high oscillator strength and a large extinction coefficient (absorptivity). Promotion of an electron from a nonbonding molecular orbital to a π-antibonding orbital, referred to as an n,π^* transition, involves orbitals that are nearly orthogonal; and it takes place only inefficiently; that is, it has a low oscillator strength and a small extinction coefficient. Such transitions are often encountered in compounds containing carbon-heteroatom or heteroatom-heteroatom double bonds. Because nonbonding molecular orbitals lie at higher energy than bonding ones, n,π^* transitions are of lower energy than the corresponding π,π^* transitions. Both n,π^* and π,π^* transitions are usually found in the ultraviolet region of the electromagnetic spectrum. Transitions involving sigma (σ) bonds (for example $n\sigma^*$ transitions in amines, alcohols, ethers, and alkyl halides and σ,σ^* transitions in alkanes) are usually encountered at the high-energy end of the ultraviolet spectrum or in the vacuum ultraviolet region. *See* CHEMICAL BONDING; ULTRAVIOLET RADIATION.

Each allowed transition of a compound registers as a band in the absorption spectrum, with the intensity of the transition (measured by its extinction coefficient) being governed by the operative selection rules. The transition intensity of a given absorption is measured by integrating over the whole absorption band. The resulting integrated absorption coefficient is directly proportional to the oscillator strength of the transition. The oscillator strength, a measure of the allowedness of an electric dipole transition compared to that of a free electron oscillating in the



Jablonski diagram. Solid arrows represent radiative processes; and wavy arrows nonradiative processes. S terms = singlet states; T terms = triplet states.

three dimensions, is directly related to an experimentally measured value, the extinction coefficient (ε). Beer's law is given by Eq. (1), where A is the observed absorbance, ε is the extinction

$$A = \varepsilon bc \tag{1}$$

coefficient, b is the path length (in centimeters) of the cell used for the measurement, and c is the molar concentration of the absorbing species. This law is used to correlate the observed absorbance with the extinction coefficient and concentration of the absorbing species. *See* Absorption of electromagnetic radiation.

Photophysics. The excited state produced by absorption of a photon is not generally a stable species. After a characteristic lifetime that can vary from femtoseconds (10^{-15} s) to hours, the excited molecule will either relax to its ground-state precursor or undergo a chemical transformation. The term photophysics is used to describe nonreactive relaxation processes, which include radiative (taking place with the emission of light) and nonradiative (taking place without the emission of light) pathways.

The energies of the lowest singlet and triplet excited states (relative to the ground state) can be obtained from the longest wavelength band of the fluorescence and phosphorescence spectra, respectively. This band is called a 0,0 band to indicate a transition between the lowest vibrational levels of the lowest-lying states. Singlet and triplet energies can also be determined indirectly by measuring quenching efficiencies. The shift between the 0,0 bands for absorption and emission in a single molecule is called its Stokes shift. A small Stokes shift is usually observed when the excited state has a geometry similar to the ground state. A Jablonski diagram (see illustration) is often used to graphically depict the relationship between competing photophysical processes.

Quantum yield, or quantum efficiency, is defined as the number of molecules participating in a given photophysical process or reaction divided by the number of photons absorbed. The quantum yield ranges between zero and one for photoreactions induced by a single photon; values larger than one are indicative of a chain process in which product is formed in a repeating, dark cycle initiated by the photoexcitation. For a photochemical reaction, the number of molecules participating in the reaction is determined spectroscopically or chromatographically as a chemical yield per volume unit per time. The number of photons absorbed is obtained by measuring with a radiometer the light flux per volume unit per time or by employing a chemical actinometer, a known chemical reaction for which the quantum yield is known and accepted as a standard. *See* Quantum chemistry.

Energy transfer. The process by which an excited state molecule, M^*, in an excited singlet or triplet state transfers all or part of its excitation energy to a reaction partner or quencher, Q, is called energy transfer or quenching when the molecule of interest is M [reaction (2)]. This same process is called sensitization when the molecule of interest is Q. In the latter case, M is called the sensitizer. Energy transfer permits an exception to the first law of photochemistry in that Q^* is produced without having absorbed the incident light.

$$M^* + Q \rightarrow M + Q^* \tag{2}$$

For energy transfer to take place, an incident wavelength must be chosen so that M is primarily excited, producing an excited state M^* whose energy lies above that of Q^*. Symmetry selection rules require that all energy transfer events preserve spin multiplicity. Thus, if M^* is an excited singlet and Q is a ground-state singlet, M will be produced as a ground-state singlet and Q^* as an excited singlet. If M^* is an excited triplet and Q is a ground-state singlet, M will be produced as a ground-state singlet and Q^* as an excited triplet.

Photochemical mechanisms. As in all studies of mechanisms of chemical reactions, determining the structure of all products is the first step in the specification of a photochemical reaction. Spectroscopic (nuclear magnetic resonance spectroscopy, electron spin resonance spectroscopy, infrared spectroscopy, mass spectroscopy, x-ray analysis, absorption spectroscopy) and chromatographic (gas, liquid, or thin-layer chromatography) techniques are used to establish product structure and to determine product yields. Monitoring the effect of solvent polarity on reaction rate, the retention or loss of optical activity during the reaction, the positions of isotopic labels, and the success of intermediate trapping experiments can distinguish step-wise chemical reactions (those that proceed through one or more intermediates) from concerted reactions (those that proceed without intermediates). In addition to these mechanistic approaches, the identity and lifetime of the reactive excited state (singlet, triplet, and so forth) and the quantum yields for both product formation and for other competing photophysical processes are required for a full photochemical mechanistic characterization. Time-resolved flash photolysis and pulse radiolysis measurements can, in addition, be used sometimes for direct spectroscopic detection of absorptive or emissive intermediates encountered in a photochemical mechanism, as well as for their kinetic characterization. The addition of specific reactive quenchers or traps, conducting a photoreaction in a low-temperature matrix in which diffusion processes are stopped, and sensitization experiments are effective means for assigning the observed transient absorptions or emissions. The energetics of a well-defined photochemical reaction can be obtained by photoacoustic calorimetry measurements. *See* Chromatography; Matrix isolation; Photolysis; Spectroscopy. [M.A.F.]

Photoclinometer

A term applied to directional surveying instruments which record photographically the direction and magnitude of well deviations from the vertical. Two instruments of this type are in wide use, the Schlumberger photoclinometer and the Surwell clinograph. Both instruments record a series of deviation measurements on one trip into and out of the well. From this series of data it is possible to plot quite accurately the course of the well.

In the Schlumberger photoclinometer (see illustration) the deviation from the vertical is indicated by a small metal ball which rolls in a transparent glass bowl graduated in circular degrees. The direction of the deviation in azimuth is indicated by a magnetic compass. With the instrument suspended by an electrical cable, the positions of the compass and steel ball are photographed on a 35-mm film by operation of electrical controls at the surface. Correlation of the pictures with the depths at which they are taken yields a measure of the magnitude and direction of deviation of the hole as a function of depth.

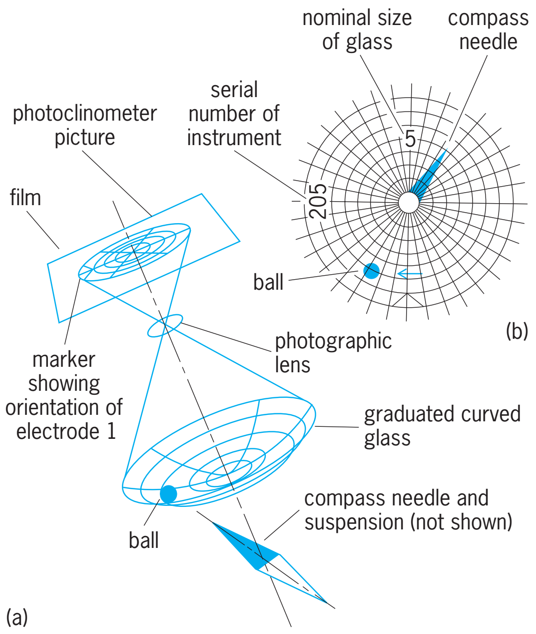


Diagram of a Schlumberger photoclinometer. (*a*) Principal features. (*b*) Type of record obtained. (*Schlumberger Well Surveying Corp.*)

The Surwell clinograph also operates electrically but is powered by batteries contained in the instrument. The deviation from the vertical is indicated by a box level gage and the direction in azimuth by a gyroscopic compass, permitting its use inside steel pipe. *See* Surveying. [H.G.Bo.]

Photoconductive cell A device for detecting electromagnetic radiation (photons) by variation of the electrical conductivity of a substance (a photoconductor) upon absorption of the radiation by this substance. During operation the cell is connected in series with an electrical source and current-sensitive meter, or in series with an electrical source and resistor. Current in the cell, as indicated by the meter, is a measure of the photon intensity, as is the voltage drop across the series resistor. Photoconductive cells are made from a variety of semiconducting materials in the single-crystal or polycrystalline form. *See* Photoconductivity; Photoelectric devices. [S.R.B.]

Photoconductivity The increase in electrical conductivity caused by the excitation of additional free charge carriers by light of sufficiently high energy in semiconductors and insulators. Effectively a radiation-controlled electrical resistance, a photoconductor can be used for a variety of light- and particle-detection applications, as well as a light-controlled switch. Other major applications in which photoconductivity plays a central role are television cameras (vidicons), normal silver halide emulsion photography, and the very large field of electrophotographic reproduction. *See* Optical detectors; Optical modulators; Particle detector; Photography; Television camera tube.

Although all insulators and semiconductors may be said to be photoconductive, that is, they show some increase in electrical conductivity when illuminated by light of sufficiently high energy to create free carriers, only a few materials show a large enough change, that is, show a large enough photosensitivity, to be practically useful in applications of photoconductors.

Since the electrical conductivity σ of a material is given by the product of the carrier density, its charge, and its mobility, an increase in the conductivity can be formally due to either an increase in carrier density or an increase in mobility. Although cases are found in which both types of effects are observable, photoconductivity in single-crystal materials is due primarily to an increase in earner density. In polycrystalline materials, on the other hand, where transport may be limited by potential barriers between the crystalline grains, an increase in mobility due to photoexcitation effects on these intergrain barriers may dominate the photoconductivity.

The variation of photoconductivity with photon energy is called the spectral response of the photoconductor. Spectral response curves typically show a fairly well-defined maximum at a photon energy close to that of the bandgap of the material, that is, the minimum energy required to excite an electron from a bond in the material into a higher-lying conduction band where it is free to contribute to the conductivity. This energy ranges from 3.7 eV, in the ultraviolet, for zinc sulfide (ZnS) to 0.2 eV, in the infrared, for cooled lead selenide (PbSe).

Another major characteristic of a photoconductor of practical concern is the rate at which the conductivity changes with changes in photoexcitation intensity. If a steady photoexcitation is turned off at some time, for example, the length of time required for the current to decrease to $1/e$ of its initial value is called the decay time of photoconductivity, t_d. The magnitude of the decay time is determined by the lifetime π and by the density of carriers trapped in imperfections as a result of the previous photoexcitation, which must now also be released in order to return to the thermal equilibrium situation. *See* Photoconductive cell. [R.H.Bu.]

Photocopying processes Processes that use light to generate copies directly from original paper documents. Light is employed to examine an original document and to detect the presence or absence of an image. In most cases, light reflected from the original subject directly exposes the medium used to produce an image on a copy. However, in an increasing number of cases, the light is converted into an electrical signal, which is later converted back to light to expose the copying medium.

Xerography, the most popular of the photocopying processes, relies on photoconductors and toner powders to create copies. The toner is fused to copy paper by heat or pressure. Microfilming employs silver halide films which must normally be developed and fixed by using wet chemicals. Electrofax, diazo, thermography, and nonmicrofilm forms of silver halide photocopying, although not used as widely as in the past, also have continuing applications. *See* Photographic materials.

The emergence of dual-imaging systems that accept both optical and digital input is making it increasingly difficult to characterize a given piece of equipment as a photocopier (optical input) or electronic printer (digital input). A number of electronic printers equipped with scanner attachments can function as either, and some employ both photocopying and digital imaging processes in generating an individual copy. *See* Printing. [R.I.E.; J.G.Ja.; T.De.]

Photodegradation Reduction in the useful properties of materials because of chemical changes resulting from the absorption of light. The chemical changes can include bond scission (especially of the molecular backbone), color formation, cross-linking, and chemical rearrangements. All organic materials can photodegrade, but the process has greatest practical relevance for polymers where scission of the polymer backbone is particularly important. Photodegradations of polymers in the absence of oxygen (photolysis) or using wavelengths shorter (more energetic) than those at the Earth's surface (<280 nanometers) have been studied extensively, but only the more practical situation of polymers exposed to terrestrial sunlight (or its equivalent) in air is discussed in this article.

Although all organic polymers can be degraded by light, the rate of degradation varies enormously from polymer to polymer, and is also dependent on the incident wavelengths. Light containing ultraviolet (uv; shorter-wavelength) components is much more destructive than visible light, so that polymers exposed indoors, behind window glass (transmitting >330 nm), will degrade much more slowly than samples exposed outdoors.

For many aromatic polymers, such as polyester and the aramids, in which the polymer itself is the chromophore (light-absorbing group), backbone scission results predominantly from this direct absorption of light energy. For many other polymers, including polyolefins, and polyvinyl chloride where only impurities absorb energy from sunlight, scission of a chemical bond by light to give free radicals is followed by reaction of these highly reactive free radicals with atmospheric oxygen. *See* Free radical.

Although numerous organic materials will undergo photodegradation, hydrocarbon polymers are particularly vulnerable because their useful properties depend entirely on their high molecular weights, in the tens or hundreds of thousands. Anything that reduces the molecular weight of polymeric systems will alter the characteristics of these systems and limit their service life. In fact, the scission of as few as one carbon-carbon bond in a thousand in a polymer molecule can completely destroy its useful physical properties. This sensitivity is not observed in lower-molecular-weight substances such as liquid hydrocarbons.

A general approach to reducing the rates of photodegradation for all types of polymers is the use of low levels of additives. These additives, known as photostabilizers or uv stabilizers, are effective at fractions of a weight percent. *See* Photochemistry; Polymer; Stabilizer (chemistry). [D.M.W.; D.J.Ca.]

Photodiode A semiconductor two-terminal component with electrical characteristics that are light-sensitive. All semiconductor diodes are light-sensitive to some degree, unless enclosed in opaque packages, but only those designed specifically to enhance the light sensitivity are called photodiodes.

Most photodiodes consist of semiconductor *pn* junctions housed in a container designed to collect and focus the ambient light close to the junction. They are normally biased in the reverse, or blocking, direction; the current therefore is quite small in the dark. When they are illuminated, the current is proportional to the amount of light falling on the photodiode. *See* Junction diode.

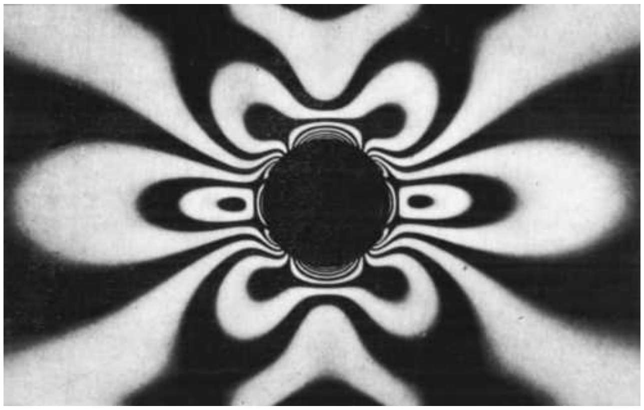
Photodiodes are used both to detect the presence of light and to measure light intensity. *See* Photoelectric devices. [W.R.Si.]

Photoelasticity An experimental technique for the measurement of stresses and strains in material objects by means of the phenomenon of mechanical birefringence. Photoelasticity is especially useful for the study of objects with irregular boundaries and stress concentrations, such as pieces of machinery with notches or curves, structural components with slits or holes, and materials with cracks. The method provides a visual means of observing overall stress characteristics of an object by means of light patterns projected on a screen or photographic film. Photoelasticity is generally used to study objects stressed in two planar directions (biaxial), but with refinements it can be used for objects stressed in three spatial directions (triaxial). *See* Birefringence.

When a stressed model is subjected to monochromatic polarized light in a polariscope the birefringence of the model causes the light to emerge refracted into two orthogonal planes. Because the velocities of light propagation are different in each direction, there occurs a phase shifting of the light waves.

When the waves are recombined with the polariscope, regions of stress where the wave phases cancel appear black, and regions of stress where the wave phases combine appear light. Therefore, in models of complex stress distribution, light and dark fringe patterns (isochromatic fringes) are projected from the model (see illustration). These fringes are related to the stresses. *See* Polarized light.

When white light is used in place of monochromatic light, the relative retardation of the model causes the fringes to appear in colors of the spectrum. White light is often used for demonstration, and monochromatic light is used for precise measurements. *See* Stress and strain. [W.Z.]



Isochromatic fringe pattern for plate with hole. (*From M. M. Frocht, Photoelasticity, vol. 2, copyright © 1948 by John Wiley and Sons, Inc.; used with permission*)

Photoelectric devices Devices which give an electrical signal in response to visible, infrared, or ultraviolet radiation. They are often used in systems which sense objects or encoded data by a change in transmitted or reflected light. Photoelectric devices which generate a voltage can be used as solar cells to produce useful electric power. The operation of photoelectric devices is based on any of the several photoelectric effects in which the absorption of light quanta liberates electrons in or from the absorbing material. *See* Photovoltaic effect; Solar cell.

Photoconductive devices are photoelectric devices which utilize the photo-induced change in electrical conductivity to provide an electrical signal. Photoemissive systems have also been used in photoelectric applications. These vacuum-tube devices utilize the photoemission of electrons from a photocathode and collection at an anode. *See* Photoconductive cell; Photoemission.

Many photoelectric systems now utilize silicon photodiodes or phototransistors. These devices utilize the photovoltaic effect, which generates a voltage due to the photoab-sorption of light quanta near a *pn* junction. Modern solid-state integrated-circuit fabrication techniques can be used to create arrays of photodiodes which can be used to read printed information. *See* Photodiode ; Phototransistor. [R.A.C.]

Photoemission The ejection of electrons from a solid (or less commonly, a liquid) by incident electromagnetic radiation. Photoemission is also called the external photoelectric effect. The visible and ultraviolet regions of the electromagnetic spectrum are most often involved, although the infrared and x-ray regions are also of interest. For important practical applications of photoemission *see* Phototube; Television camera tube.

The salient experimental features of photoemission are the following: (1) There is no detectable time lag between irradiation of an emitter and the ejection of photoelectrons. (2) At a given frequency the number of photoelectrons ejected per second is proportional to the intensity of the incident radiation. (3) The photoelectrons have kinetic energies ranging from zero up to a well-defined maximum, which is proportional to the frequency of the incident radiation and independent of the intensity.

In 1905 Albert Einstein made the clarifying assumption that electromagnetic radiation had characteristics like those of particles when it delivered energy to electrons in the emitter. In Einstein's approach the light beam behaves like a stream of photons, each of energy $h\nu$, where h is Planck's constant, and ν is the frequency of the photon. The energy required to eject an electron from the emitter has a well-defined minimum value ϕ

called the photoelectric threshold energy. When a photon interacts with an electron, the latter absorbs the entire photon energy. *See* PHOTON.

For $h\nu$ values below the threshold, photoelectrons are not ejected. Even though the electrons absorb photon energy, they do not receive enough to surmount the potential barrier at the surface, which normally holds the electrons in the solid. For photon energies above ϕ, the kinetic energies of photo-electrons range from zero up to a maximum value, $E = h\nu - \phi$. This is the Einstein photoelectric law, and E is commonly termed the Einstein maximum energy. *See* HEAT RADIATION; SCHOTTKY EFFECT. [L.Ap.]

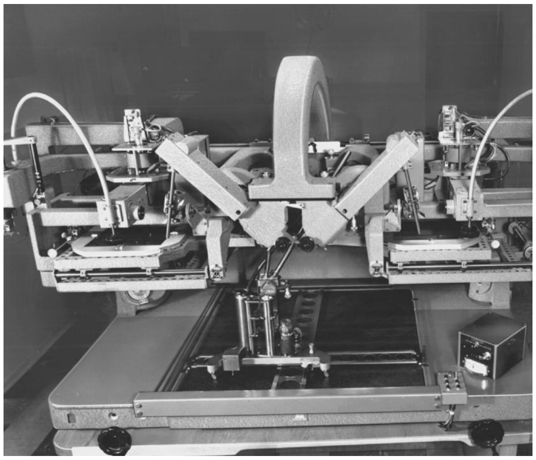
Photoferroelectric imaging The process of storing an image in a ferroelectric material by utilizing either the intrinsic or extrinsic photosensitivity in conjunction with the ferroelectric properties of the material. Specifically, photoferroelectric (PFE) imaging is a process of storing photographic images or other optical information in transparent lead lanthanum zirconate titanate (PLZT) ceramics. The photoferroelectric imaging device consists simply of a thin flat plate (about 0.01 in. or 0.2–0.3 mm thick) of optically polished PLZT ceramic with transparent conductive indium-tin oxide (ITO) electrodes sputter-deposited on the two major surfaces. The image to be stored is exposed onto one of the ITO electroded surfaces by using near-ultraviolet illumination in the intrinsic photosensitivity region (corresponding to a bandgap energy of approximately 3.35 eV) of the PLZT. Simultaneously, a voltage pulse is applied across the electrodes to switch the ferroelectric polarization from one stable remanent state to another. Images are stored both as spatial distributions of light-scattering centers in the bulk of the PLZT and as surface deformation strains which form a relief pattern of the image on the exposed surface. Both the light scattering and surface strains are related to spatial distributions of ferroelectic domain orientations introduced during the image-storage process. These spatial distributions correspond to brightness variations in the image to which the PLZT is exposed. The stored image may be viewed directly or it may be projected onto a screen by using either transmitted or reflected light.

Important potential applications of photoferroelectric imaging are temporary image storage and display. Various types of image processing, including image contrast enhancement, are also offered by the capability of switching from a positive to a negative stored image in discrete steps. *See* ELECTRONIC DISPLAY; FERROELECTRICS; PHOTOCONDUCTIVITY. [C.E.L.]

Photogrammetry The practice of obtaining surveys by means of photography. The camera commonly is airborne with its axis vertical, but oblique and horizontal (ground-based) photographs also are applicable. Data reduction is accomplished by stereoscopic line-of-sight geometry with use of both analytical and analog methods. *See* AERIAL PHOTOGRAPH; REMOTE SENSING; SURVEYING.

In vertical aerial surveys adjacent photos are overlapped. The two images of the same terrain are then superimposed for three-dimensional viewing by human operators or automated sensors.

In a widely used analog procedure the two photos are placed in the projectors of a stereoplotting instrument. With the aid of visible ground-control points the photos are oriented to the relative positions they had at the instants of exposure. In a typical automated stereoplotting system (see illustration) scanning devices substitute for human eyes to sense model-surface slope and thus to control servomechanisms that raise and lower the plotting table and translate it along a succession of closely spaced parallel horizontal dimensions, or ground profiles. [R.H.D.]



Typical automated stereoplotting system. (***Lockwood,hfill Kessler, and Bartlett, Inc.***)

Photographic materials The light-sensitive recording materials of photography, that is, photographic films, plates, and papers. They consist primarily of a support of plastic sheeting, glass, or paper, respectively, and a thin, light-sensitive layer, commonly called the emulsion, in which the image will be formed and stored. The material will usually embody additional layers to enhance its photographic or physical properties.

Film support, for many years made mostly of flammable cellulose nitrate, is now exclusively made of slow-burning "safety" materials, usually cellulose triacetate or polyester terephthalate, which are manufactured to provide thin, flexible, transparent, colorless, optically uniform, tear-resistant sheeting. Film supports usually range in thickness from 0.0025 to 0.009 in. (0.06 to 0.23 mm) and are made in rolls up to 60 in. (1.5 m) wide and 6000 ft (1800 m) long. *See* ESTER; POLYESTER RESINS.

Glass is the predominant substrate for photographic plates, though methacrylate sheet, fused quartz, and other rigid materials are sometimes used. Plate supports are selected for optical clarity and flatness. Thickness, ranging usually from 0.04 to 0.25 in. (1 to 6 mm), is increased with plate size as needed to resist breakage and retain flatness. *See* GLASS.

Photographic paper is made from bleached wood pulp of high α-cellulose content, free from ground wood and chemical impurities. It is often coated with a suspension of baryta (barium sulfate) in gelatin for improved reflectance and may be calendered for high smoothness. Fluorescent brighteners may be added to increase the appearance of whiteness. *See* PAPER.

Most emulsions are basically a suspension of silver halide crystals in gelatin. The crystals, ranging in size from 2.0 to less than 0.05 micrometers, are formed by precipitation by mixing a solution of silver nitrate with a solution containing one or more soluble halides in the presence of a protective colloid. During manufacture, the emulsion is ripened to control crystal size and structure. Chemicals are added in small but significant amounts to control speed, image tone, contrast, spectral sensitivity, keeping qualities, fog, and hardness; to facilitate uniform coating; and, in the case of color films and papers, to participate in the eventual formation of dye instead of metallic silver images upon development. The gelatin, sometimes modified by the addition of synthetic polymers, is more than a simple vehicle for the silver halide crystals. It interacts with the silver halide crystals during manufacture, exposure, and processing and contributes to the stability of the latent image. *See* EMULSION; GELATIN; SILVER.

The silver halides (and silver behenates) are normally sensitive only to x-radiation and to ultraviolet, violet, and blue wavelengths, but they can be made sensitive to longer wavelengths by adding special dyes, predominantly polymethines, to the emulsion. The process is known as spectral sensitizing to distinguish it from the chemical sensitizing used to raise the overall or inherent sensitivity of the grains. *See* PHOTOGRAPHY. [R.D.Anw.]

Photography The process of forming stable or permanent visible images directly or indirectly by the action of light or other forms of radiation on sensitive surfaces. Traditional photography uses the action of light to cause changes in a film of silver halide crystals in which development converts exposed silver halide to (nonsensitive) metallic silver. Following exposure in a camera or other device, the film or plate is developed, fixed in a solution that dissolves the undeveloped silver halide, washed to remove the soluble salts, and dried. Printing from the original, if required, is done by contact or optical projection onto a second emulsion-coated material, and a similar sequence of processing steps is followed. Digital photography captures images directly with an electronic photosensor. *See* PHOTOGRAPHIC MATERIALS.

Photography is practiced on a professional level for portraiture and for various commercial and industrial applications, including the preparation of photographs for advertising, illustration, display, and record-keeping. Press photography is for newspaper and magazine illustrations of topical events and objects. Photography is used at several levels in the graphic arts to convert original photographs or other illustrations into printing plates for high-quality reproduction in quantity. Industrial photography includes the generation and reproduction of engineering drawings, high-speed photography, schlieren photography, metallography, and many other forms of technical photography which can aid in the development, design, and manufacture of various products. Aerial photography is used for military reconnaissance and mapping, civilian mapping, urban and highway planning, and surveys of material resources. Biomedical photography is used to reveal or record biological structures, often of significance in medical research, diagnosis, or treatment. Photography is widely applied to preparing projection slides and other displays for teaching through visual education. *See* PRINTING; SCHLIEREN PHOTOGRAPHY.

Photography is one of the most important tools in scientific and technical fields. It extends the range of vision, allowing records to be made of things or events which are difficult or impossible to see because they are too faint, too brief, too small, or too distant, or associated with radiation to which the eye is insensitive. Technical photographs can be studied at leisure, measured, and stored for reference or security. The acquisition and interpretation of images in scientific and technical photography usually requires direct participation by the scientist or skilled technicians.

Infrared photography. Emulsions made with special sensitizing dyes can respond to radiation at wavelengths up to 1200 nanometers, though the most common infrared films exhibit little sensitivity beyond 900 nm. One specialized color film incorporates a layer sensitive in the 700–900-nm region and is developed to false colors to show infrared-reflecting subjects as bright red. *See* INFRARED RADIATION.

Photographs can thus be made of subjects which radiate in the near-infrared, such as stars, certain lasers and light-emitting diodes, and hot objects with surface temperatures greater than 500°F (260°C). Infrared films are more commonly used to photograph subjects which selectively transmit or reflect near-infrared radiation, especially in a manner different from visible radiation. Infrared photographs taken from long distances or high altitudes usually show improved clarity of detail because atmospheric scatter (haze) is diminished with increasing wavelength and because the contrast of ground objects may be higher as a result of their different reflectances in the near-infrared. Grass and foliage appear white because chlorophyll is transparent in the near-infrared, while water is rendered black because it is an efficient absorber of infrared radiation. *See* INFRARED IMAGING DEVICES.

Ultraviolet photography. Two distinct classes of photography rely on ultraviolet radiation. In the first, the recording material is exposed directly with ultraviolet radiation emitted, reflected, or transmitted by the subject; in the other, exposure is made solely with visible radiation resulting from the fluorescence of certain materials when irradiated in the ultraviolet. In the direct case, the wavelength region is usually restricted by the camera lens and filtration to 350–400 nm, which is readily detected with conventional black-and-white films. Ultraviolet photography is accomplished at shorter wavelengths in spectrographs and cameras fitted with ultraviolet-transmitting or reflecting optics, usually with specialized films. In ultraviolet-fluorescence photography, ultraviolet radiation is blocked from the film by filtration over the camera lens and the fluorescing subject is recorded readily with conventional color or panchromatic films. Both forms of ultraviolet photography are used in close-up photography and photomicrography by mineralogists, museums, art galleries, and forensic photographers. *See* ULTRAVIOLET RADIATION.

High-speed photography. Photography at exposure durations shorter than those possible with conventional shutters or at frequencies (frame rates) greater than those achievable with motion picture cameras with intermittent film movements is useful in a wide range of technical applications.

The best conventional between-the-lens shutters rarely yield exposures shorter than 1/500 s. Some focal plane shutters are rated at 1/2000 or 1/4000 s but may take 1/100 s to traverse the film format. Substantially shorter exposures are possible with magnetooptical shutters (using the Faraday effect), with electrooptical shutters (using the Kerr effect), or with pulsed electron image tubes. Alternatively, a capping shutter may be used in combination with various pulsed light sources which provide intense illumination for very short durations, including pulsed xenon arcs (electronic flash), electric arcs, exploding wires, pulsed lasers, and argon flash bombs. Flash durations ranging from 1 millisecond to less than 1 nanosecond are possible. Similarly, high-speed radiographs have been made by discharging a short-duration high-potential electrical pulse through the x-ray tube. *See* FARADAY EFFECT; KERR EFFECT; LASER; STROBOSCOPIC PHOTOGRAPHY.

The classical foundation for serial frame separation is the motion picture camera. Intermittent movement of the film in such cameras is usually limited to 128 frames/s (standard rates are 16 and 24). For higher rates (up to 10,000 frames/s or more) continuous film movement is combined with optical compensation, as with a rotating plane-parallel glass block, to avoid image smear. Pictures made at these frequencies but projected at normal rates slow down (stretch) the motion according to the ratio of taking and projection rates. Higher rates, up to 10^7 frames/s, have been achieved with a variety of ingenious special-purpose cameras. In some, the sequence of photographs is obtained with a rapidly rotating mirror at the center of an arcuate array of lenses, and a stationary strip of film. In others, the optics are stationary and the film strip is moved at high speed by mounting it around the outside or inside of a rapidly rotating cylinder. To overcome mechanical limitations on the rotation of mirrors or cylindrical film holders at high speeds, image dissection methods have been employed, that is, an image is split into slender sections and rearranged to fill a narrow slit at the film. The image is unscrambled by printing back through the dissecting optics. *See* CINEMATOGRAPHY.

Remote sensing. The art of aerial photography, in which photographs of the Earth's surface are made with specialized roll-film cameras carried aloft on balloons, airplanes, and spacecraft, is an important segment of a broader generic technology, remote sensing. The film is often replaced with an electronic sensor, the sensor system may be mounted on an aircraft or spacecraft, and the subject may be the surface of a distant planet instead of Earth. Remote sensing is used to gather military intelligence; to provide most of the information for plotting maps; for evaluating natural resources (minerals, petroleum, soils, crops, water) and natural disasters; and for planning cities, highways, dams, pipelines, and airfields. Aerial photography normally provides higher ground resolution and geometric accuracy than the imagery obtained with electronic sensors, especially when covering small areas, so it continues as the foundation for mapmaking, urban planning, and some other applications. Films designed for aerial photography, both black-and-white and color, have somewhat higher contrast than conventional products because the luminance range of the Earth's surface as seen from altitudes of 5000 ft (1500 m) or more is roughly 100 times lower than that of landscapes photographed horizontally. *See* Aerial photograph; Photogrammetry; Topographic surveying and mapping.

The acquisition of image information with scanning sensors mounted on spacecraft provides an inexpensive means for gathering photographs of large areas of the Earth or the whole Earth at regular intervals (minutes or hours for meteorological satellites, days for Earth resources satellites) or for photographing subjects which cannot be reached with aircraft or approached with spacecraft. Some sensors operate at wavelengths beyond those detected by infrared films. The image information is transmitted to receiving stations on Earth, usually processed electronically to correct for geometric and atmospheric factors, and recorded on a variety of image recorders. Scanning sensors, as well as film cameras, are employed in aerial reconnaissance because they can transmit tactical information to ground stations for evaluation before the aircraft returns to base or is shot down. Synthetic aperture radar, which maps the reflectance of microwaves from the surface of the Earth and other planets, represents another form of remote sensing for both military and commercial purposes in which the information is returned to Earth and reconstructed in photographic form for study. *See* Aerial photograph; Meteorological satellites; Military satellites; Remote sensing. [R.D.Anw.]

Digital photography. The process of electronic acquisition, the equivalent of taking a photograph, is often referred to as image capture.

Light intensity is detected in digital camera by an photosensor. This is normally a charge-coupled device (CCD), although complementary metal oxide silicon (CMOS) devices are beginning to appear in some systems. *See* Charge-coupled devices.

When photons strike the sensor, they give up energy. This causes electrons to be emitted, turning the energy of the photons into electrical energy. The number of electrons that are emitted can be measured to determine how many photons struck the capture element, and from this the scanner can generate a value for the intensity of light arriving from the point on the original being analyzed.

The aim of the digitization stage is to capture all the information from an original that will be needed in the reproduction and convert it into an array of binary numbers that a computer can process. The human visual system actively seeks cues that will give it information about the objects within the visual field, and a reproduction of an image that contains a large amount of detail is almost always preferred to one in which some of the detail has been lost. The more information that the reproduction contains about the original scene—the objects in it, their colors, textures—the more realistic the reproduction appears. *See* Image processing.

Like conventional cameras, digital cameras come in compact, single-lens reflex, and large-format varieties. Low-resolution compacts are useful for producing classified advertisements and tend to have relatively simple optics, image-sensing electronics, and controlling software. Digital cameras are often based on existing single-lens reflex camera designs with the addition of CCD backs and storage subsystems. The capture resolution of these cameras is ideal for news photography and other applications with similar quality requirements. *See* Camera. [T.De.]

Photoionization

The ejection of one or more electrons from an atom, molecule, or positive ion following the absorption of one or more photons. The process of electron ejection from matter following the absorption of electromagnetic radiation has been under investigation for over a century. The earliest measurements involved the ultraviolet irradiation of metal surfaces. The theoretical interpretation of this phenomenon, known as the photoelectric effect, played an important role in establishing quantum mechanics. It was shown that, contrary to classical ideas, energy exchanges between radiation and matter are mediated by integral numbers of photons. In the gas phase the photoeffect is called either photoionization (atoms, molecules, and their positive ions) or photodetachment (atomic and molecular negative ions). *See* Photoemission.

Photoionization involves a radiative bound-free transition from an initial state consisting of n photons and an atom, molecule, or ion in a bound state to a final continuum state consisting of a residual ion (or an atom in the case of photodetachment) and m free electrons: that is,

$$nh\nu + X \rightarrow X^{m+} + me^{-}$$

In the simplest atomic photoionization process a single electron is ejected from an atom following the absorption of a single photon. Each mode of fragmentation defines a final-state channel that is characterized by the energy and angular momentum of the outgoing electron as well as the excitation state of the residual ion. Since the photoionization process is endoergic, each channel has a well-defined threshold energy below which the channel is energetically closed. The threshold photon energy for a particular channel is equal to the binding energy of the electron that is to be ejected plus the excitation energy, if any, of the residual ion.

Above threshold, the energy carried off by the outgoing electron represents the balance between the energy supplied by the photon and the binding energy of the electron plus the excitation energy of the residual ion (neglecting the small recoil of the heavy ion). A photoelectron spectrum is characterized by a discrete set of peaks, each peak being associated with a particular state of the residual ion. Information on the excitation state of the ion following photoionization can also be obtained by monitoring the fluorescence emitted in the subsequent radiative decay of the state. One of the earliest applications of photoionization measurements was the investigation of the structure of atoms by determining the binding energies of both outer- and inner-shell electrons by means of photoelectron spectroscopy. *See* Atomic structure and spectra; Electron spectroscopy. [D.J.Pe.]

Photoluminescence

A luminescence excited in a body by some form of electromagnetic radiation incident on the body. The term photoluminescence is generally limited to cases in which the incident radiation is in the ultraviolet, visible, or infrared regions of the electromagnetic spectrum.

Photoluminescence may be either a fluorescence or a phosphorescence, or both. Energy can be stored in certain luminescent materials by subjecting them to light or some other exciting agent, and can be released by subsequent illumination of the material with light of certain wavelengths. This type of photoluminescence is called stimulated photoluminescence. *See* Fluorescence; Luminescence; Phosphorescence. [C.C.K.; J.H.S.]

Photolysis

The chemical decomposition of matter due to absorption of incident light. For example, illumination of microcrystals of silver bromide embedded in gelatin results in formation of metallic silver, and is the basis of the photographic process. *See* Photographic materials.

Numerous metal complexes, azides, nitrides, and sulfides, and most organometallic compounds undergo decomposition upon illumination, often with concomitant evolution of a gaseous product. In the presence of water and oxygen, illumination of many semiconductors results in their corrosion; for example, an aqueous suspension of cadmium sulfide (CdS) undergoes rapid decomposition upon irradiation with sunlight. The outcome of these photochemical processes can often be controlled by addition of adventitious materials. For example, illumination of cadmium sulfide in aqueous solution containing hydrogen sulfide (H_2S) and colloidal platinum results in evolution of hydrogen gas. Here, the semiconductor photosensitizes (or photocatalyzes) decomposition of hydrogen sulfide into its elements, and the reaction can be used to remove sulfides from industrial waste. *See* Coordination complexes; Semiconductor.

Many ketones, for example, acetone, abstract hydrogen atoms from adjacent organic matter under illumination. According to the circumstances, the resultant free radicals may be used to initiate polymerization of a monomer or cause decomposition of a plastic film. Both reactions have important commercial applications, and photoinitiators are commonly used for emulsion paints, inks, polymers, explosives, fillings for teeth and for development of photodegradable plastics. Photolysis of carbonyl compounds, released into the atmosphere by combustion of fossil fuels, is responsible for the onset of photochemical smog. Many other types of photochemical transformation of organic molecules are known, including isomerization of unsaturated bonds, cleavage of carbon-halogen bonds, olefin addition reactions, halogenation of aromatic species, hydroxylation, and oxygenation processes. Indeed, photochemistry is often used to produce novel pharmaceutical products that are difficult to synthesize by conventional methods. *See* FREE RADICAL; PHOTODEGRADATION; SMOG.

The most important photochemical reaction is green plant photosynthesis. Here, chlorophyll that is present in the leaves absorbs incident sunlight and catalyzes reduction of carbon dioxide to carbohydrate. *See* PHOTOSYNTHESIS.

Excitation of an organic molecule results in spontaneous generation of the singlet excited state. In most molecules, this highly unstable excited singlet state may undergo an intersystem-crossing process that results in population of the corresponding (less energetic) excited triplet state, in competition to fluorescence. The excited triplet state, because of spin restriction rules, retains a significantly longer lifetime than is found for the corresponding excited singlet state, and may be formed in high yield.

Almost without exception, these triplet states react quantitatively with molecular oxygen (O_2) present in the system via a triplet energy-transfer process. The resulting product is singlet molecular oxygen. This species is a potent and promiscuous reactant, and it is responsible for widespread damage to both synthetic and natural environments. Indeed, plants and photosynthetic bacteria contain carotenoids to protect the organism against attack by singlet oxygen. The same species is known to be responsible, at least in part, for photodegradation of paint, plastic, fabric, colored paper, and dyed wool. Secondary reactions follow from attack on a substrate by singlet oxygen, resulting in initiation of chain reactions involving free radicals. However, modern technological processes have evolved in which singlet molecular oxygen is used to destroy unwanted organic matter, such as tumors, viruses, and bacteria, in a controlled and specific manner. In photodynamic therapy a dye is injected into a tumor and selectively illuminated with laser light. The resultant singlet oxygen destroys the tumor. Similar methodology can be used to produce photoactive soap powders, bleaches, bactericides, and pest-control reagents. *See* CHAIN REACTION (CHEMISTRY); FLUORESCENCE; TRIPLET STATE. [A.Ha.]

Photometer An instrument used for making measurements of light, or electromagnetic radiation, in the visible range. In general, photometers may be divided into two classifications: laboratory photometers, which are usually fixed in position and yield results of high accuracy; and portable photometers, which are used in the field or outside the laboratory and yield results of lower accuracy. Each class may be subdivided into visual (subjective) photometers and photoelectric (objective or physical) photometers. These in turn may be grouped according to function, such as photometers to measure luminous intensity (candelas or candlepower), luminous flux, illumination (illuminance), luminance (photometric brightness), light distribution, light reflectance and transmittance, color, spectral distribution, and visibility. Visual photometric methods have largely been supplanted commercially by physical methods, but because of their simplicity, visual methods are still used in educational laboratories to demonstrate photometric principles. *See* ILLUMINANCE; LUMINANCE; LUMINOUS FLUX; LUMINOUS INTENSITY. [G.A.Ho.]

Photometry That branch of science which deals with measurements of light (visible electromagnetic radiation) according to its ability to produce visual sensation. Specifically, photometry deals with the attribute of light that is perceived as intensity, while the related attribute of light that is perceived as color is treated in colorimetry. *See* COLOR; COLORIMETRY.

The purely physical attributes of light such as energy content and spectral distribution are treated in radiometry. Sometimes the word photometry is used to denote measurements that have nothing to do with human vision, but this is a mistake according to modern usage. Such measurements are properly referred to as radiometry, even if they are performed in the visible spectral region. *See* RADIOMETRY.

The relative visibility of a fixed power level of monochromatic electromagnetic radiation varies with wavelength over the visible spectral region (400–700 nanometers). The relative visibility of radiation also depends upon the illumination level that is being observed. The cone cells in the retina determine the visual response at high levels of illumination, while the rod cells dominate in the dark-adapted eye at very low levels (such as starlight). Cone-controlled vision is called photopic, and rod-controlled vision is called scotopic, while the intermediate region where both rods and cones play a role is called mesopic. *See* VISION.

Originally, photometry was carried out by using the human visual sense as the detector of light. As a result, photometric measurements were subjective. In order to put photometric measurements on an objective basis, and to allow convenient electronic detectors to replace the eye in photometric measurements, the Commission Internationale de l'Eclairage (CIE; International Commission on Illumination) has adopted two relative visibility functions as standards. These internationally accepted functions are called the spectral luminous efficiency functions for photopic and scotopic vision, and are denoted by $V(\lambda)$ and $V'(\lambda)$, respectively. *See* LUMINOUS EFFICIENCY.

Thus photopic and scotopic (but not mesopic) photometric quantities have objective definitions, just as do the purely physical quantities. However, there is a difference. The purely physical quantities are defined in terms of physical laws, whereas the photometric quantities are defined by convention. In recognition of this difference the photometric quantities are called psychophysical quantities.

According to the International System of Units, SI, the photometric units are related to the purely physical units through a defined constant called the maximum spectral luminous efficacy. This quantity, which is denoted by K_m, is the number of lumens per watt at the maximum of the $V(\lambda)$ function. K_m is defined in SI to be 683 lm/W for monochromatic radiation whose wavelength is 555 nanometers, and this defines the photometric units with which the photometric quantities are to be measured.

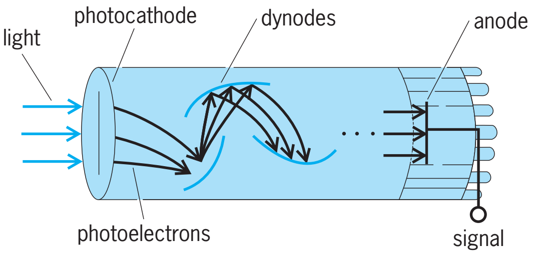
At various times, the photometric units have been defined in terms of the light from different standard sources, such as candles made according to specified procedures, and blackbodies at the freezing point of platinum. According to these definitions, K_m was a derived, rather than defined, quantity. *See* ILLUMINATION; LIGHT; PHYSICAL MEASUREMENT; UNITS OF MEASUREMENT. [J.Gei.]

Photomorphogenesis The regulatory effect of light on plant form, involving growth, development, and differentiation of cells, tissues, and organs. Morphogenic influences of light on plant form are quite different from light effects that nourish the plant through photosynthesis, since the former usually occur at much lower energy levels than are necessary for photosynthesis. Light serves as a trigger in photomorphogenesis, frequently resulting in energy expenditure orders of magnitude larger than the amount required to induce a given response. Photomorphogenic processes determine the nature and direction of a plant's growth and thus play a key role in its ecological adaptations to various environmental changes. *See* PHOTOSYNTHESIS.

Morphogenically active radiation is known to control seed and spore germination, growth and development of stems and leaves, lateral root initiation, opening of the hypocotyl or epicotyl hook in seedlings, differentiation of the epidermis, formation of epidermal hairs, onset of flowering, formation of tracheary elements in the stem, and form changes in the gametophytic phase of ferns, to mention but a few of such known phenomena. Many nonmorphogenic processes in plants are also basically controlled by light independent of photosynthesis. Among these are chloroplast movement, biochemical reactions involved in the synthesis of flavonoids, anthocyanins, chlorophyll, and carotenoids, and leaf movements in certain legumes. [W.R.Br.]

Photomultiplier A very sensitive vacuum-tube detector of light or radiant flux containing a photocathode which converts the light to photoelectrons; one or more secondary-electron-emitting electrodes or dynodes which amplify the number of photoelectrons; and an output electrode or anode which collects the secondary electrons and provides the electrical output signal. It is also known as a multiplier phototube. Because of the very large amplification provided by the secondary-emission mechanism, and the very short time variation associated with the passage of the electrons within the device, the photomultiplier is applied to the detection and measurement of very low light levels, especially if very high speed of response is required.

The illustration is a schematic of a typical photomultiplier and shows its operation. Light incident on a semitransparent photocathode located inside an evacuated envelope causes photoelectron emission from the opposite side of the photocathode. The efficiency of the photoemission process is called the quantum efficiency, and is the ratio of emitted photoelectrons to incident photons (light particles). Photoelectrons are directed by an accelerating electric field to the first dynode, where from 3 to 30 secondary electrons are emitted for each incedent electron, depending upon the dynode material and the applied voltage. These secondaries are directed to the second dynode, where the process is repeated and so on until the multiplied electrons from the last dynode are collected by the anode.



Schematic of a photomultiplier. (*After P. W. Engstrom, Photomultipliers—then and now, RCA Eng., 24(1):18–26, June–July 1978*)

A typical photomultiplier may have 10 stages of secondary emission and may be operated with an overall applied voltage of 2000 V. In most photomultipliers the focusing of the electron streams is done by electrostatic fields shaped by the design of the electrodes. Some special photomultipliers designed for very high speed utilize crossed electrostatic and magnetic fields which direct the electrons in approximate cycloidal paths between electrodes.

Ever since their invention, photomultipliers have been found useful in low-level photometry and spectrometry. The most important applications of photomultipliers are related to scintillation counting, and these form the basis of a whole science of tracer chemistry that has been applied to agriculture, medicine, and industrial problems. In medicine, photomultiplier-scintillator combinations are used in the gamma-ray camera, computerized tomography, and the positron scanner. *See* COMPUTERIZED TOMOGRAPHY; GAMMA-RAY DETECTORS; NUCLEAR MEDICINE; RADIOLOGY; SCINTILLATION COUNTER. [R.W.E.]

Photon An entity that can be loosely described as a quantum of energy of electromagnetic radiation. According to classical electromagnetic theory, an electromagnetic wave can transfer arbitrarily small amounts of energy to matter. According to the quantum theory of radiation, however, the energy is transferred in discrete amounts. The energy of a photon is the product of Planck's constant and the frequency of the electromagnetic field. In addition to energy, the photon possesses momentum and also possesses angular momentum corresponding to a spin of unity. The interaction of radiation with matter involves the absorption, scattering, and emission of photons. Consequently, the energy interchange is inherently quantized. *See* ANGULAR MOMENTUM; ENERGY; MOMENTUM; SPIN (QUANTUM MECHANICS).

For many purposes, the photon behaves like a particle of zero rest mass moving at the speed of light. The particlelike nature of the photon is vividly exhibited by the photoelectric effect, predicted by A. Einstein, in which light is absorbed in a metal, causing electrons to be ejected. An electron absorbs a photon, gaining its energy. In leaving the metal, it loses energy because of interactions with the surface; the energy loss equals the product of the so-called work function of the surface and the charge of the electron. The final kinetic energy of the electron therefore equals the energy of the incident photon minus this energy loss. *See* PHOTOEMISSION.

A second demonstration of the particlelike behavior of photons is provided by the scattering of an x-ray photon from an electron bound in an atom. The electron recoils because of the momentum of the photon, thereby gaining energy. As a result, the frequency, and hence the wavelength of the scattered x-ray, is altered. If the x-ray is scattered through a certain angle, the wavelength is shifted by an amount determined by this scattering angle and the mass of an electron, according to the laws of conservation of energy and momentum. *See* COMPTON EFFECT.

From a more fundamental view, the photon is the quantum of excitation of a single mode of a radiation field. The dynamical equations for the electric and magnetic energy in such a field are identical to those of a harmonic oscillator. According to quantum theory, the allowed energies of a harmonic oscillator are given by $E = (j + {}^1\!/_2)hf$, where h is Planck's constant, f is the frequency of the oscillator, and the quantum number $j = 0, 1, 2, \ldots$, describes the state of excitation of the oscillator. This quantum relation was first postulated by M. Planck for the material oscillators in the walls of a thermal enclosure in order to obtain the correct form for the density of radiation in a thermal field, but it was quickly applied by Einstein to describe the state of the radiation field itself. In this picture, j describes the number of photons in the field. *See* HARMONIC OSCILLATOR; NONRELATIVISTIC QUANTUM THEORY; QUANTUM ELECTRODYNAMICS; QUANTUM MECHANICS. [D.Kl.]

Photoperiodism The growth, development, or other responses of organisms to the length of night or day or both. Photoperiodism has been observed in plants and animals, but not in bacteria (prokaryotic organisms), other single-celled organisms, or fungi.

A true photoperiodism response is a response to the changing day or night. Some species respond to increasing day lengths and decreasing night lengths (for example, by forming flowers or developing larger gonads); this is called a long-day response. Other species may exhibit the same response, or the same species may respond in some different way, to decreasing days and increasing nights; this is a short-day response. Sometimes a response is independent or nearly independent of day length, and is said to be day-neutral. There are many plant responses to photoperiod. These include development of reproductive structures in lower plants (mosses) and in flowering plants; rate of flower and fruit development; stem elongation in many herbaceous species as well as coniferous and deciduous trees (usually a long-day response and possibly the most widespread photoperiodism response in higher plants); autumn leaf drop and formation of winter dormant buds (short days); development of frost hardiness (short days); formation of roots on cuttings; formation of many underground storage organs such as bulbs (onions, long days), tubers (potato, short days), and storage roots (radish, short days); runner development (strawberry, short day); balance of male to female flowers or flower parts (especially in cucumbers); aging of leaves and other plant parts; and even such obscure responses as the formation of foliar plantlets (such as the minute plants formed on edges of *Bryophyllum* leaves), and the quality and quantity of essential oils (such as those produced by jasmine plants). Note that a single plant, for example, the strawberry, might be a short-day plant for one response and a long-day plant for another response.

Animal responses. There are also many responses to photoperiod in animals, including control of several stages in the life cycle of insects (for example, diapause) and the long-day promotion in birds of molting, development of gonads, deposition of body fat, and migratory behavior. Even feather color may be influenced by photoperiod (as in the ptarmigan). In several mammals the induction of estrus and spermatogenic activity is controlled by photoperiod (sheep, goat, snowshoe hare), as is fur color in certain species (snowshoe hare). Growth of antlers in American elk and deer can be controlled by controlling day length. Increasing day length causes antlers to grow, whereas decreasing day length causes them to fall off. By changing day lengths rapidly, a cycle of antler growth can be completed in as little as 4 months; slow changes can extend the cycle to as long as 2 years. When attempts are made to shorten or extend these limits even more, the cycle slips out of photoperiodic control and reverts to a 10–12-month cycle, apparently controlled by an internal annual "clock."

Seasonal responses. Response to photoperiod means that a given manifestation will occur at some specific time during the year. Response to long days (shortening nights) normally occurs during the spring, and response to short days (lengthening nights) usually occurs in late summer or autumn. Since day length is accurately determined by the Earth's rotation on its tilted axis as it revolves in its orbit around the Sun, detection of day length provides an extremely accurate means of determining the season at a given latitude. Such other environmental factors as temperature and light levels also vary with the seasons but are clearly much less dependable from year to year.

Mechanisms. It has long been the goal of researchers on photoperiodism to understand the plant or animal mechanisms that account for the responses. Light must be detected, the duration of light or darkness must be measured, and this time measurement must be metabolically translated into the observed response: flowering, stem elongation, gonad development, fur color, and so forth. Basic mechanisms differ not only between plants and animals but among different species as well. The roles (synchronization, anticipation, and so on) are similar in all organisms that exhibit photoperiodism, but the mechanisms through which these roles are achieved are apparently quite varied.

Strongest inhibition of flowering in short-day plants comes when the light interruption occurs around the time of the critical night (about 7–9 h for cocklebur plants), but actual effectiveness also depends on the length of the dark period. With short-day cockleburs, the shorter the night, the less the flowering and the longer the time that light inhibits flowering.

Orange-red wavelengths used as a night interruption are by far the most effective part of the spectrum in inhibition of short-day responses and promotion of long-day responses (flowering in most studies), and effects of orange-red light can be completely reversed by subsequent exposure of plants to light of somewhat longer wavelengths, called far-red light. These observations led in the early 1950s to discovery of the phytochrome pigment system, which is apparently the molecular machinery that detects the light effective in photoperiodism of higher plants. *See* PHYTOCHROME.

In photoperiodism of short-day plants, an optimum response is usually obtained when phytochrome is in the far-red receptive form during the day and the red-receptive form during the night. Although normal daylight contains a balance of red and far-red wavelengths, the red-receptive form is most sensitive, so the pigment under normal daylight conditions is driven mostly to the far-red receptive form. At dusk this form is changed metabolically, and the red-receptive form builds up. It is apparently this shift in the form of phytochrome that initiates measurement of the dark period. This is how a plant "sees": when the far-red-sensitive form of the pigment is abundant, the plant "knows" it is in the light; the red-sensitive form (or lack of far-red form) indicates to the plant's biochemistry that it is in the dark.

The measurement of time—the durations of the day or night—is the very essence of photoperiodism. The discovery of a biological clock in living organisms was made in the late 1920s. It was shown that the movement of leaves on a bean plant (from horizontal at noon to vertical at midnight) continued uninterruptedly for several days, even when plants were placed in total darkness and at a constant temperature, and that the time between given points in the cycle (such as the most vertical leaf position) was almost but not exactly 24 h. In the case of bean leaves, it was about 25.4 h. Many other cycles have now been found with similar characteristics in virtually all groups of plants and animals. There is strong evidence that the clocks are internal and not driven by some daily change in the environment. Such rhythms are called circadian.

Circadian rhythms usually have period lengths that are remarkably temperature-insensitive, which is also true of time measurement in photoperiodism. Furthermore, the rhythms are normally highly sensitive to light, which may shift the cycle to some extent. Thus, daily rhythms in nature are normally synchronized with the daily cycle as the Sun rises and sets each day. Their circadian nature appears only when they are allowed to manifest themselves under constant conditions of light (or darkness) and temperature, so that their free-running periods can appear. [F.B.S.]

Photophore gland A highly modified integumentary gland which arises from an epithelial invagination into the dermis. It becomes cut off from its site of origin and develops into a luminous organ composed of a lens and a light-emitting gland, at the back of which is a pigmented reflector of probably dermal-cell origin. These luminous bodies occur in deep-sea teleosts and elasmobranchs which live in areas of total darkness. *See* EPITHELIUM; GLAND. [O.E.N.]

Photoreception The process of absorption of light energy by plants and animals and its utilization for biologically important purposes. In plants photoreception plays an essential role in photosynthesis and an important role in orientation. Photoreception in animals is the initial process in vision. *See* PHOTOSYNTHESIS; TAXIS; VISION.

The photoreceptors of animals are highly specialized cells or cell groups which are light-sensitive because they contain pigments which are unstable in the presence of light of appropriate wavelengths. These light-sensitive receptor pigments absorb radiant energy and then undergo physicochemical changes, which lead to the initiation of nerve impulses that are conducted to the central nervous system. *See* EYE (INVERTEBRATE); EYE (VERTEBRATE). [V.J.W.]

Photorespiration Light-dependent carbon dioxide release and oxygen uptake in photosynthetic organisms caused by the fixation of oxygen instead of carbon dioxide during photosynthesis. This oxygenation reaction forms phosphoglycolate, which represents carbon lost from the photosynthetic pathway. Phosphoglycolate also inhibits photosynthesis if it is allowed to accumulate in the plant. The reactions of photorespiration break down phosphoglycolate and recover 75% of the carbon to the photosynthetic reaction sequence. The remaining 25% of the carbon is released as carbon dioxide. Photorespiration reduces the rate of photosynthesis in plants in three ways: carbon dioxide is released; energy is diverted from photosynthetic reactions to photorespiratory reactions; and competition between oxygen and carbon dioxide reduces the efficiency of the important photosynthetic enzyme ribulose-bisphosphate (RuBP) carboxylase. There is no known function of the oxygenation reaction; most scientists believe it is an unavoidable side reaction of photosynthesis. *See* PHOTOSYNTHESIS.

The rate of photosynthesis can be stimulated as much as 50% by reducing photorespiration. Since photosynthesis provides the material necessary for plant growth, photorespiration inhibits plant growth by reducing the net rate of carbon dioxide assimilation (photosynthesis). Plants grow faster and larger under nonphotorespiratory conditions, in either low oxygen or high carbon dioxide atmospheres. Most of the beneficial effects on plant growth achieved by increasing CO_2 may result from the reduced rate of photorespiration. *See* PLANT GROWTH.

There are some plants that avoid photorespiration under certain conditions by actively accumulating carbon dioxide inside the cells that have ribulose-bisphosphate carboxylase/oxygenase. Many cacti do this by taking up carbon dioxide at night and then releasing it during the day to allow normal photosynthesis. These plants are said to have crassulacean acid metabolism (CAM). Another group of plants, including corn (*Zea mays*), take up carbon dioxide by a special accumulating mechanism in one part of the leaf, then transport it to another part of the leaf for release and fixation by normal photosynthesis. The compound used to transport the carbon dioxide has four carbon atoms, and so these plants are called C_4 plants. Plants that have no mechanism for accumulating carbon dioxide produce the three-carbon compound phosphoglycerate directly and are therefore called C_3 plants. Most species of plants are C_3 plants. *See* PLANT RESPIRATION. [T.D.S.]

Photosphere The apparent, visible surface of the Sun. The photosphere is a gaseous atmospheric layer a few hundred miles deep with a diameter of 864,000 mi (1,391,000 km; usually considered the diameter of the Sun) and an average temperature of approximately 5800 K (10,500°F). Radiation emitted from the photosphere accounts for most of the solar energy flux at the Earth.

Convective cells give the photosphere a granular appearance with bright cells (hot rising gas) surrounded by dark intergranular lanes (cool descending gas). A typical granule is approximately 600 mi (1000 km) in diameter. Measurements of horizontal velocity reveal a larger convective pattern, the supergranulation; the horizontal motion of individual granules reveals intermediate-scale convective flows. *See* SUN. [S.L.K.]

Photosynthesis The manufacture in light of organic compounds (primarily certain carbohydrates) from inorganic materials by chlorophyll- or bacteriochlorophyll-containing cells. This process requires a supply of energy in the form of light. In chlorophyll-containing plant cells and in cyanobacteria, photosynthesis involves oxidation of water (H_2O) to oxygen molecules, which are released into the environment. In contrast, bacterial photosynthesis does not involve O_2 evolution—instead of H_2O, other electron donors, such as H_2S, are used. This article will focus on photosynthesis in plants. *See* BACTERIAL PHYSIOLOGY AND METABOLISM; CHLOROPHYLL; PLANT RESPIRATION.

The light energy absorbed by the pigments of photosynthesizing cells, especially by the pigment chlorophyll or bacteriochlorophyll, is efficiently converted into stored chemical energy. Together, the two aspects of photosynthesis—the conversion of inorganic into organic matter, and the conversion of light energy into chemical energy—make it the fundamental process of life on Earth: it is the ultimate source of all living matter and of all life energy.

The net overall chemical reaction of plant photosynthesis is shown in the equation below, where $\{CH_2O\}$ stands for a carbohydrate (sugar).

$$H_2O + CO_2 + \text{light energy} \xrightarrow[\text{enzymes}]{\text{chlorophyll}} \{CH_2O\} + O_2$$

The photochemical reaction in photosynthesis belongs to the type known as oxidation-reduction, with CO_2 acting as the oxidant (hydrogen or electron acceptor) and water as the reductant (hydrogen or electron donor). The unique characteristic of this particular oxidation-reduction is that it goes "in the wrong direction" energetically; that is, it converts chemically stable materials into chemically unstable products. Light energy is used to make this "uphill" reaction possible.

Photosynthesis is a complex, multistage process. Its main parts are (1) the primary photochemical process in which light energy absorbed by chlorophyll is converted into chemical energy, in the form of some energy-rich intermediate products; and (2) the enzyme-catalyzed "dark" (that is, not photochemical) reactions by which these intermediates are converted into the final products—carbohydrates and free oxygen.

Experiments suggest that plants contain two pigment systems. One (called photosystem I, or PS I, sensitizing reaction I) contains the major part of chlorophyll *a*; the other (called photosystem II, or PS II, sensitizing reaction II) contains some chlorophyll *a* and the major part of chlorophyll *b* or other auxiliary pigments (for example, the red and blue pigments, called phycobilins, in red and blue-green algae, and the brown pigment fucoxanthol in brown algae and diatoms). It appears that efficient photosynthesis requires the absorption of an equal number of light quanta in PS I and in PS II; and that within both systems excitation energy undergoes resonance migration from one pigment to another until it ends in special molecules of chlorophyll *a* called the reaction centers. The latter molecules then enter into a series of chemical reactions that result in the oxidation of water to produce O_2 and the reduction of nicotinamide adenine dinucleotide phosphate ($NADP^+$). Chromatophores from photosynthetic bacteria and chloroplasts from green plants, when illuminated in the presence of adenosine diphosphate (ADP) and inorganic phosphate, also use light energy to synthesize adenosine triphosphate (ATP); this photophosphorylation could be associated with some energy-releasing step in photosynthesis. [G.; R.Gov.]

The light-dependent conversion of radiant energy into chemical energy as ATP and reduced nicotinamide adenine

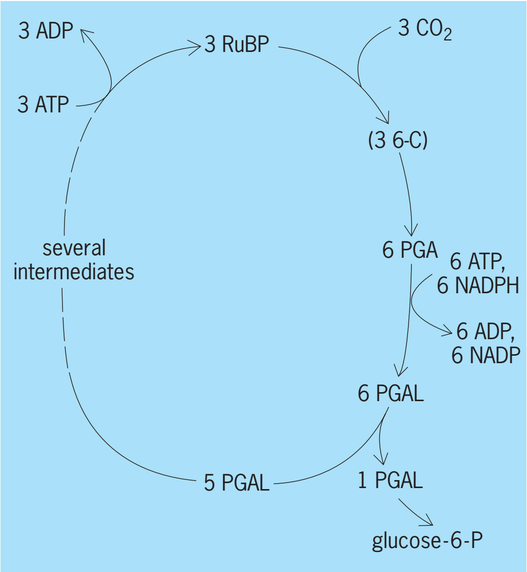


Fig. 1. Schematic outline of the Calvin (C_3) carbon dioxide assimilation cycle.

dinucleotide phosphate (NADPH) serves as a prelude to the utilization of these compounds for the reductive fixation of CO_2 into organic molecules. Such molecules, broadly designated as photosynthates, are usually but not invariably in the form of carbohydrates such as glucose polymers or sucrose, and form the base for the nutrition of all living things. Collectively, the biochemical processes by which CO_2 is assimilated into organic molecules are known as the photosynthetic dark reactions, not because they must occur in darkness, but because light—in contrast to the photosynthetic light reactions—is not required.

C_3 photosynthesis. The essential details of C_3 photosynthesis can be seen in Fig. 1. Three molecules of CO_2 combine with three molecules of the five-carbon compound ribulose bisphosphate (RuBP) in a reaction catalyzed by RuBP carboxylase to form three molecules of an enzyme-bound six-carbon compound. These are hydrolyzed into six molecules of the three-carbon compound phosphoglyceric acid (PGA), which are phosphorylated by the conversion of six molecules of ATP (releasing ADP for photophosphorylation via the light reactions). The resulting compounds are reduced by the NADPH formed in photosynthetic light reactions to form six molecules of the three-carbon compound phosphoglyceraldehyde (PGAL). One molecule of PGAL is made available for combination with another three-carbon compound, dihydroxyacetone phosphate, which is isomerized from a second PGAL (requiring a second "turn" of the Calvin-cycle wheel) to form a six-carbon sugar. The other five PGAL molecules, through a complex series of enzymatic reactions, are rearranged into three molecules of RuBP, which can again be carboxylated with CO_2 to start the cycle turning again. The net product of two "turns" of the cycle, a six-carbon sugar (glucose-6-phosphate) is formed either within the chloroplast in a pathway leading to starch (a polymer of many glucose molecules), or externally in the cytoplasm in a pathway leading to sucrose (condensed from two six-carbon sugars, glucose and fructose).

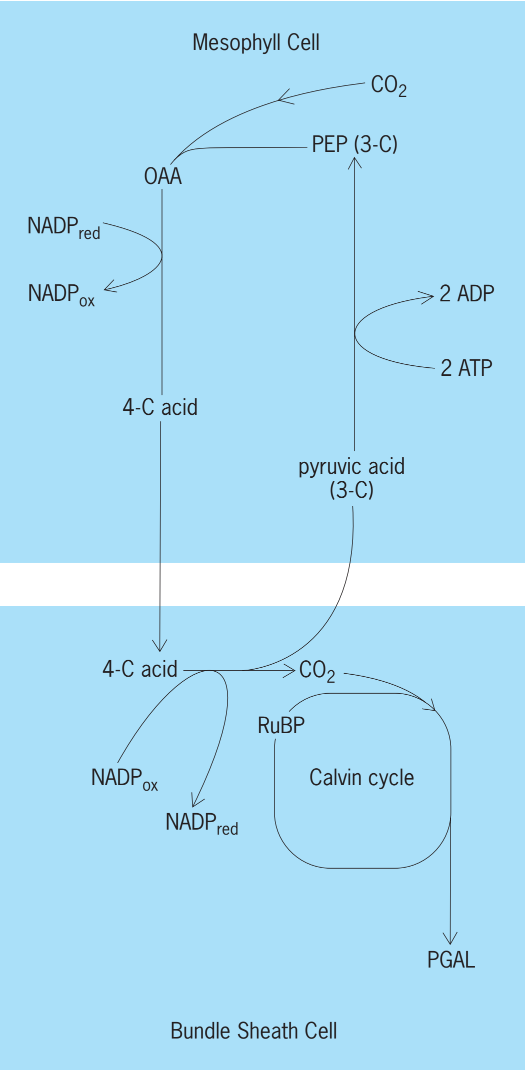

Fig. 2. Schematic outline of the Hatch-Slack (C_4) carbon dioxide assimilation route in two cell types of a NADP-ME-type plant.

C_4 photosynthesis. Initially, the C_3 cycle was thought to be the only route for CO_2 assimilation, although it was recognized by plant anatomists that some rapidly growing plants (such as maize, sugarcane, and sorghum) possessed an unusual organization of the photosynthetic tissues in their leaves (Kranz morphology). It was then demonstrated that plants having the Kranz anatomy utilized an additional CO_2 assimilation route now known as the C_4-dicarboxylic acid pathway (Fig. 2). Carbon dioxide enters a mesophyll cell, where it combines with the three-carbon compound phosphoenolpyruvate (PEP) to form a four-carbon acid, oxaloacetic acid, which is reduced to malic acid or transaminated to aspartic acid. The four-carbon acid moves into bundle sheath cells, where the acid is decarboxylated, the CO_2 assimilated via the C_3 cycle, and the resulting three-carbon compound, pyruvic acid, moves back into the mesophyll cell and is transformed into PEP, which can be carboxylated again. The two cell types, mesophyll and bundle sheath, are not necessarily adjacent, but in all documented cases of C_4 photosynthesis the organism had two distinct types of green cells. C_4 metabolism is classified into three types, depending on the decarboxylation reaction used with the four-carbon acid in the bundle sheath cells:

1. NADP-ME type (sorghum):

$$\text{NADP}^+ + \text{malic acid} \xrightarrow[\text{enzyme}]{\text{NADP-malic}} \text{pyruvic acid} + CO_2 + \text{NADPH}$$

2. NAD-ME type (*Atriplex* species):

$$\text{NAD}^+ + \text{malic acid} \xrightarrow[\text{enzyme}]{\text{NAD-malic}} \text{pyruvic acid} + CO_2 + \text{NADH}$$

3. PCK type (*Panicum* species):

$$\text{Oxaloacetic acid} + \text{ATP} \xrightarrow{\substack{\text{phosphoenol}\\ \text{pyruvate}\\ \text{carboxykinase}}} \text{PEP} + CO_2 + \text{ADP}$$

CAM photosynthesis. Under arid and desert conditions, where soil water is in short supply, transpiration during the day when temperatures are high and humidity is low may rapidly deplete the plant of water, leading to desiccation and death. By keeping stomata closed during the day, water can be conserved, but the uptake of CO_2, which occurs entirely through the stomata, is prevented. Desert plants in the Crassulaceae, Cactaceae, Euphorbiaceae, and 15 other families evolved, apparently independently of C_4 plants, an almost identical strategy of assimilating CO_2 by which the CO_2 is taken in at night when the stomata open; water loss is low because of the reduced temperatures and correspondingly higher humidities. First studied in plants of the Crassulaceae, the process has been called crassulacean acid metabolism (CAM).

In contrast to C_4, where two cell types cooperate, the entire process occurs within an individual cell; the separation of C_4 and C_3 is thus temporal rather than spatial. At night, CO_2 combines with PEP through the action of PEP carboxylase, resulting in the formation of oxaloacetic acid and its conversion into malic acid. The PEP is formed from starch or sugar via the glycolytic route of respiration. Thus, there is a daily reciprocal relationship between starch (a storage product of C_3 photosynthesis) and the accumulation of malic acid (the terminal product of nighttime CO_2 assimilation). [M.G.; G.A.B.]

Phototransistor A semiconductor device with electrical characteristics that are light-sensitive. Phototransistors differ from photodiodes in that the primary photoelectric current is multiplied internally in the device, thus increasing the sensitivity to light. *See* PHOTODIODE; TRANSISTOR.

Some types of phototransistors are supplied with a third, or base, lead. This lead enables the phototransistor to be used as a switching, or bistable, device. The application of a small amount of light causes the device to switch from a low current to a high current condition. *See* PHOTOELECTRIC DEVICES. [W.R.Si.]

Phototube An electron tube comprising a photocathode and an anode mounted within an evacuated glass envelope through which radiant energy is transmitted to the photocathode. A gas phototube contains, in addition, argon or other inert gas which provides amplification of the photoelectric current by partial ionization of the gas. The photocathode emits electrons when it is exposed to ultraviolet, visible, or near-infrared radiation. The anode is operated at a positive potential with respect to the photocathode. *See* ELECTRICAL CONDUCTION IN GASES; ELECTRON TUBE.

A phototube responds to radiation over a limited range of the spectrum that is determined by the photocathode material. Radiant sensitivity is the photoelectric current emitted per unit of incident monochromatic radiant power. *See* PHOTOEMISSION.

Quantum efficiency, or photoelectron yield, is the number of electrons emitted per incident photon. For photometric applications a useful parameter is luminous sensitivity: the photoelectric current per lumen incident from a specified source of light. A source commonly used is a tungsten-filament lamp operated at a color temperature of 4700°F (2870 K). *See* INCANDESCENCE; LUMINOUS FLUX; PHOTON.

Photocathodes are semiconductors which contain one or more of the alkali metals sodium, potassium, rubidium, or cesium chemically combined with bismuth, antimony, or silver oxide. The cathode surface contains a critical excess of the alkali metal which enhances photoelectric emission by decreasing the affinity of the surface for electrons. Negative affinity for electrons is achieved with the gallium arsenide:cesium (GaAs:Cs) and indium gallium arsenide:cesium (InGaAs:Cs) photocathodes used in photomultipliers. Phototubes also emit electrons thermionically at ambient temperatures. This "dark current," observed in the absence of all irradiance, increases almost exponentially with temperature. Thermionic emission from the cesium antimonide (CsSb) photocathode is about 10^{-15} A/cm^2 at 68°F (20°C). *See* PHOTOMULTIPLIER; SEMICONDUCTOR.

Vacuum phototubes are used as detectors of radiant energy in the spectral range from 200 to 1100 nanometers. Since the photoelectric current is directly proportional to the intensity of the radiation, these tubes are used in radiometers, photometers, and colorimeters. By virtue of their narrow pulse response, vacuum phototubes are also used to measure the intensity of very short pulses of light generated by lasers and visible nuclear radiation. Gas phototubes can be used in light-operated relays and for the reproduction of sound from motion picture film, although their response to intensity-modulated light is limited to frequencies below 15 kHz. Vacuum as well as phototubes have been replaced in many applications by semiconductor photodiodes and photovoltaic cells. *See* COLORIMETRY; LASER; PHOTODIODE; PHOTOMETER; PHOTOVOLTAIC CELL; RADIOMETRY. [J.L.We.]

Photovoltaic cell A device that detects or measures electromagnetic radiation by generating a current or a voltage, or both, upon absorption of radiant energy. Specially designed photovoltaic cells are used for power generation, as in solar batteries or solar cells, and for sensitive detection of electromagnetic radiation in radiometry, optical communications, spectroscopy, and other applications. An important advantage of the photovoltaic cell in these particular applications is that no separate bias supply is needed—the device generates a signal (voltage or current) simply by the absorption of radiation.

Most photovoltaic cells consist of a semiconductor *pn* junction or Schottky barrier in which electron-hole pairs produced by absorbed radiation are separated by the internal electric field in the junction to generate a current, a voltage, or both, at the device terminals. Under open-circuit conditions (current $I = 0$) the terminal voltage increases with increasing light intensity, and under short-circuit conditions (voltage $V = 0$) the magnitude of the current increases with increasing light intensity. When the current is negative and the voltage is positive, the photovoltaic cell delivers power to the external circuit. In this case, if the source of radiation is the Sun, the photovoltaic cell is referred to as a solar battery or solar cell. When a photovoltaic cell is used as a photographic exposure meter, it produces a current proportional to the light intensity, which is indicated by a low-impedance galvanometer or microammeter. For use as sensitive detectors of infrared radiation, specially designed photovoltaic cells can be operated with either low-impedance (current) or high-impedance (voltage) amplifiers, although the lowest noise and highest sensitivity are achieved in the current or short-circuit mode. Another mode of operation of a *pn* junction diode as a photodetector involves the application of a reverse bias voltage to the diode. In this case, the photogenerated current is directly proportional to the incident power, and the diode is said to be operated in the photodiode mode rather than the photovoltaic mode. *See* EXPOSURE METER; JUNCTION DIODE; OPTICAL DETECTORS; PHOTODIODE; PHOTOELECTRIC DEVICES; PHOTOVOLTAIC EFFECT; RADIOMETRY; SEMICONDUCTOR; SEMICONDUCTOR DIODE; SOLAR CELL. [G.E.Sti.]

Photovoltaic effect The conversion of electromagnetic radiation into electric power through absorption by a semiconducting material. Devices based on this effect serve as power sources in remote terrestrial locations and for satellites and other space applications. Photovoltaic powered calculators and other consumer electronic products are widely available, and solar photovoltaic automobiles and aircraft have been demonstrated.

The basic requirements for the photovoltaic effect are (1) the absorption of photons through the creation of electron-hole pairs in a semiconductor; (2) the separation of the electron and hole so that their recombination is inhibited and the electric field within the semiconductor is altered; and (3) the collection of the electrons and holes, separately, by each of two current-collecting electrodes so that current can be induced to flow in a circuit external to the semiconductor itself.

There are many approaches to achieving these three requirements simultaneously. A very common approach for separating the electrons from the holes is to use a single-crystal semiconductor, for example, silicon, into which a *pn* junction has been diffused. Silicon is often chosen because its optical band gap permits the absorption of a substantial portion of solar photons via the generation of electron-hole pairs. The fabrication of such a device structure causes a local transfer of negative charges from the *n* layer into the *p* layer, bending the conduction and valence bands in the vicinity of the *p-n* boundary, and thereby creating a rectifying junction. Electrons generated in the *p* region can lower their energy by migrating into the *n* region, which they will do by a random walk process in the electric-field-free region far from the junction, or by drift induced by the electric field in the junction region. Holes created in the *n* region, conversely, lose energy by migrating into the *p* region. Thus the presence of such a junction leads to the spontaneous spatial separation of the photogenerated carriers, thereby inducing a voltage difference between current-carrying electrodes connected to the *p* and *n* regions. This process will continue until the difference in potential between the two electrodes is large enough to flatten the bands in the vicinity of the junction, canceling out the internal electric field existing there and so eliminating the source of carrier separation. The resulting voltage is termed the open-circuit voltage, and approximates the built-in voltage associated with the *pn* junction in the dark, a value which cannot exceed the band gap of the semiconductor. *See* HOLE STATES IN SOLIDS; SEMICONDUCTOR; SEMICONDUCTOR DIODE.

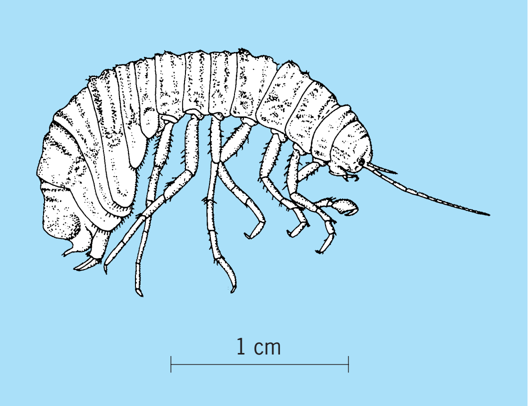
In the limit when the device is short-circuited by the external circuit, no such buildup of potential can occur. In this case, one electron flows in the external circuit for each electron or hole which crosses the junction, that is, for each optically generated electron-hole pair which is successfully separated by the junction. The resulting current is termed the short-circuit current and, in most practical photovoltaic devices, approaches numerically the rate at which photons are being absorbed within the device. Losses can arise from the recombination of minority carriers (for example, electrons in the *p*-type region, holes in the *n*-type region) with majority carriers. *See* ELECTRON-HOLE RECOMBINATION.

For a photovoltaic device to generate power, it is necessary to provide a load in the external circuit which is sufficiently resistive to avoid short-circuiting the device. In this case, the voltage will be reduced compared to the open-circuit voltage because a continuing requirement exists for carrier separation at the junction; thus some band bending and its associated internal field must be retained.

Various multiple-layered device configurations based on doped and undoped alloys of amorphous silicon have been developed for photovoltaic devices used in applications ranging from solar watches and calculators to remote power generators. The photovoltaic effect in these devices is particularly intriguing since it is possible to build up so-called tandem devices by stacking one device electrically and optically in series above another. In addition to the increased voltage and concomitant reduction in the required current-carrying capability of electrode grid structures, such devices permit, in principle, an increased efficiency of solar photovoltaic energy conversion. *See* SOLAR CELL. [J.P.deN.]

Phreatoicoidea A suborder of the Isopoda and class Crustacea. The body is subcylindrical, appearing laterally compressed, mainly because of the downward development of the pleura of the pleon (see illustration). The first and occasionally the second thoracic segment is fused with the head. Antennules are shorter than the antennae. The eyes may be large, small, or absent. Mouthparts are primitive.

The suborder is divided into two families, the Amphisopidae, and the Phreatoicidae. The suborder is an ancient one and includes a fossil, *Protamphisopus wianamattensis*, from the Triassic beds of New South Wales. Three extant species are recorded from Australia, Tasmania, New Zealand, and South Africa and one that is subterranean from India. Most species occur in fresh water. Several are blind, subterranean forms and one occurs in hot water from deep artesian bores. A few are semiterrestrial, burrowing forms. [E.M.S.]



Onchotelson brevicaudatus, **adult male.**

Phrynophiurida An order of Ophiuroidea in which the vertebrae usually articulate by means of hourglass-shaped surfaces and the arms are able to coil upward or downward in the vertical plane. There is usually a leathery integument, in which calcareous granules or platelets are embedded. Most species are found in deep water. Of the families, the Gorgonocephalidae often have branched arms, the Asteronychidae have a large disk and slender arms, and the Asteroschematidae have a small disk and stout arms.

These families share a number of characteristics and are grouped in one suborder, Euryalina. One remaining family, the Ophiomyxidae, differs in having a soft, unprotected integument. *See* OPHIUROIDEA. [H.B.F.]

Phycobilin Any member of a class of intensely colored pigments found in some algae that absorb light for photosynthesis. Phycobilins are structurally related to mammalian bile pigments, and they are unique among photosynthetic pigments in being covalently bound to proteins (phycobiliproteins). In at least two groups of algae, phycobiliproteins are aggregated in a highly ordered protein complex called a phycobilisome.

Phycobilins occur only in three groups of algae: cyanobacteria (blue-green algae), Rhodophyta (red algae), and Cryptophyceae (cryptophytes), and are largely responsible for their distinctive colors, including blue-green, yellow, and red. Five different phycobilins have been identified to date, but the two most common are phycocyanobilin, a blue pigment, and phycoerythrobilin, a red pigment. In the cell, these pigments absorb light maximally in the orange (620-nanometers) and green (550-nm) portion of the visible light spectrum, respectively. A blue-green light (495-nm) absorbing pigment, phycourobilin, is found in some cyanobacteria and red algae. A yellow light (575-nm) absorbing pigment, phycobiliviolin (also called cryptoviolin) is apparently found in all cryptophytes but in only a few cyanobacteria. A fifth phycobilin, which absorbs deep-red light (697 nm), has been identified spectrally in some cryptophytes, but its chemical properties are unknown. *See* CRYPTOPHYCEAE; CYANOPHYCEAE; RHODOPHYCEAE.

Phycobilins are associated with the photosynthetic light-harvesting system in chloroplasts of red algae and cryptophytes and with the photosynthetic membranes of cyanobacteria, which lack chloroplasts. Phycobilins are covalently bound to a water-soluble protein that aggregates on the surface of the photosynthetic membrane. All other photosynthetic pigments (for example, chlorophylls and carotenoids) are bound to photosynthetic membrane proteins by hydrophobic attraction. Phycobiliprotein can constitute a major fraction of an alga. In some cyanobacteria, phycobiliproteins can account for more than 50% of the soluble protein and one-quarter of the dry weight of the cell. *See* CELL PLASTIDS.

Phycobilins are photosynthetic accessory pigments that absorb light efficiently in the yellow, green, orange, or red portion of the light spectrum, where chlorophyll *a* only weakly absorbs. Light energy absorbed by phycobilins is transferred with greater than 90% efficiency to chlorophyll *a*, where it is used for photosynthesis. *See* CHLOROPHYLL; PHOTOSYNTHESIS. [T.M.K.]

Phylactolaemata A class of ectoproct bryozoans. Phylactolaemates have lophophores which usually are markedly U-shaped (or rarely nearly circular but still kidney-shaped) in basal outline, and relatively short, wide zooecia; these animals dwell only in fresh waters. *See* BRYOZOA; LOPHOPHORE.

Phylactolaemate colonies are either encrusting threadlike networks of relatively isolated zooecia with solid chitinous uncalcified walls, or small to large masses of gelatinous material in which the individual zooids are embedded side-by-side without definite separating zooecial walls. Stolons are not present.

Only a few (about 50) phylactolaemate species exist, all classified in a single order, the Plumatellida (or Plumatellina). Exclusively fresh-water, the phylactolaemates may have evolved relatively recently from ctenostomes, although some workers have suggested that phylactolaemates might be very primitive ectoprocts surviving as evolutionary relics. *See* CTENOSTOMATA.

[R.J.Cu.]

Phyllite A type of metamorphic rock formed during low-grade metamorphism of clay-rich sediments called pelites. Phyllites are very fine grained rocks with a grain size barely visible in a hand specimen. They have a well-developed planar element called cleavage defined by alignment of mica grains and interlayering of quartz-rich and mica-rich domains. Typically, mica grains show the greater alignment, although other mineral components (quartz, carbonate, and feldspars) may show a preferred shape orientation. Where all minerals of a particular type show the same degree of alignment and the fabric is well developed throughout the rock, the fabric is termed a penetrative fabric. Cleavage surfaces in phyllites have a glittery, lustrous sheen due to light reflecting off grains of chlorite and muscovite. The mineralogy of phyllites is dependent on chemical composition; typical minerals in phyllites are chlorite, muscovite, and quartz. Other minerals that may be present in phyllites formed during low-grade metamorphism include chlorotoid, garnet (rarely), sodium-mica, and sulfide minerals. *See* CHLORITE; MUSCOVITE; QUARTZ.

Phyllite is found in most regionally metamorphosed terranes in the world, including the Appalachians of eastern North America, the Scottish Highlands, and the Alps. *See* METAMORPHIC ROCKS.

[M.W.N.]

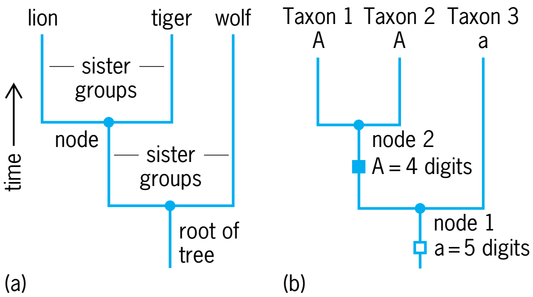
Phyllocarida A subclass of the crustacean class Malacostraca containing the extant order Leptostraca and the fossil order Archiostraca. The Phyllocarida has a long fossil record, and many early fossil taxa were referred to this subclass. However, studies of presumed phyllocarids from the Burgess Shale have shown that only the archiostracans agree with the definition of the Phyllocarida.

Phyllocarids are distinct from other malacostracan crustaceans because of two other characteristics considered to reflect the primitive condition, which strengthen the hypothesis of early separation from the main evolutionary line. The first is the presence of a bivalve carapace. The second is an abdomen consisting of seven fully formed somites and terminating in a telson that bears caudal rami. *See* CRUSTACEA; LEPTOSTRACA; MALACOSTRACA.

[P.A.McL.]

Phylogeny The genealogical history of organisms, both living and extinct. Phylogeny represents the historical pattern of relationships among organisms which has resulted from the actions of many different evolutionary processes. Phylogenetic relationships are depicted by branching diagrams called cladograms, or phylogenetic trees. Cladograms show relative affinities of groups of organisms called taxa. Such groups of organisms have some genealogical unity, and are given a taxonomic rank such as species, genera, families, or orders. For example, two species of cats—say, the lion (*Panthera leo*) and the tiger (*Panthera tigris*)—are more closely related to each other than either is to the gray wolf (*Canis latrans*). The family including all cats, Felidae, is more closely related to the family including all dogs, Canidae, than either is to the family that includes giraffes, Giraffidae. The lion and tiger, and the Felidae and Canidae, are called sister taxa because of their close relationship relative to the gray wolf, or to the Giraffidae, respectively.

Cladograms thus depict a hierarchy of relationships among a group of taxa (illus. *a*). Branch points, or nodes, of a cladogram represent hypothetical common ancestors (not specific real ancestors), and the branches connect descendant sister taxa. If the taxa being considered are species, nodes are taken to signify speciation events. The goal of the science of cladistics, or phylogenetic analysis, is to discover these sister-group (cladistic) relationships and to identify what are termed monophyletic groups—two or more taxa postulated to have a single, common origin.



Phylogenetic trees. (*a*) A tree representing a hierarchical pattern of sister-group relationships (those taxa descended from a common ancestor). (*b*) Relationships are determined by identifying derived characters; in this case the condition of five digits is primitive, whereas the loss of a digit is derived and unites taxa 1 and 2.

The acceptance of a cladogram depends on the empirical evidence that supports it relative to alternative hypotheses of relationship for those same taxa. Evidence for or against alternative phylogenetic hypotheses comes from the comparative study of the characteristics of those taxa. Similarities and differences are determined by comparison of the anatomical, behavioral, physiological, or molecular [such as deoxyribonucleic acid (DNA) sequences] attributes among the taxa. A statement that two features in two or more taxa are similar and thus constitute a shared character is, in essence, a preliminary hypothesis that they are homologous; that is, the taxa inherited the specific form of the feature from their common ancestor. However, not all similarities are homologs; some are developed independently through convergent or parallel evolution, and although they may be similar in appearance, they had different histories and thus are not really the same feature. In cladistic theory, shared homologous similarities are either primitive (plesiomorphic condition) or derived (apomorphic condition), whereas nonhomologous similarities are termed homoplasies (or sometimes, parallelisms or convergences). This distinction over concepts and terminology is important because only derived characters constitute evidence that groups are actually related.

As evolutionary lineages diversify, some characters will become modified. Examples include the enlargement of forelimbs or the loss of digits on the hand. Thus, during evolution the foot of a mammal might transform from a primitive condition of having five digits to a derived form with only four digits (illus. *b*). Following branching at node 1, the foot in one lineage undergoes an evolutionary modification involving the loss of a digit (expressed as character state A). A subsequent branching event then produced taxa 1 and 2, which inherited that derived character. The lineage leading to taxon 3, however, retained the primitive condition of five digits (character state a). The presence of the shared derived character, A, is called a synapomorphy, and identifies taxa 1 and 2 as being more closely related to each other than either is to taxon 3. Distinguishing between the primitive and derived conditions of a character within a group of taxa (the ingroup) is usually accomplished by comparisons to groups postulated to have more distant relationships (outgroups). Character states that are present in ingroups but not outgroups are postulated to be derived. Systematists have developed computer programs that attempt to identify shared derived characters (synapomorphies) and, at the same time, use them to construct the best phylogenetic trees for the available data.

Knowledge of phylogenetic relationships provides the basis for classifying organisms. A major task of the science of systematics is to search for monophyletic groups. Some groups, such as birds and mammals, are monophyletic; that is, phylogenetic analysis suggests they are all more closely related to each other than to other vertebrates. However, other traditional groups, such as reptiles, have been demonstrated to be nonmonophyletic (some so-called reptiles, such as dinosaurs and their relatives, are more closely related to birds than they are to other reptiles such as snakes). Classifications based on monophyletic groups are termed natural classifications. Phylogenies are also essential for understanding the distributional history, or biogeography, of organisms. Knowing how organisms are related to one another helps the biogeographer to decipher relationships among areas and to reconstruct the spatial histories of groups and their biotas. *See* ANIMAL EVOLUTION; ANIMAL SYSTEMATICS; BIOGEOGRAPHY; TAXONOMIC CATEGORIES. [J.Cr.]

Phymosomatoida

An order of regular sea urchins, class Echinoidea, characterized by imperforate tubercles, complex ambulacral compounding in which one or more elements are occluded from the perradial suture, and a stirodont lantern with unfused epiphyses. They comprise two families.They first appeared in the Lower Jurassic and are probably paraphyletic, since they include the ancestors of camarodonts. The two extant genera are each known from a single species: *Glyptocidaris*, from a depth of 30–490 ft (10–150 m) around northen Japan, and *Stomechinus*, a common inhabitant of rocky shores around the Indo-West Pacific. They are epifaunal grazers. *See* ECHINODERMATA; ECHINOIDEA. [A.Sm.]

Physical anthropology

The subfield of anthropology that deals with human and nonhuman primate evolution, the biological bases of human behavior, and human biological variability and its significance. Some refer to the field as biological anthropology in order to signal the close links with other biological sciences. The term physical anthropology is largely an American and British invention; in most European and many other countries physical anthropologists are the only anthropologists, while persons who study behavioral aspects of the human condition are known as archeologists, ethnologists, linguists, or prehistorians.

Paleoanthropology. Paleoanthropology is the multidisciplinary study of human evolution as evidenced by fossils, artifacts, and their geological and burial site contexts. Physical anthropologists organize expeditions and direct excavations that lead to discoveries of fossil Hominidae, and then engage in the painstaking repair and reconstruction of specimens, their anatomical description, comparison with other specimens, and placement in hominid phylogeny. *See* FOSSIL HUMANS.

Morphological paleoanthropologists must have detailed knowledge of human and other primate anatomy and the principles of taxomony in order to restore and interpret their discoveries. In addition to traditional anatomical descriptions and measurements, it is requisite that the variations in samples be presented and, when possible, be tested for statistical significance. Because of the fragmentary nature of many fossils, one of the most difficult problems is to decide whether the new discoveries belong with previously described species or represent new undescribed ones.

Paleoprimatology. Physical anthropologists also look to nonhuman primates for clues to human physical history and status as mammals, and for analogies to the behavior and cognitive abilities of human ancestors. Like paleoanthropologists, paleoprimatologists employ methods of other paleobiologists to collect, describe, and interpret fossil specimens phylogenetically and functionally. Contextual information, including the manner in which specimens were deposited and their possible alteration over time, is vital. *See* FOSSIL PRIMATES.

Comparative primate morphology. Recent primates, including humans, are the current end products of evolution. Anatomical studies of modern primates are essential for reconstructing the morphologies of fossil forms and for revealing their singularity. Carefully controlled comparative studies on extant primates hold the greatest promise for modeling the functional morphology, physiology, and habitat preferences of extinct forms. Since 1970, advanced techniques and concepts from rehabilitation medicine, orthopedics, orthodontics, radiology, and neurology have been used to establish a truly functional morphology of the primates.

Molecular anthropology. The explosion of molecular biology that followed the cracking of the genetic code attracted physical anthropologists who wished to test hypotheses about the propinquity of humans with the apes, and the relationships of other primates to one another and to other creatures. Some have endeavored to find "molecular clocks" that could tell when species diverged from one another. Assuming that genetic changes occur at fairly steady rates and given a few well-dated fossils, the time when the living species may have branched from one another can be calculated. *See* MOLECULAR ANTHROPOLOGY.

Primate behavior and ecology. Although firmly rooted in comparative psychology, behavioral primatology has also become a major section of physical anthropology; anthropologists have contributed mainly through field studies. An original goal of primate field studies by anthropologists was to find predictable relationships between specific habitats and the patterns of sociality of the primates that inhabit them. Because of their close genetic relationships to humans, chimpanzees have emerged as the most popular model for early hominid sociality. But theorists emphasizing different aspects of their behavior arrive at markedly different models for early hominid behavior.

Human variation. The term human variation is rapidly replacing its historical predecessor "race" in anthropology because the latter carries so much negative connotation. Many scientists believe that the concept of race should be abandoned. Instead, researchers should simply record the gene frequencies and biological traits of human populations that are otherwise identified only by their geographic localities. This genotypic and phenotypic information would be interpreted in terms of historical and proximate selective forces in each environment. *See* HUMAN GENETICS; HUMAN VARIATION.

Skeletal biology. Some skeletal biologists have adopted functional approaches from primatological anthropology, and have been discerning the genetic determinants of nonmetric (discrete) and measurable (continuous) traits that would allow them to document the local history of burial populations in an area.

Paleopathology. Human bones and teeth sometimes reflect diseases and mechanical trauma during the lifetime of an individual. Rehydrated soft tissues of mummies may show evidence of parasitic infestations and lesions, such as those from cancer and tuberculosis. Such studies allow reasonable correlations of disease features with demography, ecology, diet, and social factors. *See* PALEOPATHOLOGY.

Growth, physique, and aging. The field of growth studies has developed robustly as part of physical anthropology since the 1940s. Standards for the appearance and ossification of bones and for sexual maturation have been established so that congenital, nutritional, and other environmental effects can be detected and often corrected clinically in children and adolescents. It has been established from global nutritional surveys that small adult size is correlated with dietary insufficiency. Since 1975, physical anthropologists have begun to apply anthropometric and microscopic techniques to the study of aging in an effort to understand why some people have greater longevity. *See* AGING; NUTRITION.

Nutritional anthropology. Refined chemical assays promise to reveal past diets from hominid skeletal remains. Hence paleonutrition has emerged as a special focus for technical research. Trace elements, such as strontium (Sr), sodium (Na), zinc (Zn), and calcium (Ca), may indicate the nutrients that were incorporated in bones, so that classes of food items can be inferred. The kind of carbon (C^{12}–C^{13} ratios) in bones may indicate the types of plants that were eaten. This is an important tool for following the spread of maize agriculture in the New World. Protein and vitamin D deficiencies are indicated by flatness of the skull base relative to the skulls of better-nourished people.

Blood group genetics and disease. Many human features such as stature, head shape, epidermal pigmentation, and fingerprints are caused by undetermined multifactorial genetic systems whose phenotypic expression is commonly affected by environmental factors. In contrast, the genetics of blood group systems (such as ABO, MNS, and Rh) are based on single gene loci and are well understood. *See* BLOOD GROUPS; FINGERPRINT; POPULATION GENETICS.

Human adaptability and ecology. *Homo sapiens* is one of the most versatile species on Earth. The invention and ramification of culture has permitted people to survive on impoverished islands and in climatic extremes of high altitude, deserts, and polar regions. In addition to many clever technological and social conventions, people show physiological and ontogenetic characteristics that enhance their survival and ability to work in harsh environments. The extent to which these features are genetically determined is still largely unknown. *See* HUMAN ECOLOGY.

Forensic anthropology. Forensic anthropology is growing quickly, as anthropologists are called as expert witnesses regarding not only classic sorts of criminal evidence (fingerprints, blood types, and skeletal remains) but also grisly exhibits such as bloody footprints and bite marks on murder victims. In criminal cases, forensic anthropologists operate best if contextual evidence is preserved, particularly when the victims were hidden in graves. Here the techniques of field archeology can be as important as those of physical anthropology. *See* ANTHROPOLOGY; ARCHEOLOGY; FORENSIC ANTHROPOLOGY. [R.H.Tu.]

Physical chemistry

The branch of chemistry that deals with the interpretation of chemical phenomena and properties in terms of the underlying physical processes, and with the development of techniques for their investigation. The term chemical physics is often employed to denote a branch of physical chemistry where the emphasis is on the interpretation and analysis of the physical properties of individual molecules and bulk systems, instead of their reactions. Theoretical chemistry is another major branch, where the emphasis is on the calculation of the properties of molecules and systems, and which used the techniques of quantum mechanics and statistical thermodynamics. It is convenient to regard physical chemistry as dealing with three aspects of matter: its equilibrium properties, structure, and ability to change.

Equilibrium properties. The study of matter in a state of equilibrium constitutes the field of chemical thermodynamics. In particular, chemical thermodynamics provides a technique for discussing the response of a system to a change in the external conditions (such as the shift in the boiling and freezing point of either a pure substance or a mixture when the applied pressure is changed, or when the composition of the mixture is modified), and for rationalizing the energy changes that occur in the course of a chemical reaction. The branch of thermodynamics dealing with the latter is called thermochemistry. Chemical thermodynamics also provides a framework for the determination of the maximum amount of work that may be generated by a system undergoing a specified change, and it therefore provides a way of establishig bounds for the efficiencies of a variety of devices, including engines, refrigerators, and electrochemical cells. Thermodynamics is used in chemistry to assess the position of equilibrium of a chemical reaction (that is, how far it will proceed), and to determine what conditions are necessary in order to optimize the yield of a particular product. The branch of chemical thermodynamics dealing with ionic reactions occurring in the presence of electrodes constitutes the field of equilibrium electrochemistry. *See* CHEMICAL EQUILIBRIUM; CHEMICAL THERMODYNAMICS; ELECTROCHEMISTRY; ENTHALPY; ENTROPY; FREE ENERGY; THERMOCHEMISTRY.

Structure. The principal role of quantum mechanics in chemistry is in the discussion of atomic and molecular structure, and in the interpretation of spectroscopic data. In the branch of physical chemistry known as computational quantum chemistry, interest centers on the numerical solution of the Schrödinger equation in order to obtain wave functions and geometries of molecules. Computational quantum chemistry is so developed that it is capable of being used to map the changes in the structures of molecules while they are in the course of reaction, when atoms and groups of atoms are being transferred from one molecule to another. *See* QUANTUM CHEMISTRY; SCHRÖDINGER'S WAVE EQUATION.

Spectroscopic techniques are used not only to identify molecules present in a sample, but also to determine their shape, size, and electron distribution. The techniques fall into four categories: absorption spectroscopy, emission spectroscopy, Raman spectroscopy, and resonance techniques. *See* ELECTRON PARAMAGNETIC RESONANCE (EPR) SPECTROSCOPY; ELECTRON SPECTROSCOPY; MOLECULAR STRUCTURE AND SPECTRA; MÖSSBAUER EFFECT; NUCLEAR MAGNETIC RESONANCE (NMR); PHOTOCHEMISTRY; RAMAN EFFECT; SPECTROSCOPY.

Techniques for the investigation of molecular structure based on diffraction depend on the observation of the direction through which radiation and particles are scattered when they impinge on a sample. Other techniques for investigating structure include the electric and magnetic properties of molecules, in particular, the determination of electric polarizabilities and dipole moments, magnetic properties, and the properties based on optical birefringenece, such a optical activity and the Faraday effect. *See* X-RAY DIFFRACTION.

Structural properties and thermodynamic properties are brought together by statistical thermodynamics. This major theoretical procedure gives a way of predicting the thermodynamic properties of assemblies of molecules in terms of their individual energy levels.

Physical and chemical change. The third major branch of physical chemistry is concerned with change: physical change and chemical change. In particular, it is concerned with the rate of change. Physical change includes the diffusion of one substance into another, or the migration of ions in an electrode solution. The application of thermodynamics to change in general constitutes the field of nonequilibrium thermodynamics. *See* GAS; TRANSPORT PROCESSES.

Chemical change may be studied at a variety of levels. Empirical chemical kinetics is the study of reactions in order to determine how their rates depend on the concentrations of the participants in the reaction and on the conditions, mainly the temperature. Investigation of the time dependence of reactions yields a detailed picture of the sequence of molecular transformations involved in a complex chemical reaction. *See* CHEMICAL DYNAMICS; SHOCK TUBE; ULTRAFAST MOLECULAR PROCESSES.

An important extension of chemical kinetics is to the reactions that occur on surfaces; these are the processes involved in heterogeneous catalysis. A special application of surface chemistry is to the stability of colloidal suspensions of species in fluids, and another is to the processes that occur at the interface between an electrode and the solution in which it is immersed. *See* ADSORPTION; COLLOID; HETEROGENEOUS CATALYSIS; SURFACE PHYSICS. [P.W.A.]

Physical geography

The study of the Earth's surface features and associated processes. Physical geography aims to explain the geographic patterns of climate, vegetation, soils, hydrology, and landforms, and the physical environments that result from their interactions. Physical geography merges with human geography to provide a synthesis of the complex interactions between nature and society.

The basic content of physical geography comprises a number of areas of specialization. Climatology, the scientific study of climates, concerns the total complex of weather conditions at a given location over an extended time period; it deals not only with average conditions but with extremes and variations. Geomorphology is the interpretive description and explanation of landforms and the fluvial, glacial, coastal, and eolian process that operate on them. The forms, processes, and patterns within the biosphere, including vegetation and animal distributions, are studied as biogeography. With strong ties to fluvial geomorphology, geographic hydrology concerns the scientific study of water from the aspects of distribution, movement, and utilization. Soil geography, with emphasis on the origin, characteristics, classification, and utilization potential of soils, provides an area of specialization with links to land use. Ultimately, the physical geography of a region is understood through an integration of the multiple aspects. [J.E.O.]

Physical law

A term that designates four different concepts: (1) objective pattern (or natural regularity), (2) formula purporting to represent an objective pattern, (3) law-based rule (or uniform procedure), and (4) principle concerning any of the preceding.

For example, Newton's second law of motion, $ma = F$, is a law of type 2. It represents, to a good approximation, the actual behavior (law of type 1) of medium-size particles moving slowly relative to the speed of light. Alternative laws of motion, such as the relativistic and quantum-mechanical ones, are different laws of type 2 representing the same objective pattern or law of type 1 to even better approximations. One of the rules (laws of type 3) associated with Newton's second law of motion is: In order to set in motion a stationary particle, exert a force on it. Another is: In order to stop a moving particle, exert on it a force in the opposite direction. An example of a law of type 4 is: Newton's laws of motion are invariant under a Galileo transformation. *See* NEWTON'S LAWS OF MOTION.

A physical law of type 1, or objective pattern, is a constant relation among two or more properties of a physical entity. In principle, any such pattern can be conceptualized in different ways, that is, as alternative laws of type 2. The history of theoretical physics is to a large extent a sequence of laws of type 2. Every one of these is hoped to constitute a more accurate representation of the corresponding objective pattern or law of type 1, which is assumed to be constant and, in particular, untouched by human efforts to grasp it. Likewise, the history of engineering is to some extent a sequence of laws of type 3, or law-based rules of action, of which there are least two for every law of type 2. As for the laws of type 4, or laws of laws, they are of two kinds: scientific and philosophical. The general covariance principle is of the first kind, whereas the hypothesis that all events are lawful is a philosophical thesis. Unlike the former, whose truth can be checked, the principle of lawfulness is irrefutable. *See* ENGINEERING; THEORETICAL PHYSICS.

Not all formulas are called physical laws. For example, the regularities found by curve fitting are called empirical formulas. In physics a formula is called a law if and only if it meets the following conditions: it is part of a theory, and it has been satisfactorily confirmed by measurement or experiment at least within a certain domain (for example, for small mass densities or high field intensities). Thus, the basic assumptions of all the standard physical theories are laws, and so are their logical consequences. In particular, the usual variational principles, such as Hamilton's, are basic laws. However, the equations of motion and field equations entailed by such principles are derived laws (theorems); so are the conservation laws entailed by the equations of motion and field equations. However, the distinction between basic and derived laws is contextual: what is a principle in one theory may be a theorem in another. For example, Newton's second law of motion is a theorem in analytical dynamics, and the first principle of thermodynamics is a theorem of statistical mechanics. *See* CONSERVATION LAWS (PHYSICS); CURVE FITTING; HAMILTON'S PRINCIPLE; PHYSICAL THEORY; SCIENTIFIC METHODS; STATISTICAL MECHANICS; THERMODYNAMIC PRINCIPLES; VARIATIONAL METHODS (PHYSICS). [M.Bun.]

Physical measurement

Quantitative information on physical conditions, properties, or relations essential for coordination of activities, efficiency of communication, and understanding of the nature of things in science and engineering and in much of everyday life. Time, distance, mass, temperature, force, power, and all other physical quantities (or parameters or variables), as well as the properties of matter, materials, and devices, must be described and measured in terms which have the same meaning for everyone. The measuring device or instrument is calibrated (that is, the functional relationship between its indication and the magnitude of the measured quantity is determined) by direct or indirect comparison with a standard which embodies, possesses, or generates a fixed or reproducible magnitude of the physical quantity which is taken as the unit or some multiple or fraction of the unit. Any measured quantity may thus be expressed by a number (the magnitude ratio) and the name of the unit, for example, a length of 1.54 meters. The general area of scientific activity relating to standards and units and the accuracy of measurement is called metrology. *See* UNITS OF MEASUREMENT.

Metric system. The basic unit of length in the decimal metric system was defined as one ten-millionth of the Earth's polar quadrant (as determined from latitude surveys), and is termed the meter. The basic unit for mass was defined as the mass of a cubic decimeter of water, to be called the kilogram.

The United States has adopted the Metric Conversion Act, declaring that "the policy of the U.S. shall be to coordinate and plan the increasing use of the metric system in the United States," and established the U.S. Metric Board "to coordinate the voluntary conversion to the metric system." However, English units have become almost universal in some worldwide industries—for example, dimensions of oil-drilling equipment, or altitude measurement in aviation. Thus it is likely that there will always be exceptions to uniformity, requiring special knowledge of special units for at least some people even as the whole world "goes metric" in principle.

International System of Units (SI). At present the International System of Units (abbreviated SI, from the French Système International d'Unités) is constructed from seven base units for independent quantities (Table 1). Units for all other quantities are derived from these seven units. In Table 2 are listed 22 SI derived units with special names. These units are derived from the base units in a coherent manner, which means they are expressed as products and quotients of the seven base units without numerical factors. All other SI derived units are similarly derived in a coherent manner from the 29 base and special-name SI units. For use with the SI units, there is a set of 20 prefixes (Table 3) to form multiples and submultiples of these units. For mass, the prefixes are to be applied to the gram instead of to the SI unit, the kilogram. *See* DIMENSIONAL ANALYSIS.

The SI units together with the SI prefixes provide a logical and interconnected framework for measurements in science, industry, and commerce.

In some cases, quantities are commonly expressed in terms of

Table 1. SI base units

Quantity*	Unit name	Symbol
Length	meter	m
Mass	kilogram	kg
Time	second	s
Electric current	ampere	A
Thermodynamic temperature	kelvin	K
Amount of substance	mole	mol
Luminous intensity	candela	cd

*Quantity here and in Table 2 means a measurable attribute.

Table 2. SI derived units with special names

Quantity	Unit name	Symbol	Expression in terms of other units	Expression in terms of SI base units
Plane angle	radian	rad		$m \cdot m^{-1} = 1$
Solid angle	steradian	sr		$m^2 \cdot m^{-2} = 1$
Frequency	hertz	Hz		s^{-1}
Force	newton	N		$m \cdot kg \cdot s^{-2}$
Pressure, stress	pascal	Pa	N/m^2	$m^{-1} \cdot kg \cdot s^{-2}$
Energy, work, quantity of heat	joule	J	$N \cdot m$	$m^2 \cdot kg \cdot s^{-2}$
Power, radiant flux	watt	W	J/s	$m^2 \cdot kg \cdot s^{-3}$
Quantity of electricity, electric charge	coulomb	C	$A \cdot s$	$s \cdot A$
Electric potential difference, electromotive force, voltage	volt	V	W/A	$m^2 \cdot kg \cdot s^{-3} \cdot A^{-1}$
Capacitance	farad	F	C/V	$m^{-2} \cdot kg^{-1} \cdot s^4 \cdot A^2$
Electric resistance	ohm	Ω	V/A	$m^2 \cdot kg \cdot s^{-3} \cdot A^{-2}$
Electric conductance	siemens	S	A/V	$m^{-2} \cdot kg^{-1} \cdot s^3 \cdot A^2$
Magnetic flux	weber	Wb	$V \cdot s$	$m^2 \cdot kg \cdot s^{-2} \cdot A^{-1}$
Magnetic flux density	tesla	T	Wb/m^2	$kg \cdot s^{-2} \cdot A^{-1}$
Inductance	henry	H	Wb/A	$m^2 \cdot kg \cdot s^{-2} \cdot A^{-2}$
Celsius temperature	degree Celsius	°C		K
Luminous flux	lumen	lm	$cd \cdot sr$	$m^2 \cdot m^{-2} \cdot cd = cd$
Illuminance	lux	lx	lm/m^2	$m^2 \cdot m^{-4} \cdot cd = m^{-2} \cdot cd$
Activity (of a radionuclide)	becquerel	Bq		s^{-1}
Absorbed dose, specific energy imparted, kerma	gray	Gy	J/kg	$m^2 \cdot s^{-2}$
Dose equivalent	sievert	Sv	J/kg	$m^2 \cdot s^{-2}$
Catalytic activity	katal	kat		$s^{-1} \cdot mol$

fundamental constants of nature, and use of these constants or "natural units" is acceptable. *See* FUNDAMENTAL CONSTANTS.

Typical examples of natural units, with their symbols, are:

elementary charge	e
electron mass	m_e
proton mass	m_p
Bohr radius	a_0
electron radius	r_e
Compton wavelength of electron	λ_c
Bohr magneton	μ_B
nuclear magneton	μ_N
speed of light	c
Planck constant	h

Certain units which are not part of the SI are used so widely that it is impractical to abandon them. The units that are accepted for continued use with the International System are listed in Table 4. It is likewise necessary to recognize, outside the International System, the following units which are used in specialized fields:

electronvolt	eV
unified atomic mass unit	u
astronomical unit	AU
parsec	pc

Logarithmic measures such as pH, dB (decibel), and Np (neper) are acceptable. *See* ASTRONOMICAL UNIT; ATOMIC MASS UNIT; DECIBEL; ELECTRONVOLT; NEPER; PARSEC; PH.

Table 3. SI prefixes

Factor	Prefix	Symbol	Factor	Prefix	Symbol
10^{24}	yotta	Y	10^{-1}	deci	d
10^{21}	zetta	Z	10^{-2}	centi	c
10^{18}	exa	E	10^{-3}	milli	m
10^{15}	peta	P	10^{-6}	micro	μ
10^{12}	tera	T	10^{-9}	nano	n
10^9	giga	G	10^{-12}	pico	p
10^6	mega	M	10^{-15}	femto	f
10^3	kilo	k	10^{-18}	atto	a
10^2	hecto	h	10^{-21}	zepto	z
10^1	deka	da	10^{-24}	yocto	y

The internationally accepted definitions for the seven base units follow:

Mass. The kilogram (kg) is equal to the mass of the International Prototype Kilogram. The International Prototype is a platinum-iridium cylinder preserved at the International Bureau of Weights and Measures at Sèvres, France.

Mass is the only one of the base quantities for which the standard is an arbitrarily defined object. No basic property of matter involving mass can be measured with more precision than is possible in comparing kilogram masses by weighing, about 1 part in 10^8. *See* BALANCE; MASS; WEIGHT MEASUREMENT. [W.A.Wi.]

Length. The meter is defined in terms of time and the speed of light: "The meter is the length of the path traveled by light in a vacuum during a time interval of 1/299 792 458 of a second." This definition defines the speed of light to be exactly 299 792 458 m/s and defines the meter in terms of the most accurately known quantity, the second. *See* LIGHT.

The most accurate method of realizing the meter is by means of an interferometrically measured distance by fringe counting in which each vacuum fringe is a half wavelength from the next one. This wavelength, λ, is obtained from the measured frequency, f,

Table 4. Units in use with the International System

Name	Symbol	Value in SI unit
Minute	min	1 min = 60 s
Hour	h	1 h = 60 min = 3600 s
Day	d	1 d = 24 h = 86,400 s
Degree	°	$1° = (\pi/180)$ rad
Minute	′	$1' = (1/60)° = (\pi/10{,}800)$ rad
Second	″	$1'' = (1/60)' = (\pi/648{,}000)$ rad
Liter	L*	$1\ L = 1\ dm^3 = 10^{-3}\ m^3$
Metric ton	t	$1\ t = 10^3$ kg
Neper[a]	Np	1 Np = 1
Bel[b]	B	1 B = (1/2) ln 10 (Np)

*An alternate symbol for liter is "l." Since "l" can be easily confused with the numeral 1, the symbol "L" is recommended for United States use.

[a] The neper is used to express values of various logarithmic quantities. Natural logarithms are used to obtain the numerical values of quantities expressed in nepers. The neper is coherent with the SI, but is not yet adopted as an SI unit.

[b] The bel is used to express values of various logarithmic quantities. Logarithms to base ten are used to obtain the numerical values of quantities expressed in bels.

using the relation $\lambda = c/f$, where c is the value of the speed of light in vacuum. To this end, major standards laboratories have measured the frequencies of several lasers stabilized to narrow molecular absorptions in the visible and near-infrared spectral regions. These stabilized lasers now serve as standards of length. *See* INTERFEROMETRY; WAVELENGTH STANDARDS. [D.A.J]

Time interval. The second (s) is the duration of 9 192 631 770 periods of the radiation corresponding to the transition between the two hyperfine levels of the ground state of the cesium-133 atom. In the best equipments the stability and accuracy of the cesium frequency generator correspond to an uncertainty of a few parts in 10^{15}.

The second was long defined, for physical measurements as well as for civil affairs, as 1/86,400 of the time required for an average complete rotation of the Earth on its axis with respect to the Sun. Because of the slight slowing of the Earth's rotation rate, now averaging about 1 second per year (that is, 3 parts in 10^8) but with erratic and unexplained fluctuations, the universal second thus defined is not a constant. A time scale called Coordinated Universal Time (UTC) recommended by the General Conference of Weights and Measures (CGPM) in 1975 is defined in such a manner that it differs from international atomic time (TAI) by an exact whole number of seconds. This difference is adjusted occasionally by the use of a positive or negative leap second at the end of certain months to keep UTC in agreement with the time defined by the rotation of the Earth with an approximation better than 9/10 second. *See* ATOMIC CLOCK; ATOMIC TIME; DYNAMICAL TIME; EARTH ROTATION AND ORBITAL MOTION; FREQUENCY MEASUREMENT; TIME. [W.A.Wi.]

Temperature. The kelvin (K), the unit of thermodynamic temperature, is the fraction 1/273.16 of the thermodynamic temperature of the triple point of water. The unit kelvin and its symbol K should also be used to express an interval or differences of temperature.

To provide convenient and adequately accurate means for practical realization and measurement of temperature, the International Temperature Scale is used, based on the assigned values of the temperatures of a number of reproducible equilibrium states (defining fixed points), on standard instruments calibrated at those temperatures, and on vapor-pressure temperature relationships. Interpolation between the fixed-point temperatures is provided by formulas used to establish the relation between indications of the standard instruments and values of International Temperature. An extensive revision, which came into effect in 1990, is called the ITS-90. *See* TEMPERATURE; TEMPERATURE MEASUREMENT. [B.W.M.]

Electric current. The ampere (A) is that constant current which, if maintained in two straight parallel conductors of infinite length and of negligible circular sections, and placed 1 meter apart in a vacuum, would produce between these conductors a force equal to 2×10^{-7} newton per meter of length. *See* ELECTRICAL UNITS AND STANDARDS.

Luminous intensity. The CGPM, in 1979, redefined the base SI unit candela as the luminous intensity, in a given direction, of a source that emits monochromatic radiation of frequency 540×10^{12} hertz and of which the radiant intensity in that direction is 1/683 watt per steradian. *See* ILLUMINATION; LIGHT; LUMINOUS EFFICACY; LUMINOUS EFFICIENCY; LUMINOUS INTENSITY; PHOTOMETRY; RADIOMETRY.

Amount of substance. The mole is the amount of substance of a system which contains as many elementary entities as there are atoms in 0.012 kilogram of carbon-12. When the mole is used, the elementary entities must be specified, and may be atoms, molecules, ions, electrons, other particles, or specified groups of such particles. *See* GRAM-MOLECULAR WEIGHT; MOLE (CHEMISTRY). [W.A.Wi.]

Physical optics The study of the interaction of electromagnetic waves in the optical range with material systems. The optical range of wavelengths may be taken as the range from about 1 nanometer to about 1 millimeter.

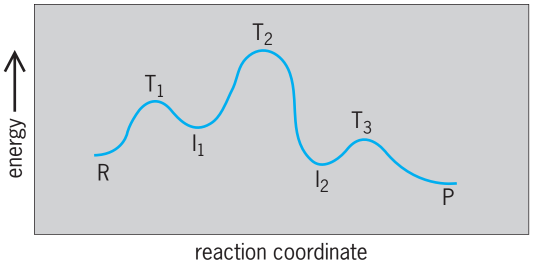
The explanation of the absorption, reflection, scattering, polarization, and dispersion of light by a material medium in terms of the properties of the atoms and molecules making up the medium is the objective of physical optics. In the course of seeking this objective, physicists have found that optical investigations are powerful methods of determining the structures of atoms and molecules and of large systems composed thereof. *See* ABSORPTION; ATOMIC STRUCTURE AND SPECTRA; CRYSTAL OPTICS; DIFFRACTION; DISPERSION (RADIATION); ELECTROMAGNETIC RADIATION; ELECTROOPTICS; FARADAY EFFECT; FLUORESCENCE; INTERFERENCE OF WAVES; LASER; LIGHT; MAGNETOOPTICS; MOLECULAR STRUCTURE AND SPECTRA; POLARIZED LIGHT; REFLECTION OF ELECTROMAGNETIC RADIATION; REFRACTION OF WAVES; SCATTERING OF ELECTROMAGNETIC RADIATION; SPECTROSCOPY. [R.C.L.]

Physical organic chemistry A branch of science concerned with the scope and limitations of the various rules, effects, and generalizations in use in organic chemistry by means of physical and mathematical methods. It includes, but is not limited to, the dynamics and energetics of organic chemical transformations, transient intermediates in these reactions, rate comparisons between families of reactions, dynamic stereochemistry, conservation of orbital symmetry, the least-motion principle, the isomer number for a given elemental composition, conformational analysis, nonexistent compounds, aromaticity, tautomerism, strain and steric hindrance, and the double-bond rule. Spectroscopy is the main tool employed, with nuclear magnetic resonance being the most widely used spectroscopic technique. With the advent of modern fast computers, computational chemistry has also become an important tool. *See* NUCLEAR MAGNETIC RESONANCE (NMR); SPECTROSCOPY.

Physical organic chemistry is traditionally distinguished from, yet totally intertwined with, synthetic organic chemistry, which deals with the question of how to obtain desired products from available compounds. This distinction can be illustrated with a diagram (see illustration) showing how the energy might vary during a chemical reaction in which the reactant R yields a product P (R → P). Whereas the synthetic organic chemist will be interested primarily in the practical problem of how to convert R into P, the physical organic chemist studies the curve or curves connecting R and P as well as the structure and physical properties at all extrema, including R and P. However,the demarcation between synthetic organic chemistry and physical organic chemistry is not sharp. Physical organic chemists have contributed greatly to the understanding of the chemistry of hydrocarbons and their derivatives and have enhanced the repertoire of the synthetic organic chemists. In turn, synthetic organic chemists have made possible the construction of the custom-made, often intricate molecules that physical organic chemists use for their studies. The efforts of both groups, moreover, have made possible the birth of such new fields as molecular biochemistry and computational chemistry. *See* COMPUTATIONAL CHEMISTRY; MOLECULAR BIOLOGY.

Chemical reaction mechanisms. The diagram shown in the illustration is also useful in discussions of the dynamics of chemical reactions. It is an attempt to portray how the atoms in the reactant molecule R may move in space to their final positions in the product molecule P, and how the potential energy of the system would vary as a function of these positions. A complete correlation would be multidimensional; what is normally shown is a cross section in which the maximum potential energy is in fact a minimum (saddle point). While an essentially infinite number of pathways between R and P can be imagined and followed, the vast majority of the molecules will in practice use the one that makes the least demand on energy to reach the next maximum; this pathway is known as the reaction mechanism. The maxima (T terms in the illustration) are known as transition states, and the minima (I terms in the illustration) as intermediates.

If a reaction has a single transition state (and, hence, no intermediate), it is known as concerted; alternatively, it is step-wise. A stepwise reaction is simply a succession of concerted steps

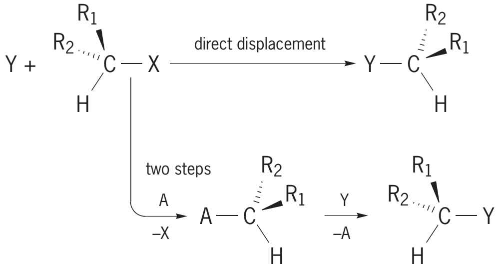


Energy profile of an organic reaction R → P. T terms indicate transition states and I terms indicate intermediates.

in which the intermediates are not isolated. *See* FREE RADICAL; ORGANIC REACTION MECHANISM; REACTIVE INTERMEDIATES; PHOTOCHEMISTRY.

Chemical kinetics. The most important route to quantitative information about a reaction is the study of its kinetics. This must begin with an experimental determination of the rate law: the expression that shows how the rate of formation of product $d[P]/dt$ (or loss of reactant: $-d[R]/dt$) depends on the concentration of all species involved in the reaction other than the solvent. The differential might be found to equal $k[R_1]$, $k[R_1]\,[R_2]$, $k[R_1]^2$, and so on; k is known as the rate constant, and the reaction is described as first-order, second-order, and so forth, depending on the total number of concentration terms. One important feature is that the reaction order equals the sum of all molecules that have participated in the formation of the transition state (T_2 in the illustration). Thus, for a reaction to be concerted, it is necessary that the order equal the sum of all reactant molecules involved in the stoichiometry. *See* CATALYSIS; CHEMICAL DYNAMICS; PERICYCLIC REACTION.

Stereochemistry. This is also a powerful tool in physical organic chemistry. Experimental work has demonstrated that when a chiral compound such as $(-)HCR_1R_2X$ is converted into optically active HCR_1R_2Y by direct displacement with Y, the product obtained has an optical rotation that is opposite to that exhibited by the same material if it is produced in two steps, via initial displacement by A to give intermediate HCR_1R_2A as shown in the following reaction scheme. This result demonstrates that displacement reactions occur with inversion; the reagent approaches in front, and the leaving group departs in the back. *See* OPTICAL ACTIVITY; STEREOCHEMISTRY.



Isomers. The isomer number has perhaps been the most important organizing principle in organic chemistry since its inception. Simply put, it means that for every elemental composition and molecular mass the isomer number can be predicted by writing all possible sequences of the atoms present, obeying the valence numbers of the atoms: four for carbon, three for nitrogen, two for oxygen, one for hydrogen and the halogens, and so forth. Once reliable atomic weights became available so that elemental compositions could be reported with confidence, this simple rule proved remarkably successful. *See* CHEMICAL BONDING; ORGANIC CHEMISTRY; VALENCE.

The need to specify molecular mass has proved more troublesome: it requires a definition of the concept of a molecule. Such definitions usually refer to covalent bonds as the entities that hold the atoms together, to rule out ionic species such as sodium chloride as candidates.

Among the extra compounds, none have affected organic chemistry more drastically than the stereoisomers. It turns out that for all but the simplest compounds a given sequence of the atoms may represent two, more than two, or even many more isomers. *See* CONFORMATIONAL ANALYSIS; MOLECULAR ISOMERISM.

Many compounds that are considered to be nonexistent, even though they are allowed by the simple rules of isomer numbers, in fact are transient intermediates in various reactions. Sometimes they can be detected spectroscopically, but cannot be isolated. There are instances in which neither of two isomers can be isolated, but mixtures of the two can. In other words, the barrier between the two is low, and the equilibrium constant is close to unity. An example is acetoacetic ester, which normally contains about 15% of the enol isomer. Such isomers are known as tautomers. *See* TAUTOMERISM. [W.J.LeN.]

Physical science

The fields of inquiry to which the general designation science may be appropriately applied are broadly divided into social science and natural science. The latter is further subdivided into biology and physical science. Physical science is generally considered to include astronomy, chemistry, geology, mineralogy, meteorology, and physics. These overlap more or less, as illustrated by astrophysics, chemical physics, physical chemistry, and geophysics. There is overlap, likewise, between the physical and biological sciences, as seen in biochemistry, biophysics, virology, and the close relation between geology and paleontology. The boundaries implied in all such classifications are artificial and consist of regions where one field shades into another. *See* ASTRONOMY; BIOLOGY; CHEMISTRY; GEOLOGY; METEOROLOGY; MINERALOGY; PHYSICS; SCIENCE. [J.H.Hi.]

Physical theory

A physical theory usually involves the attempt to explain a certain class of physical phenomena by deducing them as necessary consequences of other phenomena regarded as more primitive and less in need of explanation. The value of a theory depends on both the success with which it coordinates a wide range of presently known facts and its fertility in suggesting places to look for presently unknown phenomena. [P.W.Br./G.Ho.]

Physics

Formerly called natural philosophy, physics is concerned with those aspects of nature which can be understood in a fundamental way in terms of elementary principles and laws. In the course of time, various specialized sciences broke away from physics to form autonomous fields of investigation. In this process physics retained its original aim of understanding the structure of the natural world and explaining natural phenomena.

The most basic parts of physics are mechanics and field theory. Mechanics is concerned with the motion of particles or bodies under the action of given forces. The physics of fields is concerned with the origin, nature, and properties of gravitational, electromagnetic, nuclear, and other force fields. Taken together, mechanics and field theory constitute the most fundamental approach to an understanding of natural phenomena which science offers. The ultimate aim is to understand all natural phenomena in these terms. *See* CLASSICAL FIELD THEORY; MECHANICS; QUANTUM FIELD THEORY.

The older, or classical, divisions of physics were based on certain general classes of natural phenomena to which the methods of physics had been found particularly applicable. The divisions are all still current, but many of them tend more and more to designate branches of applied physics or technology, and less and less inherent divisions in physics itself. The divisions or branches, of modern physics are made in accordance with particular types of structures in nature with which each branch is concerned.

In every area physics is characterized not so much by its subject-matter content as by the precision and depth of understanding which it seeks. The aim of physics is the construction of a unified theoretical scheme in mathematical terms whose structure and behavior duplicates that of the whole natural world in the most comprehensive manner possible. Where other sciences are content to describe and relate phenomena in terms of restricted concepts peculiar to their own disciplines, physics always seeks to understand the same phenomena as a special manifestation of the underlying uniform structure of nature as a whole. In line with this objective, physics is characterized by accurate instrumentation, precision of measurement, and the expression of its results in mathematical terms.

For the major areas of physics and for additional listings of articles in physics *see* ACOUSTICS; ASTROPHYSICS; ATOMIC PHYSICS; BIOPHYSICS; CLASSICAL MECHANICS; ELECTRICITY; ELECTROMAGNETISM; ELEMENTARY PARTICLE; FLUID MECHANICS; HEAT; LOW-TEMPERATURE PHYSICS; MOLECULAR PHYSICS; NUCLEAR PHYSICS; OPTICS; SOLID-STATE PHYSICS; STATISTICAL MECHANICS; THEORETICAL PHYSICS. [W.G.P.]

Physiological acoustics The study of specific responses that may occur in the ear or elsewhere along the central auditory pathways, following presentation of an appropriate stimulus at any level of the auditory system. Such responses may be recorded with the aid of various techniques which may be mechanical, electrical, optical, and so forth. The specific stimulus for the ear is acoustic energy. Experimentally, signals with well-defined parameters are used. The approach employed by physiological acoustics thus is purely analytical. This is in contrast to the holistic approach employed by psychoacoustics, which lends itself well to experiments on human subjects. Systematic physiological experiments can be performed only in animals, but differences between humans and other mammals are mainly in degree, not in principle. *See* EAR; HEARING (HUMAN); PSYCHOACOUSTICS. [J.T.]

Physiological action spectra Representations of the comparative effects of different wavelengths of light on living systems or on the components of living systems. A knowledge of the effects of different wavelengths on living systems helps lead to an understanding of the detailed mechanisms of energy transfer and utilization and to a determination of the essential compounds involved in light action of living systems. The work of action spectroscopy is founded on the firm bases that energy must be absorbed before it is utilized and that each chemical compound has a characteristic absorption spectrum. Therefore, the shape of the action spectrum may lead to the identification of the absorbing molecules. Action spectroscopy has been used extensively to study three classes of compounds: porphyrin-containing proteins, nucleic acid polymers, and plant pigments. *See* ABSORPTION OF ELECTROMAGNETIC RADIATION. [R.B.Se.]

Physiological ecology (animal) A discipline that combines the study of physiological processes, the functions of living organisms and their parts, with ecological processes that connect the individual organism with population dynamics and community structure. *See* POPULATION ECOLOGY.

Physiological ecologists focus on whole-animal function and adjustments to ever-changing environments, in both laboratory and field. Short-term behavioral adjustments and longer-term physiological adjustments tend to maximize the fitness of animals, that is, their capacity to survive and reproduce successfully. Among the processes that physiological ecologists study are temperature regulation, energy metabolism and energetics, nutrition, respiratory gas exchange, water and osmotic balance, and responses to environmental stresses. These environmental stresses may include climate variation, nutrition, disease, and toxic exposure. For instance, climate affects animal heat and mass balances, and such changes affect body temperature regulation. Behavioral temperature regulation (typically, avoidance of temperature extremes) modifies mass and energy intake and expenditure, and the difference between intake and expenditure provides the discretionary mass for growth and reproduction. Mortality risk (survivorship) also depends on temperature-dependent behavior, which determines daily activity. Activity time constrains the time for foraging and habitat selection, which in turn influence not only mortality risk but also community composition. Animals are similarly constrained in their discretionary mass and energy by reduction in nutrition, which decreases absorbed food, and by disease and toxins, which may elevate the costs to maintain a higher body temperature (fever). *See* BEHAVIORAL ECOLOGY; HOMEOSTASIS. [W.Po.]

Physiological ecology (plant) The branch of plant science that seeks physiological (mechanistic) explanations for ecological observations. Emphasis is placed on understanding how plants cope with environmental variation at the physiological level, and on the influence of resource limitations on growth, metabolism, and reproduction of individuals within and among plant populations, along environmental gradients, and across different communities and ecosystems. The responses of plants to natural, controlled, or manipulated conditions above and below ground provide a basis for understanding how the features of plants enable their survival, persistence, and spread. Information gathered is often used to identify the physiological and morphological features of a plant that permit adaptation to different sets of environmental conditions.

The environments that plants occupy are often subject to variation or change. The ecophysiological characteristics of these plants must be able to accommodate this or the plants face extinction. Given the right conditions, ample time, and genetic variation among a group of interbreeding individuals, plant populations and species can evolve to accommodate marked ecological change or habitat heterogeneity. If evolutionary changes in physiology or morphology occur on a local or regional scale, populations within a single species may diverge in their characteristics. Separate ecological races (ecotypes) arise in response to an identifiable, set of environmental conditions. Ecotypes are genetically distinct and are particularly well suited to the local or regional environment they occupy. Such ecotypes can often increase the geographical range and amplitude of environmental conditions that the species occupies or tolerates. Ecotypes may also occur as a series of populations arrayed over a well-defined environmental gradient called an ecocline. In contrast, if ecotypes are not present, some plant species may still be able to accommodate a wide range of growth conditions through morphological and physiological adjustments, by acclimation to a single factor (such as light) or acclimatization to a complex suite of factors which define the entire habitat. Acclimatization can occur when individuals from several different regions or populations are grown in a common location and adjust, physiologically or morphologically, to this location. Acclimation and acclimatization can therefore be defined as the ability of a single genotype (individual) to express multiple phenotypes (outward appearances) in response to variable growing conditions. Neither requires underlying genetic changes, though some genetic change might occur which could mean that the response seen may itself evolve. Acclimation and acclimatization may also be called phenotypic plasticity. *See* PLANT EVOLUTION.

Studies of metabolic rates in relation to environmental conditions within populations, ecotypes, or species provide a way to measure the tolerance limits expressed at different scales. These data in turn help identify the scales at which different adaptations are expressed, and enhance an understanding of the evolution of physiological processes. Combining observations and measurements from the field with those obtained in laboratory and controlled environment experiments can help identify which conditions may be most influential on plant processes and therefore what may have shaped the physiological responses seen. Laboratory and controlled environment (common garden) experiments also assist in helping identify how much of the variation expressed in a particular metabolic process can be assigned to a particular environmental factor and how much to the plants themselves and the genetic and developmental plasticity they possess. *See* ECOLOGY; ECOSYSTEM; PLANT PHYSIOLOGY. [T.E.D.]

Phytamastigophorea A class of the subphylum Sarcomastigophora, also known as the Phytomastigina. These are the plant flagellates which contain chlorophyll and other pigments, but colorless forms are also included. Encystment is frequent among phytoflagellates, cyst composition being one method of determining relationships for some colorless species.

The Phytamastigophorea include 10 orders: Chrysomonadida, Silicoflagellida, Coccolithophora, Heterochlorida, Cryptomonadida, Dinoflagellida, Ebriida, Euglenida, Chloromonadida, and Volvocida. See articles on these groups. *See* SARCOMASTIGOPHORA. [J.B.L.]

Phytoalexin Any antibiotic produced by plants in response to microorganisms. Plants use physical and chemical barriers as a first line of defense. When these barriers are breached, however, the plant must actively protect itself by employing a variety of strategies. Plant cell walls are strengthened, and special cell layers are produced to block further penetration of the pathogen. These defenses can permanently stop a pathogen when fully implemented, but the pathogen must be slowed to gain time.

The rapid defenses available to plants include phytoalexin accumulation, which takes a few hours, and the hypersensitive reaction, which can occur in minutes. The hypersensitive reaction is the rapid death of plant cells in the immediate vicinity of the pathogen. Death of these cells is thought to create a toxic environment of released plant components that may in themselves interfere with pathogen growth, but more importantly, damaged cells probably release signals to surrounding cells and trigger a more comprehensive defense effort. Thus, phytoalexin accumulation is just one part of an integrated series of plant responses leading from early detection to eventual neutralization of a potentially lethal invading microorganism.

The tremendous capacity of plants to produce complex chemical compounds is reflected in the structural diversity of phytoalexins. Each plant species produces one or several phytoalexins, and the types of phytoalexins produced are similar in related species. The diversity, complexity, and toxicity of phytoalexins may provide clues about their function. The diversity of phytoalexins may reflect a plant survival strategy. That is, if a plant produces different phytoalexins from its neighbors, it is less likely to be successfully attacked by pathogens adapted to its neighbor's phytoalexins. Diversity and complexity, therefore, may reflect the benefits of using different deterrents from those found in other plants. *See* PLANT PATHOLOGY. [A.R.A.]

Phytochrome A pigment that controls most photomorphogenic responses in higher plants. Mechanisms have evolved in plants that allow them to adapt their growth and development to more efficiently seek and capture light and to tailor their life cycle to the climatic seasons. These mechanisms enable the plant to sense not only the presence of light but also its intensity, direction, duration, and spectral quality. Plants thus regulate important developmental processes such as seed germination, growth direction, growth rate, chloroplast development, pigmentation, flowering, and senescence, collectively termed photomorphogenesis.

To perceive light signals, plants use several receptor systems that convert light absorbed by specific pigments into chemical or electrical signals to which the plants respond. This signal conversion is called photosensory transduction. Pigments used include cryptochrome, a blue light-absorbing pigment; an ultraviolet light-absorbing pigment; and phytochrome, a red/far-red light-absorbing pigment.

Phytochrome consists of a compound that absorbs visible light (chromophore) bound to a protein. The chromophore is an open-chain tetrapyrrole closely related to the photosynthetic pigments found in the cyanobacteria and similar in structure to the circular tetrapyrroles of chlorophyll and hemoglobin. Phytochrome is one of the most intensely colored pigments found in nature, enabling phytochrome in seeds to sense even the dim light present well beneath the surface of the soil and allowing leaves to perceive moonlight. *See* CHLOROPHYLL; HEMOGLOBIN.

Phytochrome can exist in two stable photointerconvertible forms, P_r or P_{fr}, with only P_{fr} being biologically active. Absorption of red light (near 666 nanometers) by inactive P_r converts it to active P_{fr}, while absorption of far-red light (near 730 nm) by active P_{fr} converts phytochrome back to inactive P_r. Plants frequently respond quantitatively to light by detecting the amount of P_{fr} produced. As a result, the amount of P_{fr} must be strictly regulated nonphotochemically by precisely controlling both the synthesis and degradation of the pigment. *See* ABSORPTION OF ELECTROMAGNETIC RADIATION.

Phytochrome has a variety of functions in plants. Initially, production of P_{fr} is required for many seeds to begin germination. This requirement prevents germination of seeds that are buried too deep in the soil to successfully reach the surface. In etiolated (dark-grown) seedlings, phytochrome can measure an increase in light intensity and duration through the increased formation of P_{fr}. Light direction also can be deduced from the asymmetry of P_{fr} levels from one side of the plant to the other. Different phytochrome responses vary in their sensitivity to P_{fr}; some require very low levels of P_{fr} (less than 1% of total phytochrome) to elicit a maximal response, while others require almost all of the pigment to be converted to P_{fr}. Thus, as the seedling grows toward the soil surface, a cascade of photomorphogenic responses are induced, with the more sensitive responses occurring first. This chain of events produces a plant that is mature and photosynthetically competent by the time it finally reaches the surface. Production of P_{fr} also makes the plant aware of gravity, inducing shoots to grow up and roots to grow down into the soil. *See* PLANT MOVEMENTS; SEED.

In light-grown plants, phytochrome allows for the perception of daylight intensity, day length, and spectral quality. Intensity is detected through a measurement of phytochrome shuttling between P_r and P_{fr}; the more intense the light, the more interconversion. This signal initiates changes in chloroplast morphology to allow shaded leaves to capture light more efficiently. If the light is too intense, phytochrome will also elicit the production of pigments to protect plants from photodamage.

Temperate plants use day length to tailor their development, a process called photoperiodism. How the plant measures day length is unknown, but it involves phytochrome and actually measures the length of night. *See* PHOTOPERIODISM.

Finally, phytochrome allows plants to detect the spectral quality of light, a form of color vision, by measuring the ratio of P_r to P_{fr}. When a plant is grown under direct sun, the amounts of red and far-red light are approximately equal, and the ratio of P_r to P_{fr} in the plant is about 1:1. Should the plant become shaded by another plant, the P_r/P_{fr} ratio changes dramatically to 5:1 or greater. This is because the shading plant's chlorophyll absorbs much of the red light needed to produce P_{fr} and absorbs almost none of the far-red light used to produce P_r. For a shade-intolerant plant, this change in P_r/P_{fr} ratio induces the plant to grow taller, allowing it to grow above the canopy.

It is not known how phytochrome elicits the diverse array of photomorphogenic responses, but the regulatory action must result from discrete changes in the molecule following photoconversion of P_r to P_{fr}. These changes must then start a chain of events in the photosensory transduction chain leading to the photomorphogenic response. Many photosensory transduction chains probably begin by responding to P_{fr} or the P_r/P_{fr} ratio and branch off toward discrete end points. *See* PHOTOMORPHOGENESIS. [R.D.V.]

Phytoplankton Mostly autotrophic microscopic algae which inhabit the illuminated surface waters of the sea, estuaries, lakes, and ponds. Many are motile. Some perform diel (diurnal) vertical migrations, others do not. Some nonmotile forms regulate their buoyancy. However, their locomotor abilities are limited, and they are largely transported by horizontal and vertical water motions.

A great variety of algae make up the phytoplankton. Diatoms (class Bacillariophyceae) are often conspicuous members of marine, estuarine, and fresh-water plankton. Dinoflagellates (class Dinophyceae) occur in both marine and fresh-water environments and are important primary producers in marine and estuarine environments. Coccolithophorids (class Haptophyceae) are also marine primary producers of some importance. They do not occur in fresh water.

Even though marine and fresh-water phytoplankton communities contain a number of algal classes in common, phytoplankton samples from these two environments will appear quite different. These habitats support different genera and species and groups of higher rank in these classes. Furthermore, fresh-water plankton contains algae belonging to additional algal classes either absent or rarely common in open ocean environments. These include the green algae (class Chlorophyceae), the euglenoid flagellates (class Euglenophyceae), and members of the Prasinophyceae.

The phytoplankton in aquatic environments which have not been too drastically affected by human activity exhibit rather regular and predictable seasonal cycles. Coastal upwelling and divergences, zones where deeper water rises to the surface, are examples of naturally occurring phenomena which enrich the mixed layer with needed nutrients and greatly increase phytoplankton production. In the ocean these are the sites of the world's most productive fisheries. *See* EUTROPHICATION. [R.W.H.]

Phytotronics Research using whole plants and conducted under controlled environmental conditions to determine responses to a single or known combination of environmental elements. Originally, the term phytotronics was used to identify research conducted specifically in phytotrons where controlled plant growth units are available for simultaneous use. The name phytotronics is also often applied to any research conducted with whole plants in a controlled environment plant growth chamber or room. [H.H.]

Piciformes A large order of land birds, second in size only to the Passeriformes, that is found throughout the world, except for the Australian region, and is concentrated in tropical areas. The Piciformes is divided into the following eight families: Primobucconidae (fossil), Galbulidae (jacamars), Bucconidae (puffbirds), Zygodactylidae (fossil), Capitonidae (barbets), Ramphastidae (toucans), Indicatoridae (honeyguides), and Picidae (woodpeckers). The family Picidae is the largest, with 204 species of woodpeckers.

The piciforms are small to medium-sized, hole-nesting land birds. The bill is short to medium-long, straight, and strong, and the wings are of medium length and rounded. The legs are short and strong, with the strong toes arranged in a zygodactylous (yoke) pattern, with two toes forward and two toes back. The tail may have stiffened feathers. The plumage, which varies greatly in hue, is frequently brightly colored and boldly patterned. Piciforms are good fliers and can easily perch and climb, but they walk poorly. Most species feed on insects. The eggs are incubated by both sexes, and both parents care for the unfeathered young, which remain in the nests. Except for a few species of woodpeckers, the piciforms are nonmigratory. *See* AVES; PASSERIFORMES. [W.J.B.]

Picornaviridae A viral family made up of the small (18–30 nanometer) ether-sensitive viruses that lack an envelope and have a ribonucleic acid (RNA) genome. The name is derived from "pico" meaning very small, and RNA for the nucleic acid type. Picornaviruses of human origin include the following subgroups: enteroviruses (polioviruses, coxsackieviruses, and echoviruses) and rhinoviruses. There are also picornaviruses of lower animals (for example, bovine foot-and-mouth disease, a rhinovirus). *See* ANIMAL VIRUS; COXSACKIEVIRUS; ECHOVIRUS; ENTEROVIRUS; FOOT-AND-MOUTH DISEASE; POLIOMYELITIS; RHINOVIRUS. [J.L.Me.]

Picrite The term picrite has been used with several different meanings. It is generally considered to include certain medium- to fine-grained igneous rocks composed chiefly of olivine with smaller amounts of pyroxene, hornblende, and plagioclase feldspar (labradorite). Its feldspar content is slightly higher than that of peridotite and lower than that of gabbro. Certain analcite-bearing types, associated with teschenite, have also been included under the term picrite. Picrite is rare and is found in small intrusives (sills and dikes). *See* GABBRO; IGNEOUS ROCKS; PERIDOTITE. [C.A.C.]

Pictorial drawing A view of an object (actual or imagined) as it would be seen by an observer who looks at the object either in a chosen direction or from a selected point of view. Pictorial sketches often are more readily made and more clearly understood than are front, top, and side views of an object. Pictorial drawings, either sketched freehand or made with drawing instruments, are frequently used by engineers and architects to convey ideas to their assistants and clients. *See* DESCRIPTIVE; GEOMETRY; ENGINEERING DRAWING.

In making a pictorial drawing, the viewing direction that shows the object and its details to the best advantage is chosen. The resultant drawing is orthographic if the viewing rays are considered as parallel, or perspective if the rays are considered as meeting at the eye of the observer. Perspective drawings provide the most realistic, and usually the most pleasing, likeness when compared with other types of pictorial views.

Several types of nonperspective pictorial views can be sketched, or drawn with instruments. In the isometric pictorial, the direction of its axes and all measurements along these axes are made with one scale (Fig. 1). Oblique pictorial drawings, while not true orthographic views, offer a convenient method for drawing circles and other curves in their true shape (Fig. 2).

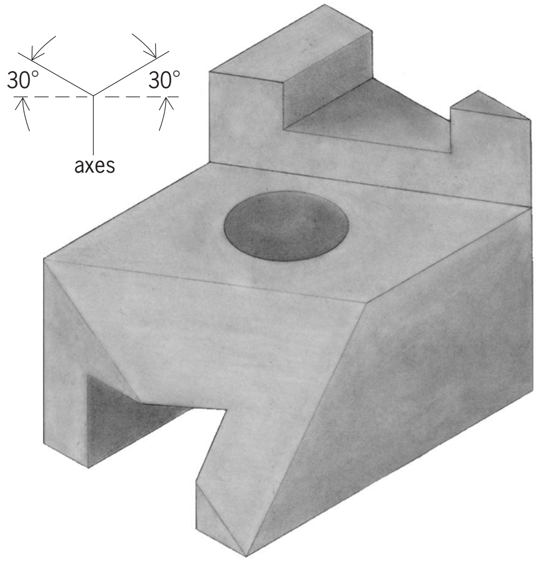


Fig. 1. Isometric drawing; measurements along each axis are made with the same scale.

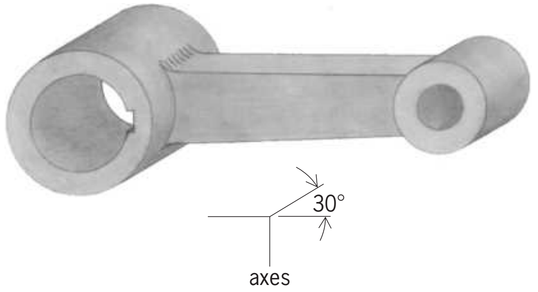

Fig. 2. Oblique pictorial drawing.

In order to reduce the distortion in an oblique drawing, measurements along the receding axis may be foreshortened. When they are halved, the method is called cabinet drawing. [C.J.B.]

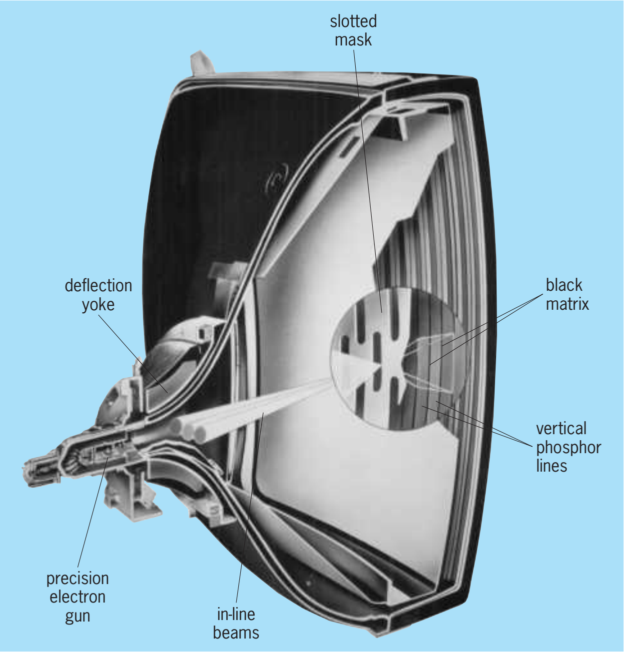
Picture tube

Picture tube A cathode-ray tube used as a television picture tube. Television picture tubes use large glass envelopes that have a light-emitting layer of luminescent material deposited on the inner face. A modulated stream of high-velocity electrons scans this luminescent layer in a series of horizontal lines so that the picture elements (light and dark areas) are recreated.

In a color picture tube (see illustration), the glass bulb is made in two pieces, the face panel and the funnel-neck region. The separate face panel allows the fabrication of the segmented phosphor screen and the mounting of the shadow mask. The two glass pieces are sealed together by a special frit to provide a strong vacuum-tight seal.

The light-emitting colored phosphors on the segmented screen can be either in dot arrays or, now more commonly, in line arrays. Typically, the trios of vertical phosphor lines are spaced 0.6–0.8 mm apart. Most tubes use a black matrix screen in which the phosphor lines are separated by opaque black lines. This black matrix reduces reflected light, thereby giving better contrast, and also provides a tolerance for the registration of the electron beam with the phosphor lines.

The shadow mask is made of a thin (0.10–0.17 mm) steel sheet in which elongated slits (one row of slits for each phosphor-line trio) have been photoetched. It is formed to a contour similar to that of the glass panel and is mounted at a precise distance from the glass. The width of the slits and their relative position to the phosphor lines are such that the electron beam from one of the three electron guns can strike only one of the sets of color phosphor lines. The shadow mask "shadows" the beam from the other two sets of phosphor lines.



Color picture tube.

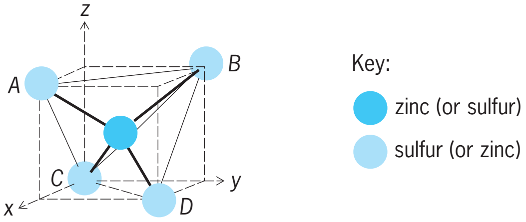
The electron gun for color is similar to that for monochrome except that there are three guns, usually arranged side by side, or in-line. This triple gun has common structural elements, but uses three independent cathodes with separate beam forming and focusing for each beam.

The electromagnetic deflection yoke deflects or bends the beams, as in a monochrome tube, to scan the screen in a television raster. In addition, the yoke's magnetic field is shaped so that the three beams will be deflected in such a way that they land at the same phosphor trio on the screen at the same time. This convergence of the beams produces three images, one in red, one in green, and one in blue, that are superimposed to give a full-color picture. *See* CATHODE-RAY TUBE; TELEVISION. [A.M.Mo.]

Piezoelectricity

Piezoelectricity Electricity, or electric polarity, resulting from the application of mechanical pressure on a dielectric crystal. The application of a mechanical stress produces in certain dielectric (electrically nonconducting) crystals an electric polarization (electric dipole moment per cubic meter) which is proportional to this stress. If the crystal is isolated, this polarization manifests itself as a voltage across the crystal, and if the crystal is short-circuited, a flow of charge can be observed during loading. Conversely, application of a voltage between certain faces of the crystal produces a mechanical distortion of the material. This reciprocal relationship is referred to as the piezoelectric effect. The phenomenon of generation of a voltage under mechanical stress is referred to as the direct piezoelectric effect, and the mechanical strain produced in the crystal under electric stress is called the converse piezoelectric effect. *See* POLARIZATION OF DIELECTRICS.

The necessary condition for the piezoelectric effect is the absence of a center of symmetry in the crystal structure. Of the 32 crystal classes, 21 lack a center of symmetry, and with the exception of one class, all of these are piezoelectric. Hydrostatic pressure produces a piezoelectric polarization in the crystals of those 10 classes that show pyroelectricity in addition to piezoelectricity. *See* CRYSTALLOGRAPHY; PYROELECTRICITY.



Tetrahedral structure of zincblende, ZnS. Only part of unit cell is shown. Size of circles has no relation to size of ions.

Molecular theory. Quantitative theories based on the detailed crystal structure are very involved. Qualitatively, however, the piezoelectric effect is readily understood for simple crystal structures. The illustration shows this for a particular cubic crystal, zincblende (ZnS). Every Zn ion is positively charged and is located in the center of a regular tetrahedron *ABCD*, the corners of which are the centers of sulfur ions, which are negatively charged. When this system is subjected to a shear stress in the *xy* plane, the edge *AB*, for example, is elongated, and the edge *CD* of the tetrahedron becomes shorter. Consequently, these edges are no longer equivalent, and the Zn ion will be displaced along the *z* axis, thus giving rise to an electric dipole moment. The dipole moments arising from different octahedrons sum up because they all have the same orientation with respect to the axes *x*, *y*, and *z*.

Applications. The sharp resonance curve of a piezoelectric resonator makes it useful in the stabilization of the frequency of radio oscillators. Quartz crystals are used almost exclusively in this application. In vacuum-tube oscillators, the crystal generally is part of the feedback circuit. Selective band-pass filters with low losses can be built by using piezoelectric resonators as circuit elements. A synthetic piezoelectric crystal which is often substituted for quartz in this application is ethylene diamine tartrate. *See* QUARTZ CLOCK.

Piezoelectric materials are used extensively in transducers for converting a mechanical strain into an electrical signal. Such devices include microphones, phonograph pickups, vibration-sensing elements, and the like. The converse effect, in which a mechanical output is derived from an electrical signal input, is also widely used in such devices as sonic and ultrasonic transducers, headphones, loudspeakers, and cutting heads for disk recording. *See* MICROPHONE; ULTRASONICS. [H.G.]

Piezoelectric materials. The principal piezoelectric materials used commercially are crystalline quartz and rochelle salt, although the latter is being superseded by other materials, such as barium titanate. Quartz has the important qualities of being a completely oxidized compound (silicon dioxide), and is almost insoluble in water. Therefore, it is chemically stable against changes occurring with time. It also has low internal losses when used as a vibrator. Rochelle salt has a large piezoelectric effect, and is thus useful in acoustical and vibrational devices where sensitivity is necessary, but it decomposes at high temperatures (131°F or 55°C) and requires protection against moisture. Barium titanate provides lower sensitivity, but greater immunity to temperature and humidity effects. Other crystals that have been used for piezoelectric devices include tourmaline, ammonium dihydrogen phosphate (ADP), and ethylenediamine tartrate (EDT). *See* QUARTZ. [F.D.L.]

Pigeonite

Monoclinic pyroxenes of the general formula $(Mg,Fe)SiO_3$ having some augite in solid solution. Pigeonite bears the same relation to the orthorhombic pyroxenes as augite does to the diopside-hedenbergite series. Pigeonite is the orthorhombic pyroxene equivalent in the volcanic rocks. *See* AUGITE; DIOPSIDE; ORTHORHOMBIC PYROXENE; PYROXENE. [G.W.DeV.]

Pigment

A finely divided material which contributes to optical and other properties of paint, finishes, and coatings. Pigments are insoluble in the coating material, whereas dyes dissolve in and color the coating. Pigments are mechanically mixed with the coating and are deposited when the coating dries. Their physical properties generally are not changed by incorporation in and deposition from the vehicle. Pigments may be classified according to composition (inorganic or organic) or by source (natural or synthetic). However, the most useful classification is by color (white, transparent, or colored) and by function. Special pigments include anticorrosive, metallic, and luminous pigments. *See* DYE; LUMINOUS PAINT; PAINT. [C.R.Ma.; C.W.Si.]

Pigmentation

A property of biological materials that imparts coloration. Hence, pigmentation determines the quantity and quality of reflected visible light. The characteristics of light returning from living matter are a function of its chemical and physical properties and, therefore, are not only due to pigments proper but can be of structural origin (for example, due to reflection, scattering, or interference) as well.

Pigments are essential constituents of the living world. Their contribution to the evolution and maintenance of life, and its manifold expressions, is most evident in the role of chlorophylls and the associated carotenoids of certain bacteria and most plants. These pigments harvest solar light energy for utilization in the photosynthesis of organic material from inorganic precursors. *See* CAROTENOID; CHLOROPHYLL; PHOTOSYNTHESIS.

The outermost structures on the animal skin are pigmented for many reasons, for example, to reduce the animal's visibility against a colored background or to provide optical signals to the other sex or to other species. Conspicuously pigmented flowers attract pollinators, and colored fruits are easily found by animals, which eat them and then disperse the undigested seeds.

The role of pigments in communication depends on the ability of organisms to discriminate between different regions of the solar spectrum. In animals with eyes, this is accomplished by differently colored visual pigments contained in specialized receptor cells. Microorganisms, fungi, and plants also have special pigment systems that permit these organisms to move or grow toward, or away from, light (positive and negative phototaxis and phototropism, respectively). *See* PLANT MOVEMENTS.

Since most organisms are totally dependent on light—at least indirectly—elaborate pigment systems have evolved which tune metabolic and activity patterns to the daily pattern of light and dark, and to the changes in the relative lengths of day and night in the course of a year. The phytochrome of plants and the pigments of the eye or of extraretinal photoreceptor organs of many vertebrates and invertebrates are typical representatives of pigments that correlate biological activity with light-dark cycles (photoperiodism). *See* COLOR VISION; PHOTOPERIODISM; PHOTORECEPTION.

In the examples listed above, pigments mediate, in various ways, the beneficial actions of light. Absorbed solar light energy may, however, also have detrimental effects by causing undesirable or even destructive reactions. Pigmentations can provide a light-absorbing shield that protects the tissue below from such potentially damaging radiation of the Sun. *See* INTEGUMENT; SKIN. [P.H.Ho.]

Pike

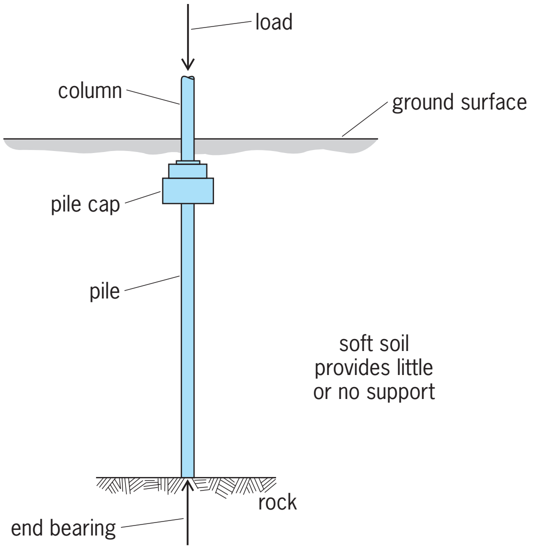
Any of about five species of fish which compose the family Esocidae in the order Clupeiformes, known by a variety of names such as pickerel and muskellunge. These fish are voracious predators with an elongated beaklike snout and sharp teeth. The head is partly scaled and the body is covered with cycloid scales that have deeply scalloped edges. The body is cylindrical and compressed; thus, these fish are well adapted for rapid movements as they dart after prey. They prey upon each other, as well as other fish, amphibians, small aquatic birds and mammals, and rats. All species are edible but are considered second-rate game fish. *See* CLUPEIFORMES. [C.B.C.]

Pile foundation

A special type of foundation that enables a structure to be supported by a layer of soil found at any depth below the ground surface. A pile foundation comprises two basic structural elements, the pile and the pile cap. A pile cap is a structural base, similar to a spread footing, that supports a structural column, wall, or slab, except that it bears on a single pile or group of piles. A pile can be described as a structural stilt hammered into the ground. Each pile carries a portion of the pile cap load and transfers it to the soil in the vicinity of the pile tip, located at the bottom of the pile (see illustration).

The pile and pile cap configuration has provided the basic design solution to the difficult problem of obtaining deep foundation support below areas where poor soil conditions prevail. Poor soil conditions may be difficult to excavate through, and are incapable of supporting structural loads. They are typically characterized by the presence of a soft, compressible layer of clay, high ground-water levels, loosely filled soils, uncontrolled landfills, boulders, abandoned underground structures, and natural bodies of water. By supporting a structure on piles in lieu of spread footings, any adverse soil condition may be virtually bypassed, and adequate foundation support can be obtained at any depth, without the need to perform deep excavation, dewater, and install temporary sheeting and bracing.

Piles are available in a variety of sizes, shapes, and materials that enable a particular type of pile foundation to be viable both economically and structurally. Principal materials are timber, concrete, and steel.



End-bearing pile.

Pile foundations are used to support marine structures and offshore platforms, since they are located over bodies of water. On land, pile foundations are used primarily in locations where poor soil conditions exist. [A.J.M.]

Pilot production The production of a product, process, or piece of equipment on a simulated factory basis. In mass-production industries where complicated products, processes, or equipment are being developed, a pilot plan often leads to the presentation of a better product to the customer, lower development and manufacturing costs, more efficient factory operations, and earlier introduction of the product. Following the engineering development of a product, process, or complicated piece of equipment and its one-of-a-kind fabrication in the model shop, it becomes desirable and necessary to "prove out" the development on a simulated factory basis. *See* PRODUCT DESIGN; PRODUCTION ENGINEERING; QUALITY CONTROL. [J.E.Wo.]

Pilotage One of four procedures used in navigating an aircraft. The other three are position fixing, homing, and dead reckoning. Pilotage is the procedure of using landmarks, such as cities, towns, rivers, railroads, and prominent highways, to guide an aircraft to a destination. The installation of lights at airports and prominent spots across the country enhanced the ability of the pilot to direct the aircraft. *See* DEAD RECKONING.

The introduction of radar brought a new dimension to pilotage. Airborne radar operating at microwaves produces very sharp maps of the terrain over which the aircraft is flying. Radar pilotage has also been adapted to missile guidance. [P.C.S.]

Piloting The form of navigation in which position is determined relative to external reference points, usually fixed points on the Earth. It is the oldest form of navigation. With the development of electronic aids, piloting techniques were extended far from shore. However, the term "piloting" is generally associated with nearness of land, where tidal and other currents may be strong, shoals and other underwater obstructions may be in near proximity, and maneuvering room is limited when other vessels are encountered. Thus it is not unusual for ships to employ the services of a local expert, called a pilot, to assist in the navigation of the vessel while it enters or leaves port.

A conspicuous object, structure, or light that serves as an indicator for establishing the position of a craft or otherwise assisting in its safe navigation is called a mark. To be useful, not only must a mark be identified, but its position must be known accurately. Artificial marks designed and erected specifically to assist the navigator are called aids to navigation and include beacons, both lighted and unlighted, lighthouses, buoys, both lighted and unlighted, and lightships. Unlighted aids are called daymarks. *See* BUOY; LIGHTHOUSE.

In addition to visible aids to navigation, bottom topography can be of assistance in locating the position of a vessel. Sound signals transmitted through water or air may be used for navigation. Electronic beacons and positioning systems have been established at a number of places to assist in navigation. *See* ELECTRONIC NAVIGATION SYSTEMS.

The measurements made for piloting purposes are of direction, distance, differential distance between two points, and distance to bottom.

Bearings are usually measured (1) by noting when two objects are in range (directly in line); (2) by means of a suitable attachment to a compass or compass repeater; (3) by pelorus, a compasslike instrument without directive properties; or (4) electronically, by radio direction finder, by radar, or by the indication of the receiver-indicator of an electronic system of navigation. Distance is generally measured by radar. The difference in distance from the ship to two points is usually measured electronically by means of the receiver-indicator of a hyperbolic navigation system. Depth measurement is usually made by an echo sounder. *See* DIRECTION-FINDING EQUIPMENT; ECHO SOUNDER; HYPERBOLIC NAVIGATION SYSTEM; RADAR.

Traditionally, position by piloting has been determined by means of lines of positions, each indicating a series of possible positions of the craft at the time of measurement. A measured bearing provides a straight line of position (actually part of a great circle) passing through the object sighted. A measured distance provides a circular line of position with the object as the center and the distance as the radius. A measured differential distance provides a hyperbolic line of position. A position, called a fix, is usually determined by crossing two or more lines of position taken simultaneously or nearly so.

Digitization of a nautical chart provides the information needed for display of an electronic facsimile of a published chart. Selective determination of features to be shown makes possible the tailoring of the facsimile to individual requirements. If a radar image is added to the display, the position of the vessel relative to its surroundings is immediately apparent. A suitable electronic positioning system such as the Global Positioning System (GPS) or differential GPS (DGPS) can be used to display a symbol indicating the position of the vessel, thus providing a check on accuracy of the radar data. Other information can be added as desired. The combined display is called an electronic chart display information system (ECDIS). *See* CELESTIAL NAVIGATION; DEAD RECKONING; MARINE NAVIGATION; NAVIGATION; POLAR NAVIGATION; SATELLITE NAVIGATION SYSTEMS. [A.B.M.]

Piltdown man The scientifically most successful fraud in the history of anthropology. Between 1908 and 1914 in the English village of Piltdown, parts of a thick human braincase, half of an apelike chinless lower jaw containing two molar teeth, a relatively large lower canine tooth, animal fossils, stone implements, and a 16-in. (41-cm) pointed tool made from a fossilized elephant bone were recovered. Within arguable limits the braincase could be restored as of modern size and shape, with a well-developed forehead; the uniform thickness was the primitive character. The jaw was decidedly apelike, but the surviving teeth showed the flat wear characteristic of premodern humans. The canine tooth was larger than in moderns but smaller than in apes. The glenoid fossa of the jaw joint on the skull had the normal form for human chewing motions, but no corresponding condyle on the lower jaw was found. All parts had the dark color of local fossilized material, as did the tools and other bones. The fauna as well as the tools could be placed as early as the Pliocene or as late as the mid-Pleistocene.

The material was presented in 1912 as a new form of early human, *Eoanthropus dawsoni*. In spite of the incongruity of brain size and jaw form, scientists generally accepted the find at face value. In 1953, when the broader picture of fossil humans had made Piltdown incongruous, logic led to the hypothesis of a deliberate hoax. Chemical tests, such as nitrogen loss or fluorine uptake, then showed that none of the human bones could be more than a few centuries old. Also, on reexamination at the same time, signs of forging were evident. The jaw was identified as that of an orangutan. The thickened skull was apparently that of someone with Paget's disease. The most important result of the Piltdown find was to cast doubt on a model for early hominids having a small brain and large, more human teeth. Thus when *Australopithecus* was reported in 1925, it was initially pronounced to be an ape. *See* FOSSIL HUMANS. [W.W.Ho.]

Pimento A type of pepper, *Capsicum annuum*, grown for its thick, sweet-fleshed red fruit. A member of the plant order Polemoniales, pimento is of American origin, and gets its name from the Spanish word designating all sweet peppers. In the United States, however, the term pimento generally refers to the heart-shaped varieties (cultivars) grown for canning and used for stuffing olives and flavoring foods. Georgia is the only important pimento-producing state. *See* PEPPER; SOLANALES. [H.J.C.]

Piña A fiber, also known as pineapple fiber, obtained from the large leaves of the pineapple plant grown in tropical countries. This natural fiber is white and especially soft and lustrous. In the Philippine Islands, it is woven into piña cloth, which is soft, durable, and resistant to moisture. Piña is also used in making coarse grass cloth and for mats, bags, and clothing. *See* NATURAL FIBER; PINEAPPLE. [M.D.P.]

Pinales An order of the class Pinopsida (=Coniferopsida), of the division Pinophyta (Gymnospermae), with about 50 genera and 600 species still living. All are woody plants, as shrubs or trees, and are often the principal trees of the forests worldwide. Pine, spruce, fir, hemlock, cedar, larch, juniper, cypress, yew, redwood, big tree, kauri, podocarpus, araucaria, and others are all part of this order. The big tree (*Sequoia gigantea*) of California is the largest plant, reaching a height of 330 ft (100 m) and a diameter of 33 ft (10 m), and being over 3500 years old. Leaves are usually needlelike or scalelike, with a few exceptions such as *Agathis* (kauri), *Podocarpus*, *Phyllocladus*, and *Araucaria*. Most species are evergreen, bearing their leaves year-round. Modern conifers form some of the most extensive forests in recent times, mainly occurring in the temperate regions or mountainous regions of the subtropics. The families of extant conifers are Araucariaceae, Pinaceae, Taxodiaceae, Cupressaceae, Podocarpaceae, Taxaceae, and Cephalotaxaceae. The phylogenetic relations among these families are practically unknown. *See* PINOPHYTA; PINOPSIDA.

The cones are unisexual. In some species, both male and female cones are borne on the same plant (monoecious); in others, on separate plants (dioecious). Usually, a year intervenes between pollination and fertilization, and another year between fertilization and embryo formation. *See* REPRODUCTION (PLANT).

The conifers are a principal source of lumber and pulp for paper and wood products. Turpentine, tar, resin, and essential oils are some by-products. The group yields little food for humans; some seeds are edible (pine, pinyon, or piñon nuts). *See* PINE NUT; PINE TERPENE. [T.A.Z.]

Pinch effect A name given to manifestations of the magnetic self-attraction of parallel electric currents having the same direction. The effect at modest current levels of a few amperes can usually be neglected, but when current levels approach a million amperes such as occur in electrochemistry, the effect can be damaging and must be taken into account by electrical engineers. The pinch effect in a gas discharge has been the subject of intensive study, since it presents a possible way of achieving the magnetic confinement of a hot plasma (a highly ionized gas) necessary for the successful operation of a thermonuclear or fusion reactor.

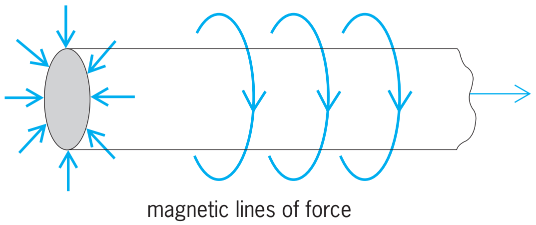


Fig. 1. Pinch pressure on a current-carrying conductor. Arrows at left show direction of pinch pressure.

The law of attraction which describes the interaction between parallel electric currents was discovered by A. M. Ampère in 1820. For a cylindrical wire of radius r meters carrying a total surface current of I amperes, it manifests itself as an inward pressure on the surface (Fig. 1) given by $I^2/2 \times 10^7 \pi r^2$ pascals. For the electric currents of normal experience, this force is small and passes unnoticed, but it is significant that the pressure increases with the square of the current, I^2. For example, at 25,000 amperes the pressure amounts to about 1 atm (100 kilopascals) for a wire of 1-cm radius, but at 10^6 amperes the pressure is about 1600 atm or about 12 tons in.$^{-2}$ (160 megapascals).

There are a number of ways in which the magnetic field of a fusion reactor can be arranged around the plasma to hold it together, and one of these methods is the pinch effect. A fusion reactor using this type of confinement would ideally be a toroidal tube in which the confined plasma would carry a large electric current induced in it by magnetic induction from a transformer core passing through the major axis of the torus. The current would have the double function of ohmically heating the plasma and compressing the plasma toward the center of the tube.

Characteristically, as can be shown by high-speed photography, the pinch forms at the inner surface of a discharge tube wall and contracts radially inward, forming an intense line, the pinch, on the axis; the pinch rebounds slightly; the contracted discharge rapidly develops necks and kinks; and in a few microseconds all structure is lost in an apparently turbulent glowing gas which fills the tube. Thus, the pinch turns out to be unstable, and plasma confinement is soon lost by contact with the wall. The cause of the instability is easily seen qualitatively: The pinch confinement can be described as being caused by the magnetic field lines encircling the pinch which are stretched longitudinally but which are in compression transversely (Fig. 2). For a uniform cylindrical pinch, the magnetic pinch pressure is everywhere equal to the

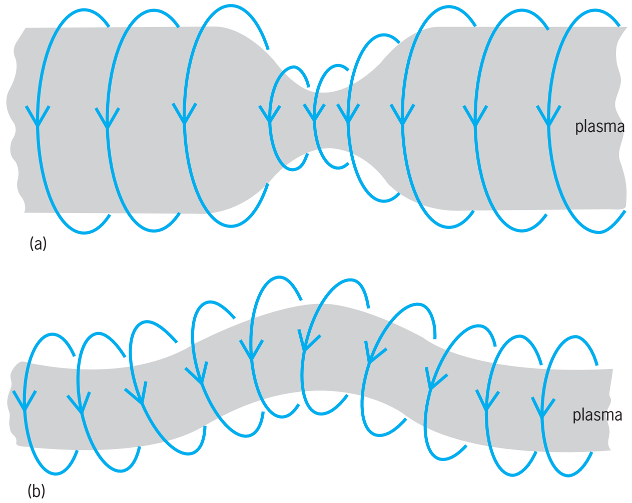

Fig. 2. Instability. (*a*) Sausage type. (*b*) Kink type.

outward plasma pressure, but at a neck or on the inward side of a kink, the magnetic field lines crowd together, creating a higher magnetic pressure than the outward gas pressure. Consequently, the neck contracts still further, the kink cuts in on the concave side and bulges out on the convex side, and both perturbations grow. The instability has a disastrous effect on the confinement time.

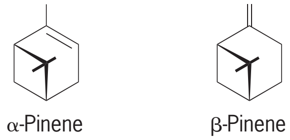
The term theta pinch has come into wide usage to denote an important plasma confinement system which relies on the repulsion of oppositely directed currents and which is thus not in accord with the original definition of the pinch effect (self-attraction of currents in the same direction). Plasma confinement systems based on the original pinch effect are known as Z pinches.

Tokamak is essentially a low-density, slow Z pinch in a torus with a very strong longitudinal field. The helical magnetic field lines, resultant from the externally applied field and that of the pinch, do not close, that is, do not complete one revolution of the minor axis in going around the major axis of the torus once. This is known theoretically to prevent the growth of certain helical distortions of the plasma. The performance of tokamak experiments has raised the possibility of achieving a net power balance. *See* NUCLEAR FUSION. [J.A.Ph.]

Pine The genus *Pinus*, of the pine family, characterized by evergreen leaves, usually in tight clusters (fascicles) of two to five, rarely single. There are about 80 known species distributed throughout the Northern Hemisphere. Botanically the leaves are of two kinds: (1) a scalelike form, the primary leaf, which subtends a much shortened and eventually deciduous shoot bearing (2) the secondary leaves or needles. The wood of pines is easily recognized by the numerous resin ducts and by the characteristic resinous odor. *See* PINALES; PINE NUT. [A.H.G./K.P.D.]

Pine nut The edible seed of more than a dozen species of evergreen cone-bearing trees in the genus *Pinus*, native to the temperate zone of the Northern Hemisphere. The important nut-producing species are the stone pine (*P. pinea*) of southern Europe; the Swiss stone pine (*P. cembra*), native to the Swiss Alps and eastward through Siberia to Mongolia; and the pinon pine (*P. cembroides* var. *edulis*) of the arid regions of the southwestern United States. The seeds or nuts, variable in size according to species, are borne in cones which take 3–4 years to develop. *See* PINE. [L.H.MacD.]

Pine terpene A major component of the essential oils obtained from various *Pinus* species. The principal terpenes of the oil of southern pines [longleaf pine (*P. palustris*) and slash pine (*P. caribaea*)] are α- and β-pinene, whose structures are shown below. *See* ESSENTIAL OIL; PINE.



Gum turpentine (gum spirits) is the volatile fraction of the oleoresin that exudes from cuts made in the trunks of live trees. The resin is collected and distilled by a process that yields about 20% turpentine, mainly α- and β-pinene, and 70% rosin; it was the basis of the original naval stores industry.

Wood turpentine is obtained by steam distillation from stumps and other logging residues. The volatile material in this case consists of about 50% turpentine and 30–40% of higher-boiling-point alcohols; the latter fraction is known as pine oil. The bulk of the wood turpentine and pine oil produced by modern industrial processes is a by-product of the sulfate wood-pulping process (sulfate turpentine).

Important uses of turpentine or the purified pinenes derived from turpentine are in terpene resins, as a thinner in paints and varnishes, and as a starting material in the synthesis of other commercially valuable terpenes.

Pine oil is a mixture of monoterpene alcohols, mainly α-terpineol, obtained in large amounts mixed with wood turpentine or sulfate turpentine. The term pine oil is also used to designate the essential oil of various species of pine.

Much of the pine oil of commerce is prepared synthetically by acid-catalyzed hydration of α-pinene. This process involves a complex series of reactions that occur via cationic intermediates.

The composition of industrial-grade pine oil is approximately 65% α-terpineol, 20–25% of other monoterpene alcohals, and 10–15% hydrocarbons. Pine oil has surfactant and emulsifying properties and is also a disinfectant. Most of the pine oil manufactured is used in the manufacture of cleansers and textile penetrants. *See* SURFACTANT; TERPENE; WOOD CHEMICALS. [J.A.Mo.]

Pineal gland An endocrine gland located in the brain which secretes melatonin, is strongly regulated by light stimuli, and is an important component of the circadian timing system. The pineal gland is virtually ubiquitous throughout the vertebrate animal kingdom. In nonmammalian vertebrates, it functions as a photoreceptive third eye and an endocrine organ. In mammals, it serves as an endocrine organ that is regulated by light entering the body via the eyes. Despite extensive species variation in anatomy and physiology, the pineal gland generally serves as an essential component of the circadian system which allows animals to internally measure time and coordinate physiological time-keeping with the external environment. *See* BIOLOGICAL CLOCKS; BRAIN.

The pineal gland is an unpaired organ attached by a stalk to the roof of the diencephalon. In frogs and lizards, one component of the pineal complex (the frontal organ or parietal eye) projects upward through the skull to lie under the skin; in all other vertebrates the pineal is located beneath the roof of the skull. Across evolution, cells within the pineal gland have progressed from classic photoreceptor cells in the earliest vertebrates, to rudimentary photoreceptors in birds, to classic endocrine cells in mammals. *See* PHOTORECEPTION; SENSE ORGAN.

In mammals, nerve fibers extend from a variety of sources in the brain to the pineal gland. The best studied of these neural inputs is through the retinohypothalamic tract, which extends from the eyes to the pineal gland in mammals. Originating in the retina, the majority of the retinohypothalamic fibers project to or around the bilateral suprachiasmatic nuclei in the hypothalamus. These nuclei serve as endogenous oscillators with period lengths close to 24 h. Thus, the suprachiasmatic nuclei function as pacemakers for the circadian system, which regulates daily physiological and behavioral rhythms. From the suprachiasmatic nuclei there are short projections to the paired paraventricular hypothalamic nuclei, and then long descending axons project from these nuclei to synapse on preganglionic sympathetic neurons in the upper thoracic spinal cord. These sympathetic neurons then extend out of the central nervous system to the superior cervical ganglia in the neck region. From there, postganglionic sympathetic axons reenter the cranium and ultimately innervate the pineal gland.

In mammals, information about environmental light and darkness is relayed from the eye to entrain circadian neural activity of the suprachiasmatic nuclei. In turn, the suprachiasmatic nuclei synchronize circadian rhythms in the pineal gland through its sympathetic innervation. One of the best-studied rhythms in the pineal gland is the biosynthesis of the hormone melatonin. Pinealocytes also have the necessary enzymes for converting tryptophan into a larger family of indole compounds, and numerous polypeptides have been localized in the pineal gland. The biological functions of these other pineal indole and peptide constituents are currently unknown.

In all vertebrate species studied, high levels of melatonin are produced and secreted during the night, while low levels are released during the day. The melatonin circadian rhythm is produced by the endogenous pacemaking activity of the suprachiasmatic nuclei, while the entrainment of this rhythm is coordinated by signals of light and darkness relayed from the eyes. Day length or photoperiod can influence the duration that melatonin production is elevated during the night. This represents a seasonal effect of light on the pineal gland. Specifically, in the summer when days are longer and nights are shorter, the duration of increased nocturnal melatonin secretion is shorter than during the winter when nights are longer. This effect of photoperiod length influencing the duration of nighttime melatonin rise has been documented in many species, including humans.

There is extensive species diversity in the capacity of melatonin to regulate physiology. Numerous species, ranging from insects to mammals, have yearly cycles of activity, morphology, reproduction, or development which are responsive to seasonal changes in day length (photoperiodism). Among many species that breed seasonally, melatonin has been shown to be a potent regulator of the reproductive axis in both males and females. The effects of melatonin on the regulation of circadian physiology has been elucidated in many vertebrate species, including humans. In addition, melatonin has been studied in different species for its influence on retinal physiology, sleep, body temperature regulation, immune function, and cardiovascular regulation. [G.C.B.]

Pineapple A low-growing perennial plant, indigenous to the Americas. The cultivated varieties (cultivars) belong to the species *Ananas sativus* of the plant order Bromeliales.

The edible portion of the pineapple develops from a mass of ovaries on a fleshy flower stock having persistent bracts (see illustration). On the cultivated types, the flowers are usually abortive. The leaves are long and swordlike and usually roughedged. Commercial plantings bear fruit at the age of 12–20 months, and may continue to be productive for as much as 8–10 years. *See* BROMELIALES.

The major producing area is Hawaii, where special methods of culture and harvesting have been developed. Pineapples are also grown in the West Indies and other tropical areas, and to a limited extent in southern Florida.

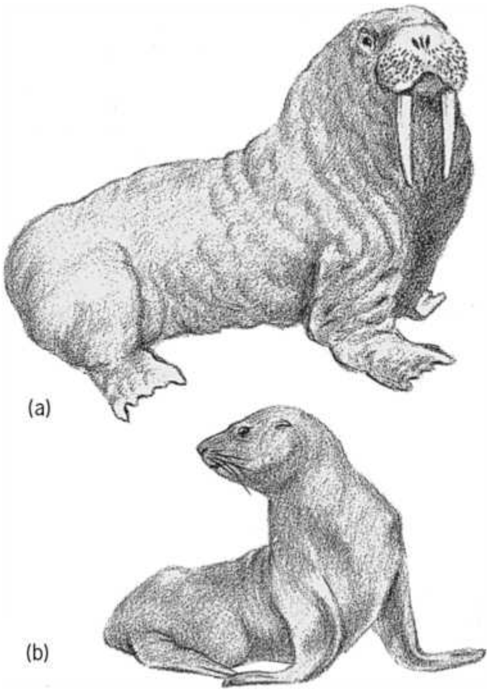
Pineapples are consumed fresh in considerable quantity, but because of distance from markets and the problems of transporting fresh fruit, most of the crop is canned as sliced pineapple or as juice. *See* FRUIT. [J.H.C.]

Pineapple (*Ananas sativus*), fruit and leaves. (*USDA*)

Pinnipeds Carnivorous mammals of the suborder Pinnipedia, which includes 32 species of seals, sea lions, and walrus in 3 families. All species of the order are found along coastal areas, from the Antarctic to the Arctic regions. Although many species have restricted distribution, the group as a whole has worldwide distribution.

Pinnipeds are less modified both anatomically and behaviorally for marine life than are other marine mammals: Each year they return to land to breed, and they have retained their hindlimbs. They are primarily carnivorous mammals, with fish supplying the basic diet. They also eat crustaceans, mollusks, and, in some instances, sea birds. Their body is covered with a heavy coat of fur, the limbs are modified as flippers, the eyes are large, the external ear is small or lacking, and the tail is absent or very short.

The single species of the family Odobenidae is the walrus (*Odobenus rosmarus*); it grows to 10 ft (3 m) and weighs 3000 lb (1350 kg). It has no external ears but does have a distinct neck region. The upper canines of both sexes are prolonged as tusks which can be used defensively (illus. *a*). The walrus feeds on marine invertebrates and fish.



Pinnipeds. (*a*) Walrus (*Odobenus rosmarus*). (*b*) Alaska fur seal (*Callorhinus ursinus*).

The family Otariidae, the eared seals, includes the sea lions and fur seals (illus. *b*), which are characterized by an external ear. The neck is longer and more clearly defined than that of true seals, and the digits lack nails. The California sea lion (*Zalophus californianus*) occurs along the Pacific coast, and is commonly seen in zoos and performing in circuses. The southern sea lion (*Otaria byronia*) is found around the Galapagos Islands and along the South American coast. Stellar's sea lion (*Eumetopias jubatus*) is a large species found along the Pacific coast. Minor species are the Australian sea lion (*Neophoca cinerea*) and the New Zealand species (*Phocarctos hookeri*).

Phocidae is the largest family of pinnipeds, the true seals. It includes the monk seals, elephant seals, common seals, and other less well-known forms. The family is unique in that the digits have nails, the soles and palms are covered with hair, and the necks are very short. Most species live in marine habitats; however, the Caspian seal (*Pusa caspica*) lives in brackish water. The only fresh-water seal is the Baikal seal (*P. sibirica*). It is estimated that there are between 40,000 and 100,000 Baikal seals in Lake Baikal. One of the best-known species is the Atlantic gray seal (*Halichoreus grypus*), a species fround in the North Atlantic along the coasts of Europe, Iceland, and Greenland. *See* CARNIVORA; MAMMALIA. [C.B.C.]

Pinophyta One of the two divisions of the seed plants, comprising about 600 to 700 species extant on all continents except Antarctica. The most familiar and common representatives are the evergreen, cone-bearing trees of the Pinales. Because the ovules (young seeds) are exposed directly to the air at the time of pollination, the Pinophyta are commonly known as the gymnosperms, in contrast to the other division of flowering plants, the angiosperms (division Magnoliophyta), which have the ovules enclosed in an ovary. The division Pinophyta consists of three classes: Ginkgoopsida, Cycadopsida, and Pinopsida. *See* CYCADOPSIDA; GINKGOOPSIDA; MAGNOLIOPHYTA; PINOPSIDA; PLANT KINGDOM. [T.A.Z.]

Pinopsida The largest and most important class of the division Pinophyta (Gymnospermae), the other classes being Ginkgoopsida and Cycadopsida. There are two orders: the Cordaitanthales, with three extinct families, and the Pinales (Coniferales), with six extinct families and seven families with some extant genera.

The living Pinopsida are woody plants; most are trees with a central axis and excurrent branches. Leaves are simple, alternate, or opposite or in whorls, scalelike or needlelike or rarely planar. The wood lacks vessels and usually has resin canals. Male reproductive structures are aggregated on microsporophylls directly attached to the cone axis. The ovules are borne in compound cones or singly or paired at the end of a stalk (Taxaceae). The main seed plane is tangential to the cone axis (if the seed scale is regarded as a modified dwarf shoot). The embryo has two or more cotyledons. *See* CYCADOPSIDA; GINKGOOPSIDA; PINALES. [T.A.Z.]

Pionium An exotic atom, also called the pi-mu atom, which is similar in structure to the hydrogen atom but with the proton replaced by a pion and the electron replaced by a muon. Pionium is unique among atoms that have been observed in the laboratory in that all of its constituents are unstable particles not found in ordinary matter. Pionium is formed during the decay of a certain heavier particle called the neutral kaon. A kaon has many modes of decay, one of which results in the formation of a pion, a muon, and a neutrino. *See* ELEMENTARY PARTICLE.

The nomenclature of exotic atoms is not well established, and the name pionium may also refer to the pion-electron atom. [P.A.S.]

Pipe flow Conveyance of fluids in closed circular ducts. Flow in closed conduits is probably the most common way of transporting fluids. Crude oil and its components are moved through pipes in a refinery. Water in the home is transported through tubing. Heated and conditioned air is distributed to all parts of a dwelling in circular or rectangular ducts. *See* PIPELINE.

Flow in a closed conduit (circular or otherwise) can be either laminar or turbulent. In laminar flow, the fluid particles move smoothly through the duct in layers called laminae. A fluid particle in one layer stays in that layer. In turbulent flow, flowing fluid particles move tortuously about the cross section, resulting in an effective mixing action. Eddies and vortices are responsible for the mixing, which does not occur in laminar flow. Turbulent flow exists at much higher flow rates than laminar flow.

The criterion for distinguishing between laminar and turbulent flow is this observed mixing action. When injected into a laminar flow in a duct, a dye moves downstream in a threadlike line. When injected into a turbulent flow, a dye disperses quickly. Experiments have shown that laminar flow exists when the dimensionless Reynolds number, $\mathrm{Re} = VD/\nu$, is less than 2100; here V is the average velocity, D is the inside diameter of the pipe or tube, and ν is the kinematic viscosity (a property of the fluid). *See* FLUID FLOW; LAMINAR FLOW; REYNOLDS NUMBER; TURBULENT FLOW.

The energy loss experienced by the fluid is manifested as a pressure drop Δp, which is found in terms of a dimensionless friction factor f as shown in Eq. (1). Here, the density ρ is a

$$\Delta p = \frac{fL}{D}\frac{\rho V^2}{2} \qquad (1)$$

property of the fluid, L is the length over which the pressure drop occurs, D is the inside diameter of the pipe or tube, V is the average velocity, and the quantity $\rho V^2/2$ is the kinetic energy of the flow per unit volume. For laminar flow through a circular duct, the friction factor is found in terms of the Reynolds number, as indicated in Eq. (2). For turbulent flow, the friction factor is

$$f = \frac{64}{\mathrm{Re}} \qquad \left(\begin{array}{l}\text{laminar flow,}\\ \text{circular duct}\end{array}\right) \qquad (2)$$

dependent upon the wall roughness, the fluid properties, the average velocity, and the pipe diameter; that is, $f = f(V, D, \rho, \mu, \varepsilon)$, in which ε is a measure of the absolute roughness of the conduit wall, having the dimension of length. Values of the roughness ε have been measured for many commercial pipe materials. The friction factor for turbulent flow may be obtained from a Moody diagram in which the friction factor f is graphed as a function of the Reynolds number Re, with the relative roughness ε/D as an independent parameter. The Moody diagram is a result of many flow rate and pressure drop measurements made on commercial pipe and tube materials. [W.S.J.]

Pipeline A line of piping and the associated pumps, valves, and equipment necessary for the transportation of a fluid. Major uses of pipelines are for the transportation of petroleum, water (including sewage), chemicals, foodstuffs, pulverized coal, and gases such as natural gas, steam, and compressed air. Pipelines must be leakproof and must permit the application of whatever pressure is required to force conveyed substances through the lines. Pipe is made of a variety of materials and in diameters from a fraction of an inch up to 30 ft (9 m). Principal materials are steel, wrought and cast iron, concrete, clay products, aluminum, copper, brass, cement and asbestos (called cement-asbestos), plastics, and wood.

Pipe is described as pressure and nonpressure pipe. In many pressure lines, such as long oil and gas lines, pumps force substances through the pipelines at required velocities. Pressure may be developed also by gravity head, as for example in city water mains fed from elevated tanks or reservoirs.

Nonpressure pipe is used for gravity flow where the gradient is nominal and without major irregularities, as in sewer lines, culverts, and certain types of irrigation distribution systems.

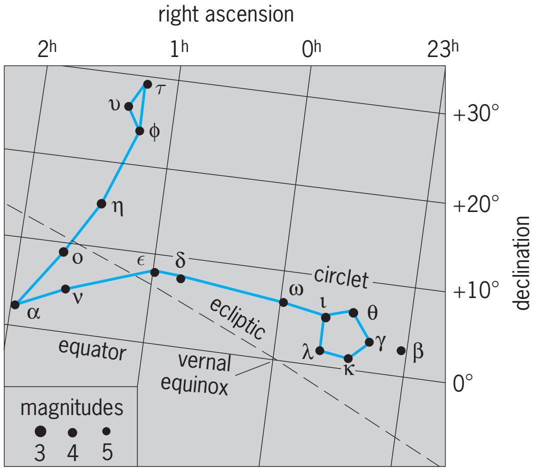
Design of pipelines considers such factors as required capacity, internal and external pressures, water- or airtightness, expansion characteristics of the pipe material, chemical activity of the liquid or gas being conveyed, and corrosion. [L.N.McC.]

Piperales A small order of flowering plants (3600 species) in the eumagnoliid group, which is composed of three anomalously woody vines (shrubs) or herbaceous families—the pipeworts (Aristolochiaceae), the black pepper family (Piperaceae), and the lizard's tail family (Saururaceae). The last two families have reduced flowers in dense spikelike flower stems, and the first has medium-sized to enormous flowers that often trap insects for a period before releasing them, covered with pollen.

Black pepper comes from *Piper nigrum* and betel nuts from *P. betle*. Several species of *Aristolochia* have medicinal properties, and some genera in each of these families are commonly grown ornamentals in the temperate zones or house plants, such as *Asarum* (wild ginger), *Peperomia* (pepper elders), and *Houttuynia*. *See* EUMAGNOLIIDS; LAURALES; MAGNOLIALES; MONOCOTYLEDONS. [M.W.C.]

Pirani gage A type of instrument used to measure vacuum by utilizing a resistance change due to a temperature change in a filament. This fine-wire filament, one of the four electrical resistances forming a Wheatstone bridge circuit, is exposed to the vacuum to be measured. Electric current heats the wire; the surrounding gas (in the vacuum) conducts heat away from the wire. At a stable vacuum, the wire quickly reaches equilibrium temperature. If the pressure rises, the gas carries away more heat, and the temperature of the wire decreases. Since the resistance of the filament is a function of temperature, the electrical balance of the Wheatstone bridge is changed. Pressure measurement range of this type of gage is usually 1 to 10^{-4} torr (10^2 to 10^{-2} pascals). *See* VACUUM MEASUREMENT. [R.C.]

Pisces (constellation) The Fishes, in astronomy, a zodiacal constellation appearing in the autumn evening sky. Pisces is the twelfth and last sign of the zodiac. It is inconspicuous, having no star brighter than the fourth magnitude. But it is an important constellation because the vernal equinox, which marks the beginning of the astronomical year, is now located in it (see illustration). *See* CONSTELLATION. [C.-S.Y.]



Line pattern in the constellation Pisces. The grid lines represent the coordinates of the sky. The apparent brightness, or magnitude, of the various stars is shown by the sizes of the dots, which are graded by appropriate numbers as indicated.

Pisces (zoology) A term that embraces all fishes and fishlike vertebrates. The Pisces include four well-defined groups that merit recognition as classes: the Agnatha or jawless fishes, the most primitive; the Placodermi or armored fishes, known only as Paleozoic fossils; the Chondrichthyes or cartilaginous fishes; and the Osteichthyes or bony fishes. *See* CHONDRICHTHYES; JAWLESS VERTEBRATES; OSTEICHTHYES; PLACODERMI. [R.M.B.]

Pistachio A tree, *Pistacia vera*, of the Anacardiaceae family. It is native to central Asia and has been grown for its edible nuts throughout recorded history in various countries of the Mediterranean region. Extensive areas in California were planted with pistachios in the 1970s, and the first commercial nut crop was harvested in 1977. *See* SAPINDALES.

The pistachio tree, relatively slow-growing, reaches a height and spread of 20–25 ft (6–8 m). It thrives under long, hot summers with low humidity, but needs moderately cold winters to satisfy its chilling requirement. Pistachio is deciduous and has imparipinnate leaves, most often 2-paired. It is dioecious, and both staminate and pistillate inflorescences are panicles that may have 150 or more individual flowers. They lack petals and nectaries and, consequently, are wind-pollinated. The fruit, a semidry drupe, is borne on 1-year-old wood in clusters similar to grapes and matures in September. The hull (exocarp and mesocarp) at that time slips easily from the shell (endocarp) which has already dehisced, exposing the kernel. Pistachio kernels contain only 5–10% sugars, but their protein and oil content of about 20 and 40%, respectively, make them high in food value. *See* NUT CROP CULTURE. [J.C.Cr.]

Pitch The psychological property of sound characterized by highness or lowness. Pitch is one of the two major auditory attributes of simple sounds, the other being loudness.

A simple sound source, such as a tuning fork, produces an acoustic wave that approximates a perfect sinusoid, and the pitch of a sinusoid wave is almost completely determined by its frequency. Many sounds, however, are complex and contain a number of sinusoidal components. Complex sounds often appear to have a strong pitch, which is the frequency of a sinusoid that appears to match the complex sound. Hence, a tuning fork that vibrates at about 440 Hz will have a pitch very nearly equal to the note A above middle C on the piano. Loudness is determined by the amplitude of the sound vibrations. *See* LOUDNESS; TUNING FORK; WAVE (PHYSICS).

A sequence of different sounds having definite pitches produces a musical tune, making pitch extremely important in music. Practically all musical conventions recognize that doubling the frequency of vibration produces a particular pitch interval, known as an octave. *See* MUSICAL ACOUSTICS; SCALE (MUSIC).

The human auditory system can hear frequencies in the range of 20–20,000 Hz. For frequencies between 100 and 4000 Hz, sinusoidal sounds have a clear pitch. Beyond these limits, the pitch of sound is not distinct. Sounds below 100 Hz may be described as rumbles, while those above 4000 Hz may be described as shrill and squeaky. The ability to detect changes in pitch is remarkably acute. The just-detectable change in frequency is about 0.3% for the midfrequency range. Frequency changes are best detected when the sound is loud. Weaker sounds require greater changes in frequency to be detectable. *See* AUDIOMETRY; HEARING (HUMAN). [D.M.Gree.]

Pitcher plant Any member of the families Sarraceniaceae and Nepenthaceae. In these insectivorous plants the leaves form deep cups or pitchers in which water collects. Visiting insects, falling into this water, are drowned and digested by the action of enzymes secreted by cells located in the walls of the pitcherlike structures of these plants. Often these plants climb by tendrils. The end of a tendril may develop into a pitcher, which captures and digests insects. *See* INSECTIVOROUS PLANTS; NEPENTHALES. [P.D.St./E.L.C.]

Pitchstone A natural glass with dull or pitchy luster and generally brown, green or gray color. It is extremely rich in microscopic, embryonic crystal growths (crystallites) which may cause its dull appearance. The water content of pitchstone is high and generally ranges from 4 to 10% by weight. Pitchstone is formed by rapid cooling of molten rock material (lava or magma) and occurs most commonly as small dikes or as marginal portions of larger dikes. *See* IGNEOUS ROCKS; VOLCANIC GLASS. [C.A.C.]

Pith The central zone of tissue of an axis in which the vascular tissue is arranged as a hollow cylinder. Pith is present in most stems and in some roots. Stems without pith rarely occur in angiosperms but are characteristic of psilopsids, lycopsids, *Sphenophyllum*, and some ferns. Roots of some ferns, many monocotyledons, and some dicotyledons include a pith, although most roots have xylem tissue in the center.

Pith is composed usually of parenchyma cells often arranged in longitudinal files. This arrangement results from predominantly transverse division of pith mother cells near the apical meristem. *See* Parenchyma; Root (botany); Stem. [H.W.Bl.]

Pitot tube A device to measure the stagnation pressure due to isentropic deceleration of a flowing fluid. In its original form it was a glass tube bent at 90° and inserted in a stream flow, with its opening pointed upstream. Water rises in the tube a distance, h, above the surface, and if friction losses are negligible, the velocity of the stream, V, is approximately 2gh, where g is the acceleration of gravity. However, there is a significant measurement error if the probe is misaligned at an angle α with respect to the stream. For an open tube, the error is about 5% at $\alpha \approx 10^\circ$.

The misalignment error of a pitot tube is greatly reduced if the probe is shielded, as in the Kiel-type probe. The Kiel probe is accurate up to $\alpha \approx 45^\circ$.

The modern application is a pitot-static probe, which measures both the stagnation pressure, with a hole in the front, and the static pressure in the moving stream, with holes on the sides. A pressure transducer or manometer records the difference between these two pressures. Pitot-static tubes are generally unshielded and must be carefully aligned with the flow to carry out accurate measurements. *See* Bernoulli's theorem.

When used with gases, estimate of the stream velocity is only valid for a low-speed or nearly incompressible flow, where the stream velocity is less than about 30% of the speed of sound of the fluid. At higher velocities, estimate of the stream velocity must be replaced with a Bernoulli-type theory, which accounts for gas density and temperature changes. If the gas stream flow is supersonic, or the stream velocity is greater than the speed of sound of the gas, a shock wave forms in front of the probe and the theory must be further corrected by complicated supersonic-flow algebraic relations. *See* Compressible flow; Gas dynamics; Shock wave.

A disadvantage of pitot and pitot-static tubes is that they have substantial dynamic resistance to changing conditions and thus cannot accurately measure unsteady, accelerating, or fluctuating flows. *See* Anemometer; Flow measurement. [F.M.Wh.]

Pituitary gland The most structurally and functionally complex organ of the endocrine system. Through its hormones, the pituitary, also known as the hypophysis, affects every physiological process of the body. All vertebrates have a pituitary gland with a common basic structure and function. In addition to its endocrine functions, the pituitary may play a role in the immune response.

The hypophysis of all vertebrates has two major segments—the neurohypophysis (a neural component) and the adenohypophysis (an epithelial component)—each with a different embryological origin. The neurohypophysis develops from a downward process of the diencephalon (the base of the brain), whereas the adenohypophysis originates as an outpocketing of the primitive buccal epithelium, known as Rathke's pouch. The adenohypophysis has three distinct subdivisions: the pars tuberalis, the pars distalis, and the pars intermedia. The neurohypophysis comprises the pars nervosa and the infundibulum. The latter consists of the infundibular stalk and the median eminence of the tuber cinereum.

The structural intimacy of neurohypophysis and adenohypophysis that is established early during embryogenesis reflects the direct functional interaction between the central nervous system and endocrine system. The extent of this anatomical intimacy varies considerably among the vertebrate classes, from limited contact to intimate interdigitation. Vascular or neuronal pathways, or both, provide the means of exchanging chemical signals, thus enabling centers in the brain to exert control over the synthesis and release of adenohypophysial hormones.

Neurohormones, which are synthesized in specific regions of the brain, are conveyed to the neurohypophysis by way of axonal tracts, where they may be stored in distended axonal endings. Axons may also contact blood vessels and discharge their neurosecretory products into the systemic circulation or into a portal system leading to the adenohypophysis, or they may directly innervate pituitary gland cells. *See* Neurosecretion.

In most animals, the vascular link is the prime route of information transfer between brain and pituitary gland. This link begins in the tuber cinereum, the portion of the third ventricle floor that extends toward the infundibulum. The lower tuber cinereum, which is known as the median eminence, is well endowed with blood vessels that drain down into the pituitary stalk and ultimately empty into the anterior pituitary. The vascular link between the median eminence and the pituitary gland is known as the hypothalamo-hypophysial portal system. The median eminence in humans is vascularized by the paired superior hypophysial arteries. The pituitary gland is believed to have the highest blood flow rate of any organ in the body. However, its blood is received indirectly via the median eminence and the hypothalamo-hypophysial portal system. Most of the blood flow is from the brain to the pituitary gland, with retrograde flow from the adenohypophysis to the hypothalamus, suggesting a two-way communication between nervous and endocrine systems. Although the brain is protected from the chemical substances in the circulatory system by the blood–brain barrier, the median eminence lies outside that protective mechanism and is therefore permeable to intravascular substances. *See* Brain.

The hormones of the adenohypophysis may be grouped into three categories based on chemical and functional similarities. The first category consists of growth hormone (also known as somatotropin) and prolactin, both of which are large, single, polypeptide chains; the second category consists of the glycoprotein hormones; this family of hormones contains the gonadotropins and thyrotropin. The gonadotropins in many species, including humans, can be segregated into two distinct hormones, follicle-stimulating hormone and luteinizing hormone. The third group comprises adrenocortiotropic hormone and melanotropin (MSH; melanocyte-stimulating hormone). *See* Adenohypophysis hormone.

The regulation of the release of pituitary hormones is determined by precise monitoring of circulating hormone levels in the blood and by genetic and environmental factors that manifest their effect through the releasing and release-inhibiting factors of the hypothalamus. The hypothalamus is located at the base of the brain (the diencephalon) below the thalamus and above the pituitary gland, forming the walls and the lower portion of the third ventricle. It receives major neuronal inputs from the sense organs, hippocampus, thalamus, and lower brainstem structures, including the reticular formation and the spinal cord. Thus, the hypothalamus is designed and anatomically positioned to receive a diversity of messages from external and internal sources that can be transmitted by way of hypothalamic releasing factors to the pituitary gland, where they are translated into endocrine action. *See* Nervous system (vertebrate).

The neurohypophysis hormones, oxytocin and vasopressin, are synthesized in different neurons of the paraventricular and supraoptic nuclei of the hypothalamus and travel by axonal flow to the terminals in the neurohypophysis for storage and ultimate release into the vascular system. Oxytocin is important in stimulating milk release through its contractile action on muscle elements in the mammary gland. It also stimulates uterine smooth muscle contraction at parturition. Vasopressin affects water retention by its action on certain kidney tubules. Thus, it also affects blood pressure. *See* Lactation; Neurohypophysis hormone.

The better-known neurotransmitters of the central nervous system include the catecholamines (dopamine, epinephrine, and norepinephrine), serotonin, acetylcholine, gamma-amino butyric acid (GABA), histamine, and the opioid peptides (enkephalins, endorphins, dynorphin, neoendorphin, rimorphin, and leumorphin). These substances are distributed widely in the central nervous system and, for most, also in the pituitary gland. If a particular amine or neurotransmitter is present in nerve fibers leading to the median eminence, it probably will influence pituitary gland activity via the portal system. Dopamine, serotonin, gamma-amino butyric acid, and acetylcholine are best known for such activity. These neurotransmitters play an important, but poorly understood, role in regulating pituitary function, either directly or by their action on neuropeptide-producing neurons. Understanding the pharmacology of neurotransmitters holds promise for the treatment of basic disorders of the hypothalamic-pituitary axis. *See* Acetylcholine; Endocrine mechanisms; Endocrine system (vertebrate); Endorphins; Histamine; Hormone; Neurobiology; Neuroimmunology; Pituitary gland disorders; Serotonin. [M.P.S.]

Pituitary gland disorders Inborn or acquired abnormalities in the structure or function of the human pituitary gland. Pituitary disorders can stem from any of five disease processes: tumors and other growths, intrinsic lesions of the anterior lobe, diseases affecting gland function, hypothalamic malfunction, and systemic disease that affects the adenohypophysis.

Tumors and other growths in and near the pituitary may cause failure of hormone secretion or impinge on nearby brain structures. The latter effect can give rise to neurological malfunctions, the most common of which is visual impairment such as narrowing of the visual fields. Intrinsic lesions of the anterior pituitary, usually benign, secrete excessive amounts of a single (rarely multiple) hormone, producing characteristic endocrine syndromes, the most dramatic of which are acromegaly and Cushing's disease. Infections, congenital anomalies, granulomas, vascular disorders, and, rarely, metastatic cancers may induce partial or total failure of one or more pituitary secretions, in which case growth hormone, follicle-stimulating hormone, and luteinizing hormone are the first to fail.

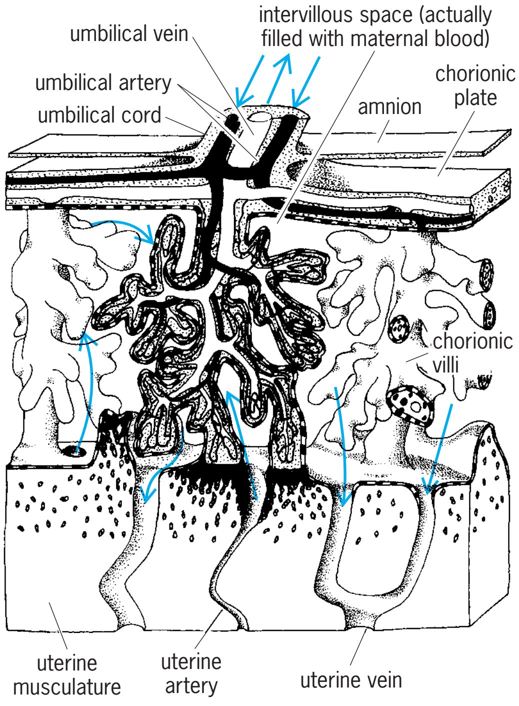
Diseases of the hypothalamus affect pituitary function through the mechanical effects of a mass or through disrupted secretion of the hypophysiotropic peptides. Typical manifestations include precocious or delayed puberty; diabetes insipidus; and derangements of sleep, eating, and temperature regulation. The dysfunction may be of congenital, traumatic, inflammatory, or neoplastic origin. However, the most important hypothalamic-pituitary diseases are tertiary hypothyroidism, precocious or delayed puberty, diabetes insipidus, and Kallmann's syndrome, which consists of a deficient sense of smell and lack of sexual development due to inborn failure of the hypothalamus to secrete gonadotropin-releasing hormone. Hypothalamic disorders can cause abnormalities of growth hormone secretion. Whereas most individuals with acromegaly (an excess of growth hormone) have intrinsic pituitary tumors that secrete growth hormone, some have excessive secretion of hypothalamic growth hormone-releasing hormone or insufficient secretion of somatostatin. Pituitary dwarfism, caused by the failure to secrete growth hormone in childhood, is usually due to primary disease of the adenohypophysis, but in some individuals the fundamental dysfunction (opposite to that in acromegaly) lies in the hypothalamus. *See* Diabetes; Dwarfism and gigantism; Somatostatin; Thyroid gland disorders.

The adenohypophysis can be affected subtly by systemic diseases, or more obviously by metastases from breast cancer. Prolonged treatment with large doses of adrenal corticosteroids, as in cases of lupus, asthma, or acute leukemia, can result in the failure of the adenohypophysis to secrete adrenocorticotropic hormone in times of physical stress. A deficiency in adrenocorticotropic hormone is a potentially fatal condition. *See* Adenohypophysis hormone; Adrenal gland disorders; Endocrine mechanisms; Pituitary gland. [N.Ch.]

pK The logarithm (to the base 10) of the reciprocal of the equilibrium constant for a specified reaction under specified conditions (for example, solvent and temperature). The p*K* values are often more convenient to tabulate and use than the equilibrium constants themselves. The value of K for the dissociation of the HSO_4^- ion in aqueous solution at 25°C (77°F) is 0.0102 mole/liter. The logarithm is $0.008_6 - 2 = -1.991_4$ The p*K* is therefore $+\ 1.991_4$. The choice of algebraic sign, although arbitrary, results in positive values for most dissociation constants applicable to aqueous solutions. The concept of p*K* is especially valuable in the study of solutions. *See* Chemical equilibrium; Ionic equilibrium; pH. [T.F.Y.]

Placentation The intimate association or fusion of a tissue or organ of the embryonic stage of an animal to its parent for physiological exchange to promote the growth and development of the young. It enables the young, retained within the body or tissues of the mother, to respire, acquire nourishment, and eliminate wastes by bringing the bloodstreams of mother and young into close association but never into direct connection. Placentation characterizes the early development of all mammals except the egg-laying duckbill platypus and spiny anteater. It occurs in some species of all other orders of vertebrates except the birds. In fact, in certain sharks and reptiles it is almost as well developed as in mammals. A few examples are also known among invertebrates (*Peripatus*, certain tunicates, and insects). *See* Fetal membrane.

Efficient interchange depends on close proximity of large areas of fetal tissues to maternal blood and glandular areas. This is provided in mammals by a remarkable regulatory cooperation between the developing outer layer (trophoblast) of the chorion, together with the vascular yolk sac or allantois or both, and the mother's uterine lining (endometrium). In the typical mammalian placenta, which is always formed by the chorion and the allantoic vessels, the fetal and maternal bloodstreams are as close as a few thousandths of a millimeter from each other (see illustration). The surface area of the fetal villi which contain the functional fetal capillaries is probably several times larger than the



Block removed from center of human placenta.

body surface of the female. In humans this ratio is known to be about 8:1. [H.W.Mo.]

Placer mining The exploitation of placer mineral deposits for their valuable heavy minerals. Placer mineral deposits consist of detrital natural material containing discrete mineral particles. They are formed by chemical and physical weathering of in-place heavy minerals, which are then concentrated through the action of wind or moving water. This concentration can be done through wave and current action in the ocean (beach and offshore placers), glacial action (moraine placers), wind action removing the lighter material (eolian placers), or the action of running water (stream placers). Stream placers are the most important of these deposits because of their common occurrence and their highly efficient concentration mechanisms. Marine placers, primarily beach placers, are the next most economically important, with the potential of offshore placers being the most recent to be recognized and developed. *See* MARINE MINING; ORE AND MINERAL DEPOSITS.

Minerals that are concentrated in placer deposits are a result of differences in specific gravity and, therefore, the economically important deposits are for minerals with high specific gravities [for example, gold (specific gravity 15–19), and platinum (14–19)].

Precious metals, primarily gold and platinum group metals, have been the most important product from placer mines. Their extremely high specific gravity coupled with their low chemical reactivity means that these minerals are efficiently concentrated in a placer environment and can be effectively recovered in a readily usable form. Although most modern gold is produced from lode, or “hard rock,” deposits, the placer deposits of northern Canada, Alaska, and Siberia represent a virtually untapped source of the metal. *See* GOLD; PLATINUM.

Of more importance than gold are placer diamond deposits. Another important placer mineral is cassiterite, an ore of tin. Additionally, rutile and ilmenite, the principal ores of titanium, are found in commercial quantities only in beach placers. These same types of placers also yield monazite, a source of the rare earths yttrium, lanthanum, cerium, and thorium. *See* CASSITERITE; DIAMOND; ILMENITE; RUTILE.

Most placer mining operations involve surface mining methods, although underground methods are sometimes used. *See* SURFACE MINING; UNDERGROUND MINING.

The two major environmental problems associated with placer mining are water pollution and land disturbance. Both the mining and the processing of placer minerals require a great deal of water, and, once used, this water contains large amounts of suspended solids. If the water is allowed to run off into the rivers, these solids can have an adverse impact on the downstream environment. In suspension they can harm aquatic habitats, and when settled out can clog waterways and choke off irrigated crops. Since most placer mining is surface mining, surface disturbance is necessary, especially where dredging operations create vast piles of cobbles as mining progresses. One method of land reclamation is a mining plan which stockpiles top soil (where possible), recontours the spoil (waste) piles, and then returns the land to useful status. *See* ENVIRONMENTAL ENGINEERING; LAND RECLAMATION; WATER POLLUTION. [D.L.Tay.]

Placodermi A class of fishes known from the Devonian Period, and a few that survived into the base of the Carboniferous. They were true fishes or gnathostomes, and can be distinguished from other fishes by the following characters: the gill chamber extends far under the cranium and is covered laterally by opercula; there is a neck joint between the cranium and the fused anterior vertebrae; often there is also a coaxial joint developed between the dermal bones of the cranial roof and shoulder girdle; the head and shoulder girdle are covered with dermal bones composed typically of cellular bone and superficially of semidentine instead of true dentine; the bones are commonly ornamented with tubercles or ridges; the endoskeleton is cartilage and may be calcified in a globular fashion or perichondrally ossified; the notochord is persistent, and the vertebrae consist only of neural and hemal arches; the tail is diphycercal or slightly heterocercal, and an anal fin is lacking.

Most placoderms were bottom-dwelling fishes, with the head and trunk dorsoventrally depressed; only the Stensioellida and some specialized arthrodires had laterally compressed and deepened bodies, suggesting a more nectic manner of life. Most of them were small or moderate-sized, but a few were, for their time, gigantic, reaching a length of as much as 20 ft (6 m). They were the dominant fishes of the Devonian, and are found in both marine and fresh-water deposits.

The Placodermi are subdivided into nine orders, each with its own distinct specializations: Stensioellida, Pseudopetalichthyida, Rhenanida, Ptyctodontida, Anthracothoraci, Petalichthyida, Phyllolepida, Arthrodira, and Antiachi. The evolution and interrelations of these orders are matters of disagreement. [R.H.De.; E.C.O.]

Placodontia A small but interesting order of marine reptiles of the subclass Euryapsida that are known only from deposits of Triassic age of Europe and the Near East (Israel). As the name implies, they are reptiles with grossly specialized dentitions—flat-crowned teeth are located in both the upper and lower jaws and on the palate—that probably functioned as crushing devices for hard-shelled prey.

The modification of the dentition had its effect on the entire skull, which became massive in relation to the body; and the coronoid region of the mandible, to which most of the masticatory muscles were attached, became greatly extended upward, giving it a superficial similarity to a mammalian jaw. The postcranial skeleton shows a number of aquatic adaptations. The thorax was box-shaped and the digits of hand and foot were probably webbed; the joint surfaces of the limb bones suggest that the animals did little if any walking on land. The advanced placodonts resemble sea turtles in overall appearance and in the fact that their body is encased in an armor of dermal bones similar to that of the dermochelyid sea turtle *Psephophorus*. The more generalized genera lack such an armor and possess a long tail. *See* REPTILIA. [R.Z.]

Plague An infectious disease of humans and rodents caused by the bacterium *Yersinia pestis*. The sylvatic (wild-animal) form persists today in more than 200 species of rodents throughout the world. The explosive urban epidemics of the Middle Ages, known as the Black Death, resulted when the infection of dense populations of city rats living closely with humans introduced disease from the Near East. The disease then was spread both by rat fleas and by transmission between humans. During these outbreaks, as much as 50% of the European population died. At present, contact with wild rodents and their fleas, sometimes via domestic cats and dogs, leads to sporadic human disease. *See* INFECTIOUS DISEASE.

After infection by *Y. pestis*, fleas develop obstruction of the foregut, causing regurgitation of plague bacilli during the next blood meal. The rat flea, *Xenopsylla cheopsis*, is an especially efficient plague vector, both between rats and from rats to humans. Human (bubonic) plague is transmitted by the bite of an infected flea; after several days, a painful swelling (the bubo) of local lymph nodes occurs. Bacteria can then spread to other organ systems, especially the lung; fever, chills, prostration, and death may occur. Plague pneumonia develops in 10–20% of all bubonic infections. In some individuals, the skin may develop hemorrhages and necrosis (tissue death), probably the origin of the ancient name, the Black Death. The last primary pneumonic plague outbreak in the United States occurred in 1919, when 13 cases resulting in 12 deaths developed before the disease was recognized and halted by isolation of cases.

Bubonic plaque is suspected when the characteristic painful, swollen glands develop in the groin, armpit, or neck of an individual who has possibly been exposed to wild-animal fleas in an area where the disease is endemic. Immediate identification is possible by microscopic evaluation of bubo aspirate stained with fluorescent-tagged antibody. Antibiotics should be given if plague is suspected or confirmed. Such treatment is very effective if started early. The current overall death rate, approximately 15%, is reduced to less than 5% among patients treated at the onset of symptoms. *See* IMMUNOFLUORESCENCE; MEDICAL BACTERIOLOGY. [D.L.Pa.]

Plains The relatively smooth sections of the continental surfaces, occupied largely by gentle rather than steep slopes and exhibiting only small local differences in elevation. Because of their smoothness, plains lands, if other conditions are favorable, are especially amenable to many human activities. Thus it is not surprising that the majority of the world's principal agricultural regions, close-meshed transportation networks, and concentrations of population are found on plains. Large parts of the Earth's plains, however, are hindered for human use by dryness, shortness of frost-free season, infertile soils, or poor drainage. Because of the absence of major differences in elevation or exposure or of obstacles to the free movement of air masses, extensive plains usually exhibit broad uniformity or gradual transition of climatic characteristics.

Somewhat more than one-third of the Earth's land area is occupied by plains. With the exception of ice-sheathed Antarctica, each continent contains at least one major expanse of smooth land in addition to numerous smaller areas. The largest plains of North America, South America, and Eurasia lie in the continental interiors, with broad extensions reaching to the Atlantic (and Arctic) Coast. The most extensive plains of Africa occupy much of the Sahara and reach south into the Congo and Kalahari basins. Much of Australia is smooth, with only the eastern margin lacking extensive plains. *See* TERRAIN AREAS.

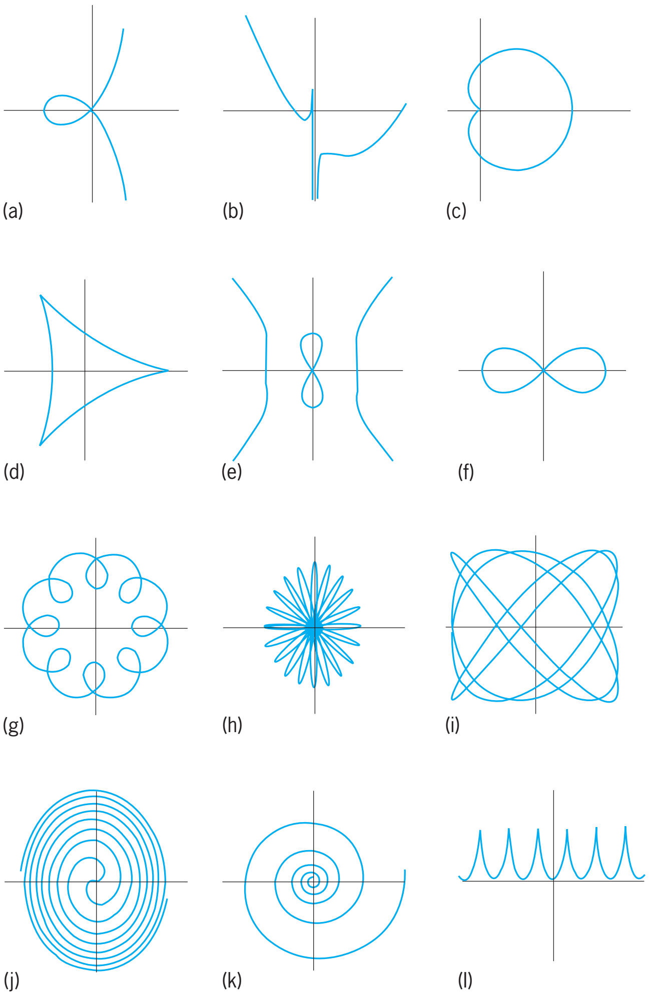
Surfaces that approach true flatness, while not rare, constitute a minor portion of the world's plains. Most commonly they occur along low-lying coastal margins, the lower sections of major river systems, or the floors of inland basins. Nearly all are the products of extensive deposition by streams or in lakes or shallow seas. The majority of plains, however, are distinctly irregular in surface form, as a result of valley-cutting by streams or of irregular erosion and deposition by continental glaciers. [E.H.Ha.]

Planck's constant A fundamental physical constant which represents the elementary quantum of action, action being defined as energy multiplied by time. Introduced by Max Planck in 1900, it has the value $h = 6.6261 \times 10^{-27}$ erg-second or 6.6261×10^{-34} joule-second. The symbol $\hbar$ sometimes called the Dirac *h*, is often used for convenience in physics to denote the quantity $h/2\pi$, where $\pi = 3.1416\ldots$

As used by Planck in deriving his radiation law, *h* multiplied by the frequency of radiation represented a bundle of energy, that is, a quantum of energy. Radiant energy at any wavelength can occur only as multiples of this energy; thus energy is quantized. *See* COMPTON EFFECT; FUNDAMENTAL CONSTANTS; HEAT RADIATION; QUANTUM MECHANICS. [H.G.S./P.J.W.]

Planck's radiation law A law of physics which gives the spectral energy distribution of the heat radiation emitted from a so-called blackbody at any temperature. Discovered by Max Planck, this law laid the foundation for the advent of the quantum theory because it was the first physical law to postulate that electromagnetic energy exists in discrete bundles, or quanta. *See* HEAT RADIATION; QUANTUM MECHANICS. [H.G.S.; P.J.W.]

Plane curve The locus of points in the euclidean plane that satisfy some geometric or algebraic definition. Not all sets of points deserve to be called a curve, but the distinction is somewhat arbitrary. For most of this article, a curve is considered to be the locus of a set of points that satisfy an algebraic or transcendental equation in two variables.



Plane curves. (*a*) Right strophoid. (*b*) Trident of Newton. (*c*) Cardioid. (*d*) Deltoid. (*e*) Devil on two sticks. (*f*) Lemniscate of Bernoulli. (*g*) Epitrochoid. (*h*) Rhodona. (*i*) Bowditch curve. (*j*) Fermat's spiral. (*k*) Logarithmic spiral. (*l*) Cycloid.

The most interesting geometric properties are those preserved by linear transformations, especially translations, rotations, reflections, and magnifications. Useful geometric properties include the number of branches into which the curve is divided; the number and degree of nodes, cusps, isolated points, and flex points; the number of loops; symmetries; branches that go to infinity; and asymptotes.

These terms can be defined informally as follows. A branch is a maximal smooth continuous portion of the curve. A multiple point is a point in the plane that lies on two or more branches; its degree is the number of branches involved. A node is a multiple point where the branches cross. A cusp is a multiple point where the branches meet but do not pass; that is, each of the branches ends at that point. An isolated point is a point of the curve through which no branches pass. Multiple and isolated points are collectively termed singular points. Any point that is not singular is termed ordinary. A flex (or point of inflection) is a point on the curve whose tangent cuts the curve. A smooth closed branch forms a loop. A curve is symmetric about a line *L* if every line perpendicular to *L* intersects the curve at equal distances from *L* on opposite sides of *L*; that is, portions of the curve form mirror images about *L*. The curve is symmetric about a point *P* if every line through *P* intersects the curve at equal distances from *P* in opposite directions. An asymptote is a line toward which a branch approaches as it moves to infinity from the origin; the curve and line are said to intersect at infinity.

In addition to these geometric properties, the form of the defining equation is of interest. This can be an algebraic (polynomial in x and y) or transcendental equation. In the former case, quadratic, cubic, and quartic equations are of special interest.

Once a coordinate system has been chosen, and the defining equation is known (in any of the forms, though the parametric form is usually the most useful), various properties of the curve can be defined in terms of the equation. These include the locations of x- and y-intercepts, local maxima and minima, flexes, nodes, and cusps. *See* ANALYTIC GEOMETRY.

The illustration shows some of the many plane curves of sufficient historical interest to have received names. *See* CARDIOID; CYCLOID; LEMNISCATE OF BERNOULLI; ROSE CURVE. [J.D.L.]

Plane geometry

The branch of mathematics that deals with geometric figures, that is, collections of points that all lie in the same plane (coplanar). Although the words "point" and "plane" are undefined concepts, for elementary applications the intuitive meanings will serve: a point is a location, and a plane is a flat surface. For similar definitions, together with a discussion of the postulates and axioms (assumed truths) used in plane geometry, *See* EUCLIDEAN GEOMETRY.

Dimensions and measures. There are three spatial dimensions; geometric figures are classified as being zero, one, two, or three dimensional. Plane geometry deals only with geometric figures having fewer than three dimensions. Three-dimensional geometric figures, called solids, are dealt with in another branch of euclidean geometry. *See* SOLID (GEOMETRY).

A dimension is any measurement associated with a geometric figure that has units of length. The measure of a geometric figure is a number multiplied by a power of a length, with the result giving information about the size of the figure. The power of the length will be 1, 2, or 3, depending on whether the figure is one, two, or three dimensional. *See* UNITS OF MEASUREMENT.

Lines, line segments, and rays. Exactly one line passes through two given points. The part of a line between (and including) two points is called a line segment, with the two defining points being the end points of the segment. That part of a line that lies on one side of a point (together with that point) is called a ray.

Angles. An angle is the geometric figure formed by joining two rays having a common end point. Each ray is a side of the angle; the common end point is the vertex of the angle.

The concept of the measure of an angle may be understood by imagining that one ray of an angle is held fixed but the other ray is hinged at the vertex and allowed to rotate in the plane. A measure of the angle is a number, together with some unit of angular measure, that tells how much the hinged ray would need to be rotated so that it would overlie the fixed ray. If a ray were to be rotated exactly one revolution, it would return to its original position. The measure of an angle can be what fraction of one revolution would enable one side of the angle to become coincident with the other.

The revolution is a convenient unit of angular measure for many applications. However, a more commonly used unit is the degree, which is defined by $360^\circ = 1$ revolution. In the modern-day use of calculators and computers, fractions of degrees are most conveniently expressed by using decimal fractions; however, another subdivision of degrees is firmly entrenched in many applications: 1 degree = 60 minutes ($1^\circ = 60'$), and 1 minute = 60 seconds ($1' = 60''$).

An angle of measure 1/4 revolution, or 90°, is called a right angle. Two lines (or rays or segments) that intersect so as to form a right angle are said to be perpendicular. Two angles are complementary if their measures have a sum of 90°. An angle of measure 1/2 revolution, or 180°, is called a straight angle. Two angles are supplementary if their measures have a sum of 180°.

Polygons. A polygon is the geometric figure formed when line segments are joined end to end so as to enclose a region of the plane. The polygon having the least number of sides (three) is the triangle. An angle whose sides are two of those segments and whose arc lies inside the triangle is an interior angle of the triangle; an exterior angle of the triangle is any angle that is adjacent and supplementary to an interior angle. The interior angles of any triangle have measures that sum to 180°. This fact allows the determination of the measures of all angles formed by the intersections of three line if the measures of only two angles with different vertices are known. *See* POLYGON.

Congruent and similar geometric figures. Two geometric figures are congruent ($\simeq$) if they have exactly the same shape and size. If two geometric figures are congruent, one figure could be made to overlie the other by a combination of these types of motion: translation (sliding), rotation (twisting), and reflection about a line (flipping over). The parts of the geometric figures that would then coincide are called corresponding parts, where a part of a geometric figure is any set of points associated with that figure.

Two geometric figures are similar ($\sim$) if they have the same shape but (perhaps) have different sizes. If two geometric figures are similar, one figure could be made to overlie the other by a combination of translation, rotation, reflection, and either expanding or shrinking. The parts that would then coincide are corresponding.

Circles. A circle is a collection of points in the plane, all of which are the same distance from another point, called the center. The region bounded by a circle sometimes is called a disk. Circumference means either the circle that is the boundary curve of a disk or the distance around that circle. A radius of a circle is any line segment that joins the center and a point of a circle. A chord is any line segment whose end points lie on the circle. A diameter is any chord that contains the center. A secant is a line that intersects a circle in two points. A tangent is a line that intersects a circle in only one point, called the point of tangency.

Associated with a circle are several important dimensions, including the lengths of a radius and a diameter, usually denoted, respectively, by r and d. These symbols appear in almost all formulas involving the length of the circumference C or the area A enclosed by a circle. Relationships between these variables for any circle are given by the equations

$$d = 2r \qquad C = \pi d \qquad A = \pi r^2$$

In these formulas, π (the lowercase Greek letter pi) represents the irrational number (value 3.141592 . . .) that is usually defined as the ratio of the circumference to the diameter of any circle. *See* CIRCLE. [H.L.Ba.]

Planer

A machine for the shaping of long, flat, or flat contoured surfaces by reciprocating the workpiece under a stationary single-point tool or tools. Usually the workpiece is too large to be handled on a shaper.

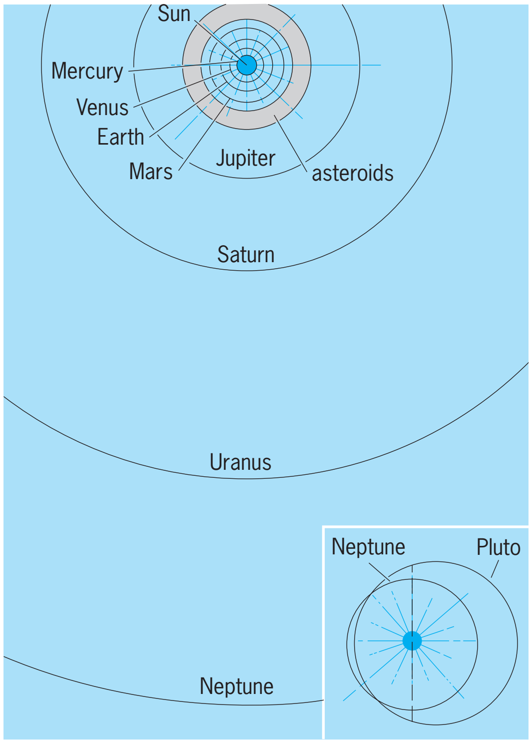
Planers are built in two general types, open-side or double-housing. The former is constructed with one upright or housing to support the crossrail and tools. The double-housing type has an upright on either side of the reciprocating table connected by an arch at the top. *See* WOODWORKING. [A.H.T.]

Planet

A relatively small, solid celestial body moving in orbit around a star, in particular the Sun.

Planets of the solar system. The nine known planets of the solar system are Mercury, Venus, Earth, Mars, Jupiter, Saturn, Uranus, Neptune, and Pluto; in addition, over 20,000 minor planets, or asteroids, mostly located between the orbits of Mars and Jupiter, are known (see illustration). *See* ASTEROID; JUPITER; MARS; MERCURY (PLANET); NEPTUNE; PLUTO; SATURN; URANUS; VENUS.

There are two basic groups of planets in the solar system: the small, dense, terrestrial planets—Mercury, Venus, Earth, Mars,



Plan of the solar system. (*After L. Rudaux and G. de Vaucouleurs, Larousse Encyclopedia of Astronomy, Prometheus Press, 1959*)

and Pluto—and the giant or Jovian planets—Jupiter, Saturn, Uranus, and Neptune. With the exception of Pluto, the terrestrial planets are all located within the inner solar system. The low-density Jovian planets extend outward from Jupiter to the remote reaches of the solar system. This distribution is not accidental, but is related to the fractionation of rocky, icy, and gaseous materials during the early stages of formation of the solar system. *See* Planetary physics; Solar system.

The planets may also be divided into inferior planets, Mercury and Venus, located inside Earth's orbit, and superior planets, from Mars to Pluto, circulating outside Earth's orbit.

The motions of the planets in their orbits around the Sun are governed by three laws discovered by Johannes Kepler at the beginning of the seventeenth century.

First law: The orbit of a planet is an ellipse, with the Sun at one of its foci.

Second law (the law of areas): As a planet revolves in its orbit, the radius vector (the line from the Sun to the planet) sweeps out equal areas in equal intervals of time.

Third law (the harmonic law): The square of the period of revolution is proportional to the cube of the orbit's semimajor axis.

Kepler's laws are true only when the mutual perturbations of the motions of the planets by the others are neglected. Table 1 gives the mean distances of the planets from the Sun and the sidereal periods of revolution. *See* Celestial mechanics; Kepler's laws.

In the course of their motions around the Sun, Earth and other planets occupy a variety of relative positions or configurations. The inferior planets are in conjunction with the Sun when closest to the Earth-Sun line, either between Earth and the Sun (inferior conjunction) or beyond the Sun (superior conjunction). On rare occasions when the planet is very close to the plane of Earth's orbit at the time of an inferior conjunction, a transit in front of the Sun is observed. Between conjunctions, the geocentric angular distance from the planet to the Sun, or the elongation, varies up to a maximum value. The superior planets are not so limited, and their elongations can reach up to 180° when they are in opposition with the Sun. *See* Transit (astronomy).

Table 1. Planetary orbits

	Mean distance from Sun (semimajor axis of orbit)			Sidereal period of revolution	
Planet	AU	10^6 mi	10^6 km	Years	Days
Mercury	0.387	36.0	57.9	0.241	87.97
Venus	0.723	67.2	108.2	0.615	224.70
Earth	1.000	93.0	149.6	1.000	365.24
Mars	1.524	141.6	227.9	1.881	686.93
Jupiter	5.203	483.6	778.3	11.857	4,330.60
Saturn	9.555	888.2	1429.4	29.424	10,746.9
Uranus	19.22	1786.	2875.	83.75	30,588.7
Neptune	30.11	2799.	4504.	164.72	59,799.9
Pluto	39.54	3676.	5916.	248.0	90,589.

The combinations of the orbital motions of Earth and of any other planet give rise to complicated apparent motions of the planets as seen from Earth. Because the orbits of the main planets are, except for Pluto, only slightly inclined to the plane of the orbit of Earth, the apparent paths of the planets (except Pluto) are restricted to the zodiac, a belt 16° wide centered on the ecliptic. The ecliptic is the path in the sky traced out by the Sun in its apparent annual journey as the Earth revolves around it. *See* Astronomical coordinate systems; Ecliptic.

The apparent motions with respect to the celestial sphere, that is, to the fixed stars, appear for the inferior planets as oscillations back and forth about the position of the Sun steadily moving eastward among the stars. For the superior planet the apparent motion is generally eastward or direct, but for short periods near the time of opposition it is westward or retrograde.

The size, mass, density, and rotation period of each of the planets is given in Table 2. [J.K.B.]

Extrasolar planets. It is technically very challenging to detect planets orbiting Sun-like stars. Planets do not generate light; they shine only by the reflected light of the host star. The largest (and easiest to detect) planet in the solar system, Jupiter, is 10^9 times fainter than the Sun. Although a photograph of a Jupiter-like planet orbiting another star is beyond current technology, a number of strategies have been suggested that might be capable of taking direct images of Jupiter-like, or even Earth-like, planets within a few decades.

In the meantime, the presence of extrasolar planets must be deduced by indirect means. The two most developed techniques, astrometry and Doppler spectroscopy, rely on the gravitational perturbations that giant planets impose on their host stars. For example, the Sun and Jupiter jointly orbit a common center of mass, which lies on the line connecting the Sun and Jupiter, just outside the surface of the Sun. A hypothetical alien astronomer

Table 2. Physical characteristics of the Sun's planets

Planet	Equatorial radius (Earth = 1)	Mass (Earth = 1)	Density, g/cm^3	Rotation period
Mercury	0.38	0.055	5.43	58 d 15.5 h
Venus	0.95	0.815	5.20	243 d 0.5 h
Earth	1.00	1.000	5.52	23 h 56 m 23 s
Mars	0.53	0.107	3.34	24 h 37 m 23 s
Jupiter	11.21	317.710	1.33	9 h 55 m 30 s*
Saturn	9.45	95.162	0.69	10 h 39 m 22 s*
Uranus	4.01	14.535	1.32	17 h 22.2 m*
Neptune	3.88	17.141	1.64	16 h 6.6 m*
Pluto	0.18	0.002	2.0	6 d 9 h 17.6 m

*Internal (System III) rotation period, the rotation period of the planet's core, as deduced from its magnetic filed.

could detect the presence of Jupiter either by noting that the position of the Sun is periodically wobbling about against the background stars (astrometry), or by measuring the periodic velocity variation of the Sun (Doppler spectroscopy) as Jupiter pulls the Sun about their common center of mass. Such measurements would reveal the orbital period and the magnitude of the wobble. From these data, the orbital radius and mass of the unseen Jupiter could be calculated from Kepler's third law of planetary motion and the principle of momentum conservation. *See* ASTROMETRY; DOPPLER EFFECT.

The Doppler spectroscopy method provided the first definitive detections of extrasolar planets orbiting normal stars. Any wave (sound or light) emitted by a moving object will be shifted as observed by a stationary observer. The velocity of the emitting object can be directly deduced from the magnitude of this frequency (or wavelength) shift. Doppler velocities are calculated based on the measured wavelength shift of absorption lines in stellar spectra. *See* ASTRONOMICAL SPECTROSCOPY; FRAUNHOFER LINES.

The first confirmed discovery of an extrasolar planet orbiting a normal star was announced in 1995 by Michel Mayor and Didier Queloz. They discovered that the Sun-like star 51 Pegasi periodically changes in its velocity by 187 ft/s (57 m/s) every 4.2 days (Fig. 7). This implies that a planet with about one-half of a Jupiter mass orbits the star at a distance of only 5×10^6 mi (8×10^6 km), 20 times closer than the Earth is to the Sun. This result was completely unexpected. Virtually all theoretical predictions of planet formation suggested that giant Jupiter-like planets should form more than 3 astronomical units away from their host stars. [R.P.Bu.]

Doppler surveys for extrasolar planets have been expanded to include about 2000 stars, providing a nearly complete sample of Sun-like stars within 30 parsecs (100 light-years). By March 2004, 111 extrasolar planets had been discovered orbiting normal stars. Of these, 24 orbit at distances less than 0.15 AU from their parent stars (with periods ranging from 3 to 30 days), indicating that at least several percent of all stars have extremely close planetary companions. These 51 Pegasi–like planets are thought to have formed considerably farther from their host stars and then migrated inward when their orbits were destabilized by gravitational interactions with other planets or with material in the circumstellar disk. *See* PROTOSTAR.

Most of the remaining 87 planets that have been discovered orbiting at distances of 0.15 AU or more travel in elliptical orbits. Indeed, all but 15 of these orbits have eccentricities greater than 0.1, whereas Jupiter and the other giant solar system planets have eccentricities of around 0.05 or less. This result, like the discovery of the 51 Pegasi-like planets, was unexpected. The nearly circular orbits of solar system planets had led to the expectation that extrasolar planets would travel in circular orbits as well. Planets probably form from disks of gas and dust following circular orbits, and friction within these disks can be expected to circularize the planetary orbits. Several explanations have been proposed for the elliptical orbits: gravitational scattering among giant planets; gravitational perturbations exerted by a companion or passing star, or by the protoplanetary disk; or instabilities in the disk.

Because many of the extrasolar planets orbit extremely close to their host stars, astronomers realized that if one of them were in an approximately edge-on orbit it would periodically pass in front of the parent star, reducing its brightness. In 1999, the transit of a planet orbiting the star HD 209458 at a distance 0.045 AU was observed as a 2% reduction in the star's brightness at the predicted time. This was the first direct observation of an extrasolar planet. *See* TRANSIT (ASTRONOMY).

Before extrasolar planets were discovered around normal stars, the discovery of planets orbiting a pulsar was announced in 1992. The discovery was based on precise measurements of arrival times of radio pulses from the 6.2-millisecond pulsar PSR B1257+12. *See* PULSAR. [J.F.We.]

Planetarium An instrument that projects the stars, Sun, Moon, planets, and other celestial objects upon a large hemispherical dome, showing their motions as viewed from the Earth or space near the Earth. Days and years may be compressed into minutes. There are over 100 major planetariums around the world with domes 50 ft (15 m) or more in diameter; and there are also over 1000 smaller planetariums in communities, schools, and colleges.

The term planetarium originally applied to a mechanical model (also known as an orrery) that depicted the motions of the planets. Today the term refers to an optical projector. Most planetariums now have mechanical movements, but planetariums projecting computer-generated displays have also been developed. Additional optical devices and computer controls are common. The term planetarium also refers to the theater or building that houses the projector.

Many projectors are patterned after the basic design of the Carl Zeiss Company. Star spheres at each end of the projector show 8900 stars down to magnitude 6.5; 32 lenses (16 located in each globe) are used to project the stars. Cages between the two star spheres contain projectors for the Sun, Moon, and planets. The center part of the machine houses the driving motors. Additional projectors show such effects as variable stars, solar and lunar eclipses, the Milky Way, comets, and various circles and coordinates. Depending on the manufacturer, there may be constellation outlines, clouds, and built-in zoom effects for the planets.

Another design philosophy, begun in the late 1940s when A. Spitz designed a small planetarium for school classrooms and museums, was to manufacture a small and relatively inexpensive projector that would do for schools and small communities what the larger machines had done for the cities.

Some planetariums have tipped domes with all-sky 70mm motion picture projection systems. Another innovation in planetarium design, based on computer-graphics television projection, is the Evans & Sutherland Digistar II. The projector utilizes a high-resolution cathode-ray tube with a special 160° wide-angle lens for projection onto domes ranging in diameter 20–80 ft (6–24 m). Software and documentation include stellar, planetary, and constellation data files. The star and planet positions are fed into the high-intensity cathode-ray tube projector by a computer and thence onto the dome via the wide-angle lens. *See* CATHODE-RAY TUBE; COMPUTER GRAPHICS. [C.F.H.]

Planetary gear train An assembly of meshed gears consisting of a central or sun gear, a coaxial internal or ring gear, and one or more intermediate pinions supported on a revolving carrier. Sometimes the term planetary gear train is used broadly as a synonym for epicyclic gear train, or narrowly to indicate that the ring gear is the fixed member. In a simple planetary gear train the pinions mesh simultaneously with the two coaxial gears. With the central gear fixed, a pinion rotates about it as a planet rotates about its sun, and the gears are named accordingly: the central gear is the sun, and the pinions are the planets.

In operation, input power drives one member of a planetary gear train, the second member is driven to provide the output, and the third member is fixed. If the third member is not fixed, no power is delivered. This characteristic provides a convenient clutch action. A clutch or brake band positioned about the intermediate member and fixed to the gearbox housing serves to lock or free the third member. The holding device itself does not enter into the power path.

Any one of these three elements can be fixed: the sun gear, the carrier, or the ring gear. Either of the two remaining elements can be driven and the other one used to deliver the output. There are six possible combinations, although three of these provide velocity ratios that are reciprocals of the other three. The ratios are entirely independent of the number of teeth on each planet.

Two simple planetary gear sets running on a common sun gear are known as a Simpson gear train. It is widely used in automotive automatic transmissions. In a compound planetary train, two planet gears are attached together on a common shaft. One planet meshes only with the central sun gear, the other only with the ring gear. As in simple planetary trains, there can be several of these planet pairs around the train to distribute the load and achieve balance. *See* AUTOMOTIVE TRANSMISSION; GEAR TRAIN; RECIPROCATING AIRCRAFT ENGINE. [J.R.Z.; D.L.An.]

Planetary nebula A gaseous shell thrown off by a dying star just before the star settles down to become a degenerate white dwarf. Planetary nebulae are among the brightest and best studied nebular objects in the sky, although they are generally a few thousand light-years from Earth. The many shapes of planetary nebulae reflect the processes that occur inside most stars late in their lives. The Sun is likely to eject a planetary nebula in about 5 billion years. *See* SUN; WHITE DWARF STAR.

Planetary nebulae appear small, round, and greenish in color, like the planet Uranus, when seen through small telescopes—hence the origin of the name. However, planetary nebulae are not planets but large (0.1–10 light-years), expanding (10–100 km/s; 6–60 mi/s), highly symmetrical gaseous clouds of stellar ejecta. The shapes of planetary nebulae vary, and are denoted as round, elliptical, or bipolar depending on their outlines. Delicate filaments, knots, and bubbles of material characterize their interiors. These features evolve as stellar winds of increasing speed (from 100 to 1000 km/s; 60 to 600 mi/s) plow into the older, much slower gas ahead of them.

About 2000 planetary nebulae have been cataloged. Ten to twenty times as many are believed to exist in the Milky Way Galaxy. Planetary nebulae last for several thousand years before they expand and become too diffuse to be seen as discrete objects.

Complex patterns appear when the spectrum of light from a given nebula is analyzed. Such studies have shown that the gas ejected from the parent stars of planetary nebulae is enriched in carbon and nitrogen. Their masses, lifetimes, and large numbers suggest that planetary nebulae are the most prolific source enriching the interstellar medium with carbon and, to a lesser degree, nitrogen. *See* INTERSTELLAR MATTER. [B.Bal.]

Planetary physics The study of the structure, composition, and physical and chemical properties of the planets of the solar system, including their atmospheres and their immediate cosmic environment.

Planetary scientists attempt to synthesize their information about the structure and properties of each of the planets by constructing models of them. The most obvious gross properties of the planet are its mass and its radius. In constructing a model, it is required that the model be in hydrostatic equilibrium. This means that at any interior point in the model, the pressure must be great enough to sustain the weight of the overlying mass of material. Thus, given the mass and the radius, estimating the interior pressures through the principles of hydrostatic equilibrium, and knowing something about the compressibilities of materials, it is generally possible to place constraints upon the interior composition of the planets. Knowledge of the equatorial bulge and the rate of spin provides additional information about the distribution of mass in the interior of the planet.

Classes of chemical composition. The planets in the solar system have an extremely wide range of properties. This distribution of characteristics can be understood in part from a knowledge of the more abundant elements in nature and their volatility properties. Approximately 98% of matter in the Sun, and therefore also presumably in the matter from which the Sun and the solar system were formed, consists of the gases hydrogen and helium. Most of the remaining material consists of carbon, nitrogen, and oxygen, which in the presence of very large amounts of hydrogen tends to form methane, ammonia, and water. These substances are collectively called ices, and they evaporate at relatively low temperatures. Both the light gases hydrogen and helium and the ices are of quite low abundance on the Earth and the other inner planets in the solar system. What constitutes the bulk of the material in these planets is the rocky material, constituting only about 3 parts in 1000 of the solar mix of elements.

The differences in the volatilities of these materials, which correlate with the properties of the planetary bodies in the solar system, give information about the properties of the environment in which the planets formed in the solar system. The inner planets, composed predominantly of rocks, evidently formed in a rather hot environment, so that the volatile gases and ices were not condensed and did not collect along with the rocky material, which presumably was condensed. The comets, residing at very large distances from the Sun in the solar system, appear to be mixtures of rocky materials and of the ices. The outer giant planets, Uranus and Neptune, appear to be primarily composed of materials heavier than hydrogen and helium, probably mixtures of rocky and icy materials. The two largest planets in the solar system, Jupiter and Saturn, are much closer in composition to that of the Sun itself, although studies of their interior structures tend to indicate that there is some degree of enrichment in the heavier elements. These differences in composition thus indicate that the tendency to collect hydrogen and helium depends upon the size of the body which has formed, the larger bodies being more successful in gravitationally capturing the elusive hydrogen and helium. *See* COMET.

These compositional classes provide a natural means for dividing the planetary objects within the solar system into separate groups, as follow.

Giant planets. The giant planets are Jupiter, Saturn, Uranus, and Neptune. Nowhere in the interiors of the giant planets can anything resembling a solid surface be expected. The temperatures in the interiors tend to be thousands to tens of thousands of degrees Celsius. The pressures range up to the order of 10^7 atmospheres (10^{12} pascals) and higher. Under these circumstances all materials behave like fluids. There may be a certain amount of compositional stratification, with denser fluids underlying lighter ones.

Terrestrial planets. The terrestrial planets include Mercury, Venus, Earth, and Mars. The Earth's Moon may also be considered a terrestrial planet. The Earth consists of a thin upper crust composed of rocks of relatively low density and low melting points, overlying a much thicker mantle composed predominantly of metallic silicates and oxides, which in turn overlies a substantial core, which is composed of much denser materials, believed predominantly to be iron with other elements, either alloyed or in solution.

It is conjectured that the interior of Venus is probably much like that of the Earth, with a core, a mantle, and a crust. Major structural features on the surface of the planet suggest extensive tectonic activity. The extent to which the crust of Venus is subject to extensive continental drift motions is quite unknown. *See* VENUS.

The mass of Mars is approximately one-tenth that of the Earth, and hence significant differences in the internal structure are to be expected. There appears to be less of a density contrast between the core of Mars and that of its mantle. Because the planet is smaller, the temperature increases less rapidly with depth than in the case of the Earth, and hence Mars should have a somewhat more rigid outer mantle and crust than the Earth. There is no indication that large amounts of continental drift have taken place on Mars. On the other hand, tectonic activity has clearly played a large role in the history of Mars. *See* MARS.

Mercury has only about half the mass of Mars. The mean density of Mercury is very high, indicating that Mercury probably has an abnormally large core predominantly composed of metallic iron. There is much evidence of extensive tectonic activity, although, like Mars, the increase of temperature below the surface of Mercury probably occurs sufficiently slowly that the crust and upper mantle are relatively rigid, and nothing resembling continental drift has probably taken place. *See* MERCURY (PLANET).

The Moon has a history which includes extensive episodes of melting and differentiation. The upper layers of the Moon, which is only just over 1% of the mass of the Earth, are quite rigid, and there is no evidence for extensive horizontal motions of the structural units. The Moon is unique in the solar system in having a relatively low density among the inner planets, and at best a very small core, indicating that the planet is practically devoid of metallic iron. *See* MOON.

Major satellites. The four Galilean satellites of Jupiter—Io, Europa, Ganymede, and Callisto—have masses which are all roughly comparable to the mass of the Earth's Moon. The Galilean satellites appear to represent a composition class which is slightly more volatile-rich than the pure rocky materials characteristic of the inner solar system. *See* JUPITER.

The Saturnian satellite system contains only one satellite comparable in mass to the Galilean satellites, Titan. Titan has a significantly higher volatile content than the Galilean satellites. It has an extensive atmosphere (virtually unique in the solar system) largely composed of methane. It is not known what lies at the bottom of this atmosphere, but it has been reasonably speculated that there is a transition layer of heavier hydrocarbons. The satellite has a relatively low density, characteristic of an extensive content of ices, quite likely more than just water ice as in the Galilean satellites. The atmosphere is completely opaque, and hence it is not known whether Titan has surface relief.

Atmospheres. The temperature at the surface of a planetary body depends in a complex manner on the properties of the overlying atmosphere, as well as upon the distance of the planet from the Sun. The atmosphere of Venus is very much hotter relative to the Earth than would be expected purely on the basis of the relative distances from the Sun. The difference appears to arise from the extensive operation of the greenhouse effect within the very thick atmosphere of Venus.

The only terrestrial planets with atmospheres are Venus, Earth, and Mars. Both Mars and Venus have atmospheres composed predominantly of carbon dioxide. The element of next greatest abundance in the atmospheres of Mars and Venus is nitrogen, which is also the predominant element in the atmosphere of the Earth. The next most abundant element in the terrestrial atmosphere is oxygen, which is maintained there predominantly as the result of the operation of life.

Magnetospheres. Some of the planets contain substantial magnetic fields; others do not. Within the inner solar system, the Earth possesses a relatively strong field, Mercury a relatively weak one, and if Venus and Mars contain significant intrinsic fields, they are sufficiently weak that they have not been confirmed. On the other hand, Jupiter and Saturn have very strong magnetic fields. The generation of planetary magnetic fields appears to depend upon a combination of planetary rotation with an inner convecting layer having significant electrical conductivity. *See* MAGNETOSPHERE; PLANET; VAN ALLEN RADIATION.

[A.G.W.C.]

Plant An organism that belongs to the Kingdom Plantae (plant kingdom) in biological classification. The study of plants is called botany. *See* BOTANY; CLASSIFICATION, BIOLOGICAL.

The Plantae share the characteristics of multicellularity, cellulose cell walls, and photosynthesis using chlorophylls *a* and *b* (except for a few plants that are secondarily heterotrophic). Most plants are also structurally differentiated, usually having organs specialized for anchorage, support, and photosynthesis. Tissue specialization for photosynthetic, conducting, and covering functions is also characteristic. Plants have a sporic (rather than gametic or zygotic) life cycle that involves both sporophytic and gametophytic phases, although the latter is evolutionarily reduced in the majority of species. Reproduction is sexual, but diversification of breeding systems is a prominent feature of many plant groups. *See* PHOTOSYNTHESIS; REPRODUCTION (PLANT).

A conservative estimate of the number of described species of plants is 250,000. There are possibly two or three times that many species as yet undiscovered, primarily in the Southern Hemisphere. Plants are categorized into nonvascular and vascular groups, and the latter into seedless vascular plants and seed plants. The nonvascular plants include the liverworts, hornworts, and mosses. The vascular plants without seeds are the ground pines, horsetails, ferns, and whisk ferns; seed plants include cycads, ginkgos, conifers, gnetophytes, and flowering plants. Each of these groups constitutes a division in botanical nomenclature, which is equivalent to a phylum in the zoological system. *See* PLANT TAXONOMY.

[M.La.]

Plant anatomy The area of plant science concerned with the internal structure of plants. It deals both with mature structures and with their origin and development.

The plant anatomist dissects the plant and studies it from different planes and at various levels of magnification. At the level of the cell, anatomy overlaps plant cytology, which deals exclusively with the cell and its contents. Sometimes the name plant histology is applied to the area of plant anatomy directed toward the study of cellular details of tissues. *See* PLANT CELL; PLANT ORGANS.

[K.E.]

Plant-animal interactions The examination of the ecology of interacting plants and animals by using an evolutionary, holistic perspective. For example, the chemistry of defensive compounds of a plant species may have been altered by natural-selection pressures resulting from the long-term impacts of herbivores. Also, the physiology of modern herbivores may be modified from that of thousands of years ago as adaptations for the detoxification or avoidance of plant defensive chemicals have arisen.

The application of the theories based on an understanding of plant-animal interactions provides an understanding of problems in modern agricultural ecosystems. In addition, plant-animal interactions have practical applications in medicine. For example, a number of plant chemicals, such as digitalin from the foxglove plant, that evolved as herbivore-defensive compounds have useful therapeutic effects on humans.

Effects of interaction types for each species*

Interaction	Effect on species A	Effect on species B
Mutualism	+	+
Commensalism	+	0
Antagonism	+	−
Competition	−	−
Amensalism	0	−
Neutralism	0	0

*+ = beneficial, − = harmful, 0 = neutral.

The evolutionary consequences of plant-animal interactions vary, depending on the effects on each participant. Interaction types range from mutualisms, that is, relationships which are beneficial to both participating species, to antagonisms, in which the interaction benefits only one of the participating species and negatively impacts the other. Interaction types are defined on the basis of whether the impacts of the interaction are beneficial, harmful, or neutral for each interacting species (see table).

[W.G.A.]

Fossil record. Plants and animals interact in a variety of ways within modern ecosystems. These interactions may range from simple examples of herbivory (animals eating plants) to more complex interactions such as pollination or seed and fruit dispersal. Animals also rely on plants for food and shelter. The complex interactions between these organisms over geologic time not only have resulted in an abundance and diversity of organisms in time and space but also have contributed to many of the evolutionary adaptations found in the biological world.

Paleobiologists have attempted to decipher some of the interrelationships that existed between plants and animals throughout geologic time. The ecological setting in which the organisms lived in the geologic past is being analyzed in association with the fossils. Thus, as paleobiologists have increased their understanding of certain fossil organisms, it has become possible to consider some aspects of the ecosystems in which they lived, and in turn, how various types of organisms interacted.

Herbivory. Perhaps the most widespread interaction between plants and animals is herbivory, in which plants are utilized as food. One method of determining the extent of herbivory in the fossil record is by analyzing the plant material that has passed through the digestive gut of the herbivore.

The stems of some fossil plants show tissue disruption similar to various types of wounds occurring in plant parts that have been pierced by animal feeding structures. As plants developed defense systems in the form of fibrous layers covering inner, succulent tissues, some animals evolved piercing mouthparts that allowed them to penetrate these thick-walled layers. In some fossil plants, it is also possible to see evidence of wound tissue that has grown over these penetration sites. *See* COAL BALLS; HERBIVORY.

Mimicry. Another example of the interactions between plants and animals that can be determined from the fossil record is mimicry. Certain fossil insects have wings that are morphologically identical to plant leaves, thus providing camouflage from predators as the insect rested on a seed fern frond.

Pollination. The transfer of pollen from the pollen sacs to the receptive stigma in angiosperms or to the seed in gymnosperms is an example of an ancient interaction between plants and animals. It has been suggested that pollination in some groups initially occurred as a result of indiscriminate foraging behavior by certain animals, and later evolved specifically as a method to effect pollination. The size, shape, and organization of fossil pollen grains provide insight into potential pollination vectors. *See* FOSSIL; PALEOBOTANY; POLLINATION. [T.N.T.]

Plant cell

The basic unit of structure and function in nearly all plants. Although plant cells are variously modified in structure and function, they have many common features. The most distinctive feature of all plant cells is the rigid cell wall, which is absent in animal cells. The range of specialization and the character of association of plant cells is very wide. In the simplest plant forms a single cell constitutes a whole organism and carries out all the life functions. In just slightly more complex forms, cells are associated structurally, but each cell appears to carry out the fundamental life functions, although certain ones may be specialized for participation in reproductive processes. In the most advanced plants, cells are associated in functionally specialized tissues, and associated tissues make up organs such as the leaves, stem, and root. *See* CELL WALLS (PLANT).

Plant and animal cells are composed of the same fundamental constituents—nucleic acids, proteins, carbohydrates, lipids, and various inorganic substances—and are organized in the same fundamental manner. A characteristic of their organization is the presence of unit membranes composed of phospholipids and associated proteins and in some instances nucleic acids.

Perhaps the most conspicuous and certainly the most studied of the features peculiar to plant cells is the presence of plastids. The plastids are membrane-bound organelles with an inner membrane system. Chlorophylls and other pigments are associated with the inner membrane system. *See* CELL (BIOLOGY); CELL PLASTIDS; CHLOROPHYLL. [W.G.W.]

Plant communication

Movement of signals or cues, presumably chemical, among individual plants or plant parts. These chemical cues are a consequence of damage to plant tissues and stimulate physiological changes in the undamaged "receiving" plant or tissue. There are very few studies of this phenomenon, and so theories of its action and significance are fairly speculative.

Plants produce a wealth of secondary metabolites that do not function in the main, or primary, metabolism of the plant, which includes photosynthesis, nutrient acquisition, and growth. Since many of these chemicals have very specific negative effects on animals or pathogens, ecologists speculate that they may be produced by plants as defenses. Plant chemical defenses either may be present all of the time (constitutive) or may be stimulated in response to attack (induced). Those produced in response to attack by pathogens are called phytoalexins. In order to demonstrate the presence of an induced defense, the chemistry of plant tissues or their suitability to some "enemy" (via a bioassay) must be compared before and after real or simulated attack. Changes found in the chemistry and suitability of control or unattacked plants when nearby experimental plants are damaged imply that some signal or cue has passed from damaged to undamaged plants. Controlled studies have shown that responses in undamaged plants are related to the proximity of a damaged neighbor. *See* ALLELOPATHY; PHYTOALEXIN; PLANT METABOLISM. [J.C.Sc.]

Plant evolution

The process of biological and organic change within the plant kingdom by which the characteristics of plants differ from generation to generation. The main levels (grades) of evolution have long been clear from comparisons among living plants, but the fossil record has been critical in dating evolutionary events and revealing extinct intermediates between modern groups, which are separated from each other by great morphological gaps. Plant evolution has been clarified by cladistic methods for estimating relationships among both living and fossil groups. These methods attempt to reconstruct the branching of evolutionary lines (phylogeny) by using shared evolutionary innovations (for example, presence of a structure not found in other groups) as evidence that particular organisms are descendants of the same ancestral lineage (a monophyletic group, or clade). Many traditional groups are actually grades rather than clades; these are indicated below by names in quotes.

Most botanists restrict the term plants to land plants, which invaded the land after 90% of Earth history. There is abundant evidence of photosynthetic life extending back 3.5 billion years to the early Precambrian, in the form of microfossils resembling cyanobacteria (prokaryotic blue-green algae) and limestone reefs (stromatolites) made by these organisms. Larger cells representing eukaryotic "algae" appear in the late Precambrian, followed by macroscopic "algae" and animals just before the Cambrian. *See* ALGAE; EUKARYOTAE; FOSSIL; PROKARYOTAE.

Origin of land plants. Cellular, biochemical, and molecular data place the land plants among the "green algae," specifically the "charophytes," which resemble land plants in their mode of cell division and differentiated male and female gametes (oogamy). Land plants themselves are united by a series of innovations not seen in "charophytes," many of them key adaptations required for life on land. They have an alternation of generations, with a haploid, gamete-forming (gametophyte) and diploid, spore-forming (sporophyte) phase. Their reproductive organs (egg-producing archegonia, sperm-producing antheridia, and spore-producing sporangia) have a protective layer of sterile cells. The sporophyte, which develops from the zygote, begins its life inside the archegonium. The spores, produced in fours by meiosis, are air-dispersed, with a resistant outer wall that prevents desiccation. *See* CHAROPHYCEAE; REPRODUCTION (PLANT).

Land plants have been traditionally divided into "bryophytes" and vascular plants (tracheophytes). These differ in the relative role of the sporophyte, which is subordinate and permanently attached to the gametophyte in "bryophytes" but dominant and independent in vascular plants. In vascular plants, tissues are differentiated into an epidermis with a waxy cuticle that retards water loss and stomates for gas exchange, parenchyma for photosynthesis and storage, and water- and nutrient-conducting cells (xylem, phloem). However, cladistic analyses imply that some "bryophytes" are closer to vascular plants than others. This implies that the land-plant life cycle originated before the full suite of vegetative adaptations to land life, and that the sporophyte began small and underwent a trend toward elaboration and tissue specialization. *See* EPIDERMIS (PLANT); PHOTOSYNTHESIS; PRIMARY VASCULAR SYSTEM (PLANT).

In the fossil record, the first recognizable macroscopic remains of land plants are Middle Silurian vascular forms with a branched sporophyte, known as "rhyniophytes." These differed from modern plants in having no leaves or roots, only dichotomously branching stems with terminal sporangia. However, spore tetrads formed by meiosis are known from older beds (Middle Ordovician); these may represent more primitive, bryophytic plants. *See* BRYOPHYTA; RHYNIOPHYTA.

In one of the most spectacular adaptive radiations in the history of life, vascular plants diversified through the Devonian. At the beginning of this period, vegetation was low and probably confined to wet areas, but by the Late Devonian, size had increased in many lines, resulting in large trees and forests with shaded understory habitats. Of the living groups of primitive vascular plants, the lycopsids (club mosses) branched off first, along with the extinct "zosterophyllopsids." A second line, the "trimerophytes," gave rise to sphenopsids (horsetails) and ferns (filicopsids). This radiation culminated in the coal swamp forests of the Late Carboniferous, with tree lycopsids (Lepidodendrales), sphenopsids (*Calamites*), and ferns (Marattiales). Remains of these plants make up much of the coal of Europe and eastern North America, which were then located on the Equator. *See* LYCOPODIALES; MARATTIALES; SPHENOPHYTA.

Seed plants. Perhaps the most significant event after the origin of land plants was evolution of the seed. Primitive seed plants ("gymnosperms") differ from earlier groups in their reproduction, which is heterosporous (producing two sizes of spores), with separate male and female gametophytes packaged inside the pollen grain (microspore), and the ovule (a sporangium with one functional megaspore, surrounded by an integument, which develops into the seed). The transfer of sperm (two per pollen grain) from one sporophyte to another through the air, rather than by swimming, represents a step toward independence from water for reproduction. This step must have helped plants invade drier areas than they had previously occupied. In addition, seed plants have new vegetative features, particularly secondary growth, which allows production of a thick trunk made up of secondary xylem (wood) surrounded by secondary phloem and periderm (bark). Together, these innovations have made seed plants the dominant organisms in most terrestrial ecosystems ever since the disappearance of the Carboniferous coal swamps. *See* ECOSYSTEM; PTERIDOSPERMS; SEED.

A major breakthrough in understanding the origin of seed plants was recognition of the "progymnosperms" in the Middle and Late Devonian. These plants, which were the first forest-forming trees, had secondary xylem, phloem, and periderm, but they still reproduced by spores, implying that the anatomical advances of seed plants arose before the seed. Like sphenopsids and ferns, they were apparently derived from "trimerophytes." The earliest seed plants of the Late Devonian and Carboniferous, called "seed ferns" because of their frondlike leaves, show steps in origin of the seed. Origin of the typical mode of branching in seed plants, from buds in the axils of the leaves, occurred at about the same time. *See* PTERIDOSPERMS.

Seed plants became dominant in the Permian during a shift to drier climate and extinction of the coal swamp flora in the European-American tropical belt, and glaciation in the Southern Hemisphere Gondwana continents. Early conifers predominated in the tropics; extinct glossopterids inhabited Gondwana. Moderation of climate in the Triassic coincided with the appearance of new seed plant groups as well as more modern ferns. Many Mesozoic groups show adaptations for protection of seeds against animal predation, while flowers of the Bennettitales constitute the first evidence for attraction of insects for cross-pollination, rather than transport of pollen by wind.

Angiosperms. The last major event in plant evolution was the origin of angiosperms (flowering plants), the seed plant group that dominates the modern flora. The flower, typically made up of protective sepals, attractive petals, pollen-producing stamens, and ovule-producing carpels (all considered modified leaves), favors more efficient pollen transfer by insects. The ovules are enclosed in the carpel, so that pollen germinates on the sticky stigma of the carpel rather than in the pollen chamber of the ovule. The carpels (separate or fused) develop into fruits, which often show special adaptations for seed dispersal. Other advances include an extreme reduction of the gametophytes, and double fertilization whereby one sperm fuses with the egg, and the second sperm with two other gametophyte nuclei to produce a triploid, nourishing tissue called the endosperm. Angiosperms also developed improved vegetative features, such as more efficient water-conducting vessels in the wood and leaves with several orders of reticulate venation. These features may have contributed to their present dominance in tropical forests, previously occupied by conifers with scale leaves. *See* RAINFOREST.

Most botanists believed that the most primitive living angiosperms are "magnoliid dicots," based on their "gymnosperm"-like pollen, wood anatomy, and flower structure. Studies of Cretaceous fossil pollen, leaves, and flowers confirm this view by showing a rapid but orderly radiation beginning with "magnoliid"-like and monocotlike types, followed by primitive eudicots (with three pollen apertures), some related to sycamores and lotuses. *See* MAGNOLIOPHYTA.

Both morphological and molecular data imply that angiosperms are monophyletic and most closely related to Bennettitales and Gnetales, a seed plant group that also radiated in the Early Cretaceous but later declined to three living genera. Since all three groups have flowerlike structures, suggesting that the flower and insect pollination arose before the closed carpel, they have been called anthophytes. These relationships, plus problematical Triassic pollen grains and macrofossils with a mixture of angiospermlike and more primitive features, suggest that the angiosperm line goes back to the Triassic, although perhaps not as fully developed angiosperms. Within angiosperms, it is believed that "magnoliids" are relatively primitive, monocots and eudicots are derived clades, and wind-pollinated temperate trees such as oaks, birches, and walnuts (Amentiferae) are advanced eudicots. However, "magnoliids" include both woody plants, and herbs, and their flowers range from large, complex, and insect-pollinated to minute, simple, and wind-pollinated. These extremes are present among the earliest Cretaceous angiosperms, and cladistic analyses disagree on which is most primitive.

Although plant extinctions at the end of the Cretaceous have been linked with radiation of deciduous trees and proliferation of fruits dispersed by mammals and birds, they were less dramatic than extinctions in the animal kingdom. Mid-Tertiary cooling led to contraction of the tropical belt and expansion of seasonal temperate and arid zones. These changes led to the diversification of herbaceous angiosperms and the origin of open grassland vegetation, which stimulated the radiation of hoofed mammals, and ultimately the invention of human agriculture. *See* AGRICULTURE; FLOWER; PALEOBOTANY; PLANT KINGDOM. [J.A.Do.]

Plant geography The study of the spatial distributions of plants and vegetation and of the environmental relationships which may influence these distributions. Plant geography (or certain aspects of it) is also known as phytogeography, phytochorology, geobotany, geographical botany, or vegetation science.

A flora is the collection of all plant species in an area, or in a period of time, independent of their relative abundances and relationships to one another. The species can be grouped and regrouped into various kinds of floral elements based on some common feature. For example, a genetic element is a group of species with a common evolutionary origin; a migration element has a common route of entry into the territory; a historical element is distinct in terms of some past event; and an ecological element is related to an environmental preference. An endemic species is restricted to a particular area, which is usually small and of some special interest. The collection of all interacting individuals of a given species, in an area, is called a population.

An area is the entire region of distribution or occurrence of any species, element, or even an entire flora. The description of areas is the subject of areography, while chorology studies their development. The local distribution within the area as a whole, as that of a swamp shrub, is the topography of that area. Areas are of interest in regard to their general size and shape, the nature of their margin, whether they are continuous or disjunct, and their relationships to other areas. Closely related plants that are mutually exclusive are said to be vicarious (areas containing such plants are also called vicarious). A relict area is one surviving from an earlier and more extensive occurrence. On the basis of areas and their floristic relationships, the Earth's surface is divided into floristic regions, each with a distinctive flora.

Floras and their distribution have been interpreted mainly in terms of their history and ecology. Historical factors, in addition to the evolution of the species themselves, include consideration of theories of shifting continental masses, changing sea levels, and orographic and climatic variations in geologic time, as well as theories of island biogeography, all of which have affected migration and perpetuation of floras. The main ecological factors include the immediate and contemporary roles played by climate, soil, animals, and humans. *See* ISLAND BIOGEOGRAPHY; PALEOBOTANY; PALEOECOLOGY.

Vegetation refers to the mosaic of plant life found on the landscape. The vegetation of a region has developed from the numerous elements of the local flora but is shaped also by nonfloristic physiological and environmental influences. Vegetation is an organized whole, at a higher level of integration than the separate species, composed of those species and their populations. Vegetation may possess emergent properties not necessarily found in the species themselves. Sometimes vegetation is very weakly integrated, as pioneer plants of an abandoned field. Sometimes it is highly integrated, as in an undisturbed tropical rainforest. Vegetation provides the main structural and functional framework of ecosystems. *See* ECOSYSTEM.

Plant communities are an important part of vegetation. No definition has gained universal acceptance, in part because of the high degree of independence of the species themselves. Thus, the community is often only a relative social continuity in nature, bounded by a relative discontinuity, as judged by competent botanists. *See* ECOLOGICAL COMMUNITIES.

In looking at vegetation patterns over larger areas, it is the basic physiognomic distinctions between grassland, forest, and desert, with such variants as woodland (open forest), savanna (scattered trees in grassland), and scrubland (dominantly shrubs), which are most often emphasized. These general classes of vegetation structure can be broken down further by reference to leaf types and seasonal habits (such as evergreen or deciduous). Geographic considerations may complete the names of the main vegetation formation types, also called biomes (such as tropical rainforest, boreal coniferous forest, or temperate grasslands). Such natural vegetation regions are most closely related to climatic patterns and secondarily to soil or other environmental factors. *See* ALTITUDINAL VEGETATION ZONES.

Vegetational plant geography has emphasized the mapping of such vegetation regions and the interpretation of these in terms of environmental (ecological) influences. Distinction has been made between potential and actual vegetation, the latter becoming more important due to human influence. *See* VEGETATION AND ECOSYSTEM MAPPING.

Some plant geographers point to the effects of ancient human populations, natural disturbances, and the large-herbivore extinctions and climatic shifts of the Pleistocene on the species composition and dynamics of so-called virgin vegetation. On the other hand, it has been shown that the site occurrence and geographic distributions of plant and vegetation types can be predicted surprisingly well from general climatic and other environmental patterns. Unlike floristic botany, where evolution provides a single unifying principle for taxonomic classification, vegetation structure and dynamics have no single dominant influence.

Basic plant growth forms (such as broad-leaved trees, stem-succulents, or forbs) have long represented convenient groups of species based on obvious similarities. When these forms are interpreted as ecologically significant adaptations to environmental factors, they are generally called life forms and may be interpreted as basic ecological types.

In general, basic plant types may be seen as groups of plant taxa with similar form and ecological requirements, resulting from similar morphological responses to similar environmental conditions. When similar morphological or physiognomic responses occur in unrelated taxa in similar but widely separated environments, they may be called convergent characteristics. *See* PLANTS, LIFE FORMS OF.

As human populations alter or destroy more and more of the world's natural vegetation, problems of species preservation, substitute vegetation, and succession have increased in importance. This is especially true in the tropics, where deforestation is proceeding rapidly. Probably over half the species in tropical rainforests have not yet even been identified. Because nutrients are quickly washed out of tropical rainforest soils, cleared areas can be used for only a few years before they must be abandoned to erosion and much degraded substitute vegetation. Perhaps the greatest current challenge in plant geography is to understand tropical vegetation and succession sufficiently well to design self-sustaining preserves of the great diversity of tropical vegetation. *See* BIOGEOGRAPHY; ECOLOGY; RAINFOREST. [E.O.B.]

Plant growth

An irreversible increase in the size of the plant. As plants, like other organisms, are made up of cells, growth involves an increase in cell numbers by cell division and an increase in cell size. Cell division itself is not growth, as each new cell is exactly half the size of the cell from which it was formed. Only when it grows to the same size as its progenitor has growth been realized. Nonetheless, as each cell has a maximum size, cell division is considered as providing the potential for growth. *See* CELL (BIOLOGY); CELL DIVISION.

While growth in plants consists of an increase in both cell number and cell size, animal growth is almost wholly the result of an increase in cell numbers. Another important difference in growth between plants and animals is that animals are determinate in growth and reach a final size before they are mature and start to reproduce. Plants have indeterminate growth and, as long as they live, continue to add new organs and tissues. In a plant new cells are produced all the time, and some parts such as leaves and flowers may die, while the main body of the plant persists and continues to grow. The basic processes of cell division are similar in plants and animals, though the presence of a cell wall and vacuole in plant cells means that there are certain important differences. This is particularly true in plant cell enlargement, as plant cells, being restrained in size by a cellulose cell wall, cannot grow without an increase in the wall. Plant cell growth is thus largely a property of the cell wall. *See* CELL WALLS (PLANT).

Sites of cell division. Cell division in plants takes place in discrete zones called meristems. The stem and root apical meristems produce all the primary (or initial) tissues of the stem and root. The cylindrical vascular cambium produces more conducting cells at the time when secondary thickening (the acquisition of a woody nature) begins. The vascular cambium is a sheet of elongated cells which divide to produce xylem or water-conducting cells on the inside, and phloem or sugar-conducting cells on the outside. Unlike the apical meristems whose cell division eventually leads to an increase in length of the stem and root, divisions of the vascular cambium occur when that part of the plant has reached a fixed length, and lead only to an increase in girth, not in length. The final meristematic zone, the cork cambium, is another cylindrical sheet of cells on the outer edge of older stems and roots of woody plants. It produces new outer cells only, and these cells differentiate into the corky layers of the bark so that new protective layers are produced as the tree increases in circumference. *See* APICAL MERISTEM; BUD; LATERAL MERISTEM; PERIDERM; ROOT (BOTANY); STEM.

Controls. Plant growth is affected by internal and external factors. The internal controls are all the product of the genetic instructions carried in the plant. These influence the extent and timing of growth and are mediated by signals of various types transmitted within the cell, between cells, or all around the plant. Intercellular communication in plants may take place via hormones (or chemical messengers) or by other forms of communication not well understood. There are several hormones (or groups of hormones), each of which may be produced in a different location, that have a different target tissue and act in a different manner. *See* ABSCISIC ACID; AUXIN; CYTOKININS; GIBBERELLIN; PLANT HORMONES.

The external environments of the root and shoot place constraints on the extent to which the internal controls can permit the plant to grow and develop. Prime among these are the water and nutrient supplies available in the soil. Because cell expansion is controlled by cell turgor, which depends on water, any deficit in the water supply of the plant reduces cell turgor and limits cell elongation, resulting in a smaller plant. *See* PLANT-WATER RELATIONS.

Mineral nutrients are needed for the biochemical processes of the plant. When these are in insufficient supply, growth will be less vigorous, or in extreme cases it will cease altogether. *See* PLANT MINERAL NUTRITION.

An optimal temperature is needed for plant growth. The actual temperature range depends on the species. In general, metabolic reactions and growth increase with temperature, though high temperature becomes damaging. Most plants grow slowly at low temperatures, 32–50°F (0–10°C), and some tropical plants are damaged or even killed at low but above-freezing temperatures.

Light is important in the control of plant growth. It drives the process of photosynthesis which produces the carbohydrates that are needed to osmotically retain water in the cell for growth. *See* PHOTOSYNTHESIS.

Fruits and seeds. Fruits and seeds are rich sources of hormones. Initial hormone production starts upon pollination and is further promoted by ovule fertilization. These hormones promote the growth of both seed and fruit tissue. Fruits grow initially by cell division, then by cell enlargement, and finally sometimes by an increase in air spaces.

The growth of a seed starts at fertilization. A small undifferentiated cell mass is produced from the single-celled zygote. This proceeds to form a small embryo consisting of a stem tip bearing two or more leaf primordia at one end and a root primordium at the other. Either the endosperm or the cotyledons enlarge as a food store. *See* FRUIT; SEED.

Flowering. At a certain time a vegetative plant ceases producing leaves and instead produces flowers. This often occurs at a particular season of the year. The determining factor for this event is day length (or photoperiod). Different species of plants respond to different photoperiods. *See* FLOWER; PHOTOPERIODISM.

The light signal for flowering is received by the leaves, but it is the stem apex that responds. Exposing even a single leaf to the correct photoperiod can induce flowering. Clearly, then, a signal must travel from the leaf to the apex. Grafting a plant that has been photoinduced to flower to one not so induced can cause the noninduced plant to flower. It has been proposed that a flower-inducing hormone travels from the leaf to the stem apex and there induces changes in the development of the cells such that the floral morphology results.

Dormancy. At certain stages of the life cycle, most perennial plants cease growth and become dormant. Plants may cease growth at any time if the environmental conditions are unfavorable. When dormant, however, a plant will not grow even if the conditions are favorable. *See* DORMANCY.

Leaf abscission. As a perennial plant grows, new leaves are continuously or seasonally produced. At the same time the older leaves are shed because newer leaves are metabolically more efficient in the production of photosynthates. A total shedding of tender leaves may enable the plant to withstand a cold period or drought. In temperate deciduous trees, leaf abscission is brought about by declining photoperiods and temperatures. *See* ABSCISSION; PLANT MORPHOGENESIS. [P.J.D.]

Plant hormones Organic compounds other than nutrients that regulate plant development and growth. Plant hormones, which are active in very low concentrations, are produced in certain parts of the plants and are usually transported to other parts where they elicit specific biochemical, physiological, or morphological responses. They are also active in tissues where they are produced. Each plant hormone evokes many different responses. Also, the effects of different hormones overlap and may be stimulatory or inhibitory. The commonly recognized classes of plant hormones are the auxins, gibberellins, cytokinins, abscisic acid, and ethylene. Circumstantial evidence suggests that flower initiation is controlled by hypothetical hormones called florigens, but these substances remain to be identified. A number of natural or synthetic substances such as brassin, morphactin, and other growth regulators not considered to be hormones nevertheless influence plant growth and development. Each hormone performs its specific functions; however, nearly all of the measurable responses of plants to heredity or environment are controlled by interaction between two or more hormones. Such interactions may occur at various levels, including the synthesis of hormones, hormone receptors, and second messengers, as well as at the level of ultimate hormone action. Furthermore, hormonal interactions may be cooperative, antagonistic, or in balance.

The term plant growth regulator is usually used to denote a synthetic plant hormone, but most of the synthetic compounds with structures similar to those of the natural hormones have also been called hormones. For instance, the synthetic cytokinin kinetin is considered a hormone. *See* ABSCISIC ACID; ABSCISSION; AUXIN; CYTOKININS; ETHYLENE; GIBBERELLIN.

There are a number of applications of plant hormones in agriculture, horticulture, and biotechnology. Synthetic auxins are used as weed killers. Auxins are also used to counteract the effects of hormones that promote the dropping of fruit from trees. Gibberellins are used extensively to increase the size of seedless grapes: when applied at the appropriate time and with the proper concentration, gibberellins cause fruits to elongate so that they are less tightly packed and less susceptible to fungal infections. Gibberellins are also used by some breweries to increase the rate of malting because they enhance starch digestion. They have also been sprayed on fruits and leaves of navel orange trees to prevent several rind disorders that appear during storage. They are used commercially to increase sugarcane growth and sugar yields. Cytokinins and auxins are used in plant cell culture, particularly in cultivating genetically engineered plants. The ability of cytokinins to retard senescence also applies to certain cut flowers and fresh vegetables. Ethylene has been used widely in promoting pineapple flowering; flowering occurs more rapidly and mature fruits appear uniformly, so that a one-harvest mechanical operation is possible. Because carbon dioxide in high concentrations inhibits ethylene production, it is often used to prevent overripening of picked fruits. Ethylene is also used for accelerating fruit ripening. *See* HORMONE; PLANT GROWTH; PLANT PHYSIOLOGY. [Cm.C.]

Plant keys Artificial analytical constructs for identifying plants. The identification, nomenclature, and classification of plants are the domain of plant taxonomy, and one basic responsibility of taxonomists is determining if the plant at hand is identical to a known plant. The dichotomous key provides a shortcut for identifying plants that eliminates searching through numerous descriptions to find one that fits the unknown plant.

A key consists of series of pairs (couplets) of contradictory statements (leads). Each statement of a couplet must "lead" to another couplet or to a plant name. Each couplet provides an either-or proposition wherein the user must accept one lead as including the unknown plant in question and must simultaneously reject the opposing lead. The user then proceeds from acceptable lead to acceptable lead of successive couplets until a name for the unknown plant is obtained. For confirmation, the newly identified plant should then be compared with other known specimens or with detailed descriptions of that species.

Keys are included in monographic or revisionary treatments of groups of plants, most often for a genus or family. Books containing extended keys, coupled with detailed descriptions of each kind of plant (taxon), for a given geographic region are called manuals or floras, though the latter technically refers to a simple listing of names of plants for a given region. *See* PLANT KINGDOM; PLANT TAXONOMY. [D.J.Pi.]

Plant kingdom The worldwide array of plant life, including plants that have roots in the soil, plants that live on or within other plants and animals, plants that float on or swim in water, and plants that are carried in the air. Fungi used to be included in the plant kindom because they looked more like plants than animals and did not move about. It is now known that fungi are probably closer to animals in terms of their evolutionary relationships. Also once included in plants were the "blue-green algae," which are now clearly seen to be bacteria, although they are photosynthetic (and presumably the group of organisms from which the chloroplasts present in true plants were derived). The advent of modern methods of phylogenetic DNA analysis has allowed such distinctions, but even so, what remains of the plantlike organisms is still remarkably divergent and difficult to classify.

Plants range in size from unicellular algae to giant redwoods. Some plants complete their life cycles in a matter of hours, whereas the bristlecone pines are known to be over 4000 years old. Plants collectively are among the most poorly understood of all forms of life, with even their most basic functions still inadequately known, including how they sense gravity and protect themselves from infection by bacteria, viruses, and fungi. Furthermore, new species are being recorded every year.

Within the land plants, a great deal of progress has been made in sorting out phylogenetic (evolutionary) relationships of extant taxa based on DNA studies, and the system of classification listed below includes these changes. The angiosperms or flowering plants (Division Magnoliophyta) have recently been reclassified based on phylogenetic studies of DNA sequences. Within the angiosperms, several informal names are indicated in parentheses; these names may at some future point be formalized, but for the present they are indicated in lowercase letters because they have not been formally recognized under the Code of Botanical Nomenclature.

It is known that the bryophytes (Division Bryophyta) are not closely related to each other, but which of the three major groups is closest to the other land plants is not yet clear. Among the extant vascular plants, Lycophyta are the sister group to all the rest, with all of the fernlike groups forming a single monophyletic (natural) group, which is reflected here in the classification by putting them all under Polypodiophyta. This group is the sister to the extant seed plants, within which all gymnosperms form a group that is sister to the angiosperms. Therefore, if Division is taken as the highest category within Embryobionta (the embryo-forming plants), then the following scheme would reflect the present state of knowledge of relationships (an asterisk indicates that a group is known only from fossils). See separate articles on names marked by daggers.

- Subkingdom Thallobionta (thallophytes)†
  - Division Rhodophycota (red algae)
    - Class Rhodophyceae†
  - Division Chromophycota†
    - Class: Chrysophyceae (golden or golden-brown algae)†
    - Prymnesiophyceae†
    - Xanthophyceae (yellow-green algae)†
    - Eustigmatophyceae†
    - Bacillariophyceae (diatoms)†
    - Dinophyceae (dinoflagellates)†
    - Phaeophyceae (brown algae)†
    - Raphidophyceae (chloromonads)†
    - Cryptophyceae (cryptomonads)†
  - Division Euglenophycota (euglenoids)
    - Class Euglenophyceae†
  - Division Chlorophycota (green algae)†
    - Class: Chlorophyceae†
    - Charophyceae†
    - Prasinophyceae
- Subkingdom Embryobionta (embryophytes)†
  - Division Rhyniophyta*†
    - Class Rhyniopsida†
  - Division Bryophyta†
    - Class Hepaticopsida (liverworts)†
      - Subclass Jungermanniidae†
        - Order: Takakiales†
        - Calobryales†
        - Jungermanniales†
        - Metzgeriales†
      - Subclass Marchantiidae†
        - Order: Sphaerocarpales†
        - Monocleales†
        - Marchantiales†
    - Class: Anthocerotopsida (hornworts)†
    - Sphagnopsida (peatmosses)†
    - Andreaeopsida (granite mosses)†
    - Bryopsida (mosses)†
      - Subclass: Archidiidae†
      - Bryidae†
        - Order: Fissidentales†
        - Bryoxiphiales†
        - Schistostegales†
        - Dicranales†
        - Pottiales†
        - Grimmiales†
        - Seligeriales†
        - Encalyptales†
        - Funariales†
        - Splachnales†
        - Order: Bryales†
        - Mitteniales†
        - Orthotrichales†
        - Isobryales†
        - Hookeriales†
        - Hypnales†
      - Subclass: Buxbaumiidae†
      - Tetraphididae†
      - Dawsoniidae†
      - Polytrichidae†
  - Division Lycophyta†
    - Class Lycopsida†
      - Order: Lycopodiales†
      - Asteroxylales*†

    - Protolepidodendrales*†
    - Selaginellales*
    - Lepidedendrales*†
    - Isoetales†
  - Class Zosterophyllopsida*†
- Division Polypodiophyta†
  - Class Polypodopsida†
    - Order: Equisetales†
    - Marattiales†
    - Sphenophyllales*
    - Pseudoborniales*
    - Psilotales
    - Ophioglossales†
    - Noeggerathiales*
    - Protopteridales*
    - Polypodiales†
  - Class Progymnospermopsida*
- Division Pinopsida
  - Class Ginkgoopsida†
    - Order: Calamopityales*
    - Callistophytales*
    - Peltaspermales*
    - Ginkgoales†
    - Leptostrobales*
    - Caytoniales†
    - Arberiales*
    - Pentoxylales*
  - Class Cycadopsida†
    - Order: Lagenostomales*
    - Trigonocarpales*
    - Cycadales†
    - Bennettiales*
  - Class Pinopsida†
    - Order: Cordaitales*†
    - Pinales†
    - Podocarpales
    - Gnetales†
- Division Magnoliophyta (angiosperms, flowering plants)†
  - Class Magnoliopsida†
- unplaced groups: Amborellaceae, Ceratophyllaceae, Chloranthaceae, Nymphaeaceae, etc.
  - eumagnoliids†
    - Order: Magnoliales†
    - Laurales†
    - Piperales†
    - Winterales
  - monocotyledons†
    - Order: Acorales†
    - Alismatales†
    - Asparagales†
    - Dioscoreales†
    - Liliales†
    - Pandanales†
    - commelinids
      - Arecales†
      - Commelinales†
      - Poales†
      - Zingiberales†
- eudicotyledons†
- (basal eudicots)
    - Order: Ranunculales†

See DEOXYRIBONUCLEIC ACID (DNA); PLANT EVOLUTION; PLANT PHYLOGENY; PLANT TAXONOMY. [M.W.C.; M.F.F.]

Plant metabolism The complex of physical and chemical events of photosynthesis, respiration, and the synthesis and degradation of organic compounds. Photosynthesis produces the substrates for respiration and the starting organic compounds used as building blocks for subsequent biosyntheses of nucleic acids, amino acids, and proteins, carbohydrates and organic acids, lipids, and natural products. *See* PHOTORESPIRATION; PHOTOSYNTHESIS; PLANT RESPIRATION. [I.P.T.]

Plant mineral nutrition The relationship between plants and all chemical elements other than carbon, hydrogen, and oxygen in the environment. Plants obtain most of their mineral nutrients by extracting them from solution in the soil or the aquatic environment. Mineral nutrients are so called because most have been derived from the weathering of minerals of the Earth's crust. Nitrogen is exceptional in that little occurs in minerals: the primary source is gaseous nitrogen of the atmosphere.

Some of the mineral nutrients are essential for plant growth; others are toxic, and some absorbed by plants may play no role in metabolism. Many are also essential or toxic for the health and growth of animals using plants as food. Six basic facts have been established: (1) plants do not need any of the solid materials in the soil—they cannot even take them up; (2) plants do not need soil microorganisms; (3) plant roots must have a supply of oxygen; (4) all plants require at least 14 mineral nutrients; (5) all of the essential mineral nutrients may be supplied to plants as simple ions of inorganic salts in solution; and (6) all of the essential nutrients must be supplied in adequate but nontoxic quantities. These facts provide a conceptually simple definition of and test for an essential mineral nutrient. A mineral nutrient is regarded as essential if, in its absence, a plant cannot complete its life cycle.

Nutrients which plants require in relatively large amounts, that is, the essential macronutrients, are nitrogen, sulfur, phosphorus, calcium, potassium, and magnesium. Iron is not required in large amounts and hence is regarded as an essential micronutrient or trace element. With the progressive development of better techniques for purifying water and salts, the list of essential nutrients for all plants has expanded to include boron, manganese, zinc, copper, molybdenum, and chlorine. Evidence has accumulated in support of nickel being essential. In addition, sodium and silicon have been shown to be essential for some plants, beneficial to some, and possibly of no benefit to others. Cobalt has also been shown to be essential for the growth of legumes when relying upon atmospheric nitrogen. Claims that two other chemical elements (vanadium and selenium) may be essential micronutrients have still to be firmly established.

Mineral nutrients may be toxic to plants either because the specific nutrient interferes with plant metabolism or because its concentration in combination with others in solution is excessive and interferes with the plant's water relations. Other chemical elements in the environment may also be toxic. High concentrations of salts in soil solutions or aquatic environments may depress their water potential to such an extent that plants cannot obtain sufficient water to germinate or grow. Some desert plants growing in saline soils can accumulate salt concentrations of 20–50% dry weight in their leaves without damage, but salt concentrations of only 1–2% can damage the leaves of many species. *See* PLANT-WATER RELATIONS; PLANTS, SALINE ENVIRONMENTS OF.

A number of elements interfere directly with other aspects of plant metabolism. Sodium is thought to become toxic when it reaches concentrations in the cytoplasm that depress enzyme activity or damage the structure of organelles, while the toxicity of selenium is probably due to its interference in metabolism of amino acids and proteins. The ions of the heavy metals, cobalt, nickel, chromium, manganese, copper, and zinc are particularly toxic in low concentrations, especially when the concentration of calcium in solution is low; increasing calcium increases the plant's tolerance. Aluminum is toxic only in acid soils. Boron may be toxic in soils over a wide pH range, and is a serious problem for sensitive crops in regions where irrigation waters contain excessive boron or where the soils contain unusually high levels of boron.

All plants grow poorly on very acid soils ($\text{pH} \leq 3.5$); some plants may grow reasonably well on somewhat less acid soils. Several factors may be involved, and their interactions with plant species are complex. The harmful effects of soil acidity in some areas have been exacerbated by industrial emissions resulting in acid rain and in deposition of substances which increase the acidity on further reaction in the soil, with consequent damage to plants and animals in these ecosystems. *See* ACID RAIN.

The elemental composition of plants is important to the health and productivity of animals which graze them. With the exception of boron, all elements which are essential for plant growth are also essential for herbivorous mammals. Animals also require sodium, iodine, and selenium and, in the case of ruminant herbivores, cobalt. As a result, animals may suffer deficiencies of any one of this latter group of elements when ingesting plants which are quite healthy but contain low concentrations of these elements. In addition, nutrients in forage may be rendered unavailable to animals through a variety of factors that prevent their absorption from the gut. Plants and animals differ also in their tolerance of high levels of nutrients, sometimes with deleterious results for grazing animals. For example, the toxicity of high concentrations of selenium in plants to animals grazing them, known as selenosis, was recognized when the puzzling and long-known "alkali disease" and "blind staggers" in grazing livestock in parts of the Great Plains of North America were shown to be symptoms of chronic and acute selenium toxicity. *See* ABSORPTION (BIOLOGY); NITROGEN CYCLE; PLANT TRANSPORT OF SOLUTES; RHIZOSPHERE; ROOT (BOTANY); SOIL CHEMISTRY. [J.F.L.]

Plant morphogenesis The origin and development of plant form and structure. Morphogenesis may be concerned with the whole plant, with a plant part, or with the subcomponents of a structure.

The establishment of differences at the two ends of a structure is called polarity. In plants, polar differences can be recognized very early in development. In the zygote, cytological differences at the two ends of the cell establish the position of the first cell division, and thus the fate of structures produced from the two newly formed cells. During the development of a plant, polarity is also exhibited in the plant axis (in the shoot and root tips). If a portion of a shoot or root is excised and allowed to regenerate, the end toward the shoot tip always regenerates shoots whereas the opposite end forms roots. Polarity is also evident on the two sides of a plant organ, such as the upper and lower surface of a leaf, sepal, or petal.

The diversity in plant form is produced mainly because different parts of the plant grow at different rates. Furthermore, the growth of an individual structure is different in various dimensions. Thus the rate of cell division and cell elongation as well as the orientation of the plane of division and of the axis of cell elongation ultimately establish the form of a structure. Such differential growth rates are very well orchestrated by genetic factors. Although the absolute growth rates of various parts of a plant may be different, their relative growth rates, or the ratio of their growth rates, are always constant. This phenomenon is called allometry (or heterogony), and it supports the concept that there is an interrelationship between the growth of various organs of a plant body. *See* PLANT GROWTH.

During development, either the removal of or changes in one part of the plant may drastically affect the morphogenesis of one or more other parts of the plant. This phenomenon is called correlation and is mediated primarily through chemical substances, such as nutrients and hormones. *See* APICAL DOMINANCE.

The ultimate factors controlling the form of a plant and its various organs are the genes. In general, several genes interact during the development of a structure, although each gene plays a significant role. Thus, a mutation in a single gene may affect the shape or size of a leaf, flower, or fruit, or the color of flower petals, or the type of hairs produced on stems and leaves. There are at least two classes of genes involved in plant morphogenesis: regulatory genes that control the activity of other genes, and effector genes that are directly involved in a developmental process. The effector genes may affect morphogenesis through a network of processes, including the synthesis and activity of proteins and enzymes, the metabolism of plant growth substances, changes in the cytoskeleton and the rates and planes of cell division, and cell enlargement. *See* GENE ACTION; PLANT HORMONES.

Plant form is also known to be affected by nutritional factors, such as sugars or nitrogen levels. For example, leaf shape can be affected by different concentrations of sucrose, and the sexuality of flowers is related to the nitrogen levels in the soil in some species. Inorganic ions (such as silver and cobalt) have also been known to affect the type of flower produced. *See* PLANT MINERAL NUTRITION.

Although genes are the ultimate controlling factors, they do not act alone, but interact with the existing environmental factors during plant development. Environmental factors, including light, temperature, moisture, and pressure, affect plant form. *See* PHYSIOLOGICAL ECOLOGY (PLANT); PLANT-WATER RELATIONS. [V.K.S.]

Plant movements The wide range of movements that allow plants to reorient themselves in relation to changed surroundings, to facilitate spore or seed dispersal, or, in the case of small free-floating aquatic plants, to migrate to regions optimal for their activities. There are two types of plant movement: abiogenic movements, which arise purely from the physical properties of the cells and therefore take place in nonliving tissues or organs; and biogenic movements, which occur in living cells or organs and require an energy input from metabolism.

Abiogenic movements. Drying or moistening of certain structures causes differential contractions or expansions on the two sides of cells and hence causes movements of curvature. Such movements are called hygroscopic and are usually associated with seed and spore liberation and dispersal. Examples of such movement occur in the "parachute" hairs of the fruit of dandelion (*Taraxacum officinale*), which are closed when damp but open when the air is dry to induce release from the heads and give buoyancy for wind dispersal.

Another type of abiogenic movement is due to changes in volume of dead water-containing cells. In the absence of a gas phase, water will adhere to lignocellulose cell walls. As water is lost by evaporation from the surface of these cells, considerable tensions can build up inside, causing them to decrease in volume while remaining full of water. The effect is most commonly seen in some grasses of dry habitats, such as sand dunes, where longitudinal rows of cells on one side of the leaf act as spring hinges, contracting in a dry atmosphere and causing the leaf to roll up into a tight cylinder, thus minimizing water loss by transpiration.

Biogenic movements. There are two types of biogenic movement. One of these is locomotion of the whole organism and is thus confined to small, simply organized units in an aqueous environment. The other involves the change in shape and orientation of whole organs of complex plants, usually in response to specific stimuli.

Locomotion. In most live plant cells the cytoplasm can move by a streaming process known as cyclosis. Energy for cyclosis is derived from the respiratory metabolism of the cell. The mechanism probably involves contractile proteins very similar to the actomyosin of animal muscles.

Cell locomotion is a characteristic of many simple plants and of the gametes of more highly organized ones. Motility in such cells is produced by cilia anchored in the peripheral layers of the cell and projecting into the surrounding medium. *See* CILIA AND FLAGELLA.

Cell locomotion is usually not random but is directed by some environmental gradient. Thus locomotion may be in response to specific chemicals, in which case it is called chemotaxis. Light gradients induce phototaxis; temperature gradients induce thermotaxis; and gravity induces geotaxis. One or more of these environmental factors may operate to control movement to optimal living conditions.

Movement of organs. In higher plants, organs may change shape and position in relation to the plant body. When bending or twisting of the organ is evoked spontaneously by some internal stimulus, it is termed autonomous movement. The most common movements, however, are those initiated by external stimuli such as light and the force of gravity. Of these there are two kinds. In nastic movements (nasties), the stimulus usually has no directional qualities (such as a change in temperature), and the movement is therefore not related to the direction from which the stimulus comes. In tropisms, the stimulus has a direction (for instance, gravitational pull), and the plant movement direction is related to it.

The most common autonomous movement is circumnutation, a slow, circular, sometimes waving movement of the tips of shoots, roots, and tendrils as they grow; one complete cycle usually takes from 1 to 3 h. These movements are due to differential growth, but some may be caused by turgor changes in the cells of special hinge organs and are thus reversible.

1. *Nastic movements*. There are two kinds of nastic movements, due either to differential growth or to differential changes in the turgidity of cells. They can be triggered by a wide variety of external stimuli.

Photonastic (light/dark trigger) movements are characteristic of many flowers and inflorescences, which usually open in the light and close in the dark. Thermonasty (temperature-change trigger) is seen in the tulip and crocus flowers, which open in a warm room and close again when cooled. The most striking nastic movements are seen in the sensitive plant (*Mimosa pudica*). Its multipinnate leaves are very sensitive to touch or slight injury. Leaflets fold together, pinnae collapse downward, and the whole leaf sinks to hang limply.

Epinasty and hyponasty occur in leaves as upward and downward curvatures respectively. They arise either spontaneously or as the result of an external stimulus, such as exposure to the gas ethylene in the case of epinasty; they are not induced by gravity.

2. *Tropisms*. Of these the most universal and important are geotropism (or more properly gravitropism) and phototropism; others include thigmotropism and chemotropism.

In geotropism, the stimulus is gravity. The main axes of most plants grow in the direction of the plumb line with shoots upward (negative geotropism) and roots downward (positive geotropism).

In phototropism the stimulus is a light gradient, and unilateral light induces similar curvatures; those toward the source are positively phototropic; those away from the source are negatively phototropic. Main axes of shoots are usually positively phototropic, while the vast majority of roots are insensitive.

In thigmotropism (sometimes called haptotropism), the stimulus is touch; it occurs in climbing organs and is responsible for tendrils curling around a support. In many tendrils the response may spread from the contact area, causing the tight coiling of the basal part of the tendril into an elaborate and elastic spring.

Chemotropism is induced by a chemical substance. Examples are the incurling of the stalked digestive glands of the insectivorous plant *Drosera* and incurling of the whole leaf of *Pinguicula* in response to the nitrogenous compounds in the insect prey. A special case of chemotropism concerns response to moisture gradients; for example, under artificial conditions in air, the primary roots of some plants will curve toward and grow along a moist surface. This is called hydrotropism and may be of importance under natural soil conditions in directing roots toward water sources. *See* PLANT HORMONES; PLANT PHYSIOLOGY. [L.J.A.]

Plant organs Plant parts having rather distinct form, structure, and function. Organs, however, are interrelated through both evolution and development and are similar in many ways.

Roots, stems, and leaves are vegetative, or asexual, plant organs. They do not produce sex cells or play a direct role in sexual reproduction. In many species, nevertheless, these organs or parts of them (cuttings), may produce new plants asexually (vegetative reproduction). Sex organs are formed during the reproductive stage of plant development. In flowering plants, sex cells are produced in certain floral organs. The flower as a whole is sometimes called an organ, although it is more appropriate to consider it an assemblage of organs. *See* FLOWER; FRUIT; LEAF; REPRODUCTION (PLANT); ROOT (BOTANY); STEM. [K.E.]

Plant pathology The study of disease in plants; it is an integration of many biological disciplines and bridges the basic and applied sciences. As a science, plant pathology encompasses the theory and general concepts of the nature and cause of disease, and yet it also involves disease control strategies, with the ultimate goal being reduction of damage to the quantity and quality of food and fiber essential for human existence.

Kinds of plant diseases. Diseases were first classified on the basis of symptoms. Three major categories of symptoms were recognized long before the causes of disease were known; necroses, destruction of cell protoplasts (rots, spots, wilts); hypoplases, failure in plant development (chlorosis, stunting); and hyperplases, overdevelopment in cell number and size (witches'-brooms, galls). This scheme remains useful for recognition and diagnosis.

When fungi, and then bacteria, nematodes, and viruses, were recognized as causes of disease, it became convenient to classify diseases according to the responsible agent. If the agents were infectious (biotic), the diseases were classified as being “caused by bacteria,” “caused by nematodes,” or “caused by viruses.” To this list were added phanerogams and protozoans, and later mollicutes (mycoplasmas, spiroplasmas), rickettsias, and viroids. In a second group were those diseases caused by such noninfectious (abiotic) agents as air pollutants, inadequate oxygen, and nutrient excesses and deficiencies.

Other classifications of disease have been proposed, such as diseases of specific plant organs, diseases involving physiological processes, and diseases of specific crops or crop groups (for example, field crops, fruit crops, vegetable crops).

Symptoms of plant diseases. Symptoms are expressions of pathological activity in plants. They are visible manifestations of changes in color, form, and structure: leaves may become spotted, turn yellow, and die; fruits may rot on the plants or in storage; cankers may form on stems; and plants may blight and wilt. Diagnosticians learn how to associate certain symptoms with specific diseases, and they use this knowledge in the identification and control of pathogens responsible for the diseases.

Those symptoms that are external and readily visible are considered morphological. Others are internal and primarily histological, for example, vascular discoloration of the xylem of wilting plants. Microscopic examination of diseased plants may reveal additional symptoms at the cytological level, such as the formation of tyloses (extrusion of living parenchyma cells of the xylem of wilted tissues into vessel elements).

It is important to make a distinction between the visible expression of the diseased condition in the plant, the symptom, and the visible manifestation of the agent which is responsible for that condition, the sign. The sign is the structure of the pathogen, and when present it is most helpful in diagnosis of the disease.

All symptoms may be conveniently classified into three major types because of the manner in which pathogens affect plants. Most pathogens produce dead and dying tissues, and the symptoms expressed are categorized as necroses. Early stages of necrosis are evident in such conditions as hydrosis, wilting, and yellowing. As cells and tissues die, the appearance of the plant or plant part is changed, and is recognizable in such common conditions as blight, canker, rot, and spot.

Many pathogens do not cause necrosis, but interfere with cell growth or development. Plants thus affected may eventually become necrotic, but the activity of the pathogen is primarily inhibitory or stimulatory. If there is a decrease in cell number or size, the expressions of pathological activity are classified as hypoplases; if cell number or size is increased, the symptoms are grouped as hyperplases. These activities are very specific and most helpful in diagnosis. In the former group are such symptoms as mosaic, rosetting, and stunting, with obvious reduction in plant color, structure, and size. In the latter group are gall, scab, and witches'-broom, all visible evidence of stimulation of growth and development of plant tissues. *See* CROWN GALL. [C.W.B.]

The primary agents of plant disease are fungi, bacteria, viruses and viroids, nematodes, parasitic seed plants, and a variety of noninfectious agents.

Fungi. More plant diseases are caused by fungi than by any other agent. The fungi that cause plant disease derive their food from the plant (host) and are called parasites. Those that can live and grow only in association with living plant tissues are obligate parasites. Some fungi obtain their food from dead organic matter and are known as saprobes or saprophytes. Still others can utilize food from either dead organic matter or from living plant cells, and are referred to as either facultative parasites or facultative saprophytes. The classes with plant disease-causing fungi are Plasmodiophoromycetes, Chytridiomycetes, Zygomycetes, Oomycetes, Ascomycetes, Basidiomycetes, and Deuteromycetes. *See* FUNGI. [C.W.E.]

Bacteria. Over 100 species of bacteria mainly in five genera cause disease in hundreds of different species of flowering plants. Destructive bacterial diseases affect the major cereal, vegetable, and fruit crops. None of the bacterial pathogens of plants causes serious diseases of humans or animals, and certain groups of green plants (mosses, ferns, conifers, and hardwood trees) have few or no major bacterial diseases. *See* BACTERIA.

Each species of bacteria produces a distinctive pattern of symptoms on those hosts that it attacks.

With a few exceptions, most of the bacteria that cause disease in plants are non-spore-forming, rod-shaped, gram-negative cells. It is not possible to separate plant pathogenic bacteria into species on the basis of colony characteristics, cell morphology, or staining characteristics. Therefore, biochemical and physical tests used to differentiate bacteria in general are also used in studies on plant pathogens. Helpful techniques include serological tests, DNA hybridization, sensitivity to phages, and gel electrophoresis of proteins. However, one of the most important of the tests for identification is the demonstration of pathogenicity to a specific plant.

Many foliage pathogens are dependent upon wind-driven splashing rain as the primary means of spread from plant to plant. Bacteria also may be spread from plant to plant by insects, in irrigation water, and by various cultural operations during the growing season. Bacteria can also survive the winter in insects such as flea beetles. Most bacterial plant pathogens survive adverse conditions in host plants. Only a small number of species survive for long periods of time in the soil in the absence of host plants. Bacterial plant pathogens are not capable of forcing their way through the cuticle of a leaf or bark of a stem. They must enter through wounds or natural openings.

The exact manner by which bacteria induce disease in plants is not fully understood. The surface area of hundreds of thousands of cells in intimate contact with the surrounding plant cells is very large, and enzymes, as well as toxic materials, can be released readily into the host tissue.

Certain vascular parasites produce gumlike substances or polysaccharides. Masses of bacterial cells embedded in the polysaccharide material and host responses to hormone imbalances reduce the rate of flow of water when such bacteria as the one causing bacterial wilt of tomato invade water-conducting tissue. The genetic control for tumor induction in the crown gall bacterium has been shown to reside in a plasmid, a nonchromosomal DNA element. The presence of the tumor-inducing plasmid ensures that genetic information in the bacterial cell is transferred and maintained in the transformed cells of the plant cancer resulting from infection.

Since primary sources of inoculum for new infections are often in undecomposed plant debris or seed, crop rotation and the use of pathogen-free seed or seed treatments are, in general, effective in reducing losses from a large number of bacterial diseases affecting foliage. Resistant varieties have been developed for a number of foliage diseases because spraying or dusting, in general, has been relatively ineffective. Certain antibiotics are effective, but not widely used because of the concern for the development of resistant strains. An insect-transmitted bacterium can be controlled if populations of the insect vector are reduced. [A.K.]

Viruses and viroids. Viruses and viroids are the simplest of the various causative agents of plant disease. The essential element of each of these two pathogens is an infective nucleic acid. The nucleic acid of viruses is covered by an exterior shell (coat) of protein, but that of viroids is not. *See* PLANT VIRUSES AND VIROIDS.

Approximately 400 plant viruses and about 10 viroids are known. The nucleic acid of most plant viruses is a single-stranded RNA; a number of isometric viruses have a double-stranded RNA. A few viruses contain double-stranded DNA, and several containing single-stranded DNA have been reported. The nucleic acid of viroids is a single-stranded RNA, but its molecular weight is much lower than that of viruses.

Some viruses, such as tobacco mosaic virus (TMV) and cucumber mosaic virus, are found in many plant species; others, such as wheat streak mosaic virus, occur only in a few grasses. Viruses are transmitted from plant to plant in several ways. The majority are transmitted by vectors such as insects, mites, nematodes, and fungi which acquire viruses during feeding upon infected plants. Some viruses are transmitted to succeeding generations by infected seed. Viroids are spread mainly by contact between healthy and diseased plants or by the use of contaminated cutting tools.

The control or prevention of virus diseases involves breeding for resistance, propagation of virus-free plants, use of virus-free seed, practices designed to reduce the spread by vectors, and, in some cases, the deliberate inoculation of plants with mild strains of a virus to protect them from the deleterious effects of severe strains. *See* PLANT VIRUSES AND VIROIDS. [R.I.H.]

Nematodes. All soils that support plant life contain nematodes living in the water films that surround soil particles. Most nematodes feed primarily on microscopic plants, animals, and bacteria, but a few are parasites of animals; another relatively small group of nematodes parasitize plants. *See* NEMATA.

Plant-parasitic nematodes are distinguished by their small size, about 1 mm average length, and mouthparts that are modified to form a hollow stylet which is inserted into plant cells. All of the plant parasites are placed into two orders, Tylenchida and Dorylaimida.

Plant injury is of three general types and is related to feeding habits. Migratory endoparasites destroy tissues as they feed, producing necrotic lesions in the root cortex. Other migratory endoparasites invade leaf tissues and produce extensive brown spots. Sedentary endoparasites do not kill host cells, but induce changes in host tissues, which lead to an elaborate feeding site or gall. The third general type of symptom is produced by certain migratory ectoparasites, where root tips are devitalized and cease to grow without any associated swelling or necrosis.

In addition to the plant injury that they cause directly, nematodes are important factors in disease complexes. Lesions and galls provide entrance courts for soil fungi and bacteria, and many diseases caused by soil-borne pathogens are more severe when nematodes are present. Important viruses are transmitted by nematodes of the order Dorylaimida.

Control of plant-parasitic nematodes often is based on selection of nonhosts for crop rotations or nematode-resistant varieties. Some plant species release compounds into the soil that are toxic to nematodes. Animal manures, compost, and other organic amendments enhance the buildup of natural enemies of nematodes. [R.A.R.]

Many parasitic seed plants (estimated at nearly 3000) attack other higher plants. In some families (for example, the mistletoes Loranthaceae and Viscaceae) all members are parasitic; in others, only a single genus is parasitic in an otherwise autotrophic family.

Most parasitic plants are terrestrial; that is, the parasitic connection with the host plant is through the roots. Other parasitic plants grow on the above-ground parts of the host. Some plants are classed as semiparasites because they can live in the soil as independent plants for a time, but are not vigorous or may not flower if they do not become attached to a suitable host. The nutritional status of parasitic plants ranges from total parasites with no chlorophyll (for example, the broomrapes, Orobanchaceae) to plants that are well supplied with chlorophyll and obtain primarily water and minerals from their hosts (many mistletoes; see illustration). [F.G.H.]

Noninfectious agents of disease. Plants with symptoms caused by noninfectious agents cannot serve as sources of further spread of the same disorder. Such noninfectious agents may be deficiencies or excesses of nutrients, anthropogenic pollutants, or biological effects by organisms external to the affected plants. On the farm, plant-damaging pollution may be caused by careless use of pesticides. Mishandled herbicides are by far the most damaging to plants. Off the farm, anthropogenic air pollutants are generated by industrial processes, and by any heating or transportation method that uses fossil fuels. The most common air pollutants that damage plants are sulfur oxides and ozone. Sulfur oxides are produced when sulfur-containing fossil fuels are burned or metallic sulfides are refined. Human-generated ozone is produced by sunlight acting on clouds of nitrogen oxides and hydrocarbons that come primarily from automobile exhausts. *See* AIR POLLUTION; WATER POLLUTION. [G.N.A.]

Many small plants of a dwarf mistletoe (*Arceuthobium vaginatum*) parasitizing a ponderosa pine branch. This is the most damaging disease of ponderosa pine in many parts of the West.

Epidemiology of plant disease. Epidemiology is the study of the intensification of disease over time and the spread of disease in space. The botanical epidemiologist is concerned with the interrelationships of the host plant (suscept), the pathogen, and the environment, which are the components of the disease triangle. With a thorough knowledge of these components, the outbreak of disease may be forecast in advance, the speed at which the epidemic will intensify may be determined, control measures can be applied at critical periods, and any yield loss to disease can be projected. The maximum amount of disease occurs when the host plant is susceptible, the pathogen is aggressive, and the environment is favorable.

Epidemiologically, there are two main types of diseases: monocyclic, those that have but a single infection cycle (with the rare possibility of a second or even third cycle) per crop season; and polycyclic, those that have many, overlapping, concatenated cycles of infection per crop season. For both epidemiological types, the increase of disease slows as the proportion of disease approaches saturation or 100%. [R.D.Ber.]

Control of plant disease is defined as the maintenance of disease severity below a certain threshold, which is determined by economic losses. Diseases may be high in incidence but low in severity, or low in incidence but high in severity, and are kept in check by preventing the development of epidemics. The principles of plant disease control form the basis for preventing epidemics. However, the practicing agriculturist uses three approaches to the control of plant disease: cultural practices affecting the environmental requirement of the suscept-pathogen-environment triangle necessary for disease development, disease resistance, and chemical pesticides. [R.E.St.]

Plant phylogeny The evolutionary chronicle of plant life on the Earth. Understanding of this history is largely based on knowledge of extant plants, but the fossil record is playing an increasingly important role in refining and illuminating this picture. Study of deoxyribonucleic acid (DNA) sequences has also been revolutionizing this process in recent years. The molecular data (largely in the form of DNA sequences from several genes) have been demonstrated to be highly correlated with other information. *See* PHYLOGENY.

"Algae" was once a taxonomic designation uniting the lower photosynthetic organisms, but ultrastructural and molecular data have uncovered a bewildering diversity of species. Algae are now recognized as 10 divergent lineages on the tree of life that join organisms as distinct as bacteria and eukaryotic protozoans, ciliates, fungi, and embryophytes (including the land plants). In a biochemical context, the term "algae" defines species characterized by chlorophyll *a* photosynthesis (except Embryophyta); some of their descendants are heterotrophic (secondary chloroplast loss). Despite the variety of species it encompasses, the term "algae" also retains phylogenetic relevance. *See* ALGAE; CHLOROPHYLL; PHOTOSYNTHESIS. [G.W.Sa.]

Embryobionta, or embryophytes, are largely composed of the land plants that appear to have emerged 475 million years ago. The evidence indicates that land plants have not evolved from different groups of green algae (Chlorophyta) as suggested in the past, but instead share a common ancestor, which was a green alga. Land plants all have adaptations to the terrestrial environment, including an alternation of generations (sporophyte or diploid and gametophyte or haploid) with the sporophyte generation producing haploid spores that are capable of resisting desiccation and dispersing widely, a cuticle covering their outside surfaces, and separate male and female reproductive organs in the gametophyte stage. The life history strategies of land plants fall into two categories that do not reflect their phylogenetic relationships. The mosses, hornworts, and liverworts represent the first type, and they have expanded the haploid generation, upon which the sporophyte is dependent. Several recent analyses of DNA data as well as evidence from mitochondrial DNA structure have demonstrated that the liverworts alone are the remnants of the earliest land plants and that the mosses and hornworts are closer to the vascular plants (tracheophytes). The tracheophytes include a large number of extinct and relatively simple taxa, such as the rhiniophytes and horneophytes known only as Silurian and Devonian fossils. All tracheophytes are of the second category, and they have expanded the sporophyte generation. Among extant tracheophytes, the earliest branching are the lycopods or club mosses (*Lycopodium* and *Selaginella*), and there are still a diversity of other forms, including sphenophytes (horsetails, *Equisetum*) and ferns (a large and diverse group in which the positions of several families still are not clear). *See* EMBRYOBIONTA.

All seeds plants take the reduction of the gametophyte generation a step further and make it dependent on the sporophyte, typically hiding it within reproductive structures, which are either cones or flowers. The first seed plants originated at least by the Devonian, and they are known to have a great diversity of extinct forms, including the seed ferns. There are two groups of extant seed-bearing plants, gymnosperms and angiosperms. In the gymnosperms, the seeds are not enclosed within tissue derived from the parent plant. There are four distinct groups of extant gymnosperms, often recognized as classes: Cycadopsida, Gnetopsida, Ginkgoopsida, and Pinopsida.

The angiosperms (also flowering plants or Magnoliopsida) are the dominant terrestrial plants, although the algae collectively must still be acknowledged as the most important in the maintenance of the Earth's ecological balance (fixation of carbon dioxide and production of oxygen). In angiosperms the seeds are covered by protective tissues derived from the parental plant. There are no generally accepted angiospermous fossils older than 120 million years, but the lineage is clearly much older based on DNA clocks and other circumstantial lines of evidence such as their current geographic distributions.

Traditionally the angiosperms have been divided into two groups, monocotyledons (monocots) and dicotyledons (dicots), based on the number of seed leaves. However, DNA sequence data have demonstrated that, although there are two groups, these are characterized by fundamentally different pollen organization, such that the monocots share with a group of dicots pollen with one pore whereas the rest of the dicots have pollen with three (or more) pores. [M.W.C.]

Plant physiology That branch of plant sciences that aims to understand how plants live and function. Its ultimate objective is to explain all life processes of plants by a minimal number of comprehensive principles founded in chemistry, physics, and mathematics.

Plant physiology seeks to understand all the aspects and manifestations of plant life. In agreement with the major characteristics of organisms, it is usually divided into three major parts: (1) the physiology of nutrition and metabolism, which deals with the uptake, transformations, and release of materials, and also their movement within and between the cells and organs of the plant; (2) the physiology of growth, development, and reproduction, which is concerned with these aspects of plant function; and (3) environmental physiology, which seeks to understand the manifold responses of plants to the environment. The part of environmental physiology which deals with effects of and adaptations to adverse conditions—and which is receiving increasing attention—is called stress physiology.

Plant physiological research is carried out at various levels of organization and by using various methods. The main organizational levels are the molecular or subcellular, the cellular, the organismal or whole-plant, and the population level. Work at the molecular level is aimed at understanding metabolic processes and their regulation, and also the localization of molecules in particular structures of the cell but with little if any consideration of other processes and other structures of the same cell. Work at the cellular level often deals with the same processes but is concerned with their integration in the cell as a whole. Research at the organismal level is concerned with the function of the plant as a whole and its different organs, and with the relationships between the latter.

Research at the population level, which merges with experimental ecology, deals with physiological phenomena in plant associations which may consist either of one dominant species (like a field of corn) or of numerous diverse species (like a forest). Work at the organismal and to some extent the population level is carried out in facilities permitting maintenance of controlled environmental conditions (light, temperature, water and nutrient supply, and so on). *See* PLANT METABOLISM; PLANT RESPIRATION; PHYSIOLOGICAL ECOLOGY (PLANT); PHYTOTRONICS. [A.L.]

Plant pigment A substance in a plant that imparts coloration. The photosynthetic pigments are involved in light harvesting and energy transfer in photosynthesis. This group of pigments comprises the tetrapyrroles, which include chlorophylls (chl) and phycobilins, and the carotenoids. The light-absorbing groups of these molecules, the chromophores, contain conjugated double bonds (alternating single and double bonds), which make them effective photoreceptors. The sum of the absorption spectra of the chlorphylls and the carotenoids, evident in the absorption spectrum of a green leaf, is equivalent to the action spectrum of photosynthesis. *See* CAROTENOID; CHLOROPHYLL; PHOTOSYNTHESIS; PHYCOBILIN; PIGMENTATION.

The second major group comprises the anthocyanins, intensely colored plant pigments responsible for most scarlet, crimson, purple, mauve, and blue colors in higher plants. About 100 different anthocyanins are known. Unlike the chlorophylls and carotenoids, which are lipid-soluble chloroplast pigments, the anthocyanins are water-soluble and are located in the cell vacuole. Chemically, they are a class of flavonoids and are particularly closely related, both structurally and biosynthetically, to the flavonols. Their value to the plant lies in the contrasting colors they provide in flower and fruit, against the green background of the leaf, to attract insects and animals for purposes of pollination and seed dispersal. *See* Flavonoid. [S.Ra.]

Plant propagation The deliberate, directed reproduction of plants using plant cells, tissues, or organs. Asexual propagation, also called vegetative propagation, is accomplished by taking cuttings, by grafting or budding, by layering, by division of plants, or by separation of specialized structures such as tubers, rhizomes, or bulbs. This method of propagation is used in agriculture, in scientific research, and in professional and recreational gardening. It has a number of advantages over seed propagation: it retains the genetic constitution of the plant type almost completely; it is faster than seed propagation; it may allow elimination of the nonfruiting, juvenile phase of the plant's life; it preserves unique, especially productive, or esthetically desirable plant forms; and it allows plants with roots well adapted for growth on poor soils to be combined with tops that produce superior fruits, nuts, or other products. *See* Breeding (plant); Reproduction (plant). [C.E.LaM.]

Tissue cultures and protoplast cultures are among the techniques that have been investigated for plant propagation; the success of a specific technique depends on a number of factors. Practical applications of such methods include the clonal propagation of desirable phenotypes and the commercial production of virus-free plants.

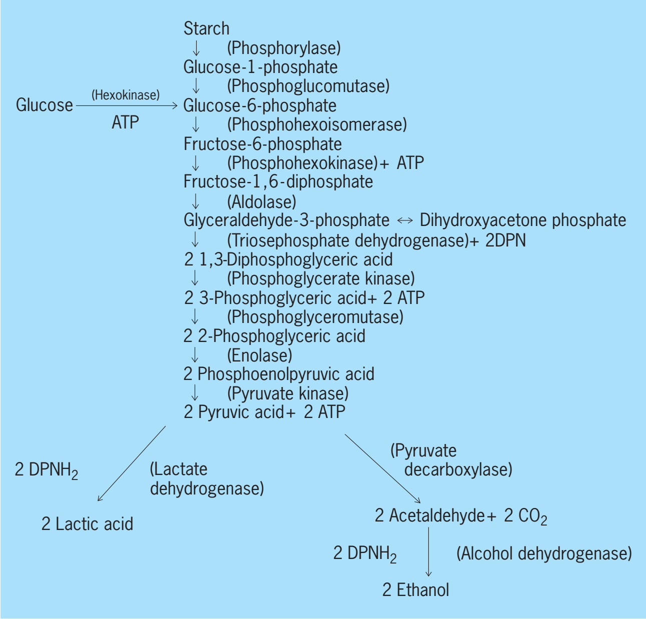
Plant tissue cultures are initiated by excising tissue containing nucleated cells and placing it on an enriched sterile culture medium. The response of a plant tissue to a culture medium depends on a number of factors: plant species, source of tissue, chronological age and physiological state of the tissue, ingredients of the culture medium, and physical culturing conditions, such as temperature, photoperiod, and aeration.

Though technically more demanding, successful culture of plant protoplasts involves the same basic principles as plant tissue culture. Empirical methods are used to determine detailed techniques for individual species; such factors as plant species, tissue source, age, culture medium, and physical culture conditions have to be considered. *See* Plant cell; Tissue culture. [K.G.F.]

Plant respiration A biochemical process whereby specific substrates are oxidized with a subsequent release of carbon dioxide, CO_2. There is usually conservation of energy accompanying the oxidation which is coupled to the synthesis of energy-rich compounds, such as adenosine triphosphate (ATP), whose free energy is then used to drive otherwise unfavorable reactions that are essential for physiological processes such as growth. Respiration is carried out by specific proteins, called enzymes, and it is necessary for the synthesis of essential metabolites, including carbohydrates, amino acids, and fatty acids, and for the transport of minerals and other solutes between cells. Thus respiration is an essential characteristic of life itself in plants as well as in other organisms.

Overall aerobic respiration is the end result of a sequence of many biochemical reactions that ultimately lead to O_2 uptake and CO_2 evolution. In the absence of O_2, as may occur in bulky plant tissues such as the potato tuber and carrot root and in submerged plants such as germinating rice seedlings, the breakdown of hexose does not go to completion. The end products are either lactic acid or ethanol, which are produced by anaerobic glycolysis or fermentation.

The sequence of reactions of anaerobic glycolysis or fermentation is shown in the illustration. The enzymes associated with anerobic glycolysis have been isolated from many plant tissues, but more often ethanol and not lactic acid is the final product.



Reaction sequence for anaerobic glycolysis. The soluble enzymes are shown in parentheses.

In aerobic tissues, pyruvic acid produced during glycolysis is completely oxidized with the accompanying synthesis of much more ATP than in anaerobic glycolysis. Pyruvic acid oxidation takes place in the mitochondria by means of a cyclic sequence of reactions, the Krebs cycle (also known as the citric acid cycle) which begins when the first product of pyruvate oxidation, acetyl coenzyme A, reacts with oxaloacetic acid to produce citric acid. Oxaloacetic acid is eventually regenerated. Thus the cycle can be repeated. In terms of conservation of chemical energy, the Krebs cycle is about 12 times more efficient than anaerobic glycolysis per mole of glucose oxidized. *See* Citric acid cycle.

In addition to anaerobic glycolysis and the Krebs cycle, there are two other sequences of biochemical reactions related to respiration that are important in plant tissues: (1) The pentose phosphate pathway permits an alternate mechanism for converting hexose phosphate to pyruvate, and (2) in germinating fatty seeds the reactions of the Krebs cycle are modified so that acetyl coenzyme A is converted to succinic acid and then to hexose by a pathway called the glyoxylate cycle. *See* Photorespiration; Photosynthesis; Plant growth; Plant metabolism. [I.Z.]

Plant taxonomy The area of study focusing on the development of a classification system, or taxonomy, for plants based on their evolutionary relationships (phylogeny). The assumption is that if classification reflects phylogeny, reference to the classification will help researchers focus their work in a more accurate manner. The task is to make phylogeny reconstruction as accurate as possible. The basic unit of classification is generally accepted to be the species, but how a species should be recognized has been intensely debated. *See* Plant kingdom; Plant phylogeny.

The earliest classifications of plants were those of the Greek philosophers such as Aristotle (384–322 B.C.) and Theophrastus (372–287 B.C.). The latter is often called the father of botany largely because he listed the names of over 500 species, some of which are still used as scientific names today. In the next 1600 years little progress occurred in plant taxonomy. It was not until the fifteenth century that there was renewed interest in botany, much of which was propelled by the medical use of plants. In 1753 Carolus Linnaeus, a Swedish botanist, published his *Species Plantarum*, a classification of all plants known to Europeans at that time. Linnaeus's system was based on the arrangement and numbers of parts in flowers, and was intended to be used strictly for identification (a system now referred to as an artificial classification as opposed to a natural classification, based on how closely related the species are).

In *Species Plantarum*, Linnaeus made popular a system of binomial nomenclature developed by the French botanist Gaspard Bauhin (1560–1624), which is still in use. Each species has a two-part name, the first being the genus and the second being the species epithet. For example, *Rosa alba* (italicized because it is Latin) is the scientific name of one species of rose; the genus is *Rosa* and the species epithet is *alba*, meaning white (it is not a requirement that scientific names be similar to common names or have real meaning, although such relevance is often the case). The genus name *Rosa* is shared by all species of roses, reflecting that they are thought to be more closely related to each other than to species in any other group.

Today, we understand that the best classification system is one that reflects the patterns of the evolutionary processes that produced these plants. The rules of botanical nomenclature (and those of zoology as well, although they are not identical) are part of an internationally accepted Code that is revised (minimally) at an international congress every 5 years. *See* PLANT EVOLUTION.

Use of common names in science and horticulture is not practical. Scientific names are internationally agreed upon so that a consistent taxonomic name is used everywhere for a given organism. In addition to genus and species, plants are classified by belonging to a family; related families are grouped into orders, and these are typically grouped into a number of yet higher and more encompassing categories. In general, higher categories are composed of many members of lower types—for example, a family may contain 350 genera, but some may be composed of a single genus with perhaps a single species if that species is distantly related to all others.

Many botanists use a number of intermediate categories between the level of genus and family, such as subfamilies, tribes, and subtribes, as well as some between species and genus, such as subgenera and sections, but none of these categories is formally mandated. They are useful nonetheless to reflect intermediate levels of relatedness, particularly in large families (composed of several hundreds or even thousands of species). Below the level of species, some botanists use the concept of subspecies (which is generally taken to mean a geographically distinct form of a species) and variety (which is often a genetic form or genotype, for example a white-flowered form of a typically blue-flowered species, or a form that is ecologically distinct).

The basic idea that plant classification should reflect evolutionary (genetic) relationships has been well accepted for some time, but the degree to which this could be assessed by the various means available differed. It has only recently become possible to assess genetic patterns of relatedness directly by analyzing DNA sequences. In the 1990s, DNA technology became much more efficient and less costly, resulting in a dramatic upsurge in the availability of DNA sequence data for various genes from each of the three genetic compartments present in plants (nuclear, mitochondrial, and plastid or chloroplast). In 1998 a number of botanists collectively proposed the first DNA-based classification of a major group of organisms, the angiosperms or flowering plants. For the first time, a classification was directly founded on assessments of the degree of relatedness made with objective, computerized methods of phylogeny reconstruction. Other data, such as chemistry and morphology, were also incorporated into these analyses, but by far the largest percentage of information came from DNA sequences—that is, relatedness was determined mostly on the basis of similarities in plants' genetic codes. The advantages of such a classification were immediately obvious: (1) it was not based on intuition about which category of information best reflected natural relationships; (2) it ended competition between systems based on differing emphases; (3) the analysis could be repeated by other researchers using either the same or different data (other genes or categories of information); and (4) it could be updated as new data emerged, particularly from studies of how chromosomes are organized and how morphology and other traits are determined by the genes that code for them. *See* DEOXYRIBONUCLEIC ACID (DNA); GENETIC MAPPING.

At the same time that DNA data became more widely available as the basis for establishing a classification, a more explicit methodology for turning the results of a phylogenetic analysis into a formal classification became popular. This methodology, called cladistics, allowed a large number of botanists to share ideas of how the various taxonomic categories could be better defined. Although there remain a number of dissenting opinions about some minor matters of classification, it is now impossible for scientists to propose alternative ideas based solely on opinion. *See* PHYLOGENY; TAXONOMY. [M.W.C.; M.F.F.]

Plant tissue systems Most plants are composed of coherent masses of cells called tissues. Large units of tissues having some features in common are called tissue systems. In actual usage, however, the terms tissue and tissue system are not strictly separated. A given tissue or a combination of tissues may be continuous throughout the plant or large parts of it.

Plant tissues are primary or secondary in origin. The primary arise from apical meristems, the perennially embryonic tissues at the tips of roots and shoots. The primary tissues include the surface layer, or epidermis; the primary vascular tissues, xylem and phloem, which conduct water and food, respectively; and the ground tissues. The ground tissues are parenchyma (chiefly concerned with manufacture and storage of food) and collenchyma and sclerenchyma (the two supporting tissues). In the stem and root, the vascular tissues and some associated ground tissue are often treated as a unit, the stele. Ground tissue may be present in the center of the stele (pith) and on its periphery (pericycle). The ground tissue system enclosing the stele on the outside is the cortex. It may have a hypodermis peripherally and an endodermis next to the stele.

The secondary tissues arise from lateral meristems, and their formation is mainly responsible for the growth in thickness of stems and roots. They comprise secondary vascular tissues and the protective tissue called periderm. Secondary growth may build up a massive core of wood, but the outer tissue system, the bark, remains relatively thin because its outer or older part becomes compressed and, in many species, is continuously sloughed off.

The production of flowers instead of vegetative shoots results from physiological and morphological changes in the apical meristem, which then becomes the flower meristem. The latter, however, produces tissue systems fundamentally similar to those in the vegetative body of the plant. [K.E.]

Plant transport of solutes The movement of organic and inorganic compounds through plant vascular tissues. Transport can take place over considerable distances; in tree species transport distances are often 100–300 ft (30–100 m).

This long-distance transport is necessary for survival in higher land plants in which specialized organs of uptake or synthesis are separated by a considerable distance from the organs of utilization. Diffusion is not rapid enough to account for the amount of material moved over such long distances. Rather, transport depends on a flowing stream of liquid in vascular tissues (phloem and xylem) that are highly developed structurally.

The movement of organic solutes occurs mainly in the phloem, where it is also known as translocation and where the direction of transport is from places of production, such as mature leaves, to places of utilization or storage, such as the shoot apex or developing storage roots. Organic materials translocated in the phloem include the direct products of photosynthesis (sugars) as well as compounds derived from them (nitrogenous compounds and plant hormones, for example). Some movement of organic solutes does occur in the xylem of certain species. Inorganic solutes or mineral elements, however, generally move with water in the xylem from sites of uptake in the roots to sites where water is lost from the plant, primarily the leaves. Some redistribution of the ions throughout the plant may then occur in the phloem.

The mechanism of phloem translocation is not known with certainty. Proposed mechanisms fall into two classes: one stresses the role of the conducting tissues in generating the moving force, and the other views the regions of supply and utilization as the source of this force. In the former group are mechanisms that depend on cytoplasmic streaming, electroosmosis, and activated diffusion in the sieve elements. The second group of theories, which has received more general acceptance in spite of a number of admitted limitations, includes a variety of mass-flow mechanisms. Theories of translocation must account for the important observations: polarity, bidirectional movement, velocity, energy requirement, turgor pressure, and phloem structure.

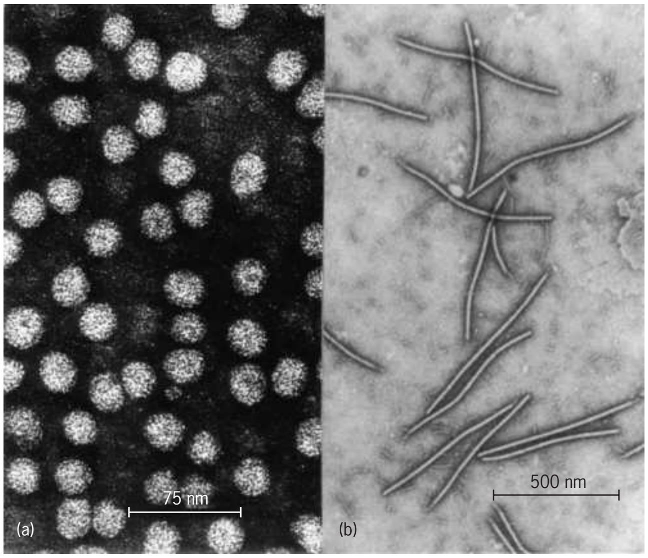
The model for the ascent of sap in the xylem which is correct according to all present evidence is called the cohesion hypothesis. According to this hypothesis, water is lost in the leaves by evaporation from cell-wall surfaces; water vapor then diffuses into the atmosphere by way of small pores between two specialized cells (guard cells). The guard cells and the pore are collectively called a stomate. This loss of water from the leaf causes movement of water out of the xylem in the leaf to the surfaces where evaporation is occurring. Water has a high internal cohesive force, especially in small tubes with wettable walls. In addition, the xylem elements and the cell walls provide a continuous water-filled system in the plant. Thus the loss of water from the xylem elements in the leaves causes a tension or negative pressure in the xylem sap. This tension is transmitted all the way down the stem to the roots, so that a flow of water occurs up the plant from the roots and eventually from the soil. The velocity of this sap flow in tree species ranges from 3 to approximately 165 ft/h (1 to 50 m/h), depending on the diameter of the xylem vessels. [S.S.D.]

Plant viruses and viroids Plant viruses are pathogens which are composed mainly of a nucleic acid (genome) normally surrounded by a protein shell (coat); they replicate only in compatible cells, usually with the induction of symptoms in the affected plant. Viroids are among the smallest infections agents known. Their circular, single-stranded riboncleic acid (RNA) molecule is less than one-tenth the size of the smallest viruses.

Viruses. Viruses can be seen only with an electron microscope (see illustration). Isometric (spherical) viruses range from 25 to 50 nanometers in diameter, whereas most anisometric (tubular) viruses are 12 to 25 nm in diameter and of various lengths (200–2000 nm), depending on the virus. The coat of a few viruses is covered by a membrane which is derived from its host.

Over 800 plant viruses have been recognized and characterized. The genomes of most of them, such as the tobacco mosaic virus (TMV), are infective single-stranded RNAs; some RNA viruses have double-stranded RNA genomes. Cauliflower mosaic virus and bean golden mosaic virus are examples of viruses having double-stranded and single-stranded deoxyribonucleic acid (DNA), respectively. The genome of many plant viruses is a single polynucleotide and is contained in a single particle, whereas the genomes of brome mosaic and some other viruses are segmented and distributed between several particles. There are also several low-molecular-weight RNAs (satellite RNAs) which depend on helper viruses for their replication. *See* Deoxyribonucleic acid (DNA); Ribonucleic acid (RNA).

The natural hosts of plant viruses are widely distributed throughout the higher-plant kingdom. Some viruses (TMV and cucumber mosaic virus) are capable of infecting over a hundred species in many families, whereas others, such as wheat streak mosaic virus, are restricted to a few species in the grass family. The replication of single-stranded RNA viruses involves release of the virus genome from the coat protein; the association of the RNA with the ribosomes of the cell; translation of the genetic information of the RNA into specific proteins, including subunits of the coat protein and possibly viral RNA-synthesizing enzymes (replicases); transmission by vectors and diseases induction; synthesis of noninfective RNA using parental RNA as the template; and assembly of the protein subunits and viral RNA to form complete virus particles.



Representative plant viruses in purified virus preparation obtained from infected leaves. (*a*) Tobacco streak virus (isometric). (*b*) Pea seed-borne mosaic virus (anisometric).

In other RNA viruses, such as lettuce necrotic yellows virus, an enzyme which is contained in the virus must first make a complementary (infective) copy of the RNA; this is then translated into enzymes and coat protein subunits. The replication of double-stranded RNA viruses is similar to that of lettuce necrotic yellows virus.

With double-stranded DNA viruses, viral DNA is uncoated in a newly infected cell and transported to the nucleus, where it associates with histones to form a closed circular minichromosome. Two major RNA species (35S and 19S) are transcribed from the minichromosome by a host-encoded enzyme and are translated in the cytoplasm to produce virus-associated proteins. The 35S RNA serves as the template for a viral enzyme which transcribes it to viral DNA, which is then encapsidated to form virus particles.

Symptoms are the result of an alteration in cellular metabolism and are most obvious in newly developing tissues. In some plants, depending on the virus, the initial infection does not spread because cells surrounding the infected cells die, resulting in the formation of necrotic lesions. Such plants are termed hypersensitive. The size and shape of leaves and fruit may be adversely affected, and in some instances plants may be killed. Not all virus infections produce distinctive symptoms.

The most common mode of transmission for many viruses is by means of vectors, mainly insects (predominantly aphids and leafhoppers), and to a lesser extent mites, soil-inhabiting fungi, and nematodes which acquire viruses by feeding on infected plants. Viruses transmitted by one class of vector are rarely transmitted by another, and there is often considerable specificity between strains of a virus and their vectors.

Some viruses are transmitted to succeeding generations mainly by embryos in seeds produced by infected plants; over 200 viruses are transmitted in this way.

Viroids. Only about 30 viroids are known, but they cause very serious diseases in such diverse plants as chrysanthemum, citrus, coconut, and potato. They can also be isolated from plants that do not exhibit symptoms. Viroids are mainly transmitted by vegetative propagation, but some, such as potato spindle tuber viroid, are transmitted by seed or by contact between infected and healthy plants. Tomato planta macho viroid is efficiently transmitted by aphids. *See* PLANT PATHOLOGY; VIROIDS; VIRUS. [R.I.H.]

Plant-water relations Water is the most abundant constituent of all physiologically active plant cells. Leaves, for example, have water contents which lie mostly within a range of 55–85% of their fresh weight. Other relatively succulent parts of plants contain approximately the same proportion of water, and even such largely nonliving tissues as wood may be 30–60% water on a fresh-weight basis. The smallest water contents in living parts of plants occur mostly in dormant structures, such as mature seeds and spores. The great bulk of the water in any plant constitutes a unit system. This water is not in a static condition. Rather it is part of a hydrodynamic system, which in terrestrial plants involves absorption of water from the soil, its translocation throughout the plant, and its loss to the environment, principally in the process known as transpiration.

Cellular water relations. The typical mature, vacuolate plant cell constitutes a tiny osmotic system, and this idea is central to any concept of cellular water dynamics. Although the cell walls of most living plant cells are quite freely permeable to water and solutes, the cytoplasmic layer that lines the cell wall is more permeable to some substances than to others.

If a plant cell in a flaccid condition—one in which the cell sap exerts no pressure against the encompassing cytoplasm and cell wall—is immersed in pure water, inward osmosis of water into the cell sap ensues. This gain of water results in the exertion of a turgor pressure against the protoplasm, which in turn is transmitted to the cell wall. This pressure also prevails throughout the mass of solution within the cell. If the cell wall is elastic, some expansion in the volume of the cell occurs as a result of this pressure, although in many kinds of cells this is relatively small.

If a turgid or partially turgid plant cell is immersed in a solution with a greater osmotic pressure than the cell sap, a gradual shrinkage in the volume of the cell ensues; the amount of shrinkage depends upon the kind of cell and its initial degree of turgidity. When the lower limit of cell wall elasticity is reached and there is continued loss of water from the cell sap, the protoplasmic layer begins to recede from the inner surface of the cell wall. Retreat of the protoplasm from the cell wall often continues until it has shrunk toward the center of the cell, the space between the protoplasm and the cell wall becoming occupied by the bathing solution. This phenomenon is called plasmolysis. *See* OSMOREGULATORY MECHANISMS.

In some kinds of plant cells movement of water occurs principally by the process of imbibition rather than osmosis. The swelling of dry seeds when immersed in water is a familiar example of this process.

Stomatal mechanism. Various gases diffuse into and out of physiologically active plants. Those gases of greatest physiological significance are carbon dioxide, oxygen, and water vapor. The great bulk of the gaseous exchanges between a plant and its environment occurs through tiny pores in the epidermis that are called stomates. Although stomates occur on many aerial parts of plants, they are most characteristic of, and occur in greatest abundance in, leaves. *See* EPIDERMIS (PLANT); LEAF.

Transpiration process. The term transpiration is used to designate the process whereby water vapor is lost from plants. Although basically an evaporation process, transpiration is complicated by other physical and physiological conditions prevailing in the plant. Whereas loss of water vapor can occur from any part of the plant which is exposed to the atmosphere, the great bulk of all transpiration occurs from the leaves. There are two kinds of foliar transpiration: (1) stomatal transpiration, in which water vapor loss occurs through the stomates, and (2) cuticular transpiration, which occurs directly from the outside surface of epidermal walls through the cuticle. In most species 90% or more of all foliar transpiration is of the stomatal type.

Transpiration is a necessary consequence of the relation of water to the anatomy of the plant, and especially to the anatomy of the leaves. Terrestrial green plants are dependent upon atmospheric carbon dioxide for their survival. In terrestrial vascular plants the principal carbon dioxide–absorbing surfaces are the moist mesophyll cells walls which bound the intercellular spaces in leaves. Ingress of carbon dioxide into these spaces occurs mostly by diffusion through open stomates. When the stomates are open, outward diffusion of water vapor unavoidably occurs, and such stomatal transpiration accounts for most of the water vapor loss from plants. Although transpiration is thus, in effect, an incidental phenomenon, it frequently has marked indirect effects on other physiological processes which occur in the plant because of its effects on the internal water relations of the plant.

Water translocation. In terrestrial rooted plants practically all of the water which enters a plant is absorbed from the soil by the roots. The water thus absorbed is translocated to all parts of the plant. The mechanism of the “ascent of sap” (all translocated water contains at least traces of solutes) in plants, especially tall trees, was one of the first processes to excite the interest of plant physiologists.

The upward movement of water in plants occurs in the xylem, which, in the larger roots, trunks, and branches of trees and shrubs, is identical with the wood. In the trunks or larger branches of most kinds of trees, however, sap movement is restricted to a few of the outermost annual layers of wood. *See* XYLEM.

Root pressure is generally considered to be one of the mechanisms of upward transport of water in plants. While it is undoubtedly true that root pressure does account for some upward movement of water in certain species of plants at some seasons, various considerations indicate that it can be only a secondary mechanism of water transport.

Upward translocation of water (actually a very dilute sap) is engendered by an increase in the negativity of water potential in the cells of apical organs of plants. Such increases in the negativity of water potentials occur most commonly in the mesophyll cells of leaves as a result of transpiration.

Water absorption. The successively smaller branches of the root system of any plant terminate ultimately in the root tips, of which there may be thousands and often millions on a single plant. Most absorption of water occurs in the root tip regions, and especially in the root hair zone. Older portions of most roots become covered with cutinized or suberized layers through which only very limited quantities of water can pass. *See* ROOT (BOTANY).

Whenever the water potential in the peripheral root cells is less than that of the soil water, movement of water from the soil into the root cells occurs. There is some evidence that, under conditions of marked internal water stress, the tension generated in the xylem ducts will be propagated across the root to the peripheral cells. If this occurs, water potentials of greater negativity could develop in peripheral root cells than would otherwise be possible. The absorption mechanism would operate in fundamentally the same way whether or not the water in the root cells passed into a state of tension. The process just described, often called passive absorption, accounts for most of the absorption of water by terrestrial plants.

The phenomenon of root pressure represents another mechanism of the absorption of water. This mechanism is localized in the roots and is often called active absorption. Water absorption of this type only occurs when the rate of transpiration is low and the soil is relatively moist. Although the xylem sap is a relatively dilute solution, its osmotic pressure is usually great enough to engender a more negative water potential than usually exists in the soil water when the soil is relatively moist. A gradient of water potentials can thus be established, increasing in negativity across the epidermis, cortex, and other root tissues, along which the water can move laterally from the soil to the xylem. *See* PLANT MINERAL NUTRITION. [B.S.M.]

Plantaginales An order of flowering plants, division Magnoliophyta (Angiospermae), in the subclass Asteridae of the class Magnoliopsida (dicotyledons). The order consists of only the family Plantaginaceae, with about 250 species. Within its subclass the order is marked by its small, chiefly wind-pollinated flowers that have a persistent regular corolla. The perianth and stamens of the flowers are attached directly to the receptacle (hypogynous) and there are typically four petals. The plants are herbs or seldom half-shrubs with mostly basal, alternate leaves. The common plantain (*Plantago major*) is a lawn weed of this order. *See* ASTERIDAE; MAGNOLIOPSIDA. [A.Cr.]

Plants, life forms of A term for the vegetative (morphological) form of the plant body. Life-form systems are based on differences in gross morphological features, and the categories bear no necessary relationship to reproductive structures, which form the basis for taxonomic classification. Features used in establishing life-form classes include deciduous versus evergreen leaves, broad versus needle leaves, size of leaves, degree of protection afforded the perennating tissue, succulence, and duration of life cycle (annual, biennial, or perennial).

There is a clear correlation between life forms and climates. For example, broad-leaved evergreen trees clearly dominate in the hot humid tropics, whereas broad-leaved deciduous trees prevail in temperature climates with cold winters and warm summers, and succulent cacti dominate American deserts. Although cacti are virtually absent from African deserts, members of the family Euphorbiaceae have evolved similar succulent life forms. Such adaptations are genetic, having arisen by natural selection.

Many life-form systems have been developed. The most successful and widely used system is that of C. Raunkiaer, proposed in 1905. Reasoning that it was the perennating buds (the tips of shoots which renew growth after a dormant season, either of cold or drought) which permit a plant to survive in a specific climate, Raunkiaer's classes were based on the degree of protection afforded the bud and the position of the bud relative to the soil surface. They applied to autotrophic, vascular, self-supporting plants. Raunkiaer's classificatory system is:

Phanerophytes: bud-bearing shoots in the air, predominantly woody trees and shrubs; subclasses based on height and on presence or absence of bud scales

Chamaephytes: bud within 10 in. (25 cm) of the surface, mostly prostrate or creeping shrubs

Hemicryptophytes: buds at the soil surface, protected by scales, snow, and litter

Cryptophytes: buds underneath the soil surface or under water

Therophytes: annuals, the seed representing the only perennating tissue

By determining the life forms of a sample of 1000 species from the world's floras, Raunkiaer showed a correlation between the percentage of species in each life-form class present in an area and the climate of the area. Raunkiaer concluded that there were four main phytoclimates: phanerophyte-dominated flora of the hot humid tropics, hemicryptophyte-dominated flora in moist to humid temperate areas, therophyte-dominated flora in arid areas, and a chamaephyte-dominated flora of high latitudes and altitudes.

Subsequent studies modified Raunkiaer's views. (1) Phanerophytes dominate, to the virtual exclusion of other life forms, in true tropical rainforest floras, whereas other life forms become proportionately more important in tropical climates with a dry season. (2) Therophytes are most abundant in arid climates and are prominent in temperate areas with an extended dry season, such as regions with Mediterranean climate. (3) Other temperate floras have a predominance of hemicryptophytes with the percentage of phanerophytes decreasing from summergreen deciduous forest to grassland. (4) Arctic and alpine tundra are characterized by a flora which is often more than three-quarters chamaephytes and hemicryptophytes, the percentage of chamaephytes increasing with latitude and altitude. *See* PLANT GEOGRAPHY.

There has been interest in developing systems which describe important morphologic features of plants and which permit mapping and diagramming vegetation. Descriptive systems incorporate essential structural features of plants, such as stem architecture and height; deciduousness; leaf texture, shape, and size; and mechanisms for dispersal. These systems are important in mapping vegetation because structural features generally provide the best criteria for recognition of major vegetation units. *See* ALTITUDINAL VEGETATION ZONES; VEGETATION AND ECOSYSTEM MAPPING. [A.W.C.]

Plasma (physics) The field of physics that studies highly ionized gases. Plasma is a gas of charged and neutral particles which exhibits collective behavior. All gases become ionized at sufficiently high temperatures, creating what has been called a fourth state of matter, together with solids, liquids, and gases. It has been estimated that more than 99% of the universe is in the plasma state. On the Earth, plasmas are much less common. Lightning is a familiar natural manifestation, and fluorescent lights are a practical application. Plasma applications and studies make use of an enormous range of plasma temperatures, densities, and neutral pressures. They extend from plasma processing applications at relatively low temperatures (such as plasma etching of semiconductor chips at low pressure, or plasma cutting torches at atmospheric pressure) to studies of controlled fusion at very high temperatures. *See* FLUORESCENT LAMP.

Plasma physics is a many-body problem that can be described by a combination of Newton's laws and Maxwell's equations. The charged particles in plasmas are usually ions, both positive and negative, and electrons. Plasmas are normally quasineutral; that is, the net positive ion charge density approximately equals the net negative charge density everywhere in the bulk of the plasma. Quasineutrality refers to charge density and does not imply equal densities of electrons and ions since ions can be multiply charged and can also have negative charge. In space and fusion plasmas, plasmas are normally magnetized, while in application plasmas on Earth, such as plasma processing, both magnetized and unmagnetized plasmas are employed. *See* MAXWELL'S EQUATIONS; NEWTON'S LAWS OF MOTION.

It is convenient to keep track of plasma properties in terms of characteristic lengths, frequencies, and velocities. Among these are the Debye length, the electron and ion plasma frequencies, the electron and ion gyrofrequencies and gyroradii, the electron and ion thermal velocities, the ion sound velocity, the Alfvén velocity, and various collision lengths. The definition of a plasma depends on several of these characteristic parameters, and the magnitude of ratios of these parameters to system size or applied frequencies determines most plasma behavior.

The simplest plasma is a collisionless, unmagnetized collection of ions and electrons with no significant currents. Such plasmas have quasineutral regions and nonneutral regions. The nonneutral regions are highly localized. They are usually located near boundaries (where they are known as sheaths), but are sometimes located within the plasma (where they are known as double layers).

Collective behavior refers to the plasma properties not present in single-particle motion. Collective behavior is a distinguishing characteristic of a plasma. It consists of flows, waves, instabilities, and so forth. Common examples are fluctuations in the aurora, generation of microwaves in devices such as magnetrons and klystrons, and reflection of electromagnetic waves from the ionosphere. *See* AURORA; KLYSTRON; MAGNETRON; RADIO-WAVE PROPAGATION.

Curiously, very high density collections of equal numbers of ions and electrons are not plasmas. Such systems are referred to as strongly coupled plasmas (even though, strictly speaking, they are not plasmas at all).

A collection of either electrons or ions can exhibit properties similar to those of an electrically neutral plasma if the charged-particle density is sufficiently large. For such so-called plasmas, the Debye length and the characteristic frequency of electrons or ions can still be defined, and collective behavior is still exhibited when the Debye length is less than the system's characteristic dimension. So-called pure electron plasmas or pure ion plasmas are unconfined in an unmagnetized system. However, particle traps consisting of a combination of electric and magnetic fields can be used to confine the charges. *See* PARTICLE TRAP.

The visual appearance of a plasma depends on the kind of ion present, the electron temperature, and the plasma density. Some plasmas are invisible. Curiously, if a plasma is present and not glowing, it is either very hot or very cold. For example, an H^+ plasma, or any other relatively hot plasma with fully stripped ions, contains atomic nuclei with no electrons, so there is no atomic physics and no optical emission or absorption. If plasma electrons and ions are very cold, there is insufficient energy to excite optical transitions. The glow often associated with plasmas indicates only where visible energy transitions are excited by energetic electrons or perhaps absorption of ultraviolet radiation, and may have little to do with the presence of bulk plasma. In fusion plasmas, the edges are often copious sources of emission associated with the dissociation and ionization of hydrogen and edge-generated impurities, while much of the hotter core plasma is fully ionized and invisible.

Direct-current glow-discharge plasmas originate from electrons created by secondary electron emission due to ion bombardment of a negatively biased cathode. The secondary electrons are accelerated through the cathode sheath potential (called the cathode fall) to energies the order of 1 keV, and partially ionize the neutral gas, releasing additional energetic electrons in a multiplicative process. The energetic electrons also undergo inelastic collisions with neutrals which result in optical emission that contributes to the so-called glow. *See* GLOW DISCHARGE; SECONDARY EMISSION.

The understanding of plasma physics begins with an understanding of the motion of single charged particles in a combination of electric and magnetic fields (E and B), produced by a combination of external fields and the motion of the charged particles themselves. The motion of a single particle, with mass m, charge q, and velocity $\mathbf{v}$, is governed by the Lorentz force, as given in Eq. (1). From the perpendicular component of Eq. (1),

$$m\frac{d\mathbf{v}}{dt} = q(\mathbf{E} + \mathbf{v} \times \mathbf{B}) \qquad (1)$$

it can be shown that the charged particles gyrate about magnetic field lines with a characteristic frequency (the cyclotron frequency). Ions rotate about the magnetic field in the clockwise direction, while electrons rotate counterclockwise with the magnetic field pointing outward. *See* ELECTRIC FIELD; PARTICLE ACCELERATOR.

In addition to the motion parallel to the magnetic field and the gyromotion about the magnetic field, there are drifts perpendicular to the magnetic field. For a general force, $\mathbf{F}$, in the presence of a magnetic field, the perpendicular drift velocity is given by Eq. (2).

$$\mathbf{v}_D = \frac{\mathbf{F} \times \mathbf{B}}{qB^2} \qquad (2)$$

Given a perpendicular electric field, particles can walk across a magnetic field. Forces associated with magnetic-field curvature give rise to a curvature drift in the direction orthogonal to the magnetic field, and to the radius of curvature of the magnetic field lines.

For gyro motion in a slowly changing magnetic field, which is approximately periodic, it can be shown that the ratio of the perpendicular energy to the magnetic field is approximately constant. This means that a charged particle moving parallel to a magnetic field and gyrating about the field will gyrate faster as the magnetic field increases. If the magnetic field changes in space and is constant in time, the total energy is conserved. For a sufficiently large magnetic field, a point is reached where the total energy equals the perpendicular energy, so that the parallel energy goes to zero and the particle reflects. This is known as magnetic mirroring.

Magnetic mirroring is the chief natural mechanism of charged-particle confinement. For example, this process confines charged particles in the ionosphere and magnetosphere. The magnetic field lines that connect the north and south magnetic poles of the Earth provide a mirror magnetic field which increases as either pole is approached. In the absence of collisions, a particle moving along and gyrating about such a magnetic field is magnetically confined, if it has a sufficiently large velocity perpendicular to the magnetic field. The Van Allen belts are composed of such mirror-trapped charged particles. The source of these particles is the solar wind, a stream of charged particles continuously emitted by the Sun.

For fully ionized plasmas, it is convenient to describe the plasma as a single fluid together with Maxwell's equations. This gives the magnetohydrodynamic (MHD) equations, which are used to describe plasma equilibria and plasma waves and instabilities. Their relative simplicity has made them ideal for solutions of fusion problems in complicated geometries, and they have been widely used to describe astrophysical plasmas and magnetohydrodynamic energy conversion. *See* MAGNETOHYDRODYNAMIC POWER GENERATOR; MAGNETOHYDRODYNAMICS.

Plasmas can support an impressive variety of electrostatic and electromagnetic waves not present in the absence of plasma. The waves are distinguished by their frequency, the presence or absence of dc magnetic fields, and the plasma temperature and density.

Ionization is the key to plasma production and can be accomplished in many different ways. The most common approach is to employ energetic electrons with energies greater than the ionization potential of the gas being ionized. In dc glow discharges, electrons produced by ion secondary electron emission are accelerated by the cathode sheath potential, as are electrons created by thermionic emission in hot-cathode plasmas. Electrons can also pick up energy by reflecting from oscillating radio-frequency sheath electric fields, or by cyclotron resonance in magnetic fields, or from collisions with other energetic electrons. *See* ELECTRICAL CONDUCTION IN GASES; GAS DISCHARGE; IONIZATION POTENTIAL; THERMIONIC EMISSION.

Several other approaches involving collisions, which do not require energetic electrons, also exist. These techniques include photoionization, ion-neutral charge exchange, surface ionization, and Penning ionization. Ions can also be produced in the dissociation of molecules. Yet another mechanism, called critical ionization velocity, is instability driven, and occurs when the kinetic energy of the neutral gas atoms streaming perpendicular to a magnetic field exceeds their ionization potential. *See* ION SOURCES; IONIZATION; PHOTOIONIZATION.

A vacuum chamber provides the simplest approach to confinement. In an unmagnetized plasma, electrons are lost more rapidly than ions, and the plasma acquires a net positive charge. The excess positive charge appears in a sheath at the plasma boundary with the bulk plasma potential more positive than the boundary potential. The decrease in potential at the boundary provides plasma electron confinement, reducing their loss rate to balance the ion loss rate.

Addition of a uniform magnetic field reduces the loss rate of ions and electrons transverse to the magnetic field, but has no effect on losses parallel to the magnetic field because the Lorentz force has no components along this field. Effective confinement by magnetic fields requires that the ion and electron gyroradii be small compared to device dimensions. Plasma transport across the magnetic field can still occur as a result of collisions or of perpendicular drifts.

In the absence of magnetic fields (both inside and outside the plasma), an equilibrium can be achieved by establishing a pressure balance between plasma and edge walls or edge gas. The existence of an equilibrium does not guarantee that a particular configuration is stable.

Plasma processing can be defined as the collection of techniques which make use of plasmas to create new materials or to modify properties of existing materials. It is used in a large variety of applications including semiconductor etching, preparing plastic surfaces to accept ink, depositing polymers, depositing diamond films, and hardening artificial hip joints. The technique has its foundations in plasma physics, chemistry, electrical and chemical engineering, and materials science.

Controlled fusion aims at taking advantage of nuclear fusion reactions to generate net power. Advances in fusion studies have been tied to the techniques developed for plasma confinement and heating. Fusion experiments employ either magnetic confinement or inertial confinement, in which fusion reactions take place before the plasma has a chance to expand to chamber boundaries. Magnetic mirrors are an example of open systems, while tokamaks, stellarators, and reversed-field pinches are examples of closed toroidal systems. Most magnetic confinement research experiments are done on tokamaks. *See* NUCLEAR FUSION. [N.He.]

Naturally occurring plasmas exist throughout the solar system and beyond. Above the atmosphere, most matter is ionized. The lower-density ionized materials are considered to be plasmas, and they behave in manners very different from the behavior of nonplasmas. Some dense materials, such as stellar matter or electrolytic solutions, are often not considered to be plasmas even though they are ionized; they behave, for the most part, as do ordinary fluids.

Some of the major plasma-physics issues that are under study with naturally occurring plasmas are the energization of charged particles, the reconnection of magnetic fields (temporal changes in magnetic-field topology), the production of magnetic fields by dynamos, the production of electromagnetic waves, the interaction between waves and particles, and the transport of mass, momentum, and energy across magnetic fields.

Naturally occurring plasmas are in general difficult to measure. The solar-wind, ionospheric, and magnetospheric plasmas are diagnosed by single-point measurements by rockets and satellites; the solar atmosphere and all astrophysical plasmas are unreachable and must be diagnosed by the light and radio waves that they emit; and lightning is unpredictable and inhospitable to instruments and must be diagnosed primarily by the light that it emits. As a consequence of limited diagnostics, theoretical analysis and laboratory-plasma experiments play supporting roles in the investigations of naturally occurring plasmas. [J.E.Bo.]

Plasma diagnostics Techniques to measure the properties and parameters of ionized gases. Plasmas are gases in which a sufficient proportion of the atoms are ionized that the resulting mixture of free electrons and positively charged ions exhibits collective behavior resulting from electromagnetic interactions. *See* PLASMA (PHYSICS).

The simplest properties of a plasma that one might wish to measure are the density (n) of particles per unit volume, the fluid velocity ($\langle \mathbf{v} \rangle$), and the temperature ($T$). These gaseous parameters may be different for the different particle species in the plasma. There are normally at least two such species, electrons (subscript e) and ions (subscript i); but often multiple ion species and neutral particles are present. (The brackets around $\mathbf{v}$ indicate that it is the average value of the particle velocities of all the particles, or of the particles of a particular species.) Because plasma temperatures are generally high, from a few thousand degrees Celsius upward, they are usually expressed in energy units such as electronvolts ($1\ eV = 1.6 \times 10^{19}\ J \simeq 11{,}600^\circ C$).

Plasmas often possess nonthermal particle distributions. That is, the velocity distribution function of electrons or ions, f_s ($s = e, i$), which measures the numbers of electrons or ions that have various velocities, has not simply the Maxwell-Boltzmann form corresponding to thermal equilibrium at some temperature but has some more complicated form $f_s(\mathbf{v}_s)$. In that case an ideal that may sometimes be approached is to measure the entire velocity distribution $f_s(\mathbf{v}_s)$ and not just the parameters n, $\langle \mathbf{v} \rangle$, and T, which are moments of this distribution. *See* BOLTZMANN STATISTICS; KINETIC THEORY OF MATTER.

The electromagnetic fields $\mathbf{E}$ and $\mathbf{B}$ are also essential parameters that affect the plasma. They are affected in turn by the charge and current densities, ρ and $\mathbf{j}$, which are simple sums of the densities and velocities of the plasma species weighted by their charge per particle.

Techniques to measure the plasma parameters, and their space- and time-variation, are based on a wide variety of physical principles. Direct invasion of the plasma using solid probes is possible only for relatively cold and tenuous plasmas; otherwise the probe will be damaged by excessive heat flux. However, powerful noncontact diagnostics are based on measurements external to the plasma of electromagnetic fields, waves propagated through or scattered by the plasma, photons emitted by plasma electrons or atoms, and particle emission, transmission, or scattering.

By far the majority of probe measurements are based on measuring the electric current carried to the probe by the plasma particles. The simplest and most direct such measurement, called the Langmuir probe, consists of an electrode of some well-defined geometry (plane, cylinder, and sphere are all used). The potential of this probe is varied and the resulting probe current is measured.

The Langmuir probe cannot provide an independent measurement of the ion temperature because the ions are usually the attracted species and their current is almost independent of probe potential. More elaborate plasma flux measurements can be performed with devices called gridded energy analyzers, which can obtain energy distribution functions of both electrons and ions at the expense of far greater complexity, greater probe size and hence plasma perturbation, and often loss of absolute density calibration.

Langmuir probes can provide measurement of the electrostatic potential in the plasma, and hence the electric field, although not quite directly. The magnetic field can be measured by sensors based either on simple induction in a coil for pulsed fields, or typically on the Hall effect in a semiconductor for static fields. The former approach dominates fusion plasma research because of its linearity, noise insensitivity, and robustness, while the latter dominates space measurements in which sensitivity and dc response are essential. *See* ELECTRIC FIELD; HALL EFFECT; MAGNETIC INSTRUMENTS; MAGNETISM.

Propagating an electromagnetic wave through the plasma and measuring the plasma's effect on it is a powerful nonperturbing diagnostic technique. The plasma's presence modifies the refractive index. The index measurement is performed by measuring the phase difference caused by the plasma along an optical path, using some form of interferometer; the Michelson or Mach-Zehnder configurations are most popular. The phase shift is approximately proportional to the average plasma density along the optical path. *See* INTERFEROMETRY.

Electromagnetic wave emission from the free electrons in the plasma occurs predominantly from acceleration either by the ambient magnetic field (cyclotron or synchrotron emission) or by collisions with other plasma particles (bremsstrahlung). Bremsstrahlung from optically thin (hot and tenuous) plasmas has a photon energy spectrum that resembles the electron energy distribution; so, for example, its logarithmic slope gives the electron temperature. The spectrum for kiloelectronvolt-temperature plasmas is measured by x-ray techniques such as pulse-height analysis or approximately using foil filters. Large, dense, or cold plasmas are often optically thick to bremsstrahlung, in which case their spectrum is blackbody and provides electron temperature. Alternatively, by backlighting the plasma (for example with x-rays), their bremsstrahlung (collisional) absorption provides a measure of line-averaged density. This last technique is particularly important for laser-produced plasmas and inertial fusion research. *See* BREMSSTRAHLUNG.

Line radiation arises from electronic transitions between bound levels of atomic species in the plasma. The characteristic wavelengths serve to identify the species, and the intensities are proportional to the excited-state densities. Therefore line radiation is the primary method for determining the atomic and molecular composition of plasmas. Excitation of the atom from the ground state usually occurs by electron impact, requiring an electron energy greater than the excitation energy. Therefore the ratio of the intensities of lines from different excited states whose excitation energies differ by an amount comparable to the electron temperature, is a measure of electron temperature. The rate of excitation is proportional to electron density; however, in order to eliminate from the measured intensity its dependence on the atomic density, a line ratio is generally chosen for measurement. If the population of one excited level of the line pair chosen is substantially affected by collisional deexcitation, because it is a metastable level for example, or is populated by recombination, then the ratio is sensitive to electron density. *See* ATOMIC STRUCTURE AND SPECTRA; SCATTERING EXPERIMENTS (ATOMS AND MOLECULES).

Neutral atoms are continually formed from plasma ions by charge exchange with other neutrals or recombination with electrons. The neutrals formed may escape promptly from the plasma, providing a means for detection of the ion distribution using a neutral-particle spectrometer. In fusion research plasmas, fusion reactions give rise to megaelectronvolt-energy neutrons and charged products. These too provide information on the ion temperature and density via the reaction rate and the emitted spectrum.

Energetic neutral or ion beams, generated specifically for the purpose, can be used for active plasma probing. Their attenuation is generally proportional to plasma density; but more important special-purpose applications include the internal measurement of potential (by local beam ionization in the plasma) and the provision of localized atomic species for other spectroscopic diagnostics. [I.H.H.]

Plasma propulsion

The imparting of thrust to a spacecraft through the acceleration of a plasma (ionized gas). A plasma can be accelerated by electrical means to exhaust velocities considerably higher than those attained by chemical rocks. The higher exhaust velocities (specific impulses) of plasma thrusters usually imply that for a particular mission the spacecraft would use less propellant than the amount required by conventional chemical rockets. This means that for the same amount of propellant a spacecraft propelled by a plasma rocket can increase in velocity over a set distance by an increment larger than that possible with a chemical propulsion system. Plasma propulsion is one of three major classes of electric propulsion, the others being electrothermal propulsion and ion (or electrostatic) propulsion. *See* ELECTROTHERMAL PROPULSION; ION PROPULSION; SPACECRAFT PROPULSION; SPECIFIC IMPULSE.

Pure electromagnetic acceleration. The most promising and thoroughly studied electromagnetic plasma accelerator is the magnetoplasmadyamic (MPD) thruster. In this device the plasma is both created and accelerated by a high-current discharge. The discharge is due to the breakdown of the gas as it is injected in the interelectrode region. The acceleration process can be described as being due to a body force acting on the plasma. This body force is the Lorentz force created by the interaction between the current conducted through the plasma and the magnetic field. The latter could either be externally applied by a magnet or self-induced by the discharge, if the current is sufficiently high. *See* MAGNETOHYDRODYNAMICS.

Microscopically, the acceleration process can be described as the momentum transfer from the electrons, which carry the current, to the heavy particles through collisions. Such collisions are responsible for the creation of the plasma (ionization) and its acceleration and heating (Joule heating).

Hybrid acceleration. The collision processes invariably heat the plasma. If the gas particles are exhausted hot, they are dissipating energy in kinetic modes useless to propulsion since their thermal motion is random. Moreover, if the exhausted atoms are in an excited or ionized state, the fraction of the internal energy tied in these internal modes is also not available for propulsion. If a fraction of these translational and internal modes is somehow recovered, the plasma acceleration is called hybrid (electromagnetic-electrothermal). Hybrid acceleration is an active area of research and is the most promising alternative for surpassing the 40% efficiency level of magnetoplasmadynamic thrusters.

Flight tests. Few tests of plasma thrusters in space are known publicly outside Russia. Most of the flown plasma propulsion systems are of the pulsed solid-fed (Teflon- ablative) type launched in the 1970s for satellite attitude control. [E.Y.C.]

Plasmal

Those aldehydic components of lipids which give positive color tests with reagents used for detecting aldehydes in tissues. The Feulgen test for plasmalogens depends on the liberation of plasmal, principally derivatives of palmitaldehyde and stearaldehyde, from these lipids by the action of mercuric chloride and acetic acid. [R.H.G.; H.E.Ca.]

Plasmid

A circular extrachromosomal genetic element that is ubiquitous in prokaryotes and has also been identified in a number of eukaryotes. In general, bacterial plasmids can be classified into two groups on the basis of the number of genes and functions they carry. The larger plasmids are deoxyribonucleic acid (DNA) molecules of around 100 kilobase (kb) pairs, which is sufficient to code for approximately 100 genes. There is usually a small number of copies of these plasmids per host chromosome, so that their replication must be precisely coordinated with the cell division cycle. The plasmids in the second group are smaller in size, about 6–10 kb. These plasmids may harbor 6–10 genes and are usually present in multiple copies (10–20 per chromosome). *See* GENE.

Plasmids have been identified in a large number of bacterial genera. Some bacterial species harbor plasmids with no known functions (cryptic plasmids) which have been identified as small circular molecules present in the bacterial DNA. The host range of a particular plasmid is usually limited to closely related genera. Some plasmids, however, are much more promiscuous and have a much broader host range.

The functions specified by different bacterial plasmids are usually quite specialized in nature. Moreover, they are not essential for cell growth since the host bacteria are viable without a plasmid when the cells are cultured under conditions that do not select for plasmid-specified gene products. Plasmids thus introduce specialized functions to host cells which provide versatility and adaptability for growth and survival. Plasmids which confer antibiotic resistance (R plasmids) have been extensively characterized because of their medical importance. Plasmids have played a seminal role in the spectacular advances in the area of genetic engineering. Individual genes can be inserted into specific sites on plasmids in cell cultures and the recombinant plasmid thus formed introduced into a living cell by the process of bacterial transformation. *See* GENETIC ENGINEERING. [R.H.R.]

Plasmin

A proteolytic enzyme which can digest many proteins through the process of hydrolysis. Plasmin (fibrinolysin) is found in plasma in the form of the inert precursor, or zymogen, plasminogen (profibrinolysin); its site of synthesis in the body is unknown. Plasma also contains several inhibitors which limit the action of plasmin.

Plasma itself has the potentiality of activating plasminogen, perhaps because it contains intrinsic activators. Plasmin activator is produced in blood vessel walls, from which it is released following vascular injury. Further, the process of blood coagulation may foster the activation of plasminogen. Moreover, the presence of a fibrin clot enhances activation of plasminogen by many agents, perhaps because plasminogen is adsorbed to the fibrin and thus separated from its inhibitors in the plasma.

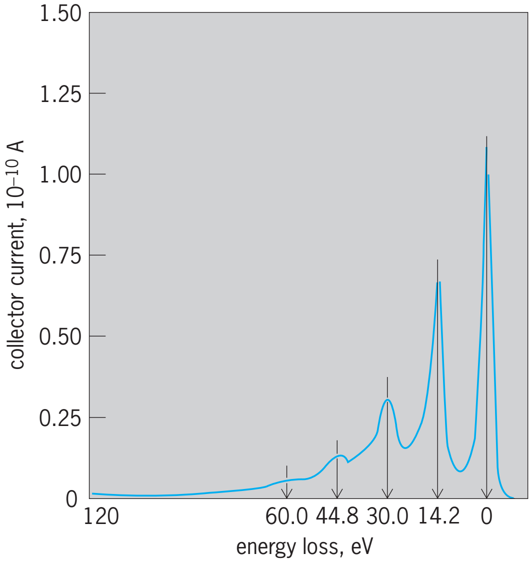
Plasmin can act on many protein substrates. It liquefies coagulated blood by digesting fibrin (fibrinolysis), the insoluble meshwork of the clot; it also digests fibrinogen, the precursor of fibrin, rendering it incoagulable. The digestion products of fibrinogen and fibrin are anticoagulant substances which further interfere with the clotting process. Plasmin also inactivates several other protein procoagulant factors, particularly proaccelerin (factor V) and antihemophilic factor (factor VIII). Other substrates attacked by plasmin include gamma globulin and several protein or polypeptide hormones found in plasma.

The action of plasmin may be related to certain body defenses. It can convert the first component of complement to a proteolytic enzyme. It can also liberate polypeptide kinins (for example, bradykinin) from plasma precursors. The kinins can reproduce such elements of the inflammatory process as pain, dilatation and increased permeability of small blood vessels, and the migration of leukocytes. Besides these physiological actions, plasmin also hydrolyzes casein, gelatin, denatured hemoglobin, and certain synthetic esters of arginine and lysine, for example, *p*-toluenesulfonylarginine methyl ester (TAME). *See* Blood; Complement; Fibrinogen; Immunology; Inflammation. [O.D.R.]

Plasmodiophorida Protozoa composing an order of Mycetozoia. They are endoparasitic in plants, primarily causing, for example, club root of cabbage, powdery scab of potatoes, and galls in *Ruppia*. Underground portions of host plants are invaded by young parasites, often a flagellate which sometimes arises from a freshly excysted ameba. Becoming intracellular, the young parasite grows and develops into a plasmodium. At maturity, the plasmodium produces uninucleate cysts (spores) which are released upon degeneration of the damaged cell. Under favorable conditions, the released spores hatch into uninucleate stages which become the infective forms. In the invaded area, the host's tissue commonly undergoes hypertrophy to form a gall. [R.P.H.]

Plasmon The quanta of waves produced by collective effects of large numbers of electrons in matter when the electrons are disturbed from equilibrium. Metals provide the best evidence of plasmons, because they have a high density of electrons free to move. The results of plasmon stimulation are seen in the illustration. The graph shows the probability of energy losses by fast electrons transmitted through a thin aluminum foil. The number of detected electrons in a beam is plotted against their energy loss during transit through the foil. Each energy-loss peak corresponds to excitation of one or more plasmons. Within experimental error, the peaks occur at integral multiples of a fundamental loss. Further evidence is the fact that the areas under the peaks (a measure of the energy-loss probability) follow a Poisson distribution. *See* Distribution (probability).

The name plasmon derives from the physical plasma as a state of matter in which the atoms are ionized. At the lowest densities this means an ionized gas, or classical plasma; but densities are much higher in a metal, or quantum plasma, the atoms of a solid metal being in the form of ions. In both types of physical plasma, the frequency of plasma-wave oscillation is determined by the electronic density. In a quantum plasma the energy of the plasmon is its frequency multiplied by Planck's constant, a basic relationship of quantum mechanics. *See* Free-electron theory of metals; Quantum mechanics.



Number of detected electrons in a beam versus their energy loss during transit through a thin aluminum foil. (Number of electrons is expressed as a current; 10^{-14} A = 6.7×10^6 electrons per second.) Peaks at approximate multiples of 14.2 eV correspond to energy donated to plasmons in the aluminum. (*After T. L. Ferrell, T. A. Calicott, and R. J. Warmack Plasmons and surfaces, Amer. Sci., 73:344–353, 1985*)

The plasmon energy for most metals corresponds to that of an ultraviolet photon. However, for silver, gold, the alkali metals, and a few other materials, the plasmon energy is sufficiently low to correspond to that of a visible or near-ultraviolet photon. This means there is a possibility of exciting plasmons by light. If plasmons are confined upon a surface, optical effects can be easily observed. In this case, the quanta are called surface plasmons, and they have the bulk plasmon energy as an upper energy limit.

Surface plasmons were first proposed to explain energy losses by electrons reflected from metal surfaces. Since then, numerous experiments have involved coupling photons to surface plasmons. Potential applications extend to new light sources, solar cells, holography, Raman spectroscopy, and microscopy. [T.L.F.]

Plaster A plastic mixture of solids and water which sets to a hard, coherent solid and which is used to line the interiors of buildings. A similar material of different composition, used to line the exteriors of buildings, is known as stucco. The term plaster is also used in the industry to designate plaster of paris.

Plaster is usually applied in one or more base (rough or scratch) coats up to $^3/_4$ in. (1.9 cm) thick, and also in a smooth, white, finish coat about $^1/_{16}$ in. (0.16 cm) thick. The solids in the base coats are hydrated (or slaked) lime, sand, fiber or hair (for bonding), and portland cement (the last may be omitted in some plasters). The finish coat consists of hydrated lime and gypsum plaster (in addition to the water). *See* Lime (industry); Mortar; Plaster of paris. [J.F.McM.]

Plaster of paris The hemihydrate of calcium sulfate, composition $CaSO_4 \cdot {}^1/_2H_2O$, made by calcining the mineral gypsum, composition $CaSO_4 \cdot 2H_2O$, at temperatures up to 480°F (250°C). It is used for making plasters, molds, and models.

When the powdered hemihydrate is mixed with water to form a paste or slurry, the calcining reaction is reversed and a solid mass of interlocking gypsum crystals with moderate strength is formed. Upon setting there is very little (a slight contraction) dimensional change, making the material suitable for accurate molds and models.

Diverse types of plaster, varying in the time taken to set, the amount of water needed to make a pourable slip, and the final hardness, are made for different applications. These characteristics are controlled by the calcination conditions (temperature and pressure) and by additions to the plaster. *See* GYPSUM; PLASTER. [J.F.McM.]

Plastic deformation of metal The permanent change in shape of a metallic body as the result of forces acting on its surface. The plasticity of a metal permits it to be shaped into various useful forms that are retained after the forming pressures have been removed. Complete comprehension of plastic deformation of metals requires an understanding of three areas: (1) the mechanisms by which plastic deformation occurs in metals; (2) the way in which different metals respond to a variety of imposed external or environmental conditions; and (3) the relation between the internal structure of a metal and its ability to plastically deform under a given set of conditions.

Pure metals are crystalline solids, or mixtures of crystalline solids in the case of some alloys. Most metals and alloys that can undergo significant amounts of plastic deformation have their atoms orderly packed in one of three types of crystal structure: hexagonal close-packed, face-centered cubic, or body-centered cubic, or slight variations thereof. *See* ALLOY; CRYSTAL STRUCTURE.

For any type of atomic packing, as the crystal is viewed from different directions, the atoms can be visualized as lying on differently oriented planes in space. Within each plane the atoms are in a regular array, and certain directions are equivalent with respect to the distance between atoms and the location of their neighbors. The primary step in the plastic deformation of a metal crystal is the translation, or slip, of one part of the crystal with respect to the other across one of a set of crystallographically equivalent planes and in one of several possible crystallographically equivalent directions. These are known as the slip plane and slip direction, respectively. The particular direction and plane orientation differ from one metal to another, depending principally on the type of atom packing and the temperature of plastic deformation. Metals with equivalent crystal structures tend to exhibit a similar plastic response to stresses even though the actual strength and temperature range of such a like response will differ from metal to metal.

When a metal consists of a single crystal, it deforms anisotropically when stressed, depending on the orientation of the operative slip system. These translations leave linear traces on the surface called slip lines which are observable under a light microscope. As normally produced, however, metals are polycrystalline; that is, they are composed of a multitude of tiny crystals or grains, all with identical packing but with each crystal having its principal slip planes or directions oriented differently from its neighbors. On a gross scale this permits a metal when stressed to act as an isotropic body even though each grain, if isolated, would behave in an anisotropic manner that would depend on both its orientation with respect to the stress imposed on it and the particular crystal structure of the metal of which it is a part. One structural factor that the metallurgist can control to alter the properties of a metal is grain size and shape.

Most substances are weak relative to the strength that is theoretically calculated for them on the basis of the strength of the bonds between atoms in the crystal and the interatomic spacing. This strength is estimated to be in the neighborhood of one-tenth of the elastic modulus of the particular metal. The observed maximum strengths of metals, moreover, are more like one-tenth of this calculated strength, and the stress under which plastic deformation begins is often several times lower than the observed maximum strength. The reason for this discrepancy between the predicted and observed strengths of metal has been explained to be caused by submicroscopic defects called dislocations. These defects permit metals to be plastically deformed even though their presence also reduces the maximum attainable strength of the metals to the observed value. Understanding the nature and behavior of individual dislocations and their interactions forms the modern basis for understanding the various phenomena associated with plastic deformation in metals. *See* CRYSTAL DEFECTS.

The phenomenology of metal behavior has been explored and documented by metalworkers and metallurgical engineers for centuries. This information has been vital to the design and manufacture or construction of metal objects from tin cans to complex gas turbines. The properties of metals that are associated with plastic deformation are ductility (the ability of a metal to be deformed considerably before breaking), behavior in creep (the time-dependent deformation of metal under stress), and the response to fatigue (conditions where the stresses are applied in a cyclic fashion rather than steadily). *See* CREEP (MATERIALS); METAL; METAL, MECHANICAL PROPERTIES OF; METAL FORMING; METALLOGRAPHY. [H.C.Ro.]

Plasticity The ability of a solid body to permanently change shape (deform) in response to mechanical loads or forces. Deformation characteristics are dependent on the material from which a body is made, as well as the magnitude and type of the imposed forces. In addition to plastic, other types of deformation are possible for solid materials.

One common test for measuring the plastic deformation characteristics of materials is the tensile test, in which a tensile (stretching) load is applied along the axis of a cylindrical specimen, with deformation corresponding to specimen elongation. The load is converted into stress; its units are megapascals (1 MPa = 10^6 newtons per square meter) or pounds per square inch (psi). Likewise, the amount of deformation is converted into strain, which is unitless. The test results are expressed as a plot of stress versus strain. *See* STRESS AND STRAIN.

Typical tensile stress-strain curves have been calculated for metal alloys and polymeric materials. For both materials, the initial regions of the curves are linear and relatively steep. Deformation that occurs within these regions is nonpermanent (nonplastic) or elastic. This means that the body springs back to its original dimensions once the stress is released, or that all of the deformation is recovered. In addition, stress is proportional to strain (Hooke's law), and the slope of this linear segment corresponds to the elastic (Young's) modulus. *See* ELASTICITY; HOOKE'S LAW; YOUNG'S MODULUS.

Plastic (permanent) deformation begins at the point where linearity ceases such that, upon removal of the load, not all deformation is recovered (the body does not assume its original or stress-free dimensions). The onset of plastic deformation is called yielding, and the corresponding stress value is called the yield strength. After yielding, all deformation is plastic and, until fracture, the curves are nonlinear. This behavior is characteristic of many metal alloys and polymeric materials. The concept of plasticity does not normally relate to ceramic materials such as glasses and metal oxides (for example, aluminum oxide). *See* PLASTIC DEFORMATION OF METAL. [W.D.C.]

Plastics processing Those methods used to convert plastics materials in the form of pellets, granules, powders, sheets, fluids, or preforms into formed shapes or parts. The plastics materials may contain a variety of additives which influence the properties as well as the processability of the plastics. After forming, the part may be subjected to a variety of ancillary operations such as welding, adhesive bonding, machining, and surface decorating (painting, metallizing).

Injection molding. This process consists of heating and homogenizing plastics granules in a cylinder until they are sufficiently fluid to allow for pressure injection into a relatively cold mold where they solidify and take the shape of the mold cavity. Solid particles, in the form of pellets or granules, constitute the main feed for injection moldable plastics. The major advantages of the injection-molding process are the speed of production, minimal requirements for postmolding operations, and simultaneous multipart molding. The development of reaction injection molding (RIM) allowed the rapid molding of liquid materials. This process has proven particularly effective for high-speed molding of such materials as polyurethanes, epoxies, polyesters, and nylons.

Extrusion. In this process, plastic pellets or granules are fluidized, homogenized, and continuously formed. Products made this way include tubing, pipe, sheet, wire and substrate coatings, and profile shapes. The process is used to form very long shapes or a large number of small shapes which can be cut from the long shapes. Extrusion can result in the highest output rate of any plastics processes; for example, pipe has been formed at rates of 2000 lb/h (900 kg/h). The extrusion process produces pipe and tubing by forcing the melt through a cylindrical die. *See* EXTRUSION.

Blow molding. This process consists of forming a tube (called a parison) and introducing air or other gas to cause the tube to expand into a free-blown hollow object or against a mold for forming into a hollow object with a definite size and shape. The parison is traditionally made by extrusion, although injection-molded tubes have increased in use.

Thermoforming. Thermoforming is the forming of plastics sheets into parts through the application of heat and pressure. Tooling for this process is the most inexpensive compared to other plastics processes, accounting for the method's popularity. It can also accommodate very large parts as well as small parts.

Rotational molding. In this process, finely ground powders are heated in a rotating mold until melting or fusion occurs. If liquid materials are used, the process is often called slush molding. The melted or fused resin uniformly coats the inner surface of the mold. When cooled, a hollow finished part is removed.

Compression and transfer molding. Compression molding consists of charging a plastics powder or preformed plug into a mold cavity, closing a mating mold half, and applying pressure to compress, heat, and cause flow of the plastic to conform to the cavity shape. The process is primarily used for thermosets, and consequently the mold is heated to accelerate the chemical cross-linking. Transfer molding is an adaptation of compression molding in that the molding powder or preform is charged to a separate preheating chamber and, when appropriately fluidized, injected into a closed mold. It is most used for thermosets, and is somewhat faster than compression molding.

Foam processes. Foamed plastics materials have achieved a high degree of importance in the plastics industry. Foams can be made in a range from soft and flexible to hard and rigid. There are three types of cellular plastics: blown (expanded matrix, such as a natural sponge), syntactic (the encapsulation of hollow organic or inorganic microspheres in the matrix), and structural (dense outer skin surrounding a foamed core). There are seven basic processes used to generate plastics foams. They include the incorporation of a chemical blowing agent that generates gas (through thermal decomposition) in the polymer liquid or melt; gas injection into the melt which expands during pressure relief; generation of gas as a by-product of a chemical condensation reaction during cross-linking; volatilization of a low-boiling liquid (for example, Freon) through the exothermic heat of reaction; mechanical dispersion of air by mechanical means (whipped cream); incorporation of nonchemical gas-liberating agents (adsorbed gas on finely divided carbon) into the resin mix which is released by heating; and expansion of small beads of thermoplastic resin containing a blowing agent through the external application of heat. *See* FOAM.

Reinforced plastics/composites. These are plastics whose mechanical properties are significantly improved because of the inclusion of fibrous reinforcements. The wide variety of resins and reinforcements that constitute this group of materials led to the more generalized description "composites." Composites consist of two main components, the fibrous material in various physical forms and the fluidized resin which will convert to a solid. There are fiber-reinforced thermoplastic materials, and these are typically processed in standard thermoplastic processing equipment. The first step in any composite fabrication procedure is the impregnation of the reinforcement with the resin. The impregnated reinforcement can be subjected to heat to remove impregnating solvents or advance the resin cure to a slightly tacky or dry state. The composite in this form is called a prepreg. Premixes, often called bulk molding compounds, are mixtures of resin, inert fillers, reinforcements, and other formulation additives which form a puttylike rope, sheet, or preformed shape. *See* COMPOSITE MATERIAL; POLYMERIC COMPOSITE.

Casting and encapsulation. Casting is a low-pressure process requiring nothing more than a container in the shape of the desired part. For thermoplastics, liquid monomer is poured into the mold and, with heat, allowed to polymerize in place to a solid mass. For vinyl plastisols, the liquid is fused with heat. Thermosets are poured into a heated mold wherein the cross-linking reaction completes the conversion to a solid. Encapsulation and potting are terms for casting processes in which a unit or assembly is encased or impregnated, respectively, with a liquid plastic which is subsequently hardened by fusion or chemical reaction. These processes are predominant in the electrical and electronic industries for the insulation and protection of components.

Calendering. In the calendering process, a plastic is masticated between two rolls that squeeze it out into a film which then passes around one or more additional rolls before being stripped off as a continuous film. Fabric or paper may be fed through the latter rolls, so that they become impregnated with the plastic. *See* POLYMER. [S.H.G.]

Plate girder A beam built up of steel plates and shapes which may be welded or bolted together to form a deep beam larger than can be produced by a rolling mill (see illustration). As such, it is capable of supporting greater loads on longer spans. The typical welded plate girder consists of flange plates welded to a deep web plate. A bolted configuration consists of flanges built of angles and cover plates bolted to the web plate. Both types may have vertical stiffeners connected to the web plate, and both may have additional cover plates on the flanges to increase the load capacity of the member. Box girders consist of

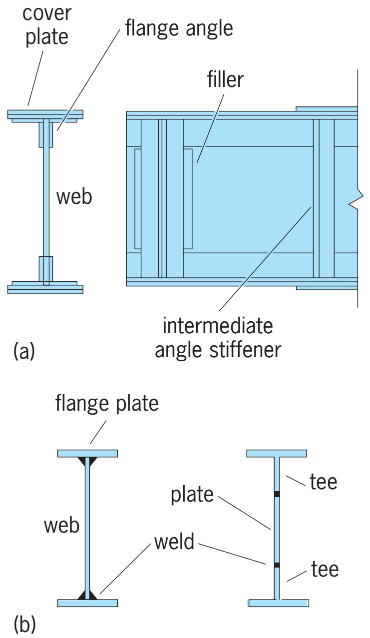


Plate girder configurations: (*a*) bolted type and (*b*) welded type.

common flanges connected to two web plates, forming a closed section.

In general, the depth of plate girders is one-tenth to one-twelfth of the span length, varying slightly for heavier or lighter loads. On occasion, the depth may be controlled by architectural considerations.

Stiffeners, plates or angles, may be attached to the girder web by welding or bolting to increase the buckling resistance of the web. Stiffeners are also required to transfer the concentrated forces of applied loads and reactions to the web without producing local buckling.

Splices are required for webs and flanges when full lengths of plates are not available from the mills or when shorter lengths are more readily fabricated. Splices provide the necessary continuity required in the web and flanges. [J.B.S.]

Plate tectonics The theory that provides an explanation for the behavior of the Earth's crust, particularly the global distribution of mountain building, earthquake activity, and volcanism in a series of linear belts. Numerous other geological phenomena such as lateral variations in surface heat flow, the physiography and geology of ocean basins, and various associations of igneous, metamorphic, and sedimentary rocks can also be logically related by plate tectonics theory.

The theory is based on a simple model of the Earth in which a rigid outer shell 30–90 mi (50–150 km) thick, the lithosphere, consisting of both oceanic and continental crust as well as the upper mantle, is considered to lie above a hotter, weaker semiplastic asthenosphere. The asthenosphere, or low-velocity zone, extends from the base of the lithosphere to a depth of about 400 mi (700 km). The brittle lithosphere is broken into a mosaic of internally rigid plates which move horizontally across the Earth's surface relative to one another. Only a small number of major lithospheric plates exist, which grind and scrape against each other as they move independently like rafts of ice on water. Most dynamic activity such as seismicity, deformation, and the generation of magma occur only along plate boundaries, and it is on the basis of the global distribution of such tectonic phenomena that plates are delineated. *See* ASTHENOSPHERE; EARTHQUAKE; LITHOSPHERE.

The plate tectonics model for the Earth is consistent with the occurrence of sea-floor spreading and continental drift. Convincing evidence exists that both these processes have been occurring for at least the last 6×10^8 years. This evidence includes the magnetic anomaly patterns of the sea floor, the paucity and youthful age of marine sediment in the ocean basins, the topographic features of the sea floor, and the indications of shifts in the position of continental blocks which can be inferred from paleomagnetic data on paleopole positions, paleontological and paleoclimatological observations, the match-up of continental margins and geological provinces across present-day oceans, and the structural style and rock types found in ancient mountain belts. *See* PALEOCLIMATOLOGY; PALEOMAGNETISM.

Geological observations, geophysical data, and theoretical considerations support the existence of three fundamentally distinct types of plate boundaries, named and classified on the basis of whether immediately adjacent plates move apart from one another (divergent plate margins), toward one another (convergent plate margins), or slip past one another in a direction parallel to their common boundary (transform plate margins). The boundaries of plates can, but need not, coincide with the contact between continental and oceanic crust. The velocity at which plates move varies from plate to plate and within portions of the same plate, ranging between 0.8 and 8 in. (2 and 20 cm) per year. *See* CONTINENTS, EVOLUTION OF; MID-OCEANIC RIDGE.

Not only does plate tectonics theory explain the present-day distribution of seismic and volcanic activity around the globe and physiographic features of the ocean basins such as trenches and mid-oceanic rises, but most Mesozoic and Cenozoic mountain belts appear to be related to the convergence of lithospheric plates. Two different varieties of modern mobile belts have been recognized, cordilleran type and collision type. The Cordilleran range, which forms the western rim of North and South America (the Rocky Mountains, Pacific Coast ranges, and the Andes) have for the most part been created by the underthrusting of an ocean lithospheric plate beneath a continental plate. Underthrusting along the Pacific margin of South America is causing the continued formation of the Andes. The Alpine-Himalayan belt, formed where the collision of continental blocks buckled intervening volcanic belts and sedimentary strata into tight folds and faults, is an analog of the present tectonic situation in the Mediterranean, where the collision of Africa and Europe has begun. *See* CORDILLERAN BELT; OROGENY.

Plate tectonics is considered to have been operative as far back as 2.5×10^9 years. Prior to that interval, evidence suggests that plate tectonics may have occurred, although in a markedly different manner, with higher rates of global heat flow producing smaller convective cells or more densely distributed mantle plumes which fragmented the Earth's surface into numerous small, rapidly moving plates. *See* CONTINENTAL DRIFT; GEODYNAMICS. [W.C.P.]

Plateau Any elevated area of relatively smooth land. Usually the term is used more specifically to denote an upland of subdued relief that on at least one side drops off abruptly to adjacent lower lands. In most instances the upland is cut by deep but widely separated valleys or canyons. Small plateaus that stand above their surroundings on all sides are often called tables, tablelands, or mesas. The abrupt edge of a plateau is an escarpment or, especially in the western United States, a rim. [E.H.Ha.]

Platinum A chemical element, Pt, atomic number 78, and atomic weight 195.09. Platinum is a soft, ductile, white noble metal. The platinum-group metals—platinum, palladium, iridium, rhodium, osmium, and ruthenium—are found widely distributed over the Earth. Their extreme dilution, however, precludes their recovery, except in special circumstances. For example, small amounts of the platinum metals, palladium in particular, are recovered during the electrolytic refining of copper. *See* IRIDIUM; OSMIUM; PALLADIUM; PERIODIC TABLE; RHODIUM; RUTHENIUM.

The platinum-group metals have wide chemical use because of their catalytic activity and chemical inertness. As a catalyst, platinum is used in hydrogenation, dehydrogenation, isomerization, cyclization, dehydration, dehalogenation, and oxidation reactions. *See* CATALYSIS; ELECTROCHEMICAL PROCESS.

Platinum is not affected by atmospheric exposure, even in sulfur-bearing industrial atmospheres. Platinum remains bright and does not visually exhibit an oxide film when heated, although a thin, adherent film forms below 450°C (840°F). Platinum may be worked to fine wire and thin sheet, and by special processes, to extremely fine wire. Important physical properties are given in the table.

Platinum can be made into a spongy form by thermally decomposing ammonium chloroplatinate or by reducing it from an aqueous solution. In this form it exhibits a high absorptive power for gases, especially oxygen, hydrogen, and carbon monoxide. The high catalytic activity of platinum is related directly to this property. *See* CRACKING; HYDROGENATION.

Platinum strongly tends to form coordination compounds. Platinum dioxide, PtO_2, is a dark-brown insoluble compound, commonly known as Adams catalyst. Platinum(II) chloride, $PtCl_2$, is an olive-green water-insoluble solid. Chloroplatinic acid, H_2PtCl_6, is the most important platinum compound. *See* COORDINATION CHEMISTRY.

In the glass industry, platinum is used at high temperatures to contain, stir, and convey molten glass. In the electrical industry, platinum is used in contacts and resistance wires because of its low contact resistance and high reliability in contaminated

Physical properties of platinum

Properties	Value
Atomic weight (^{12}C = 12.00000)	195.09
Naturally occurring isotopes and % abundance	190, 0.0127%
	192, 0.78%
	194, 32.9%

Hard	90–95

atmospheres. Platinum is clad over tungsten for use in electron tube grid wires. In the medical field, the simple coordination compounds cisplatin and carboplatin are two of the most active clinical anticancer agents. In combination with other agents, cisplatin is potentially curative for all stages of testicular cancer. Both agents are used for advanced gynecologic malignancies, especially ovarian tumors, and for head and neck and lung cancers. Carboplatin was developed in attempts to alleviate the severe toxic side effects of the parent cisplatin, with which is shares a very similar spectrum of anticancer efficacy. *See* CANCER (MEDICINE); CHEMOTHERAPY. [H.J.A.; N.F.]

Platyasterida A Paleozoic (Ordovician and Devonian) order of sea stars of the class Asteroidea; only two genera have been recognized. Platyasteridans have relatively elongate flat arms; broad, transversely aligned ventral arm plates; and paxilliform aboral plates. Fundamental differences in ambulacral system construction have been found between modern asteroids and all of the well-known early Paleozoic asteroids, including the platyasteridans. Similarities between platyasteridans and modern asteroids are attributable to evolutionary convergence. *See* ASTEROIDEA; ECHINODERMATA. [D.B.B.]

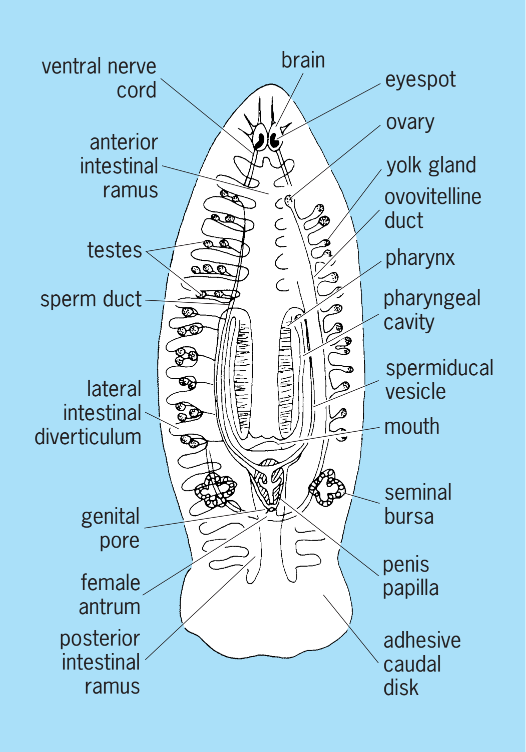
Platycopida An order of the Podocopa (Ostracoda) containing a single family, Cytherellidae, and two extinct superorders. Platycopids are small marine or brackish-water ostracods with an asymmetrical shell that is oblong, nearly rectangular, and laterally compressed; their six pairs of appendages are adapted for burrowing and filter feeding.

Species are dimorphic. The female carapace is wider near the rear and longer than that of the male, providing a brood chamber behind the body. All living species are benthic, and fossil forms probably were also. Some species live at great depths in the Atlantic Ocean, but others have been found in the Arabian, Caribbean, and Mediterranean seas in shallower water. *See* CRUSTACEA; OSTRACODA; PODOCOPA. [P.A.McL.]

Platyctenida An order of the phylum Ctenophora comprising four families (Ctenoplanidae, Coeloplanidae, Tjalfiellidae, Savangiidae) and six genera. All species are highly modified from the planktonic ctenophores. The platyctenes are fairly small (1–6 cm or 0.4–2.4 in.) and brightly colored. They have adopted a variety of swimming, creeping, and sessile habits, with concomitant morphological changes and loss of typical ctenophoran characteristics. The body is compressed in the oral-aboral axis, and the oral part of the stomodeum is everted to form a creeping sole. Sexual reproduction involves internal fertilization in many species, with retention of the developing cydippid larvae in brood pouches. Some species also reproduce asexually by fission. Most platyctenids are found in tropical coastal waters, where many are ectocommensals on benthic organisms. *See* CTENOPHORA. [L.P.M.]

Platyhelminthes A phylum of the invertebrates, commonly called the flatworms. They are bilaterally symmetrical, nonsegmented, dorsoventrally flattened worms characterized by lack of coelom, anus, circulatory and respiratory systems, and exo- or endoskeleton. They possess a protonephridial excretory system, a complicated hermaphroditic reproductive system, and a solid mesenchyme which fills the interior of the body (see illustration). Three classes occur in the phylum: (1) the Turbellaria, mainly free-living, predacious worms; (2) the Trematoda, or flukes, holozoic ecto- or endoparasites; and (3) the Cestoda, or tapeworms, saprozoic endoparasites in the enteron of vertebrates, whose larvae are found in the tissues of invertebrates or vertebrates.

Turbellaria are widespread in fresh water and the littoral zones of the sea, while one group of triclads occurs on land in moist habitats. Adult trematodes occur on, or in, practically all tissues and cavities of the vertebrates on which they feed. They are responsible for troublesome diseases in humans and animals. Larval flukes are frequent in mollusks, mainly gastropods, and occasionally occur in pelecypods. Vector hosts, such as insects and fish, are often interpolated between mollusk and vertebrate. Adult tapeworms, living in the enteron or the biliary ducts, compete with the host for food and accessory food factors such as



Bdelloura candida **(Tricladida), ectocommensal on the king crab, *Limulus*. Complete digestive and male systems are shown on left, female systems on right.**

vitamins. Larval tapeworms reside chiefly in arthropods, but larvae of one group, the Cyclophyllidea, develop in mammals, which may be severely impaired, or even killed, by the infection. *See* CESTODA; TREMATODA; TURBELLARIA. [C.G.G.]

Platypus The single species *Ornithorhynchus anatinus* of the family Ornithorhynchidae in the order Monotremata, which occurs in eastern Australia and Tasmania. This mammal is a monotreme, which lays eggs and incubates them in a manner similar to birds. The platypus is also known as the duckbill, duckmole, and water mole. One of the most primitive mammals, it retains some reptilian characteristics. The female lacks a marsupium; however, marsupial or epipubic bones are well developed.

The platypus, a primitive aquatic mammal, showing the webbed digits which aid in swimming.

Ornithorhynchus is well adapted to aquatic life. It ranges from the tropical, sea-level streams to cold lakes at altitudes of 6000 ft (1800 m). It is covered with short dense fur, typical of many aquatic mammals; the external ears are lacking; and the tail is broad and flattened, resembling that of the beaver (see illustration). The rubbery bill is covered with a highly sensitive skin. There are no teeth, but horny ridges are used for crushing food and grubbing on the bottom of rivers. *See* MONOTREMATA. [C.B.C.]

Playa A nearly level, generally dry surface in the lowest part of a desert basin with internal drainage (see illustration). When its surface is covered by a shallow sheet of water, it is a playa lake. Playas and playa lakes are also called dry lakes, alkali flats, mud flats, saline lakes, salt pans, inland sabkhas, ephemeral lakes, salinas, and sinks.

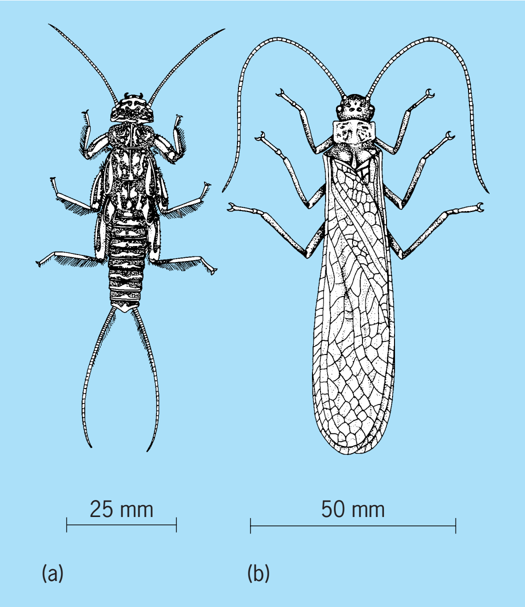
Light-colored playa in lowest part of Sarcobatus Flat in southern Nevada.

A playa surface is built up by sandy mud that settles from floodwater when a playa is inundated by downslope runoff during a rainstorm. A smooth, hard playa occurs where ground-water discharge is small or lacking and the surface is flooded frequently. These mud surfaces are cut by extensive desiccation polygons caused by shrinkage of the drying clay. Puffy-ground playas form by crystallization of minerals as ground water evaporates in muds near the surface.

Subsurface brine is present beneath many playas. The type of brine depends on the original composition of the surface water and reflects the lithology of the rocks weathered in the surrounding mountains. *See* GROUND-WATER HYDROLOGY.

Numerous playas in the southwestern United States yield commercial quantities of evaporite minerals, commonly at shallow depths. Important are salt ($NaCl$) and the borates, particularly borax ($Na_2B_4O_7 \cdot 10H_2O$), kernite ($Na_2B_4O_7 \cdot 4H_2O$), ulexite ($NaCaB_5O_9 \cdot 8H_2O$), probertite ($NaCaB_5O_9 \cdot 5H_2O$), and colemanite ($Ca_2B_6O_{11} \cdot 5H_2O$). Soda ash (sodium carbonate; Na_2CO_3) is obtained from trona ($Na_3H(CO_3)_2 \cdot 2H_2O$) and gaylussite ($Na_2Ca(CO_3)_2 \cdot 5H_2O$). Lithium and bromine are produced from brine waters. *See* DESERT EROSION FEATURES; SALINE EVAPORITES. [J.F.Hu.]

Plecoptera An order of primitive insects known as the stoneflies. Except for wings and tracheal gills, there are relatively slight differences between aquatic immature stages and adult mature ones. The soft and somewhat flattened body, strong legs, paired tarsal claws, chewing mouthparts, and rusty blacks, dull yellows, and browns are characteristic of both immature and adult stages (see illustration).



Plecoptera. (*a*) Nymph of *Perla*, (*b*) Adult of *Pteronarcys.* (*After A. H. Morgan, Field Book of Ponds and Streams, Putnam, 1930*)

Immature stoneflies live in the rapid, stony parts of clean, swift streams, although a few species occur along the rocky shores of large temperate lakes.

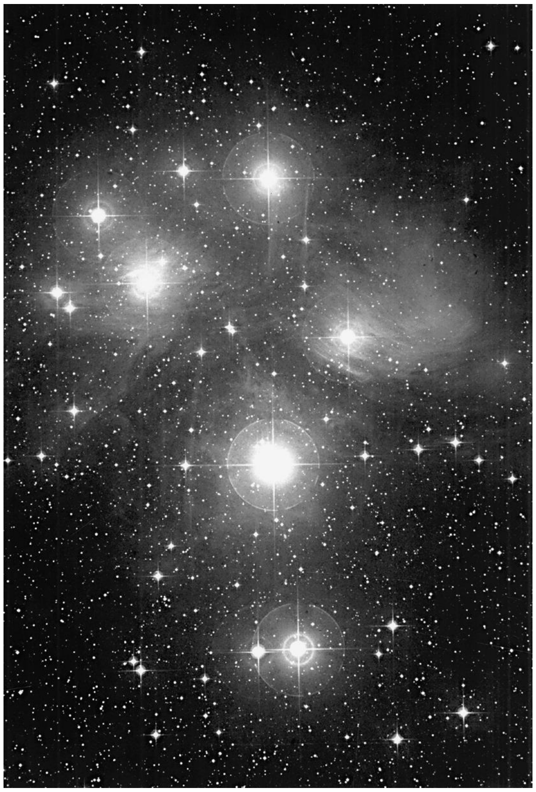
Adult stoneflies hold the wings close to the backs when at rest or walking. The hindwings are pleated and hidden. The name Plecoptera means pleated wings.

In various parts of North America stonefly adults emerge in every month of the year. Successions of species reach their peaks of abundance from November to March, with some extending to August. Nymphs and adults of some species are plant feeders; others are carnivorous. *See* INSECTA. [L.Ber.]

Plectomycetes A class of the phylum Ascomycota. The Plectomycetes produce a well-developed mycelium on which both sexual (asci) and asexual (conidia) states occur. The asci form in association with small ascomata of varying complexity. These arise from special coiled or intertwined hyphal branches that are sometimes differentiated into male (antheridium) and female (ascogonium) structures. The ascomata may consist of a loose grouping of hyphae around the asci forming a gymnothecium, or may be spherical, with a definite wall or peridium that lacks an opening, forming a cleistothecium. The asci are usually spherical, are scattered throughout the ascoma, and have thin walls that dissolve at maturity. The ascospores are small, colorless or sometimes pigmented, round in face view, somewhat flattened in side view, and may be ornamented or flanged.

The two recognized orders, Onygenales and Eurotiales, are differentiated by the structure of the ascoma and the type of asexual conidia produced. In the Onygenales, the ascoma usually is not well developed (gymnothecium), but many species form characteristic peridial hyphae. These fungi occur in soil, on dung, and on plant debris. The most serious fungal pathogens of humans belong in the Onygenales. *Arthroderma simii*. In the Eurotiales, the ascomata have a definite wall (peridium) enclosing the asci, and they are often brightly colored. They are common in soil and on plant materials. The most important species is *Penicillium chrysogenum*, the original source of penicillin. *See* ASCOMYCOTA; EUMYCOTA; FUNGI. [R.T.Ha.]

Pleiades A beautiful group of stars resembling a little dipper, in the constellation of Taurus, known since earliest records. The Pleiades is a typical open cluster (see illustration). Its distance is 410 light-years (2.4×10^{15} mi or 3.9×10^{15} km), its linear diameter about 15 light-years (9×10^{13} mi or 1.4×10^{14} km). The cluster is permeated with diffuse nebulosity. Though early accounts refer to the Pleiades in terms of seven stars, only six are now conspicuous to the unaided eye, which raises a theory that one, the lost Pleiad, has faded. The observation of flare stars and x-ray emission has increased interest in this cluster. *See* CONSTELLATION; STAR CLUSTERS. [H.S.H.]



The Pleiades. (***Lick Observatory photograph***)

Pleistocene The older of the two epochs of the Quaternary Period. The Pleistocene Epoch represents the interval of geological time (and rocks accumulated during that time) extending from the end of the Pliocene Epoch (and the end of the Tertiary Period) to the start of the Holocene Epoch. Most recent time scales show the Pleistocene Epoch spanning the interval from 1.8 million years before present (m.y. B.P.) to 10,000 years B.P. The Pleistocene is commonly characterized as an epoch when the Earth entered its most recent phase of widespread glaciation. *See* HOLOCENE; PLIOCENE; QUATERNARY; TERTIARY.

In modern geological time scales, the Pleistocene is subdivided into a lower and an upper series. In Europe the lower series is considered equivalent to the Calabrian Stage, while the upper series is equated with the Sicilian and Tyrrehenian stages.

The onset of the Pleistocene brought glaciations that were more widespread than those in the Pliocene. Mountain glaciers expanded and continental ice fields covered large areas of the temperate latitudes. Sea ice also became more widespread. As evidence has accumulated in recent decades from both the land and the sea, it clearly shows at least 17 glacial events occurred during the Pleistocene. *See* CLIMATE HISTORY; GLACIAL EPOCH.

The expansion and decay of the ice sheets had a direct effect on the global sea level. Global sea-level fluctuations of 50–150 m (170–500 ft) have been estimated for various glacial-interglacial episodes during the Pleistocene. Since the last deglaciation, which began some 17,000 years ago, the sea level has risen by about 110 m (360 ft) worldwide, drowning all of the ancient lowstand shorelines. One important product of the sea-level drops was the migration of large river deltas to the edges of the continental shelves and to the deeper parts of the basins. Conversely, the last marine transgression that started in the late Pleistocene after rapid deglaciation and ended in the Holocene (6000 to 7000 years ago) resulted in new deltas that formed at the mouths of modern rivers. *See* DELTA; PALEOCEANOGRAPHY.

The onset of cooler climate and Pleistocene glaciation is also approximated with a wave of mammalian migration from the east to the west. A relatively modern-looking fauna that included the first true oxen, elephants, and the first one-toed horse appeared at the beginning of Pleistocene. The modern horse, *E. caballus*, made its first appearance some 250,000 years ago in the late Pleistocene in North America. From North America it migrated to Asia and then west to Europe. However, during the last glacial maximum, some 18,000 years ago, it became extinct in North America when it was unable to cross the deserts to migrate to South America. Oxen, deer and reindeer, large cats, mammoth, great elk, wolf, hyena, and woolly rhinos proliferated during the middle and late Pleistocene. Mammoths, which have been found preserved nearly intact in frozen soils in Siberia, ranged over much of Europe during the glacial times. *See* GEOLOGIC TIME SCALE; MAMMALIA.

The unique Pleistocene mammalian faunas of some of the isolated islands, such as Madagascar, the Philippines, Taiwan, and the Japanese Archipelago, indicate restriction in the dispersal of species during the Pleistocene. The Pliocene Epoch had given rise to the human precursor, *Homo habilis*, around 2 m.y. B.P. The appearance of *H. erectus* came on the scene almost at the Plio-Pleistocene boundary around 1.8 m.y. B.P. The first archaic *H. sapiens* are now considered to have arrived on the scene around about a million years ago. The appearance of *H. neanderthalensis* or the Neanderthal Man, is now dated at least as far back as 250,000 years B.P. Recent datings have the appearance of the first true modern *H. sapiens* (the Cro-Magnon Man) to around 100,000 years B.P. *See* FOSSIL HUMANS; GEOLOGIC TIME SCALE. [B.U.H.]

Pleochroic halos Spherical or elliptical regions up to 40 micrometers in diameter in which there is a change in color from the surrounding mineral when viewed with a petrographic microscope. Pleochroic halos are found around small inclusions of radioactive minerals—for example, zircon, monazite, allanite, xenotime, and apatite—and in rock-forming minerals, principally quartz, micas, amphiboles, and pyroxenes. Halos have also been identified in coalified wood preserved in deposits on the Colorado Plateau. *See* CORDIERITE; PETROFABRIC ANALYSIS; RADIOACTIVE MINERALS.

The change in color is a result of radiation damage caused by alpha particles emitted during the radioactive decay of nuclides in the decay chains of uranium-238, uranium-235, and thorium-232. The range of the alpha particle and ionization effects account for the size and color of the halos. The halos have a distinctive ring structure with varying degrees of discoloration between the rings: the coloration in the halos increases, saturates, and finally diminishes with increasing ion dose. *See* ALPHA PARTICLES; METAMICT STATE.

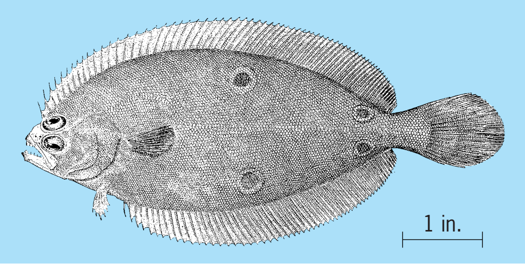
The early interest in pleochroic halos was in their use for geologic age dating. Careful attempts were made to correlate the halo color with the alpha-irradiation dose in order to estimate the age of the enclosing mineral. Additionally, the constant size of the rings of the uranium and thorium halos for minerals of different ages was taken as evidence that the decay constants for radionuclides used in age dating had remained constant throughout geologic time. Thermal annealing of the halos has been used to model the thermal histories of rock units. *See* FISSION TRACK DATING; GEOCHRONOMETRY. [R.Ew.]

Pleochroism In some colored transparent crystals, the effect wherein the color is quite different in different directions through the crystals. In such a crystal the absorption of light is different for different polarization directions. In colored transparent tourmaline the effect may be so strong that one polarized component of a light beam is wholly absorbed, and the crystal can be used as a polarizer. *See* DICHROISM; TRICHROISM. [B.H.Bi.]

Plesiosauria An order of extinct aquatic diapsid reptiles within the infraclass Sauropterygia, common throughout the world during the Jurassic and Cretaceous periods. These large carnivores are characterized by long, paddle-shaped limbs and short, dorsoventrally compressed bodies. Unlike the nothosaurs (more primitive members of the Sauropterygia), plesiosaurs have greatly expanded ventral portions of both pectoral and pelvic girdles to provide large areas for the attachment of muscles to move the limbs anteriorly and posteriorly. Lateral undulation of the trunk was severely restricted by elaboration of the ventral scales.

Approximately 40 genera of plesiosaurs are recognized, divided into two large groups: The plesiosauroids include the most primitive genera and others that have small heads and very long necks. Among the plesiosauroids, the elasmosaurids had as many as 76 cervical vertebrae. The pliosauroids had shorter necks but larger skulls. Both elasmosaurs and pliosaurs persisted until the end of the Mesozoic. *See* DIAPSIDA; NOTHOSAURIA; REPTILIA; SAUROPTERYGIA. [R.L.C.]

Pleuronectiformes One of the most distinctive orders of actinopterygian fishes, also called Heterosomata, composed of the flatfishes: halibut, plaice, flounders, soles, tonguesoles, and their allies. The striking feature of the group is the loss of bilateral symmetry (see illustration), a characteristic of almost all vertebrates. Like the ancestors of pleuronectiforms, young flatfishes are symmetrical and swim upright; early in life, however, one eye migrates across the top of the skull to lie on the same side as the other eye. This transformation is associated with deformation of the skull bones and nerves, a change in position so that the fish lies on one (the blind) side, partial or complete depigmentation of the blind surface, and sometimes modification and development of asymmetry in paired fins, dentition, squamation, visceral anatomy, and other structures. *See* ACTINOPTERYGII. [R.M.B.]



Fourspot flounder (*Paralichthys oblongus*), of the Pleuronectiformes. 1 In. = 2.5 cm. (*After G. B. Goode, Fishery Industries of the United States, sect. 1, 1884*)

Pliocene The youngest of the five geological epochs of the Tertiary Period. The Pliocene represents the interval of geological time (and rocks deposited during that time) extending from the end of the Miocene Epoch to the beginning of the Pleistocene Epoch of the Quaternary Period. Modern time scales assign the duration of 5.0 to 1.8 million years ago (Ma) to the Pliocene Epoch. *See* MIOCENE; PLEISTOCENE; QUATERNARY; TERTIARY.

Pliocene marine sediments are commonly distributed along relatively restricted areas of the continental margins and in the deep-sea basins. Continental margin sediments are most often terrigenous and range from coarser-grained sandstone to finer-grained mudstone and clay. Major rivers of the world, such as the Amazon, Indus, and Ganges, contain thick piles of Pliocene terrigenous sediments in their offshore fans. The Pliocene deep-sea sediments are carbonate-rich (commonly biogenic oozes) and are often very thick (up to 5000 m or 16,400 ft). *See* BASIN; CONTINENTAL MARGIN.

Modern stratigraphic usage subdivides the Pliocene Epoch into two standard stages, the lower, Zanclean stage and the upper, Piacenzian stage.

The most notable tectonic events in the Pliocene include the beginning of the third and last phase of the Himalayan uplift, the Attican orogeny that began in the late Miocene and continued into the Pliocene, and the Rhodanian and Walachian orogenies that occurred during the later Pliocene. *See* OROGENY.

The latest Miocene is marked by a global cooling period that continued into the earliest Pliocene, and there is evidence that the East Antarctic ice sheet had reached the continental margins at this time. The global sea level had been falling through the late Miocene, and with the exception of a marked rise in the mid-Zanclean, the trend toward lowered sea levels continued through the Pliocene and Pleistocene. The mid-Zanclean sea-level rise (3.5–3 Ma) was also accompanied by a significant global warming event. The oxygen isotopic data, which record the prevailing sea surface temperatures and total ice volume on the ice caps, show little variations in the Equatorial Pacific during the middle Pliocene. By early Pliocene time, the major surface circulation patterns of the world ocean and the sources of supply of bottom waters were essentially similar to their modern counterparts. *See* GEOLOGIC THERMOMETRY.

By Pliocene time, much of the marine and terrestrial biota had essentially evolved its modern characteristics. The late Pliocene cooling led to the expansion of cooler-water marine assemblages of the higher latitudes into lower latitudes, particularly the foraminifers, bivalves, and gastropods. At the onset of cooling, the warm-water-preferring calcareous nannoplankton group of discoasters began waning in the late Pliocene and became extinct at the close of the epoch. *See* BIVALVIA; COCCOLITHOPHORIDA; FORAMINIFERIDA; GASTROPODA.

The widespread grasslands of the Pliocene were conducive to the proliferation of mammals and increase in their average size.

The mid-Zanclean sea-level rise led to the geographic isolation of many groups of mammals and the increase in endemism. But the late Pliocene-Pleistocene lowering of sea level facilitated land connections and allowed extensive mammalian migration between continents with interchanges between North and South America. The arrival of the North American mammals led to increased competitive pressure and extinction of many typically South American groups. Horses evolved and spread widely in the Pliocene. *See* Mammalia.

The Pliocene Epoch also saw the appearance of several hominid species that are considered to be directly related to modern human ancestry. The earliest hominid bones have been discovered from Baringo, Kenya, in sediments that are dated to be of earliest Pliocene age. After this first occurrence, a whole suite of australopithicine species made their appearance in the Pliocene. *See* Australopithecine; Fossil humans; Paleontology. [B.U.H.]

Plum Any of the smooth-skinned stone fruits grown on shrubs or small trees. Plums are widely distributed in all land areas of the North Temperate Zone, where many species and varieties are adapted to different climatic and soil conditions.

There are four principal groups: (1) Domestica (*Prunus domestica*) of European or Southwest Asian origin, (2) Japanese or Salicina (*P. salicina*) of Chinese origin, (3) Insititia or Damson (*P. insititia*) of Eurasian origin, and (4) American (*P. americana* and *P. hortulana*). The Domesticas are large, meaty, prune-type plums. A prune is a plum which dries without spoiling. [R.P.L.]

Plumbaginales An order of flowering plants, division Magnoliophyta (Angiospermae), in the subclass Caryophyllidae of the class Magnoliopsida (dicotyledons). The order consists of only the family Plumbaginaceae, with about 400 species. The plants are herbs or less often shrubs. The flowers are strictly pentamerous (that is, each floral whorl has five members); the petals are fused (sympetalous condition) and all alike in shape and size; the pollen is trinucleate; and there is a single basal ovule located in a compound ovary that has a single locule or cell. The Plumbaginaceae differ from most families of their subclass in their straight embryo, copious endosperm, absence of perisperm, and the presence of anthocyanin pigments instead of betalains. The family contains a few garden ornamentals, such as species of *Armeria*, known as thrift or sea-pink. *See* Caryophyllidae; Magnoliophyta; Magnoliopsida. [A.Cr.; T.M.Ba.]

Pluto Commonly considered the outermost planet, Pluto is actually the largest member of a disk of icy planetesimals that surround the solar system beyond the orbit of Neptune. Pluto was discovered in 1930.

Pluto is visible only through fairly large telescopes. Periodic variations in its brightness demonstrate that the surface of Pluto is covered with bright and dark markings and indicate a period of rotation of 6.4 days.

Pluto has a small satellite named Charon. The radius of Pluto was found to be 730 ± 20 mi (1170 ± 30 km), so Pluto is significantly smaller than the Earth's Moon (whose radius is 1080 mi or 1738 km), while Charon's radius is 390 ± 15 mi (625 ± 25 km). Charon is thus about half the size of Pluto itself, making this the most closely matched pair in the solar system. The combined mass of Pluto and Charon is 0.0025 times the mass of the Earth. Their densities are close to 2.0 g/cm^3, indicating a composition of ice and rock, similar to that of the large icy satellites of Jupiter and Saturn, but surprisingly dense for bodies this small.

The near-infrared spectrum of Pluto reveals absorption features of solid nitrogen (N_2), carbon monoxide (CO), and methane (CH_4) ice. From these absorptions it is possible to conclude that nitrogen is the dominant ice on Pluto's surface, which means it must also be the major constituent of the planet's atmosphere. The nitrogen absorption in the spectrum indicates a surface temperature near 38 K (−391°F), consistent with an atmospheric surface pressure roughly 10^{-5} times that on Earth.

Demonstrating a striking difference with Pluto, Charon apparently has little if any frozen methane on its surface, which instead exhibits the spectral signature of water ice. The orbit of Charon is unique in the solar system in that the satellite's period of revolution is identical to the rotational period of the planet. Thus an inhabitant of Pluto who lived on the appropriate hemisphere would see Charon hanging motionless in the sky. [T.C.O.]

Pluton A solid rock body that formed by cooling and crystallization of molten rock (magma) within the Earth. Most plutons, or plutonic bodies, are regarded as the product of crystallization of magma intruded into surrounding "country rocks" within the Earth (principally within the crust). Igneous rock bodies are referred to generally as either extrusive or volcanic on one hand, or as intrusive or plutonic on the other, although the term volcanic is sometimes also used to refer to small, shallow intrusive bodies associated with volcanoes. *See* Igneous rocks; Magma.

Plutons occur in a nearly infinite variety of shapes and sizes, so that definition of types is arbitrary in many cases. In general, two modes of emplacement can be recognized with regard to the country rock. Concordant plutons are intruded between layers of stratified rock, whereas the more common discordant plutons are characterized by boundaries that cut across preexisting structures or layers in the country rock. The principal types of concordant plutons are sills, laccoliths, and lopoliths; the principal types of discordant plutons are dikes, volcanic necks or plugs, stocks, and batholiths.

Several mechanisms of magma intrusion are known or proposed. The most simple ones, pertaining to smaller plutonic bodies, are forceful injection or passive migration into fractures. Larger plutons may form by several processes. For example, less dense magma may migrate upward along a myriad of channelways to accumulate as a large molten body within the upper crust. Further migration could occur by forceful injection, by stoping (a process where the magma rises as blocks of the roof of the magma chamber break off and sink), and by diapiric rise, where country rocks flow around the upward-moving magma body. *See* Petrology. [W.R.V.S.]

Plutonium A chemical element, Pu, atomic number 94. Plutonium is a reactive, silvery metal in the actinide series of element elements. The principal isotope of chemical interest is ^{239}Pu, with a half-life of 24,131 years. It is formed in nuclear reactors by the process shown in the following reaction. Plutonium-239 is fissionable, but may also capture neutrons to form higher plutonium isotopes. *See* Periodic table.

$$^{238}\mathrm{U} + n \longrightarrow {}^{239}\mathrm{U} \xrightarrow[23.5\ \mathrm{min}]{\beta^-} {}^{239}\mathrm{Np} \xrightarrow[2.33\ \mathrm{days}]{\beta^-} {}^{239}\mathrm{Pu}$$

Plutonium-238, with a half-life of 87.7 years, is utilized in heat sources for space application, and has been used for heart pacemakers. Plutonium-239 is used as a nuclear fuel, in the production of radioactive isotopes for research, and as the fissile agent in nuclear weapons.

Plutonium exhibits a variety of valence states in solution and in the solid state. Plutonium metal is highly electropositive. Numerous alloys of plutonium have been prepared, and a large number of intermetallic compounds have been characterized.

Reaction of the metal with hydrogen yields two hydrides. The hydrides are formed at temperatures as low as 150°C (300°F). Their decomposition above 750°C (1400°F) may be used to prepare reactive plutonium powder. The most common oxide is PuO_2, which is formed by ignition of hydroxides, oxalates, peroxides, and nitrates of any oxidation state in air of 870–1200°C (1600–2200°F). A very important class of plutonium compounds are the halides and oxyhalides. Plutonium hexafluoride, the most volatile plutonium compound known, is a strong fluorinating agent. A number of other binary compounds are known. Among these are the carbides, silicides, sulfides, and selenides, which are of particular interest because of their refractory nature.

Because of its radiotoxicity, plutonium and its compounds require special handling techniques to prevent ingestion or inhalation. Therefore, all work with plutonium and its compounds must be carried out inside glove boxes. For work with plutonium and its alloys, which are attacked by moisture and by atmospheric gases, these boxes may be filled with helium or argon. *See* ACTINIDE ELEMENTS; NEPTUNIUM; NUCLEAR CHEMISTRY; TRANSURANIUM ELEMENTS; URANIUM. [F.We.]

Plywood A wood product in which thin sheets of wood are glued together, grains of adjacent sheets being at right angles to each other in the principal plane. Because of this cross-grained orientation, mechanical properties are less directional than those of natural lumber and more dimensionally stable. Tree farms are now cultivated specifically to yield logs suitable for processing into sheets for plywood.

The American Plywood Association identifies several grades of product. Plywood is designated group 1 when made from northern-grown Douglas-fir, western larch, and such southern pines as loblolly and longleaf, or other woods noted for their strength. Plywoods in groups 2, 3, and 4 are made from woods of successively lower strengths. Consequently, group 1 plywood offers the greatest stiffness, group 4 the least.

Plywood with waterproof glue is designated exterior type; it is also used interiorly where moisture is present. Plywood with nonmoisture-resistant glue is designated interior type; it can withstand an occasional soaking but neither repeated soakings nor continuous high humidity.

Veneer grades A through D extend from a smooth surface to a surface with occasional knotholes and limited splits. If the outer face of the plywood is cut from only heartwood or sapwood, free from open defects, the plywood is assigned veneer grade N, indicating that it will take a natural finish. *See* STEM; VENEER.

Most commonly used plywoods are $^{1}/_{4}$-in. (0.6-cm) sanded interior paneling or $^{1}/_{2}$-in. (1.3-cm) exterior grade plywood sheeting. Other standard thicknesses extend to 1 in. (2.5 cm) for interior types and to $1^{1}/_{8}$ in. (2.8 cm) for exterior types. The most common panel size is 4 × 8 ft (1.2 × 2.4 m); larger sizes are manufactured for such special purposes as boat hulls.

Finished plywood may be unsanded, sanded, or overlayed with several types of coatings for decorative and specialty uses. Plywood in appropriate grades is used in many different applications, such as furniture, wall facings, shelving, containers, crates, fences, forms, subflooring, and roof decking. *See* WOOD PRODUCTS. [F.H.R.; R.M.Ro.]

Pneumatolysis The alteration of rocks or crystallization of minerals by gases or supercritical fluids (generically termed magmatic fluids) derived from solidifying magma. At surface conditions, magmatic fluids contain steam with lesser amounts of carbon dioxide, sulfur dioxide, hydrogen sulfide, hydrogen chloride, and hydrogen fluoride, and trace amounts of many other volatile constituents. Magmatic fluids may contain relatively high concentrations of light and heavy elements, particularly metals, that do not crystallize readily in common rock-forming silicates constituting most of the solidifying magma; thus, valuable rare minerals and ores are sometimes deposited in rocks subjected to pneumatolysis. Magmatic fluids are acidic and may react extensively with rocks in the volcanic edifice or with wall rocks surrounding intrusions. Penetration of magmatic fluids into adjacent rocks is greatly aided by faults, fractures, and cracks developed during intrusion and eruption or created by earlier geologic events. *See* MAGMA; METAMORPHISM; METASOMATISM; ORE AND MINERAL DEPOSITS; VOLCANO.

Pneumatolysis describes specific mechanisms of mineral deposition, hydrothermal alteration, or metasomatism in which magmatic fluids play an extremely significant role. For example, lavas and ejecta at volcanoes may contain blocks (xenoliths) of wall rock that react with magmatic fluids to form pneumatolytic minerals such as vesuvianite (idocrase). Gases streaming from volcanic fumaroles deposit sublimates of sulfur, sulfates, chlorides, fluorides, and oxides of many metals. Wall rocks surrounding volcanic conduits may be thoroughly altered to mixtures of quartz, alunite, anhydrite, pyrite, diaspore, kaolin, as well as other minerals by acidic fluids degassed from magma. Rarely, gold, silver, base-metal sulfides, arsenides, and tellurides are deposited by the fluids, making valuable ores. *See* LAVA; METASOMATISM; PYROCLASTIC ROCKS; SUBLIMATION; VESUVIANITE; XENOLITH. [F.Go.]

Pneumococcus The major causative microorganism (*Streptococcus pneumoniae*) of lobar pneumonia. Pneumococci occur singly or as pairs or short chains of oval or lancet-shaped cocci, 0.05–1.25 micrometers each, flattened at proximal sides and pointed at distal ends. A capsule of polysaccharide envelops each cell or pair of cells. The organism is nonmotile and stains gram-positive unless degenerating.

Pneumococci have been isolated from the upper respiratory tract of healthy humans, monkeys, calves, horses, and dogs. Epizootics of pneumococcal infection have been described in monkeys, guinea pigs, and rats but are not the source of human infection. In humans, pneumococci may be found in the upper respiratory tract of nearly all individuals at one time or another. Following damage to the epithelium lining the respiratory tract, pneumococci may invade the lungs. They are the principal cause of lobar pneumonia in humans and may cause also pleural empyema, pericarditis, endocarditis, meningitis, arthritis, peritonitis, and infection of the middle ear. Approximately one of four cases of pneumococcal pneumonia is accompanied by invasion of the bloodstream by pneumococci, producing bacteremia. Although the high mortality of untreated pneumococcal infection has been reduced significantly by treatment with antibiotics, one of every six patients with bacteremic lobar pneumonia still succumbs despite optimal therapy. In addition, the number of isolates of pneumococci resistant to one or more antimicrobial drugs has been gradually but steadily increasing. For these reasons, prophylactic vaccination is recommended, especially for those segments of the population that are at high risk for fatal infection. The polyvalent vaccine contains the purified capsular polysaccharides of the 23 types that are responsible for 85% of bacteremic pneumococcal infection and has an aggregate efficacy of 65–70% in preventing infection with any of the types represented in it. [R.Au.]

Pneumonia An acute or chronic inflammatory disease of the lungs. More specifically when inflammation is caused by an infectious agent, the condition is called pneumonia; when the inflammatory process in the lung is not related to an infectious organism, it is called pneumonitis.

An estimated 45 million cases of infectious pneumonia occur annually in the United States, with up to 50,000 deaths directly attributable to it. Pneumonia is a common immediate cause of death in persons with a variety of underlying diseases. With the use of immunosuppressive and chemotherapeutic agents for treating transplant and cancer patients, pneumonia caused by infectious agents that usually do not cause infections in healthy persons (that is, pneumonia as an opportunistic infection) has become commonplace. Moreover, individuals with acquired immune deficiency syndrome (AIDS) usually die from an opportunistic infection, such as pneumocystis pneumonia or cytomegalovirus pneumonia. Concurrent with the variable and expanding etiology of pneumonia and the more frequent occurrence of opportunistic infections is the development of new antibiotics and other drugs used in the treatment of pneumonia. *See* ACQUIRED IMMUNE DEFICIENCY SYNDROME (AIDS); OPPORTUNISTIC INFECTIONS.

Bacteria, as a group, are the most common cause of infectious pneumonia, although influenza virus has replaced *Streptococcus pneumoniae* (*Diplococcus pneumoniae*) as the most common single agent. Some of the bacteria are normal inhabitants of the body and proliferate to cause disease only under certain conditions. Other bacteria are contaminants of food or water.

Most bacteria cause one of two main morphologic forms of inflammation in the lung. *Streptococcus pneumoniae* causes lobar pneumonia, in which an entire lobe of a lung or a large portion of a lobe becomes consolidated (firm, dense) and nonfunctional secondary to an influx of fluid and acute inflammatory cells that represent a reaction to the bacteria. This type of pneumonia is uncommon today, usually occurring in people who have poor hygiene and are debilitated. If lobar pneumonia is treated adequately, the inflammatory process may entirely disappear, although in some instances it undergoes a process called organization, in which the inflammatory tissue changes into fibrous tissue, usually rendering that portion of the lung nonfunctional.

The other morphologic form of pneumonia, which is caused by the majority of bacteria, is called bronchopneumonia. In this form there is patchy consolidation of lung tissue, usually around the small bronchi and bronchioles, again most frequently in the lower lobes. This type of pneumonia may also undergo complete resolution if there is adequate treatment, although rarely it organizes.

Viral pneumonia is usually a diffuse process throughout the lung and produces a different type of inflammatory reaction than is seen in bronchopneumonia or lobar pneumonia. Mycoplasma pneumonia, caused by *Mycoplasma pneumoniae*, is referred to as primary atypical pneumonia and causes an inflammatory reaction similar to that of viral pneumonia.

Pneumonia can be caused by a variety of other fungal organisms, especially in debilitated persons such as those with cancer or AIDS. *Mycobacterium tuberculosis*, the causative agent of pulmonary tuberculosis, produces an inflammatory reaction similar to fungal organisms. *See* MYCOBACTERIAL DISEASES; TUBERCULOSIS.

Legionella pneumonia, initially called Legionnaire's disease, is caused by bacteria of the genus *Legionella*. The condition is frequently referred to under the broader name of legionellosis. *See* LEGIONNAIRES' DISEASE.

The signs and symptoms of pneumonia and pneumonitis are usually nonspecific, consisting of fever, chills, shortness of breath, and chest pain. Fever and chills are more frequently associated with infectious pneumonias but may also be seen in pneumonitis. The physical examination of a person with pneumonia or pneumonitis may reveal abnormal lung sounds indicative of regions of consolidation of lung tissue. A chest x-ray also shows the consolidation, which appears as an area of increased opacity (white area). Cultures of sputum or bronchial secretions may identify an infectious organism capable of causing the pneumonia.

The treatment of pneumonia and pneumonitis depends on the cause. Bacterial pneumonias are treated with antimicrobial agents. If the organisms can be cultured, the sensitivity of the organism to a specific antibiotic can be determined. Viral pneumonia is difficult to treat, as most drugs only help control the symptoms. The treatment of pneumonitis depends on identifying its cause; many cases are treated with cortisone-type medicines. [S.P.H.]

Poales An order of flowering plants (angiosperms) that includes the bromeliads, grasses, restios, rushes, and sedges. It comprises approximately 18 families and more than 18,000 species, over half of which are grasses (Poaceae). These families in general include plants without showy flowers (except for Bromeliaceae, Xyridaceae, and Rapateaceae) and with a grasslike form. These plants dominate vast areas of the Earth's surface and include some important grain crops, such as corn (*Zea mays*), rice (*Oryza sativa*), and wheat (*Triticum aestivum*), as well as rushes, sedges, grasses used for thatch, and bamboos used for construction. *See* DUNE VEGETATION; GRAIN CROPS; GRASS CROPS. [M.W.C.; M.F.F.]

Podicipediformes A small order of aquatic birds that contains only a single living family, the Podicipedidae (grebes), with 20 species found throughout the world. They are small to medium-sized birds that are specialized for aquatic life and can swim and dive skillfully. Their legs are placed far posteriorly with lobed—not webbed—toes that are used to propel the bird through the water, but their terrestrial locomotion is awkward. Their wings are small, and they rarely fly; yet they migrate over long distances and have colonized many remote islands. The body is compact with a dense, waterproof plumage. The neck is medium to long, the head is large, and the bill is short to medium and pointed. Grebes feed on fish and other aquatic animals they pursue under water. Grebes are monogamous, with an elaborate courtship and strong pair bond. Grebes are found throughout the world except on some remote oceanic islands. *See* AVES. [W.J.B.]

Podocopa One of two Recent subclasses of Ostracoda. The two may share many characteristics but differ significantly in others. Shared characteristics include a carapace (shell) with a straight-to-concave ventral margin and somewhat convex dorsal margin; adductor muscle-scar patterns varying from numerous to few; the absence of an anterior notch in the bivalve shell; and the absence of lateral eyes, heart, and frontal organ (Bellonci organ). Podocopid ostracods are small, rarely exceeding 0.25 in. (7 mm). The carapace valves are unequal, weakly or strongly calcified, and may be heavily ornamented. The hinge varies from simple to complex. Six or seven pairs of appendages are present; the seventh is adapted for walking, for cleaning, or as a clasping leg in males. The subclass is represented by the two extant orders, Platycopida and Podocopida.

Podocopid ostracods are found in fresh-water, marine, and brackish-water environments, and a few are terrestrial. The majority are burrowing or crawling inhabitants of the benthos and are filter or detritus feeders or herbivores. Some are capable of swimming, but none appear to ever lead a planktonic existence. *See* OSTRACODA. [P.A.McL.]

Podocopida An order of the subclass Podocopa, class Ostracoda, that consists of the extant suborder Podocopina and the extinct Metacopina. There is agreement on the assignment of the superfamilies Cypridoidea, Bairdioidea, Cytheroidea, and Darwinuloidea to the Podocopida; however, some researchers also include the Sigillioidea, and others consider the Terrestrichtheroidea a podocopid taxon of equivalent rank. In all podocopids the two valves fit firmly, hermetically sealing the animal inside when closed.

Appendages include antennules, antennae, mandibles, maxillules, and three pairs of thoracic legs. Antennules and antennae are both used in locomotion; swimming forms are provided with long, feathered setae, whereas crawling forms have only short, stout setae. Mandibles are strongly constructed and, with rare exceptions, used for mastication. The maxilla has setiferous endites and bears a large branchial plate to circulate water alongside the body. The furca is variously developed but never lamelliform. If eyes are present, the two lateral eyes and the median eye are joined into one central structure. No heart is developed. *See* CRUSTACEA; PODOCOPA. [P.A.McL.]

Podostemales An order of flowering plants, division Magnoliophyta (Angiospermae), in the subclass Rosidae of the class Magnoliopsida (dicotyledons). The order consists of only the family Podostemaceae, with about 200 species, the greatest number occurring in tropical America. They are submerged aquatics with modified, branching, often thalluslike shoots, and small, perfect flowers with a much reduced perianth. *See* MAGNOLIOPSIDA; ROSIDAE. [A.Cr.]

Poecilosclerida An order of sponges of the class Demospongiae in which the skeleton includes two or more types of megascleres, each localized in a particular part of the sponge colony. Frequently one type of megasclere is restricted to the dermis and another type occurs in the interior of the sponge. Sometimes one category is embedded in spongin fibers while a second category, usually spinose, protrudes from the fibers at right angles. Spongin is always present but varies in amount from species to species. Microscleres are usually present; often several types occur in one species. A wide variety of microsclere categories is found in the order but asters are never present. *See* DEMOSPONGIAE. [W.D.H.]

Poecilostomatoida One of two major orders of parasitic Copepoda that were previously included in the Cyclopoida. The classification of parasitic copepods has been established on the basis of the structure of the mouth. In poecilostomatoids the mouth is represented by a transverse slit, partially covered by the overhanging labrum, which resembles an upper lip. Although there is variability in the form of the mandible among poecilostomatoids, it can be generalized as being falcate. Body segmentation is typically podoplean, having prosome-urosome articulation between the fifth and sixth thoracic somites; however, this segmentation is often lost with the molt to adulthood. The antennules frequently are reduced in size and the antennae modified to terminate in small hooks or claws that are used in attachment to host organisms.

Most poecilostomatoid copepods are ectoparasites of marine fishes or invertebrates, usually attaching to the external surface of the host or in the branchial cavity on the walls or gill surfaces. Representatives of one family, however, have successfully made the transition to fresh-water habitats, and a second family has evolved an endoparasitic mode of life. *See* COPEPODA; CRUSTACEA; CYCLOPOIDA. [P.A.McL.]

Pogonophora The beard worms—a phylum of sedentary marine worms living in cool waters of all the world's oceans, generally at depths between 330 and 13,200 ft (100 and 4000 m), shallower at higher latitudes and deeper in trenches. They were first dredged late in the nineteenth century but first investigated in the 1950s. Pogonophorans construct a tube, and are the only nonparasitic metazoans to have no mouth, gut, or anus in their postembryonic anatomy. These are long, slender worms, the diameter in most being less than 1 mm and the length being over 100 times the diameter. Superficially the tubes remind one of corn silk or coarse thread, but most have a characteristic banding pattern with annuli of brown or yellow pigments. The larger tubes are sometimes rigid, thicker, and darkcolored.

The evidence now suggests that these worms absorb their nutrients, such as amino acids, glucose, and fatty acids, through the pinnules and microvilli of the tentacles without the aid of digestive enzymes. This is accomplished against concentration gradients and may be supplemented by limited pinocytosis and phagocytosis by tentacular surfaces in a few species. The presence of internal symbiotic bacteria was demonstrated in several genera. These chemosynthetic organisms also play an important role in providing nutrients to these worms.

The sexes are separate, with the gonopore location being the only sexual dimorphism. Spermatophores with long tail filaments are released by the male. Fertilization has not been observed but must occur within the maternal tube, as fertilized eggs and developing larvae have been found there.

The Pogonophora consist of two orders: Athecanephria and Thecanephria. *See* ATHECANEPHRIA; THECANEPHRIA. [E.B.Cu.]

Poison A substance which by chemical action and at low dosage can kill or injure living organisms. Broadly defined, poisons include chemicals toxic for any living form: microbes, plants, or animals. In common usage the word is limited to substances toxic for humans and mammals, particularly where toxicity is a substance's major property of medical interest. Because of their diversity in origin, chemistry, and toxic action, poisons defy any simple classification. Almost all chemicals with recognized physiological effects are toxic at sufficient dosage.

Origin and chemistry. Many poisons are of natural origin. Some bacteria secrete toxic proteins (for example, botulinus, diphtheria, and tetanus toxins) that are among the most poisonous compounds known. Lower plants notorious for poisonous properties are ergot (*Claviceps purpurea*) and a variety of toxic mushrooms. *See* ERGOT AND ERGOTISM; MUSHROOM; TOXIN.

Higher plants, which constitute the major natural source of drugs, contain a great variety of poisonous substances. Many of the plant alkaloids double as drugs or poisons, depending on dose. These include curare, quinine, atropine, mescaline, morphine, nicotine, cocaine, picrotoxin, strychnine, lysergic acid, and many others. *See* ATROPINE; COCAINE; MORPHINE ALKALOIDS; QUININE.

Poisons of animal origin (venoms) are similarly diverse. Toxic marine animals alone include examples of every phylum. Insects and snakes represent the best-known venomous land animals, but on land, too, all phyla include poison-producing species. Among mammalian examples are certain shrews with poison-producing salivary glands. *See* POISON GLAND.

Poisons of nonliving origin vary in chemical complexity from the toxic elements, for example, the heavy metals, to complex synthetic organic molecules. Most of the heavy metals (gold, silver, mercury, arsenic, and lead) are poisons of high potency in the form of their soluble salts. Strong acids or bases are toxic largely because of corrosive local tissue injury.

The chemically reactive gases hydrogen sulfide, hydrocyanic acid, chlorine, bromine, and ammonia are also toxic, even at low concentration, both because of their corrosiveness and because of more subtle chemical interaction with enzymes or other cell constituents.

Many organic substances of synthetic origin are highly toxic and represent a major source of industrial hazard. Most organic solvents are more or less toxic on ingestion or inhalation. Many alcohols, such as methanol, are much more toxic. Many solvents (for example, carbon tetrachloride, tetrachloroethane, dioxane, and ethylene glycol) produce severe chemical injury to the liver and other viscera, sometimes from rather low dosage.

Physiological actions. The action of poisons is generally described by the physiological or biochemical changes which they produce. For most poisons, a descriptive account can be given which indicates what organic system (for example, heart, kidney, liver, brain, and bone marrow) appears to be most critically involved and contributes most to seriously disordered body function or death. In many cases, however, organ effects are multiple, or functional derangements so generalized that a cause of death cannot be localized.

More precise understanding of the mechanism of poisons requires detailed knowledge of their action in chemical terms. Information of this kind is available for only a few compounds, and then in only fragmentary detail. Poisons that inhibit acetylcholinesterase have toxic actions traceable to a single blocked enzyme reaction, hydrolysis of normally secreted acetylcholine. Detailed understanding of the mechanism of chemical inhibition of cholinesterase is not complete, but allows some prediction of chemical structures likely to act as inhibitors. *See* ACETYLCHOLINE.

Carbon monoxide toxicity is also partly understood in chemical terms, since formation of carboxyhemoglobin, a form incapable of oxygen transport, is sufficient to explain the anoxic features of toxicity.

Heavy metal poisoning in many cases is thought to involve inhibition of enzymes by formation of metal mercaptides with enzyme sulfhydryl groups, the unsubstituted form of which is necessary for enzyme action. This is a general reaction that may occur with a variety of sulfhydryl-containing enzymes in the body. Specific susceptible enzymes whose inhibition explains toxicity have not yet been well documented.

Metabolic antagonists active as poisons function by competitive blocking of normal metabolic reactions. Some antagonists may act directly as enzyme inhibitors, others may be enzymatically altered to form derivatives which are even more potent inhibitors at a later metabolic step. *See* ENZYME INHIBITION.

Where poison mechanisms are relatively well understood, it has sometimes been possible to employ rationally selected antidotes.

Potency. The strength or potency of poisons is most frequently measured by the lethal dose, potency being inversely proportional to lethal dose. From statistically treated dose-response data, the dose killing 50% of the sample population can be determined, and is usually designated the MLD (median lethal dose) or LD_{50}. This is the commonest measure of toxic potency. *See* LETHAL DOSE 50; TOXICOLOGY. [E.A.]

Poison gland

Poison gland The specialized gland of certain fishes, as well as the granular glands and some mucous glands of many aquatic and terrestrial Amphibia. The poison glands of fishes are simple or slightly branched acinous structures which use the holocrine method of secreting a mucuslike substance. The poison glands of snakes are modified oral or salivary glands. Amphibian glands are simple, acinous, holocrine, with granular secretion. In some cases these amphibian poison glands produce mucus by a merocrine method of secretion. These glands function as protective devices. *See* GLAND. [O.E.N.]

Poison ivy

Poison ivy A general name applied to certain species of the genus *Toxicodendron*, previously known as *Rhus*, in the sumac family (Anacardiaceae). *Toxicodendron radicans* is the poison ivy of eastern North America; *T. diversiloba* is the poison oak of California. These plants are natives of North America. Both cause ivy poisoning, an annoying and often painful dermatitis. *Toxicodendron radicans*, the most widespread species, is extremely variable. It has a bushy or climbing habit and three-foliolate leaves which are smooth and glossy or hairy and are entire, toothed, or lobed. Poison ivy bears white fruits whereas the nonpoisonous sumacs bear red fruits. *See* HYPERSENSITIVITY; SAPINDALES. [P.D.St.; E.L.C.]

Poison sumac

Poison sumac The plant *Toxicodendron vernix* (previously in the genus *Rhus*), a member of the sumac family (Anacardiaceae). It is an inhabitant of swamps ranging from Quebec to Minnesota, and southward to Florida, Louisiana, and Texas. It is a tall bush or small tree bearing pinnately compound leaves with 7–13 entire (without marginal teeth) leaflets, and drooping, axillary clusters of persisting white fruits (see illustration). Like poison ivy, this plant is poisonous to touch, causing in many persons a severe inflammation of the skin, or dermatitis. The presence of white fruit separates this species from the nonpoisonous sumacs with their red fruits. *See* HYPERSENSITIVITY; SAPINDALES. [P.D.St.; E.L.C.]

Poison sumac fruits and leaf (*Toxicodendron vernix*).

Poisonous plants

Poisonous plants More than 700 species of seed plants, ferns, horsetails, and fungi that cause toxic, though rarely fatal, reactions in humans and animals. Human allergic responses, including hay fever, asthma, and dermatitis, are widespread. Allergic responses are produced by many different plant species, but most common are poison ivy, poison sumac, and Pacific poison oak (all are species of *Toxicodendron*). Internal injury by toxic plants is less common but can be detrimental or lethal. *See* ASTHMA; POISON IVY; POISON SUMAC.

Glycoside-containing plants. Glycosides are common compounds in plants. They decompose to form one or more sugars, but sometimes the remaining compounds, aglycones, can be quite poisonous. Cyanogenic glycosides, which produce hydrocyanic acid, are found worldwide in many plant families; the best known are in the rose family (Rosaceae) and in the pea family (Fabaceae). Leaves, bark, and seeds of stone fruits such as cultivated and wild cherries, plums, peaches, bitter almonds, and apricots contain the glycoside amygdalin, which hydrolyzes to form hydrocyanic acid that can be fatally toxic to humans or animals. The same toxic substance is found in apple and pear seeds. Cardiac glycosides are found in many unrelated species of plants. Those of the foxglove (*Digitalis purpurea*) contain a number of these glycosides used medicinally to slow and strengthen the heartbeat. Oleander (*Nerium oleander*), which is cultivated in the warmer parts of the United States, contains a toxic glycoside that has an action similar to that of digitalis. *See* CYANIDE; DIGITALIS; GLYCOSIDE.

Alkaloid-containing plants. Alkaloids, compounds containing a nitrogen atom, have specific pharmacological effects on both humans and animals. Found in many different plant families, they have been used in drug therapy since ancient times, but misuse of these plants can produce poisonings. The potato family (Solanaceae) has many species that contain a number of alkaloids. Hyoscyamine and atropine are the alkaloids occurring in belladonna or deadly nightshade (*Atropa belladonna*), black henbane (*Hyoscyamus niger*), thornapples and jimsonweed (*Datura*), and tree daturas or angel's-trumpets (*Brugmansia*). The black nightshades (*Solanum*) contain glycoalkaloids. Plants of tobacco, *Nicotiana*, contain numerous alkaloids, principally the very toxic nicotine or its isomer anabasine. Plants of poison hemlock (*Conium macalatum*) have several alkaloids similar to nicotine, which affect the central nervous system. Plants of rattlebox (*Crotalaria*), groundsel (*Senecio*), and fiddleneck (*Amsinckia*) have alkaloids of similar molecular structure. Anagyrine is a toxic alkaloid found in several species of lupine (*Lupinus*) in the western United States. Alkaloids present in species of monkshood (*Aconitum*) are extremely toxic. Larkspur plants (*Delphinium*) have similar toxic alkaloids affecting the central nervous system, causing excitability and muscular spasms. Plants of false hellebores (*Veratrum*) and death camas (*Zigadenus*) have complex alkaloids of similar structure and cause livestock deaths in the western United States. *See* ALKALOID; ATROPINE.

Heath plants. Toxic resins, andromedotoxins, formed by members of the heath family (Ericaceae) are derived from diterpenes. The most toxic species are mountain laurel, sheep laurel, and bog laurel, all in the genus *Kalmia*.

Pokeweed. Pokeweed (*Phytolacca americana*) is a garden weed throughout the United States. but it is native to the eastern and central areas. The entire plant, especially the seeds and the large root, is poisonous. Human poisonings have resulted from inadvertently including parts of the root along with the shoots.

Waterhemlock. The waterhemlocks (*Cicuta*) are widespread in North America. The large underground tubers, mistakenly considered edible, have caused human poisonings and death.

Livestock usually do not eat waterhemlock, but have been fatally poisoned. The highly toxic principle is an unsaturated aliphatic alcohol which acts directly on the central nervous system.

Oxalate poisoning. Oxalic acid, as oxalate salts, accumulates in large amounts in some species of plants such as those of the genera *Halogeton*, *Bassia*, *Rumex*, and *Oxalis*.

Nitrate poisoning. Nitrate poisoning is widespread and results in many cattle deaths yearly. Any disruption of the normal synthesis of nitrates into amino acids and proteins causes large accumulations of nitrates in various species of plants, particularly in the goosefoot family (Chenopodiaceae).

Allelopathic toxins. Allelopathic phytotoxins are chemical compounds produced by vascular plants that inhibit the growth of other vascular plants. Residues of grain sorghum (*Sorghum bicolor*) can markedly reduce the following year's growth of wheat and some weedy grass seedlings. Locoweeds, belonging to the genera *Oxytropis* and *Astragalus*, produce an unknown toxin that causes loss of livestock that become addicted to eating these unpalatable plants. Other species of *Astragalus* produce toxic aliphatic nitro compounds. Still other species of *Astragalus* accumulate toxic quantities of selenium which usually causes chronic poisoning of livestock. *See* ALLELOPATHY.

Fungi. Every year human fatalities occur from ingestion of wild poisonous mushrooms. Those gathered in the wild require individual identification since toxic species may grow alongside edible ones. Ergot fungus, infecting many species of grasses, causes widespread poisoning of livestock. *See* ERGOT AND ERGOTISM; TOXICOLOGY. [T.C.F.]

Polar meteorology

The science of weather and climate in the high latitudes of the Earth. In the polar regions the Sun never rises far above the horizon and remains below it continuously for part of the year, so that snow and ice can persist for long periods even at low elevations. The meteorological processes that result have distinctive local and large-scale characteristics in both polar regions. [U.R.]

Polar molecule

A molecule possessing a permanent electric dipole moment. Molecules containing atoms of more than one element are polar except where forbidden by symmetry; molecules formed from atoms of a single element are nonpolar (except ozone). The dipole moments of polar molecules result in stronger intermolecular attraction, increased viscosities, higher melting and boiling points, and greater solubility in polar solvents than in nonpolar molecules. [R.D.W.]

Polar navigation

The complex of navigational techniques modified from those used in other areas to suit the distinctive regional character of polar areas. Although polar navigation has become routine to a rising number of navigators operating in and through such high-latitude parts of the word, their success continues to be based on a sound grasp of the regional differences and the developing adaptations of navigational principles and aids to suit these peculiar area needs. For example, in polar regions the meridians radiate outward from the poles, and parallels are concentric circles. Thus the rectangular coordinates familiar to the navigator accustomed to using the Mercator projection are replaced by polar coordinates.

Limitations. Piloting in polar regions is strongly affected by the absence of any great number of aids to navigation. Also, natural landmarks may not be shown on the chart, or may be difficult to identify. The appearance of some landmarks changes markedly under different ice conditions. When snow covers both the land and a wide ice foot attached to the shore and extending for miles seaward, even the shoreline is difficult to locate. *See* PILOTING.

Charts of polar regions are less reliable than those of other regions, because relatively little surveying has been done in the polar areas. Because relatively few soundings are shown on charts, ships entering harbors often send small boats ahead to determine the depth of water available. However, the reliability of charts of polar regions has steadily improved as additional information has become available.

Coverage of electronic navigation systems has also improved, but is still somewhat limited. Loran C sky waves are available throughout the Arctic, and ground waves extend to some parts of this area, but neither ground waves nor sky waves are available in the Antarctic. Radar is useful, but experience in interpretation of the scope in polar regions is essential for reliable results. This is particularly true in aircraft, where the relative appearance of water and land areas often reverse in winter and summer. A radio direction finder is useful, when radio signals are available. The use of electronics in polar regions is further restricted by magnetic storms, which are particularly severe in the auroral zones. *See* ELECTRONIC NAVIGATION SYSTEMS; RADAR.

Reliable dead reckoning depends upon the availability of accurate measurement of direction and distance (or speed and time). There are difficulties in meeting these requirements in polar regions. Direction is measured largely by a compass. The magnetic compass becomes unreliable in the vicinity of the magnetic poles of the Earth, and the north-seeking gyrocompass becomes unreliable in the vicinity of the geographical poles of the Earth. One solution to the directional problem in high latitudes is to use a directional gyro, a gyroscopic device that maintains its axis in a set direction but must be reset at frequent intervals, as every 15 min, because of gyroscopic drift. One of the devices discussed below for celestial direction determination can provide the directional data needed for setting or resetting a directional gyro. Directional gyros are not generally used aboard ship, and in aircraft they have been largely replaced by inertial navigators, which are also used by submarines and to a limited extent by surface ships. However, because inertial systems are self-contained, without reference to external signals, the insertion of incorrect data is always a possibility. *See* AIRCRAFT COMPASS SYSTEM; DEAD RECKONING; GYROSCOPE; INERTIAL GUIDANCE SYSTEM.

Several types of devices have been developed to facilitate the use of celestial bodies for determination of direction. The oldest is the sun compass, which utilizes the shadow of a shadow pin, or gnomon, and a suitable dial. A sky compass indicates direction of the Sun by means of polarized light in the sky when the Sun is near the horizon, even though it may be below the horizon or otherwise obscured. This device may offer the only means of determining direction during the brighter part of the long polar twilight. An astrocompass can be set for the coordinates of any celestial body and the latitude of the observer, and then gives an indication of azimuth, true north, and heading.

Distance or speed measurement in polar regions presents no problems in aircraft. When ships operate in ice, however, the sensing element in the water may be adversely affected or damaged by the ice. At best, dead reckoning is difficult aboard a ship operating in the ice, not only because of the difficulty encountered in measuring course and speed, but also because neither of these may be constant for very long.

Celestial navigation is of great importance in polar regions, sometimes providing the only means of determining position accurately, or establishing a directional reference. When operating in lower latitudes, navigators generally avoid observation of bodies near the horizon because of the uncertainty of the refraction correction there. In polar regions, even though refraction is more uncertain, navigators often have no choice. Near the equinoxes the Sun may be the only body available for several weeks, and it remains close to the horizon. During the polar summer the Sun is often the only celestial body available. When only one body is available, it is observed at frequent intervals, perhaps hourly, and a series of running fixes is plotted. *See* CELESTIAL NAVIGATION.

Modern technology. Advances in technology have contributed significantly to the safety and reliability of navigation in polar regions. The availability of modern echo sounders has made possible a continuous plot of the bottom profile beneath a vessel while under way. Sonar indicates the presence of an underwater obstruction. Reliable inertial navigators are available to make aircraft navigation in polar regions almost routine, providing both positional and directional data. Ship inertial navigation systems are available and have made practicable submarine operations under sea ice. *See* Echo sounder; Sonar.

The NAVSTAR Global Positioning System (GPS) of the U.S. Department of Defense has eliminated the limitations of the now defunct Navy Navigation Satellite System. Although all GPS satellites operate on the same frequencies (1227 and 1575 MHz), signals are modulated with two codes, one of which provides for identification of and lock-on to the desired signal. *See* Navigation; Satellite navigation systems. [A.B.M.]

Polarimetric analysis A method of chemical analysis based on the optical activity of the substance being determined. Optically active materials are asymmetric; that is, their molecules or crystals have no plane or center of symmetry. These asymmetric molecules can occur in either of two forms, *d*- and *l*-, called optical isomers. Asymmetric substances possess the power of rotating the plane of polarization of plane-polarized light. Measurement of the extent of this rotation, polarimetry, is performed by an instrument known as a polarimeter. Polarimetry is applied to both organic and inorganic materials. *See* Optical activity.

The extent of the rotation depends on the character of the substance, the length of the light path, the temperature of the solution, the wavelength of the light which is being used, the solvent (if there is one), and the concentration of the substance. In most work, the yellow light of the D line of the sodium spectrum (589.3 nanometers) is used to determine the specific rotation, according to the equation below. Here α is the measured angle

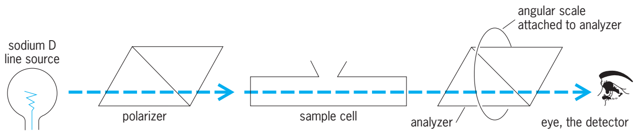
$$\text{Specific rotation} = [\alpha]_{\mathrm{D}}^{20} = \frac{\alpha}{l\rho}$$

of rotation, l is the length of the column of liquid in decimeters, and ρ the density of the solution. In other words, the specific rotation is the rotation in degrees which this plane-polarized light of the sodium D line undergoes in passing through a 10-cm-long (4-in.) sample tube containing a solution of 1 g/ml concentration at 20°C (68°F).

In the illustration, light from the sodium lamp is polarized by the polarizer (prism). It then passes through the cell containing the material being analyzed. After that, it passes through the analyzer (another prism) and then is detected (by eye or photocell). A comparison of the angular orientation of the analyzer as measured on the scale with the cell empty and with the cell filled with solution serves to measure the rotation of the polarized light by the sample. This rotation may be either clockwise (+) or counterclockwise (−).

Polarimetry may be used for either qualitative or quantitative analytical work. In qualitative applications, the presence of an optically active material is shown, and then a calculation of specific rotation often leads to the identification of the unknown. In quantitative work, the concentration of a given optically active material is determined.

Polarimetry is used in carbohydrate chemistry, especially in the analysis of sugar solutions. Since there is great difference between the biological activities of the different optical forms of organic compounds, polarimetry is used in biochemical research to identify the molecular configurations.



Simplified diagram of a polarimeter.

Optical rotatory dispersion is the measurement of the specific rotation as a function of wavelength. The information obtained by this method has shown that minor changes in configuration of a molecule have a marked effect on its dispersion properties. By using the properties of compounds of known configuration, it has been possible to determine the absolute configurations of many other molecules and to identify various isomers. Most of the applications have been to steroids, sugars, and other natural products, including amino acids, proteins, and polypeptides. *See* Cotton effect; Optical rotatory dispersion; Polarized light. [R.F.G.; J.N.L.]

Polarimetry The science of determining the polarization state of electromagnetic radiation (x-rays, light or radio waves). Radiation is said to be linearly polarized when the electric vector oscillates in only one plane. It is circularly polarized when the x-plane component of the electric vector oscillates 90° out of phase with the y-plane component.

To completely specify the polarization state, it is necessary to make six intensity measurements of the light passed by a quarter-wave retarder and a rotatable linear polarizer, such as a Polaroid or a Nicol prism. The retarder converts circular light into linear light.

Most starlight is unpolarized. However, atoms in the presence of a magnetic field align themselves at fixed, quantized angles to the field direction. Then the spectral lines they emit are circularly polarized when the magnetic field is parallel to the line of sight, and linearly polarized when the field is perpendicular. The light from sunspots is polarized because the magnetic fields impose some direction in the emitting gas. Other phenomena also remove isotropy and produce polarization. *See* Solar magnetic field; Zeeman effect.

Electrooptical devices are rapidly replacing rotating polarizers and fixed retarders. The magnetograph consists of a spectrograph to isolate the atomic spectral line for study; a Pockels cell, an electrooptic crystal whose retardance depends on an applied voltage; a polarizing prism to isolate the polarization state passed by the retarder; a pair of photocells to detect the transmitted light; and a scanning mechanism to sweep the solar image across the spectrograph entrance slit. Two photocells are needed to simultaneously measure left- and right-circular polarization. *See* Spectrograph.

A magnetograph can be made sensitive to linear polarization, but the signal levels are about 100 times weaker for the inferred transverse fields than for longitudinal fields of comparable strength. To improve signal-to-noise levels, the spectrograph can be replaced with an optical filter having a narrow passband, and the photocells can be replaced with an array of photosensitive picture elements (pixels). [D.M.R.]

Polaris The star α Ursae Minoris, also known as the North Star or Pole Star. It is perhaps the best-known star in the northern sky. Its location only 1 degree of arc from the north celestial pole, the point where the Earth's rotation axis intersects the celestial sphere, has made it a very useful reference point for navigation. It may easily be found by following the line joining the two bright stars at the end of the bowl of the Big Dipper. *See* Ursa Major; Ursa Minor.

Polaris (apparent magnitude 1.99) is a supergiant with an intrinsic brightness about 1500 times that of the Sun. It is accompanied by a 9th-magnitude main-sequence star, and its spectrum shows evidence of another, much closer companion in an eccentric orbit with a period of 30 years. *See* Supergiant star.

Polaris is a variable star, displaying slight changes in brightness with a period close to 4 days. Polaris is a member of an important group of stars known as the Cepheid variables. However, it is atypical in that the amplitude of the variations is very small compared to other Cepheids and has decreased steadily over 100 years to the point where the pulsation of the star has virtually stopped. *See* Cepheids; Star; Variable star. [D.W.L.]

Polarization of dielectrics A vector quantity representing the electric dipole moment per unit volume of a dielectric material. *See* DIELECTRIC MATERIALS.

Dielectric polarization arises from the electrical response of individual molecules of a medium and may be classified as electronic, atomic, orientation, and space-charge or interfacial polarization, according to the mechanism involved.

Electronic polarization represents the distortion of the electron distribution or motion about the nuclei in an electric field.

Atomic polarization arises from the change in dipole moment accompanying the stretching of chemical bonds between unlike atoms in molecules. *See* MOLECULAR STRUCTURE AND SPECTRA.

Orientation polarization is caused by the partial alignment of polar molecules, that is, molecules possessing permanent dipole moments, in an electric field. This mechanism leads to a temperature-dependent component of polarization at lower frequencies.

Space-charge or interfacial polarization occurs when charge carriers are present which can migrate an appreciable distance through a dielectric but which become trapped or cannot discharge at an electrode. This process always results in a distortion of the macroscopic field and is important only at low frequencies. *See* ELECTRIC FIELD; ELECTRIC SUSCEPTIBILITY. [R.D.W.]

Polarization of waves The directional dependence of certain wave phenomena, at right angles to the propagation direction of the wave. In particular, ordinary light may be regarded as composed of two such asymmetrical components, referred to as its two states of linear polarization.

These two components are refracted differently by doubly refracting crystals, such as calcite, or Iceland spar. Each state of linear polarization is refracted according to its own separate refractive index. On a subsequent refraction by the same crystal, but now rotated through an angle θ about the direction of the beam, each component appears as a mixture of the original two polarization components, according to the proportions $\cos^2\theta : \sin^2\theta$. *See* BIREFRINGENCE; CRYSTAL OPTICS; REFRACTION OF WAVES.

In the early nineteenth century, T. Young suggested that light polarization arises from transverse oscillations. In J. C. Maxwell's theory of light as electromagnetic waves, visible light—and also other types of electromagnetic radiation such as radio waves, microwaves, and x-rays (distinguished from visible light only by wavelength)—consists of electric and magnetic fields, each oscillating in directions perpendicular to the propagation direction, the electric and magnetic field vectors being perpendicular to each other. The plane of polarization of the wave contains the electric vector (or magnetic vector; there is no general agreement which) and the propagation direction. *See* ELECTROMAGNETIC RADIATION; LIGHT; MAXWELL'S EQUATIONS.

If the plane of polarization remains constant along the wave (as in the case of each light component in a doubly refracting medium), the wave has linear (or plane) polarization. However, the plane of polarization can also rotate. If the rotation rate is constant, the intensity of the wave being also constant, a circularly polarized wave results. These are of two types: right-handed and left-handed.

Any electromagnetic wave can be considered to be composed of monochromatic components, and each monochromatic component can be decomposed into a left-handed and a right-handed circularly polarized part. The states of linear polarization are each made up of equal magnitudes of the two circularly polarized parts, with differing phase relations to provide the different possible directions of plane polarization. Monochromatic waves composed of unequal magnitudes of the two circularly polarized parts are called elliptically polarized. This refers to the fact that the electric and magnetic vectors trace out ellipses in the plane perpendicular to the direction of motion.

Photons have quantum-mechanical spin, which refers to the angular momentum of the photon, necessarily about its direction of motion. A photon's spin has magnitude 1, in fundamental units. This spin can point along the direction of motion (positive helicity, right-handed spin) or opposite to it (negative helicity, left-handed spin), and this corresponds (depending on conventions used) to a classical electromagnetic wave of right- or left-handed circular polarization. *See* HELICITY (QUANTUM MECHANICS); PHOTON.

Electromagnetic and gravitational waves both have the specific property that they are entirely transverse in character, which is a consequence of their speed of propagation being the absolute speed of relativity theory (the speed of light). This corresponds to the fact that their respective quanta, namely photons and gravitons, are massless particles. In the case of waves that travel at a smaller speed, as with fields whose quanta are massive rather than massless, there can be (unpolarized) longitudinal as well as transverse effects. Seismic waves traveling through the Earth's material, for example, can be transverse (polarized sideways oscillations) or longitudinal (unpolarized pressure waves). *See* SEISMOLOGY; SOUND; WAVE MOTION IN FLUIDS.

In most situations encountered in practice, light (or gravitational waves) consists of an incoherent mixture of different polarization states, and is referred to as unpolarized. However, light reflected off a refracting surface (for example, glass or water) is polarized to some extent; that is, there is a certain preponderence of one state of linear polarization over the orthogonal possibility. Complete polarization occurs for a particular angle of incidence, known as the Brewster angle. *See* POLARIZED LIGHT; REFLECTION OF ELECTROMAGNETIC RADIATION; WAVE MOTION. [R.Pe.]

Polarized light Light which has its electric vector oriented in a predictable fashion with respect to the propagation direction. In unpolarized light, the vector is oriented in a random, unpredictable fashion. Even in short time intervals, it appears to be oriented in all directions with equal probability. Most light sources seem to be partially polarized so that some fraction of the light is polarized and the remainder unpolarized.

According to all available theoretical and experimental evidence, it is the electric vector rather than the magnetic vector of a light wave that is responsible for all the effects of polarization and other observed phenomena associated with light. Therefore, the electric vector of a light wave, for all practical purposes, can be identified as the light vector. *See* CRYSTAL OPTICS; ELECTROMAGNETIC RADIATION; LIGHT; POLARIZATION OF WAVES.

One of the simplest ways of producing linearly polarized light is by reflection from a dielectric surface. At a particular angle of incidence, known as Brewster's angle, the reflectivity for light whose electric vector is in the plane of incidence becomes zero. The reflected light is thus linearly polarized at right angles to the plane of incidence.

Linear polarizing devices. The first polarizers were glass plates inclined so that the incident light was at Brewster's angle. Such polarizers are quite inefficient since only a small percentage of the incident light is reflected as polarized light.

Certain natural materials absorb linearly polarized light of one vibration direction much more strongly than light vibrating at right angles. Such materials are termed dichroic. Tourmaline is one of the best-known dichroic crystals, and tourmaline plates were used as polarizers for many years. *See* DICHROISM.

Other natural materials exist in which the velocity of light depends on the vibration direction. These materials are called birefringent. One of the best-known of these birefringent crystals is transparent calcite (Iceland spar). The Nicol prism is made of two pieces of calcite cemented together (Fig. 1). The cement is Canada balsam, in which the wave velocity is intermediate between the velocity in calcite for the fast and the slow ray. The angle at which the light strikes the boundary is such that for one ray the angle of incidence is greater than the critical angle for total reflection. Thus the rhomb is transparent for only one polarization direction. *See* BIREFRINGENCE; CRYSTAL; OPTICS.

A different type of polarizer, made of quartz, is shown in Fig. 2. Here the vibration directions are different in the two pieces so

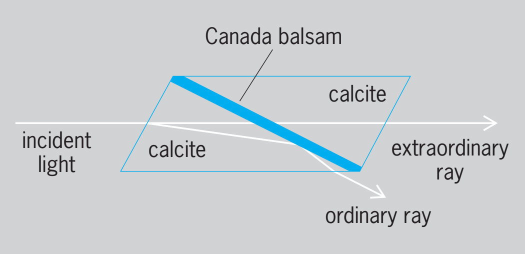


Fig. 1. Nicol prism. The ray for which Snell's law holds is called the ordinary ray.

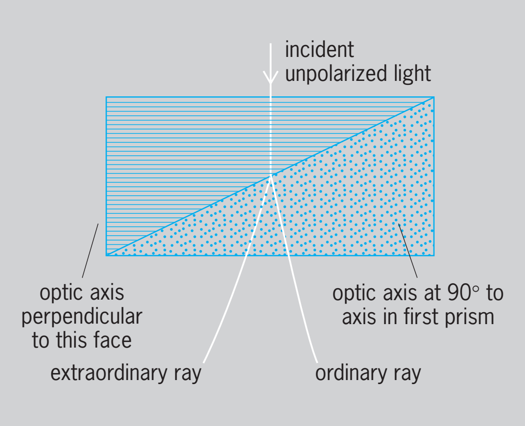

Fig. 2. Wollaston prism.

that the two rays are deviated as they pass through the material. The incoming light beam is thus separated into two oppositely linearly polarized beams which have an angular separation between them, and it is possible to select either beam.

A third mechanism for obtaining polarized light is the Polaroid sheet polarizer, of which there are three types. The first is a microcrystalline polarizer in which small crystals of a dichroic material are oriented parallel to each other in a plastic medium. The second type depends for its dichroism on a property of an iodine-in-water solution. The iodine appears to form a linear high polymer. If the iodine is put on a transparent oriented sheet of material such as polyvinyl alcohol (PVA), the iodine chains apparently line themselves parallel to the PVA molecules and the resulting dyed sheet is strongly dichroic. A third type of sheet polarizer depends for its dichroism directly on the molecules of the plastic itself. This plastic consists of oriented polyvinylene.

Polarization by scattering. When an unpolarized light beam is scattered by molecules or small particles, the light observed at right angles to the original beam is polarized. The best-known example of polarization by scattering is the light of the north sky. *See* SCATTERING OF ELECTROMAGNETIC RADIATION.

Types. Polarized light is classified according to the orientation of the electric vector. In linearly polarized light, the electric vector remains in a plane containing the propagation direction. For monochromatic light, the amplitude of the vector changes sinusoidally with time. In circularly polarized light, the tip of the electric vector describes a circular helix about the propagation direction. The amplitude of the vector is constant. The frequency of rotation is equal to the frequency of the light. In elliptically polarized light, the vector also rotates about the propagation direction, but the amplitude of the vector changes so that the projection of the vector on a plane at right angles to the propagation direction describes an ellipse.

Circular and elliptical polarizing devices. Circularly and elliptically polarized light are normally produced by combining a linear polarizer with a wave plate. A Fresnel rhomb can be used to produce circularly polarized light.

A plate of material (quartz, calcite, or other birefringent crystals) which is linearly birefringent is called a wave plate or retardation sheet. Wave plates have a pair of orthogonal axes which are designated fast and slow. Polarized light with its electric vector parallel to the fast axis travels faster than light polarized parallel to the slow axis. The thickness of the material can be chosen so that for light traversing the plate, there is a definite phase shift between the fast component and the slow component. A plate with a 90° phase shift is termed a quarter-wave plate.

If linearly polarized light is incident normally on a quarter-wave plate and oriented at 45° to the fast axis, the transmitted light will be circularly polarized. If the linearly polarized light is at an angle other than 45° to the fast axis, the transmitted radiation will be elliptically polarized.

Analyzing devices. Polarized light is one of the most useful tools for studying the characteristics of materials. The absorption constant and refractive index of a metal can be calculated by measuring the effect of the metal on polarized light reflected from its surface. *See* REFLECTION OF ELECTROMAGNETIC RADIATION.

The analysis of polarized light can be performed with a variety of different devices. If the light is linearly polarized, it can be extinguished by a linear polarizer and the direction of polarization of the light determined directly from the orientation of the polarizer. If the light is elliptically polarized, it can be analyzed with the combination of a quarter-wave plate and a linear polarizer. Any such combination of polarizer and analyzer is called a polariscope. [B.H.Bi.]

Polarized light microscope

A microscope that utilizes polarized light to form a highly magnified image of an object. Polarizing microscopes play an important role in crystallography, petrography, microchemistry, and biology. Although all light microscopes compare poorly with electron microscopes with respect to image resolution, polarized light microscopes have the unique ability to deliver information about the submicroscopic structure of the objects being examined. They also have the advantage of being relatively nondestructive, and may be used safely with living cells. Polarized light interactions with electromagnetically anisotropic structures, down to atomic dimensions, can be measured by polarized light microscopy. The sensitivity of polarized light microscopy as well as its importance to biology have been enhanced by the use of video technology. *See* POLARIZED LIGHT.

A polarizing microscope differs from a conventional light microscope in a number of ways. A polarizing microscope has a pair of polars (polarizing devices) in the optical train. The first polar (polarizer) defines the initial plane of polarization for light entering the microscope and is located between the illuminator and the condenser. The other polar (analyzer) is usually placed between the objective and the ocular tube and defines the plane of polarization of the light reaching the ocular. One or both must be accurately rotatable about the optical axis of the instrument. Usually the analyzer is also removable from the optical path.

The most frequently used type of polar is a dichroic sheet polarizing filter. For petrographic, crystallographic, and most microchemical applications, dichroic filter polars are the better choice. For critical biological applications, such as investigating the weak birefringence of cytoskeletal structures in living cells, the expense and complication attendant to the use of prism polars can be justified by the attainment of sensitivity unobtainable by other means.

In addition to the polars, all polarizing microscopes need rotatable specimen stages and one or more removable birefringence compensators. The compensators are birefringent devices used to measure magnitude and sign of retardation due to specimen birefringence, to enhance specimen image contrast, and to manipulate the state of polarization of light passing through any point in the specimen. *See* BIREFRINGENCE.

Polarizing microscopes for different applications have some differences in construction. For petrography and crystallography, the microscope should be able to accept a universal specimen stage capable of rotating the specimen about three axes. A polarizing microscope for biological use has less rigid requirements for angular orientation but needs rectified optics (to eliminate or greatly reduce depolarization at high numerical apertures), prism polars, and a sensitive elliptic compensator because the birefringence of the typical biological specimen is much smaller. An ocular telescope or a Bertrand lens (a built-in lens that optionally converts the ocular into a telescope) is essential for some applications and useful for all.

There are two traditional modes of use for the polarizing microscope, the orthoscopic mode and the conoscopic mode. In the orthoscopic mode, the ocular projects an image of the specimen, as in conventional microscopy. Rotation of the specimen stage reveals the location and orientation of any anisotropic features in the specimen. The conoscopic mode is used to characterize crystalline specimens. Here the ocular is not used to project an image of the specimen, but rather—with the aid of a special lens—the image of the objective exit pupil is examined to reveal the relative retardation experienced by polarized light as a function of its angle of incidence on the specimen. *See* CRYSTAL OPTICS; MICROSCOPE. [G.W.E.]

Polarographic analysis An electrochemical technique used in analytical chemistry. Polarography involves measurements of current-voltage curves obtained when voltage is applied to electrodes (usually two) immersed in the solution being investigated. One of these electrodes is a reference electrode: its potential remains constant during the measurement. The second electrode is an indicator electrode. Its potential varies in the course of measurement of the current-voltage curve, because of the change of the applied voltage. In the simplest version, so-called dc polarography, the indicator electrode is a dropping-mercury electrode, consisting of a mercury drop hanging at the orifice of a fine-bore glass capillary. The capillary is connected to a mercury reservoir so that mercury flows through it at the rate of a few milligrams per second. The outflowing mercury forms a drop at the orifice, which grows until it falls off. The lifetime of each drop is several seconds (usually 2 to 5). Each drop forms a new electrode; its surface is practically unaffected by processes taking place on the previous drop. Hence each drop represents a well-reproducible electrode with a fresh, clean surface. *See* ELECTRODE; ELECTROCHEMICAL TECHNIQUES.

The dropping-mercury electrode is immersed in the solution to be investigated and placed in a cell containing the reference electrode. Polarographic current-voltage curves can be recorded with a simple instrument consisting of a potentiometer or another source of voltage and a current-measuring device. The voltage can be varied by manually changing the applied voltage in finite increments, measuring current at each, and plotting current as a function of the voltage. Alternatively, commercial instruments are available in which voltage is increased linearly with time (a voltage ramp), and current variations are recorded automatically.

Another polarographic technique is called pulse or differential pulse polarography. This technique is more sensitive by two orders of magnitude than dc polarography, and in inorganic trace analysis competes with atomic absorption and neutron activation analysis. The sensitivity of differential pulse polarography has found application in drug analysis. There is also a polarographic technique called ac polarography that is particularly useful for obtaining information on adsorption-desorption processes at the surface of the dropping-mercury electrode.

Polarographic studies can be applied to investigation of electrochemical problems, to elucidation of some fundamental problems of inorganic and organic chemistry, and to solution of practical problems. In electrochemistry, polarography allows measurement of potentials, and yields information about the rate of the electrode process, adsorption-desorption phenomena, and fast chemical reactions accompanying the electron transfer. In fundamental applications, polarography makes it possible to distinguish the form and charge of the species (for example, inorganic complex or organic ion) in the solution. Polarography also permits the study of equilibria (complex formation, acid-base, tautomeric), rates, and mechanisms.

Polarography can be used for investigation of the relationship between electrochemical data and structure. In inorganic analysis, polarography is used predominantly for trace-metal analysis (with increased sensitivity of differential pulse polarography and stripping analysis). In organic analysis, it is possible in principle to use polarography in elemental analysis and functional group analysis. The most important fields of application of inorganic determinations are in metallurgy, environmental analysis (air, water, and seawater contaminants), food analysis, toxicology, and clinical analysis. The possibility of being able to determine vitamins, alkaloids, hormones, terpenoid substances, and natural coloring substances has made polarography useful in analysis of biological systems, analysis of drugs and pharmaceutical preparations, and determination of pesticide or herbicide residues in foods. [P.Z.]

Polaron The object that results when an electron in the conduction band of a crystalline insulator or semiconductor polarizes or otherwise deforms the lattice in its vicinity. The polaron comprises the electron plus its surrounding lattice deformation. (Polarons can also be formed from holes in the valence band.) If the deformation extends over many lattice sites, the polaron is "large," and the lattice can be treated as a continuum. Charge carriers inducing strongly localized lattice distortions form "small" polarons. *See* BAND THEORY OF SOLIDS; HOLE STATES IN SOLIDS; SEMICONDUCTOR. [D.M.L.]

Poliomyelitis An acute infectious viral disease which in its serious form affects the central nervous system and, by destruction of motor neurons in the spinal cord, produces flaccid paralysis. However, about 99% of infections are either inapparent or very mild. *See* ANIMAL VIRUS; CENTRAL NERVOUS SYSTEM.

The virus probably enters the body through the mouth; primary multiplication occurs in the throat and intestine. Transitory viremia occurs; the blood seems to be the most likely route to the central nervous system. The severity of the infection may range from a completely inapparent through minor influenzalike illness, or an aseptic meningitis syndrome (nonparalytic poliomyelitis) with stiff and painful back and neck, to the severe forms of paralytic and bulbar poliomyelitis. In all clinical types, virus is regularly present in the enteric tract. In paralytic poliomyelitis the usual course begins as a minor illness but progresses, sometimes with an intervening recession of symptoms (hence biphasic), to flaccid paralysis of varying degree and persistence. When the motor neurons affected are those of the diaphragm or of the intercostal muscles, respiratory paralysis occurs. Bulbar poliomyelitis results from viral attack on the medulla (bulb of the brain) or higher brain centers, with respiratory, vasomotor, facial, palatal, or pharyngeal disturbances.

Poliomyelitis occurs throughout the world. In temperate zones it appears chiefly in summer and fall, although winter outbreaks have been known. It occurs in all age groups, but less frequently in adults because of their acquired immunity. The virus is spread by human contact; the nature of the contact is not clear, but it appears to be associated with familial contact and with interfamily contact among young children. The virus may be present in flies.

Inactivated poliovirus vaccine (Salk; IPV), prepared from virus grown in monkey kidney cultures, was developed and first used in the United States, but oral poliovirus vaccine (Sabin; OPV) is now generally used throughout the world. The oral vaccine is a living, attenuated virus. [J.L.Me.]

Pollen The small male reproductive bodies produced in the pollen sacs of seed plants (gymnosperms and angiosperms).

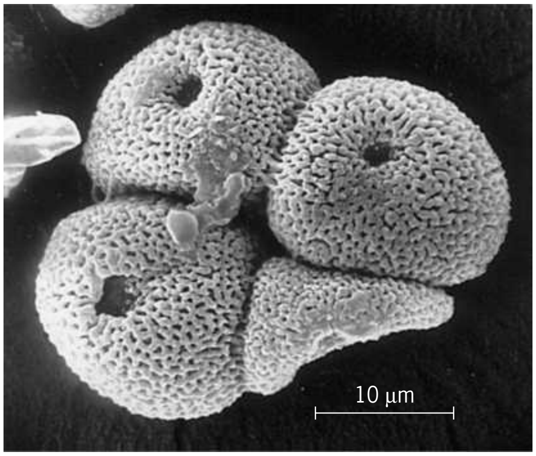

Fig. 1. Tetrad of cattail (*Typha latifolia*), with grains cohering, one-pored, exine reticulate. (*Scanning electron micrograph by C. M. Drew, U.S. Naval Weapons Center, Cina Lake, California*).

On maturation in the pollen sac, a pollen grain may reach 0.00007 mg as in spruce, or less than 1/20 of this weight. A grain usually has two waxy, durable outer walls, the exine, and an inner fragile wall, the intine. These walls surround the contents with their nuclei and reserves of starch and oil.

Pollen identification depends on interpretation of morphological features. Exine and aperture patterns are especially varied in the more highly evolved dicots, so that recognition at family, genus, or even species level may be possible despite the small surface area available on a grain (Figs. 1 and 2). Since the morphological characters are conservative in the extreme, usually changing very slowly through geologic time, studies of fine detail serve to establish the lineal descent of many plants living today. *See* PALYNOLOGY.

Extreme variations in size may occur within a family, but pollen grains range mainly from 24 to 50 micrometers, with the dicot range being from 2 μm in *Myosotis* to 250 μm in *Mirabilis*; the monocots range from about 15 to 150 μm or more in the ginger family, with eelgrass (*Zostera*) having pollen measuring 2550 × 3.7 μm in a class of its own; living gymnosperms range from 15 μm in *Gnetum* to about 180 μm in *Abies* (including sacs), while fossil types range from about 11 μm (one-furrowed) to 300 μm.

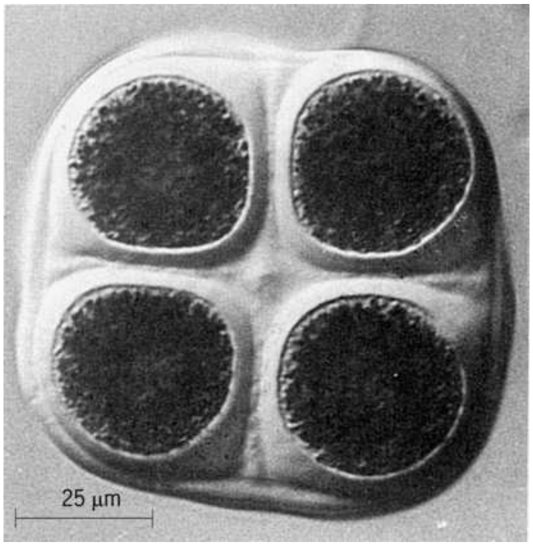

Fig. 2. Young tetrad of *Lavatera* (mallow family), with grains free in callose of pollen mother cell. (*Photomicrograph by Luc Waterkeyn*)

Most grains are free (monads) though often loosely grouped because of the spines or sticky oils and viscin threads. Compound grains (polyads) are richly developed in some angiosperm families, commonly occurring in four (tetrads), or in multiples of four up to 64 or more.

In most microspores (pollen and spore) the polar axis runs from the inner (proximal) face to the outer (distal) face, as oriented during tetrad formation. The equator crosses it at right angles. Bilateral grains dominate in the gymnosperms and monocots, the polar axis usually being the shorter one, with the single aperture on the distal side. On the other hand, almost all dicot pollen is symmetrical around the polar axis (usually the long axis), with shapes ranging mainly from spheroidal to ellipsoidal, with rounded equatorial outlines, and sometimes "waisted" as in the Umbelliferae. Three-pored grains often have strikingly triangular outlines in polar view.

Rarely lacking, the flexible membranes of apertures are sometimes covered only by endexine. They allow for sudden volume changes, as for the emergence of the germ tube. They are classified as furrows, with elongate outlines, and pores usually more or less circular in shape. Short slitlike intermediate forms occur. A few families have no apertures, some as a result of reduction of exine as an adaptation to wind- or water-pollination. Gymnosperms may also lack openings, or have one small papilla; most have one furrow, or a long weak area.

Few pollen grains are completely smooth (psilate) at ordinary magnifications; most have sculpture both on the surface and the structure below it. *See* FLOWER; POLLINATION; REPRODUCTION (PLANT). [L.M.C.]

Pollination

The transport of pollen grains from the plant parts that produce them to the ovule-bearing organs, or to the ovules (seed precursors) themselves. In gymnosperms, the pollen, usually dispersed by the wind, is simply caught by a drop of fluid excreted by each freely exposed ovule. In angiosperms, where the ovules are contained in the pistil, the pollen is deposited on the pistil's receptive end (the stigma), where it germinates. *See* FLOWER.

Without pollination, there would be no fertilization; it is thus of crucial importance for the production of fruit crops and seed crops. Pollination also plays an important part in plant breeding experiments aimed at increasing crop production through the creation of genetically superior types. *See* BREEDING (PLANT); REPRODUCTION (PLANT).

Self- and cross-pollination. In most plants, self-pollination is difficult or impossible, and there are various mechanisms which are responsible. For example, in dichogamous flowers, the pistils and stamens reach maturity at different times; in protogyny, the pistils mature first, and in protandry, the stamens mature before the pistils. Selfing is also impossible in dioecious species, where some plants bear flowers that have only pistils (pistillate or female flowers), while other individuals have flowers that produce only pollen (staminate or male flowers). In monoecious species, where pistillate and staminate flowers are found in the same plant, self-breeding is at least reduced. Heterostyly is another device that promotes outbreeding. Here some flowers (pins) possess a long pistil and short stamens, while others (thrums) exhibit the reverse condition; each plant individual bears only pins or only thrums.

Flower attractants. As immobile organisms, plants normally need external agents for pollen transport. These can be insects, wind, birds, mammals, or water, roughly in that order of importance. In some plants the pollinators are simply trapped; in the large majority of cases, however, the flowers offer one or more rewards, such as sugary nectar, oil, solid food bodies, perfume, sex, an opportunity to breed, a place to sleep, or some of the pollen itself. For the attraction of pollinators, flowers provide either visual or olfactory signals. Color includes ultraviolet, which is perceived as a color by most insects and at least some hummingbird species. Fragrance is characteristic of flowers pollinated by bees, butterflies, or hawkmoths, while carrion or dung odors are produced by flowers catering to certain beetles and flies. A few orchids, using a combination of olfactory and visual signals, mimic the females of certain bees or wasps so successfully that the corresponding male insects will try to mate with them, thus achieving pollination (pseudocopulation).

While some flowers are "generalists," catering to a whole array of different animals, others are highly specialized, being pollinated by a single species of insect only. Extreme pollinator specificity is an important factor in maintaining the purity of plant species in the field, even in those cases where hybridization can easily be achieved artificially in a greenhouse or laboratory, as in most orchids. The almost incredible mutual adaptation between pollinating animal and flower which can frequently be observed exemplifies the idea of coevolution. *See* POLLEN. [B.J.D.M.]

Polonium A chemical element, Po, atomic number 84. Marie Curie discovered the radioisotope ^{210}Po in pitchblende. This isotope is the penultimate member of the radium decay series. All polonium isotopes are radioactive, and all are short-lived except the three α-emitters, artificially produced ^{208}Po (2.9 years) and ^{209}Po (100 years), and natural ^{210}Po (138.4 days). *See* PERIODIC TABLE.

Polonium (^{210}Po) is used mainly for the production of neutron sources. It can also be used in static eliminators and, when incorporated in the electrode alloy of spark plugs, is said to improve the cold-starting properties of internal combustion engines.

Most of the chemistry of polonium has been determined using ^{210}Po, 1 curie of which weighs 222.2 micrograms; work with weighable amounts is hazardous, requiring special techniques. Polonium is more metallic than its lower homolog, tellurium. The metal is chemically similar to tellurium, forming the bright red compounds $SPoO_3$ and $SePoO_3$. The metal is soft, and its physical properties resemble those of thallium, lead, and bismuth. Valences of 2 and 4 are well established; there is some evidence of hexavalency. Polonium is positioned between silver and tellurium in the electrochemical series.

Two forms of the dioxide are known: low-temperature, yellow, face-centered cubic (UO_2 type), and high-temperature, red, tetragonal. The halides are covalent, volatile compounds, resembling their tellurium analogs. *See* RADIOACTIVITY; TELLURIUM. [K.W.B.]

Poly(ethylene glycol) Any of a series of water-soluble polymers with the general formula $HO{-}(CH_2{-}CH_2{-}O)_n{-}H$. These colorless, odorless compounds range in appearance from viscous liquids to waxy solids. The low-molecular-weight members, diethylene glycol ($n = 2$) through tetraethylene glycol ($n = 4$), are produced as pure compounds and find use as humectants, dehydrating solvents for natural gas, textile lubricants, heat-transfer fluids, solvents for aromatic hydrocarbon extractions, and intermediates for polyester resins and plasticizers.

The intermediate members of the series with average molecular weights of 200 to 20,000 are used commercially in ceramic, metal-forming, and rubber-processing operations; as drug suppository bases and in cosmetic creams, lotions, and deodorants; as lubricants; as dispersants for casein, gelatins, and inks; and as antistatic agents. The highest members of the series have molecular weights from 100,000 to 10,000,000. They are of interest because of their ability at very low concentrations to reduce friction of flowing water. *See* ETHYLENE OXIDE; GLYCOLIPID; POLYMERIZATION. [R.K.B.]

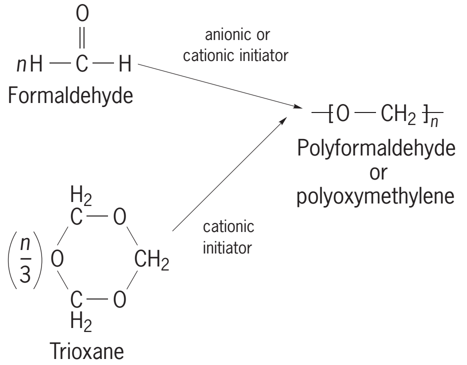
Poly(ethylene glycol) has a range of properties making it suitable for medical and biotechnical applications. Since poly(ethylene glycol) is soluble both in water and in most organic solvents, many applications are derived from this amphiphilicity. Other properties include lack of toxicity and immunogenicity, and a tendency to avoid other polymers and particles also present in aqueous solution.

Poly(ethylene glycol) is attached to drugs to enhance water and blood solubility. Similarly, poly(ethylene glycol) is attached to enzymes to impart solubility in organic solvents. These poly(ethylene glycol) enzymes are used as catalysts for industrial reactions in organic solvents. *See* CATALYSIS.

The tendency of poly(ethylene glycol) to avoid interaction with cellular and molecular components of the immune system results in the material being nonimmunogenic. This property leads to a greatly enhanced blood circulation lifetime of poly(ethylene glycol) proteins and to application as pharmaceuticals. Similarly, adsorption of proteins and cells to surfaces is greatly reduced by attaching poly(ethylene glycol) to the surface, and such coated materials find wide application as biomaterials. *See* BIOMEDICAL CHEMICAL ENGINEERING. [J.M.Ha.]

Polyacetal A polyether derived from aldehydes (RCHO) or ketones (RR′CO) and containing —O—R—O— groups in the main chain. Of the many possible polyacetals, the most common is a polymer or copolymer of formaldehyde, polyoxymethylene $({-}O{-}CH_2{-})_n$. While the substance paraformaldehyde contains oligomers or low-molecular-weight polyoxymethylenes (n very small), high-molecular-weight, crystalline polyoxymethylenes constitute an important class of engineering plastics that, in commerce, is often simply referred to as polyacetal. Cellulose and its derivatives also have a polyacetal structure. *See* ACETAL; CELLULOSE; FORMALDEHYDE; POLYETHER RESINS; POLYMER.

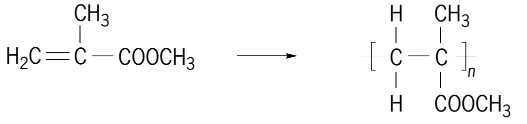
As shown below, formaldehyde can be readily polymerized by using anionic initiators such as triphenylphosphine and, somewhat less readily, by using cationic initiators such as protonic acids. Alternatively, a similar polymer can be obtained by the ring-opening polymerization of trioxane using, for example, a boron trifluoride complex as initiator. *See* POLYMERIZATION.



At temperatures above ~110°C (230°F; the ceiling temperature, above which depolymerization becomes favored over polymerization), the polymers degrade by an unzipping reaction to monomer. To prevent this, one of two approaches is commonly used: esterification of the hydroxyl end groups, or copolymerization with a small amount of a monomer such as ethylene oxide or 1,3-dioxolane.

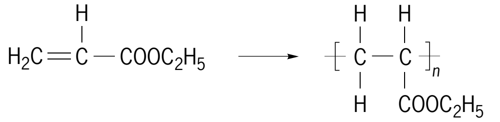
Polyacetals are typically strong and tough, resistant to fatigue, creep, organic chemicals (but not strong acids or bases), and have low coefficients of friction. Electrical properties are also good. Improved properties for particular applications may be attained by reinforcement with fibers of glass or polytetrafluoroethylene, and by incorporation of an elastomeric toughening phase. The combination of properties has led to many uses such as plumbing fittings, pump and valve components, bearings and gears, computer hardware, automobile body parts, and appliance housings. [J.A.M.]

Polyacrylate resins Polymers obtained from a variety of acrylic monomers, such as acrylic and methacrylic acids, their salts, esters, and amides, and the corresponding nitriles. The most important monomers with corresponding repeat units are shown here.



$$H_2C{=}\overset{CH_3}{\underset{}{C}}{-}COOCH_3 \longrightarrow \left[\overset{H}{\underset{H}{C}} - \overset{CH_3}{\underset{COOCH_3}{C}} \right]_n$$

Methyl methacrylate Poly(methyl methacrylate)



$$H_2C{=}\overset{H}{C}{-}COOC_2H_5 \longrightarrow \left[\overset{H}{\underset{H}{C}} - \overset{H}{\underset{COOC_2H_5}{C}} \right]_n$$

Ethyl acrylate Poly(ethyl acrylate)

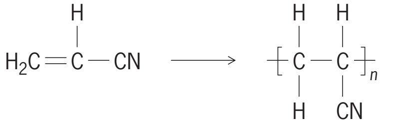
Poly(methyl methacrylate) is a hard, transparent polymer with high optical clarity, high refractive index, and good resistance to the effects of light and aging. It and its copolymers are useful for lenses, signs, indirect lighting fixtures, transparent domes and skylights, dentures, and protective coatings.

Solutions of poly(methyl methacrylate) and its copolymers are useful as lacquers. Aqueous latexes formed by the emulsion polymerization of methyl methacrylate with other monomers are useful as water-based paints and in the treating of textiles and leather.

Poly(ethyl acrylate) is a tough, somewhat rubbery product. The monomer is used mainly as a plasticizing or softening component of copolymers.

Methyl methacrylate is of interest as a polymerizable binder for sand or other aggregates, and as a polymerizable impregnant for concrete; usually a cross-linking acrylic monomer is also incorporated. The binder systems (polymer concrete) are used as overlays for bridge decks as well as for castings, while impregnation is used to restore concrete structures and protect bridge decks against corrosion by deicing salts. *See* Plastics processing; Polymerization. [J.A.M.]

Polyacrylonitrile resins Hard, relatively insoluble, and high-melting materials produced by the polymerization of acrylonitrile, as shown in the reaction below. Polyacrylonitrile is used almost entirely in copolymers. The copolymers fall into three groups: fibers, plastics, and rubbers. The presence of acrylonitrile in a polymeric composition tends to increase its resistance to temperature, chemicals, impact, and flexing. The polymerization of acrylonitrile can be readily initiated by means of the conventional free-radical catalysts such as peroxides, by irradiation, or by the use of alkali metal catalysts. Although polymerization in bulk proceeds too rapidly to be commercially feasible, satisfactory control of a polymerization or copolymerization may be achieved in suspension and in emulsion, and in aqueous solutions from which the polymer precipitates. Copolymers containing acrylonitrile may be fabricated in the manner of thermoplastic resins.



$$H_2C{=}\overset{H}{C}{-}CN \longrightarrow \left[\overset{H}{\underset{H}{C}} - \overset{H}{\underset{CN}{C}} \right]_n$$

(Acrylonitrile) (Polyacrylonitrile)

The major use of acrylonitrile is in the form of fibers. By definition, an acrylic fiber must contain at least 85% acrylonitrile. The high strength; high softening temperature; resistance to aging, chemicals, water, and cleaning solvents; and the soft woollike feel or fabrics have made the product popular for many uses such as sails, cordage, blankets, and various types of clothing. *See* Manufactured fiber.

Copolymers of vinylidene chloride with small proportions of acrylonitrile are useful as tough, impermeable, and heat-sealable packaging films. Extensive use is made of copolymers of acrylonitrile with butadiene, often called NBR (formerly Buna N) rubbers, which contain 15–40% acrylonitrile. The NBR rubbers resist hydrocarbon solvents such as gasoline, abrasion, and in some cases show high flexibility at low temperatures. *See* Rubber.

The development of blends and interpolymers of acrylonitrile-containing resins and rubbers represented a significant advance in polymer technology. The products, usually called ABS resins, typically are made by blending acrylonitrile-styrene copolymers with a butadiene-acrylonitrile rubber, or by interpolymerizing polybutadiene with styrene and acrylonitrile. The combination of low cost, good mechanical properties, and ease of fabrication by a variety of methods led to the rapid development of new uses for ABS resins. Applications include products requiring high impact strength, such as pipe, and sheets for structural uses, such as industrial duct work and components of automobile bodies. *See* Acrylonitrile; Plastics processing; Styrene. [J.A.M.]

Polyamide resins Products of polymerization of an amino acid or the condensation of a diamine with a dicarboxylic acid. They are used for fibers, bristles, bearings, gears, molded objects, coatings, and adhesives. The term nylon formerly referred specifically to synthetic polyamides as a class. Because of many applications in mechanical engineering, nylons are considered engineering plastics.

The most common commercial aliphatic polamides are nylons-6,6; -6; -6,10; -11; and -12. Nylon-6,6, nylon-6,10, nylon-6,12, and nylon-6 are the most commonly used polyamides for general applications as molded or extruded parts; nylon-6,6 and nylon-6 find general application as fibers.

As a group, nylons are strong and tough. Mechanical properties depend in detail on the degree and distribution of crystallinity, and may be varied by appropriate thermal treatment or by nucleation techniques. Because of their generally good mechanical properties and adaptability to both molding and extrusion, certain nylons are often used for gears, bearings, and electrical mountings. Nylon bearings and gears perform quietly and need little or no lubrication. Nylon resins are also used extensively as filaments, bristles, wire insulation, appliance parts, and film. Properties can also be modified by copolymerization. Reinforcement of nylons with glass fibers results in increased stiffness, lower creep and improved resistance to elevated temperatures. *See* Heterocyclic polymer; Plastics processing; Polyether resins; Polymerization. [J.A.M.]

Polychaeta The largest class of the phylum Annelida, containing 68–70 families. About 1600 genera and 10,000 species have been named from worldwide areas; about one-fourth of this number may be synonymous. Polychaeta (meaning “many setae”) is conveniently though not clearly divisible into the Errantia, or free-moving annelids, and Sedentaria, or tubicolous families. *See* Errantia; Sedentaria.

The body may be long, cylindrical, and multisegmented, or short and compact, with a limited number of segments. It consists of prostomium (Fig. 1), or head; peristomium, or first segment around the mouth; trunk, or body proper; and tail region, or pygidium. Most segments have highly diagnostic paired, lateral fleshy appendages called parapodia. These are provided with secreted supporting rods and spreading fascicles of setae, or hooks, which display remarkable specificity.

The anterior end, or prostomium, may be a simple lobe derived from the larval trochophore, modified as a pseudoannulated cone, or covered by peristomial structures so as to be invisible. Oral tentacles for food gathering may be eversible from the buccal cavity; they may be long, slender, or thick and their surface smooth or papillated.

The anterior, preoral end may be developed as a thick, fleshy papillated, nonretractile proboscis (Fig. 2), or the prostomium may be completely retractile into the first several segments and protected by a cage formed of setae directed forward, or

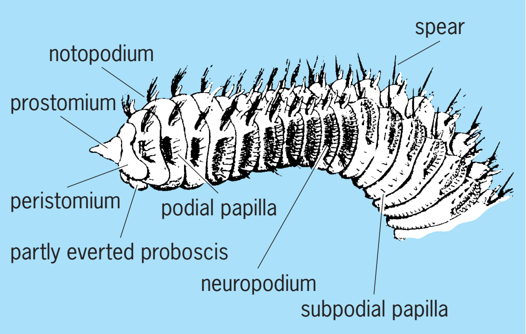


Fig. 1. Terminology of the anterior parts of the body, based on *Phylo* (Orbiniidae).

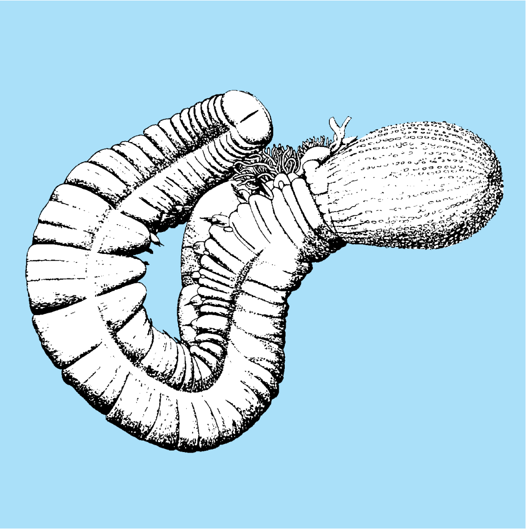

Fig. 2. Nonretractile proboscis organ preceding prostomium in *Artacama* (Terebellidae).

concealed by a compact operculum formed of setae of the first several segments. The anterior end of the alimentary tract is muscular or epithelial; it may be covered with soft papillae or hard structures. These structures function for secretion, food gathering, and maintaining traction; they are named for their form or function.

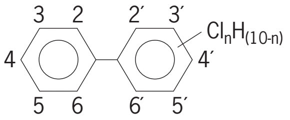
The trunk is the main body region and is composed of metameres numbering few to many. They may be similar to one another (homonomous) as in Errantia, or different (heteronomous) resulting in anterior thoracic and posterior abdominal regions.

Reproduction is highly evolved and diversified; it can be sexual or asexual. Sexual reproduction is usually dioecious, with the two sexes similar. In rare cases it is dimorphic.

Polychaetes range in length from a fraction of 0.04 in. (1 mm) to more than 144 in. (360 cm). Colors and patterns are varied and specific, due to pigment and refraction of light. Littoral, warm-water species may be brilliant and multicolored, whereas polar and deep-water species tend to be drab or sometimes melanistic to almost black.

Most polychaetes are free-living; some of the remaining members are commensal with another animal for attachment surface, for food, or for protection. Polychaetes are distributed in all marine habitats and show remarkable specificity according to latitude, depth, and kinds of substrata. Most of the families tend to be represented in any major geographic area, although taxa may differ with place. *See* Annelida. [O.H.]

Polychlorinated biphenyls A generic term for a family of 209 chlorinated isomers of biphenyl. The biphenyl molecule is composed of two six-sided carbon rings connected at one carbon site on each ring. Ten sites remain for chlorine atoms to join the biphenyl molecule. The term polychlorinated biphenyl (PCB) has been used to refer to the biphenyl molecule with one to ten chlorine substitutions, as shown below.



Polychlorinated biphenyl (PCB)

PCBs were introduced into United States industry on a large scale in 1929. The qualities that made PCBs attractive were chemical stability, resistance to heat, low flammability, and high dielectric constant. The PCB mixture is a colorless, viscous fluid, is relatively insoluble in water, and can withstand high temperatures without degradation (higher-chlorinated isomers are not readily degraded in the environment).

The major use of PCBs has been as dielectric fluid in electrical equipment, particularly transformers capacitors, electromagnets, circuit breakers, voltage regulators, and switches. PCBs have also been used in heat transfer systems and hydraulic systems, and as plasticizers and additives in lubricating and cutting oils. *See* Dielectric materials.

PCBs have been reported in animals, plants, soil, and water all over the world, even in animals living under 11,000 ft (3400 m) of water. These phenomena are the result of bioaccumulation and biomagnification in the food chain. In a few instances, poultry products, cattle, and hogs have been found to contain high concentrations of PCBs after the animals have eaten feed contaminated with PCBs. It is not known what quantities of PCBs have been released to the environment, but major sources are industrial and municipal waste disposal, spills and leaks from PCB-containing equipment, and manufacture and handling of PCB mixtures. *See* Atmospheric general circulation; Biosphere; Food web; Human ecology.

PCBs can enter the body through the lungs, gastrointestinal tract, and skin, circulate throughout the body, and be stored in adipose tissue. PCBs have been detected in human adipose tissues and in the milk of cows and humans. Some PCBs have the ability to alter reproductive processes in mammals. There is concern that PCBs may be carcinogenic in humans. [G.Ku.]

Polycladida A class of marine Turbellaria which are several millimeters to several centimeters in length and whose leaflike bodies have a central intestine with radiating branches. Most species live in the littoral zone on the bottom, on seaweed or on other objects, or as commensals in the shells of mollusks and hermit crabs. None are parasitic. Except in warm waters, they are seldom brightly colored. *See* Turbellaria. [E.R.J.]

Polyester resins Synthetic polymers made by esterification of dicarboxylic acids with diols. The aliphatic polyesters tend to be relatively soft, and the aromatic derivatives are usually hard and brittle, or tough. The properties of either group may be modified by cross linking, crystallization, plasticizers, or fillers. *See* Ester.

The commercial products are alkyds which are used in paints, enamels, and molding compounds; unsaturated polyesters or unsaturated alkyds which are used extensively with fiber glass for boat hulls and panels; aliphatic saturated polyesters; aromatic polyesters, such as polyethylene terephthalate which is used in the form of fibers and films; and the aromatic polycarbonates. The polydiallyl esters, while frequently listed with the polyesters, are not true polyesters as defined above. *See* Polyvinyl resins.

The alkyds are commonly used as coatings. Combinations of conventional vegetable drying oils and alkyd resins represent the basis of most of the oil-soluble paints. The drying oil–alkyd may be further modified by the inclusion of a vinyl monomer, such as styrene. Some of the styrene polymerizes, probably as a graft polymer, and the remainder polymerizes and copolymerizes in the final drying or curing of the pain. *See* DRYING OIL; PAINT; POLYMERIZATION.

The unsaturated polyesters, in combination with glass fiber, have found applications as panels, roofing, radar domes, boat hulls, and protective armor for soldiers. The compositions are distinguished by ease of fabrication and high impact resistance. *See* POLYMERIC COMPOSITE.

Saturated aliphatic polyesters have long been frequently used as intermediates in the preparation of prepolymers for making segmented polyurethanes. Lactone rings can also be opened to yield linear polyesters.

The aromatic polyesters which have achieved general importance are the polyethylene terephthalates, which yield very strong and chemically resistant fibers and films. Polyethylene terephthalate is the principal ingredient of polyester fibers. Polyethylene terephthalate may be molded or extruded to yield materials that can replace metals or thermoset resins in some automotive, electrical, and specialty applications, especially when reinforced with glass fibers or mineral fillers.

Aromatic polycarbonates are a strong, tough group of thermoplastic polymers formed most frequently from bisphenol A and phosgene. The products, polycarbonates, are noted for high softening temperatures, and high impact resistance, clarity, and resistance to creep. Polycarbonate is usually available as a molding compound. Because of its high strength, toughness, and softening point, the resin, both by itself and as a glass-reinforced material, has found many electrical domestic and engineering applications. It is often used to replace glass and metals. Examples include bottles, unbreakable windows, applicance parts, electrical housings, marine propellers, and shotgun shells. Flame-retardant grades are of interest because of low toxicity and smoke emission on burning.

Polydiallyl esters are polymers of diallyl esters. Thermosetting molding compounds may be produced by careful limitation of the initial polymerization to yield a product which is fusible. Major applications are in electronic components, sealants, coatings, and glass-fiber composites. *See* PLASTICS PROCESSING. [J.A.M.]

Polyether resins Thermoplastic or thermosetting materials which contain ether-oxygen linkages, —C—O—C—, in the polymer chain. Depending upon the nature of the reactants and reaction conditions, a large number of polyethers with a wide range of properties may be prepared. The main groups of polyethers in use are epoxy resins, phenoxy resins, polyethylene oxide and polypropylene oxide resins, polyoxymethylene, and polyphenylene oxides.

The epoxy resins form an important and versatile class of cross-linked polyethers characterized by excellent chemical resistance, adhesion to glass and metals, electrical insulating properties, and ease and precision of fabrication. Various fillers such as calcium carbonate, metal fibers and powders, and glass fibers are commonly used in epoxy formulations in order to improve such properties as the strength and resistance to abrasion and high temperatures. Some reactive plasticizers act as curing agents, become permanently bound to the epoxy groups, and are usually called flexibilizers. Rubbery polymers are added to improve toughness and impact strength. Epoxies are commonly used in protective coatings. They are used as potting or encapsulating compositions for the protection of delicate electronic assemblies from the thermal and mechanical shock of rocket flight, and as dies for stamping metal forms.

Polyethylene oxide and polypropylene oxide are thermoplastic products whose properties are greatly influenced by molecular weight. Low-to-moderate-molecular-weight polyethylene oxides vary in form from oils to waxlike solids. They are relatively nonvolatile, are soluble in a variety of solvents, and have found many uses as thickening agents, plasticizers, lubricants for textile fibers, and components of various sizing, coating, and cosmetic preparations. The polypropylene oxides of similar molecular weight have somewhat similar properties, but tend to be more oil-soluble (hydrophobic) and less water-soluble (hydrophilic). While polyalkylene oxides are not of interest as such in structural materials, polypropylene oxides are used extensively in the preparation of polyurethane foams.

Phenoxy resins are transparent, strong, ductile, and resistant to creep, and, in general, resemble polycarbonates in their behavior. The major application is as a component in protective coatings, especially in metal primers. *See* POLYESTER RESINS.

Polyphenylene oxide (PPO) is the basis for an engineering plastic characterized by chemical, thermal, and dimensional stability. Polyphenylene oxide is outstanding in its resistance to water. Uses include medical instruments, pump parts, and insulation.

Polyoxymethylene, or polyacetal, resins are polymers of formaldehyde. Having high molecular weights and high degrees of crystallinity, they are strong and tough and are established in the general class of engineering thermoplastics. Polyacetals are typically resistant to fatigue, creep, organic chemicals (but not strong acids or bases), and have low coefficients of friction. Electrical properties are also good. The combination of properties has led to many uses such as plumbing fittings, pump and valve components, bearings and gears, computer hardware, automobile body parts, and appliance housings. *See* PLASTICS PROCESSING; POLYMERIZATION. [J.A.M.]

Polyfluoroolefin resins Resins distinguished by their resistance to heat and chemicals and by the ability to crystallize to a high degree. Several main products are based on tetrafluoroethylene, $F_2C{=}CF_2$ (TFE); hexafluoropropylene, $F_2C{=}CFCF_3$ (HFP); and monochlorotrifluoroethylene, $FClC{=}CF_2$ (CTFE).

Poly(tetrafluoroethylene) is the polymer of tetrafluoroethylene and is commonly known by the trade name Teflon®. It is insoluble, resistant to heat (up to 275°C or 527°F) and chemical attack, and has the lowest coefficient of friction of any solid. However, special surface treatments are required to ensure adhesion because poly(tetrafluoroethylene) does not adhere well to anything. Poly(tetrafluoroethylene) (TFE resin) is used for bearings, valve seats, packings, gaskets, coatings and tubing, and can withstand relatively severe conditions. Because of its excellent electrical properties, poly(tetrafluoroethylene) is useful when a dielectric material is required for service at a high temperature. The nonadhesive quality is often used to coat articles such as rolls and cookware to which materials might otherwise adhere.

The properties of poly(chlorotrifluoroethylene) (CTFE resin) are generally similar to those of poly(tetrafluoroethylene); however, the presence of the chlorine atoms in the former causes the polymer to be a little less resistant to heat and to chemicals. The applications of poly(chlorotrifluoroethylene) are in general similar to those for poly(tetrafluoroethylene). Because of its stability and inertness, the polymer is useful in the manufacture of gaskets, linings, and valve seats that must withstand hot and corrosive conditions. It is also used as a dielectric material, as a vapor and liquid barrier, and for microporous filters.

Poly(vinylidene fluoride) properties has generally similar to those of the other fluorinated resins: relative inertness, low dielectric constant, and thermal stability (up to about 150 or 300°F). The resins (PVF_2 resins) are, however, stronger and less susceptible to creep and abrasion than TFE and CTFE resins. Applications of poly(vinylidene fluoride) are mainly as electrical insulation, piping, process equipment, and as a protective coating in the form of a liquid dispersion.

Several types of fluorinated, noncrystallizing elastomers were developed in order to meet needs (usually military) for rubbers which possess good low-temperature behavior with a high degree of resistance to oils and to heat, radiation, and weathering. *See* HALOGENATED HYDROCARBON; PLASTICS PROCESSING; POLYMERIZATION. [J.A.M.]

Polygalales An order of flowering plants, division Magnoliophyta (Angiospermae), in the subclass Rosidae of the class Magnoliopsida (dicotyledons). The order consists of 7 families and nearly 2300 species, mostly of tropical and subtropical regions. The vast majority of the species belong to only 3 families, the Malpighiaceae (about 1200 species), Polygalaceae (about 750 species), and Vochysiaceae (about 200 species). Within its subclass the order is distinguished by its simple leaves and usually irregular flowers, which have the perianth and stamens attached directly to the receptacle (hypogynous), and often have the anthers opening by terminal pores instead of longitudinal slits. The Barbados cherry (*Malpighia glabra*), noted for the high vitamin-C content of its fruits, is a well-known member of the Polygalales. *See* MAGNOLIOPSIDA; PLANT KINGDOM; ROSIDAE. [A.Cr.; T.M.Ba.]

Polygon A geometric figure consisting of an ordered set of three or more (but a finite number of) points called vertices, each vertex connected by line segments called sides or edges to two other vertices. These two sides are said to be adjacent, and so are any two vertices that are end points of a side. The perimeter of the polygon is the sum of the lengths of the sides. The line segments that join two nonadjacent vertices of a polygon are called diagonals. A polygon is said to be directed, or oriented, if a preferred direction is assigned to each side so that at each vertex one of the adjacent sides is directed toward the vertex and the other away from it.

The angle between the two sides of a polygon at a vertex is called an angle of the polygon. Thus an n-sided polygon, called an n-gon, has n vertices and n angles. In particular, if n is 3, 4, 5, 6, 7, 8, 10, or 12, the polygon is called a triangle (3), quadrangle (4) [or quadrilateral, meaning four sides], pentagon (5), hexagon (6), heptagon (7), octagon (8), decagon (10), or dodecagon (12).

A plane polygon is one whose vertices all lie in the same plane. Other polygons are called skew polygons, except for the spherical polygons described below. Skew polygons can be constructed in any number of dimensions.

A plane polygon is called ordinary if no point belongs to more than two edges; it is proper if no two adjacent sides are collinear; it is simple if no two edges intersect each other except at vertices. A simple polygon divides the plane into two regions: an unbounded outside region and an inside region whose area is called the area of the polygon.

A simple polygon is called convex if its interior lies entirely on one side of each (infinite) line through any two adjacent vertices. A nonconvex polygon has at least one interior angle that exceeds 180°. The sum of the interior angles in a convex n-gon is $(n-2)180^\circ$. A plane polygon is called regular if all its sides are equal and all its angles are equal; it is semiregular if all its angles are equal. *See* REGULAR POLYTOPES.

A spherical polygon consists of points on a spherical surface called vertices, each connected to two adjacent vertices by great-circle arcs, called sides, that are measured by their central angles. The n angles of a convex spherical n-gon are the angles at each vertex between the tangent lines to the two sides that meet there, and their sum exceeds $(n-2)180^\circ$ by an amount, called the spherical excess, that is proportional to the spherical area enclosed by the polygon. [J.S.Fra.]

Polygonales An order of flowering plants, division Magnoliophyta (Angiospermae), in the subclass Caryophyllidae of the class Magnoliopsida (dicotyledons). The order consists only of the family Polygonaceae, with about 800 species, most abundant in north temperate regions. Within its subclass the order is characterized by its well-developed endosperm; an ovary with but one chamber (unilocular), mostly tricarpellate with a single basal ovule which is usually straight and has the micropyle at the opposite end from the stalk (orthotropous); the flowers are often trimerous, that is, with floral parts in sets of three, and usually two or three sets of stamens. Rhubarb (*Rheum rhaponticum*) and buckwheat (*Fagopyrum esculentum*) are familiar members of the Polygonales. *See* BUCKWHEAT; CARYOPHYLLIDAE; MAGNOLIOPSIDA; RHUBARB. [A.Cr.]

Polyhedron A solid whose boundary consists of a finite number of polygonal faces, that is, planar regions that are bounded by polygons. The sides of the faces are edges of the polyhedron; the vertices of the faces also are vertices of the polyhedron. *See* PLANE GEOMETRY; POLYGON.

Most polyhedra met in applied geometry are convex and simply connected. A polyhedron is convex if it passes this test: if any face is placed coincident with a plane, then all other points of the polyhedron lie on the same side of that plane. A more informal test is to imagine enclosing the polyhedron within a stretched elastic membrane; the polyhedron is convex if all points on the boundary are in contact with the membrane. A simply connected polyhedron has a boundary that is topologically equivalent to a sphere: if the boundary were made of some perfectly elastic material, then the boundary could be distorted into a sphere without tearing or piercing the surface. A simply connected polyhedron is said to be eulerian, because the number of faces F, the number of edges E, and the number of vertices V satisfy Euler's formula:

$$F + V = E + 2$$

Polyhedra exist having any number of faces greater than three. Some polyhedra have names that convey the number of faces (but not the shape) of the polyhedron: tetrahedron, 4 faces; pentahedron, 5 faces; hexahedron, 6 faces; octahedron, 8 faces; dodecahedron, 12 faces; and icosahedron, 20 faces.

A polyhedron is regular (or platonic) if all faces are congruent and all dihedral angles (the angles between adjacent faces) are equal. There are only five regular polyhedra: the tetrahedron, cube, octahedron, dodecahedron, and icosahedron. [H.L.Ba.]

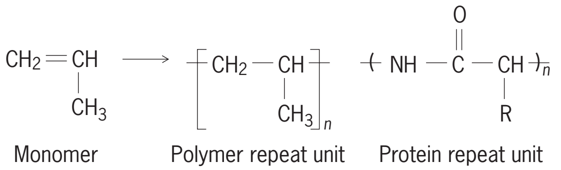
Polymer Polymers, macromolecules, high polymers, and giant molecules are high-molecular-weight materials composed of repeating subunits. These materials may be organic, inorganic, or organometallic, and synthetic or natural in origin. Polymers are essential materials for almost every industry as adhesives, building materials, paper, cloths, fibers, coatings, plastics, ceramics, concretes, liquid crystals, photoresists, and coatings. They are also major components in soils and plant and animal life. They are important in nutrition, engineering, biology, medicine, computers, space exploration, health, and the environment. *See* CERAMICS; MANUFACTURED FIBER; NATURAL FIBER; SURFACE COATING.

Natural inorganic polymers include diamonds, graphite, sand, asbestos, agates, chert, feldspars, mica, quartz, and talc. Natural organic polymers include polysaccharides (or polycarbohydrates) such as starch and cellulose, nucleic acids, and proteins. Synthetic inorganic polymers include boron nitride, concrete, many high-temperature superconductors, and a number of glasses. Siloxanes or polysiloxanes represent synthetic organometallic polymers. *See* SILICONE RESINS.

Synthetic polymers used for structural components weigh considerably less than metals, helping to reduce the consumption of fuel in vehicles and aircraft. They even outperform most metals when measured on a strength-per-weight basis. Polymers have been developed which can also be used for engineering purposes such as gears, bearings, and structural members.

Nomenclature. Many polymers have both a common name and a structure-based name specified by the International Union of Pure and Applied Chemistry (IUPAC). Some polymers are commonly known by their acronyms. Some companies use trade names to identify the specific polymeric products they manufacture. For example, Fortrel® polyester is a poly(ethylene terephthalate) (PET) fiber. Polymers are often generically named, such as rayon, polyester, and nylon. *See* Organic nomenclature; Polyacrylate resin; Polyamide resins; Polyester resins.

Composition. Polymer structures can be represented by similar or identical repeat units. These are derived from smaller molecules, called monomers, which react to form the polymer. Propylene monomer and the repeat unit it forms in polypropylene are shown below. With the exception of its end groups, polypropylene is composed entirely of this repeat unit. The number of units (n) in a polymer chain is called the degree of polymerization (DP). Other polymers, such as proteins, can be described in terms of the approximate repeat unit where the nature of R (a substituted atom or group of atoms) varies. *See* Polyvinyl resins; Protein.



$$CH_2{=}CH(CH_3) \longrightarrow \left[CH_2-CH(CH_3)\right]_n \qquad \left(NH-C(=O)-CH(R)\right)_n$$

Monomer Polymer repeat unit Protein repeat unit

Primary structure. The sequence of repeat units within a polymer is called its primary structure. Unsymmetrical reactants, such as substituted vinyl monomers, react almost exclusively to give a "head-to-tail" product, in which the R substituents occur on alternate carbon atoms. A variety of head-to-head structures are also possible.

Each R-substituted carbon atom is a chiral center (an atom in a molecule attached to four different groups) with different geometries possible. Arrangements where the substitutes on the chiral carbon are random are referred to as atactic structures. Arrangements where the geometry about the chiral carbon alternates are said to be syndiotactic. Structures where the geometry about the chiral atom has the same geometry are said to be isotactic or stereoregular.

Stereoregular polymers are produced using special stereoregulating catalyst systems. A series of soluble catalysts have been developed that yield products with high stereoregularity and low chain-size disparity. As expected, polymers with regular structures—that is, isotactic and syndiotactic structures—tend to be more crystalline and stronger.

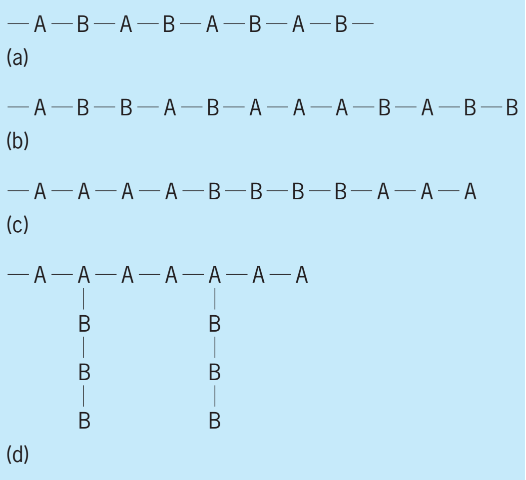
Polymers can be linear or branched with varying amounts and lengths of branching. Most polymers contain some branching.

Copolymers are derived from two different monomers, which may be represented as A and B. There exists a large variety of possible structures and, with each structure, specific properties. These varieties include alternating, random, block, and graft (see illustration). *See* Copolymer.

Secondary structure. This refers to the localized shape of the polymer, which is often the consequence of hydrogen bonding. Most flexible to semiflexible linear polymer chains tend toward two structures—helical and pleated sheet/skirtlike. The pleated skirt arrangement is most prevalent for polar materials where hydrogen bonding can occur. In nature, protein tissue is often of a pleated skirt arrangement. For both polar and nonpolar polymer chains, there is a tendency toward helical formation with the inner core having "like" secondary bonding forces. *See* Hydrogen bond.

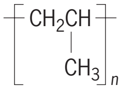
Tertiary structure. This refers to the overall shape of a polymer, such as in polypeptide folding. Globular proteins approximate rough spheres because of a complex combination of environmental and molecular constraints, and bonding opportunities. Many natural and synthetic polymers have "superstructures," such as the globular proteins and aggregates of polymer chains, forming bundles and groupings.

Quaternary structure. This refers to the arrangement in space of two or more polymer subunits, often a grouping of tertiary structures. For example, hemoglobin (quaternary structure) is essentially the combination of four myoglobin (tertiary structure) units. Many crystalline synthetic polymers form spherulites. *See* Hemoglobin.



Copolymer structures: (*a*) alternating, (*b*) random, (*c*) block, (*d*) graft.

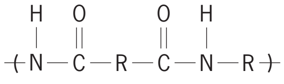
Synthesis. For polymerization to occur, monomers must have at least two reaction points or functional groups. There are two main reaction routes to synthetic polymer formation—addition and condensation. In chain-type kinetics, initiation starts a series of monomer additions that result in the reaction mixture consisting mostly of unreacted monomer and polymer. Vinyl polymers, derived from vinyl monomers and containing only carbon in their backbone, are formed in this way. Examples of vinyl polymers include polystyrene, polyethylene, polybutadiene, polypropylene, and poly(vinyl chloride).



$$\left[CH_2CH(CH_3)\right]_n$$

Polypropylene, PP

The second main route is a step-wise polymerization. Polymerization occurs in a step-wise fashion so that the average chain size within the reaction mixture may have an overall degree of polymerization of 2, then 5, then 10, and so on, until the entire mixture contains largely polymer with little or no monomer left. Polymers typically produced using the step-wise process are called condensation polymers, and include polyamides, polycarbonates, polyesters, and polyurethanes. Condensation polymer chains are characterized as having a noncarbon atom in their backbone. For polyamides the noncarbon is nitrogen (N), while for polycarbonates it is oxygen (O). Condensation polymers are synthesized using melt (the reactants are heated causing them to melt), solution (the reactants are dissolved), and interfacial (the reactants are dissolved in immiscible solvents) techniques. *See* Polymerization; Polyolefin resins; Polyurethane resins.



$$\left(N(H)-C(=O)-R-C(=O)-N(H)-R\right)$$

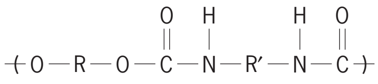
$$\left(O-C(=O)-O-R\right)$$

Polycarbonate



$$\left(O-R-O-C(=O)-N(H)-R'-N(H)-C(=O)\right)$$

Polyurethane, PU

Molecular properties. These are used to help determine the structure and behavior of the polymer. The molecular weight of a particular polymer chain is the product of the number of units times the molecular weight of the repeating unit. Two statistical averages describe polymers, the number-average molecular weight and the weight-average molecular weight. *See* MOLECULAR WEIGHT.

Size is the most important property of polymers allowing for storage of information (nucleic acids and proteins). Polymeric materials remember any action that distorts or moves polymer chains or segments (such as bending, stretching, and melting). Size also accounts for an accumulation of the interchain and intrachain secondary attractive forces called van der Waals forces. For nonpolar polymers, such as polyethylene, the attractive forces for each repeating unit are less than that for polar polymers. Polyvinyl chloride, a polar polymer, has attractive forces that include both dispersion and dipole-dipole forces so that the total attractive forces are proportionally larger than those for polyethylene. Polymers with hydrogen bonding (such as proteins, polysaccharides, nucleic acids, and nylons) have attractive forces that are even greater. Hydrogen bonding is so strong in cellulose that cellulose is not soluble in water until the inter- and intrachain hydrogen bonds are broken. *See* CELLULOSE.

Polymers often have a combination of ordered regions, called crystalline regions, and disordered or amorphous regions. Crystalline regions are more rigid, contributing to strength and resistance to external forces. The amorphous regions contribute to polymers' flexibility. Most commercial polymers have a balance between amorphous and crystalline regions, allowing a balance between flexibility and strength.

Polymers are viscoelastic materials. Ductile polymers, such as polyethylene and polypropylene, "give" or "yield," and at high elongations some strengthening and orientation occur. A brittle polymer, such as polystryene, does not give much and breaks at a low elongation. A fiber, a polymer material that is much longer than it is wide, exhibits high strength, high stiffness, and little elongation.

Materials. Fibers are polymer materials that are strong in one direction, and they are much longer (>100 times) than they are wide. Elastomers (or rubbers) are polymeric materials that can be distorted through the application of force, and when the force is removed, the material returns to its original shape. Plastics are materials that have properties between fibers and elastomers—they are hard and flexible. Coatings and adhesives are generally derived from polymers that are members of other groupings (for example, polysiloxanes are elastomers, but also are used as adhesives). Industrially important adhesives and coatings include laminates, sealants and caulks, composites, films, polyblends, liquid crystals, ceramics, cements, and smart materials. *See* ADHESIVE; CEMENT; COMPOSITE LAMINATES; LIQUID CRYSTALS; POLYMERIC COMPOSITE; RUBBER.

Additives. Processed polymeric materials are generally a combination of the polymer and the materials that are added to modify its properties, assist in processing, and introduce new properties. Additives can be solids, liquids, or gases. Typical additives are plasticizers, antioxidants, colorants, fillers, and reinforcements. *See* ANTIOXIDANT; INHIBITOR (CHEMISTRY).

Recycling. Many polymers are thermoplastics, that is, they can be reshaped through application of heat and pressure and used in the production of other thermoplastic materials. The recycling of thermosets, polymers that do not melt but degrade prior to softening, is more difficult. These materials are often ground into a fine powder, are blended with additives (often adhesives or binders), and then are reformed. *See* RECYCLING TECHNOLOGY. [C.E.Ca.]

Polymer-supported reaction

An organic chemical reaction where one of the species, such as the substrate, the reagent, or a catalyst, is bound to a cross-linked, and therefore insoluble, polymer support. A major attraction of polymer-supported reactions is that at the end of the reaction period the polymer-supported species can be separated cleanly and easily, usually by filtration, from the soluble species. This easy separation can greatly simplify product isolation procedures, and it may even allow the polymer-supported reactions to be automated. Because it is possible to reuse or recycle polymer-supported reactants and because they are insoluble, involatile, easily handled, and easily recovered, polymer-supported reactants are also attractive from an environmental point of view. *See* ASYMMETRIC SYNTHESIS; CATALYSIS.

Polymer-supported reactants are usually prepared in the form of beads of about 50–100 micrometers' diameter. Such beads can have a practically useful loading only when their interiors are functionalized, that is, carry functional groups. With a typical polymer-supported reactant, more than 99% of the reactive groups are inside the beads. An important consequence is that for soluble species to react with polymer-supported species the former must be able to diffuse freely into the polymer beads. *See* POLYMER.

In a typical application of reactions involving polymer-supported substrates, a substrate is first attached to an appropriately functionalized polymer support. The synthetic reactions of interest are then carried out on the supported species. Finally, the product is detached from the polymer and recovered. Often the polymer-supported species has served as a protecting group that is also a physical "handle" to facilitate separation. Combinatorial synthesis is carried out on polymer-supported substrates. This approach is used in the pharmaceutical industry to identify lead compounds, which can thus be identified in weeks rather than years.

Reactions involving polymer-supported reagents are generally more useful than those involving polymer-supported substrates, because no attachment or detachment reactions are needed, and it is not necessary for all the polymer-supported species to react in high yield. Indeed, polymer-supported reagents are often used in excess to drive reactions to high conversions. Polymer-supported catalysts are the most attractive type of polymer-supported reactants; in such reactions, the loadings of catalytic sites need not be high, not all sites need be active and, in most cases, the polymer-supported catalyst is recovered in a suitable form for reuse. [P.H.]

Polymeric composite

Any of the combinations or compositions that comprise two or more materials as separate phases, at least one of which is a polymer. By combining a polymer with another material, such as glass, carbon, or another polymer, it is often possible to obtain unique combinations or levels of properties. Typical examples of synthetic polymeric composites include glass-, carbon-, or polymer-fiber-reinforced thermoplastic or thermosetting resins, carbon-reinforced rubber, polymer blends, silica- or mica-reinforced resins, and polymer-bonded or -impregnated concrete or wood. It is also often useful to consider as composites such materials as coatings (pigment-binder combinations) and crystalline polymers (crystallites in a polymer matrix). Typical naturally occurring composites include wood (cellulosic fibers bonded with lignin) and bone (minerals bonded with collagen). On the other hand, polymeric compositions compounded with a plasticizer or very low proportions of pigments or processing aids are not ordinarily considered as composites.

Typically, the goal is to improve strength, stiffness, or toughness, or dimensional stability by embedding particles or fibers in a matrix or binding phase. A second goal is to use inexpensive, readily available fillers to extend a more expensive or scarce resin; this goal is increasingly important as petroleum supplies become costlier and less reliable. Still other applications include the use of some fillers such as glass spheres to improve processability, the incorporation of dry-lubricant particles such as molybdenum sulfide to make a self-lubricating bearing, and the use of fillers to reduce permeability.

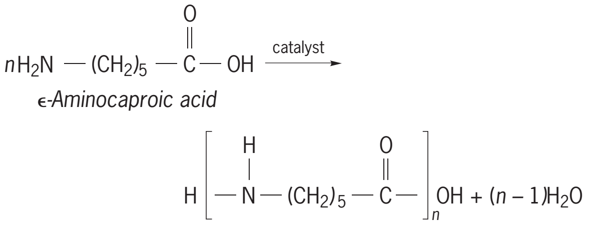
The most common fiber-reinforced polymer composites are based on glass fibers, cloth, mat, or roving embedded in a matrix of an epoxy or polyester resin. Reinforced thermosetting resins containing boron, polyaramids, and especially carbon fibers confer especially high levels of strength and stiffness. Carbon-fiber composites have a relative stiffness five times that of steel. Because of these excellent properties, many applications are uniquely suited for epoxy and polyester composites, such as components in new jet aircraft, parts for automobiles, boat hulls, rocket motor cases, and chemical reaction vessels.

Although the most dramatic properties are found with reinforced thermosetting resins such as epoxy and polyester resins, significant improvements can be obtained with many reinforced thermoplastic resins as well. Polycarbonates, polyethylene, and polyesters are among the resins available as glass-reinforced composition. The combination of inexpensive, one-step fabrication by injection molding, with improved properties has made it possible for reinforced thermoplastics to replace metals in many applications in appliances, instruments, automobiles, and tools.

In the development of other composite systems, various matrices are possible; for example, polyimide resins are excellent matrices for glass fibers, and give a high-performance composite. Different fibers are of potential interest, including polymers [such as poly(vinyl alcohol)], single-crystal ceramic whiskers (such as sapphire), and various metallic fibers. *See* COMPOSITE MATERIAL; GLASS; GRAPHITE; POLYACRYLATE RESIN; POLYAMIDE RESINS; POLYESTER RESINS; POLYETHER RESINS; POLYMER; POLYSTYRENE RESIN; POLYVINYL RESINS; RUBBER. [J.A.M.]

Polymerization The linking of small molecules (monomers) to make larger molecules. Polymerization requires that each small molecule have at least two reaction points or functional groups. There are two distinct major types of polymerization processes, condensation polymerization, in which the chain growth is accompanied by elimination of small molecules such as H_2O or CH_3OH, and addition polymerization, in which the polymer is formed without the loss of other materials. There are many variants and subclasses of polymerization reactions.

An example of the condensation process is the reaction (1)



$$n\,H_2N-(CH_2)_5-\overset{\overset{O}{\|}}{C}-OH \xrightarrow{\text{catalyst}} H\left[-\overset{\overset{H}{|}}{N}-(CH_2)_5-\overset{\overset{O}{\|}}{C}-\right]_n OH + (n-1)H_2O \qquad (1)$$

ε-Aminocaproic acid

Polyamide, nylon-6

of ε-aminocaproic acid in the presence of a catalyst to form the polyamide, nylon-6. The repeating structural unit is equivalent to the starting material minus H and OH, the elements of water. The molecules formed are linear because the total functionality of the reaction system (functional groups per molecule) is always two. However, if a trifunctional material, such as a tricarboxylic acid, were added to the nylon-6,6 polymerizing mixture, a branched polymeric structure would result, because two of the carboxylic groups would participate in one polymer chain, and the third carboxylic group would start the growth of another. Under appropriate conditions, these chains can become bridges between linear chains and the polymer becomes cross-linked. The arrangements of the chains are shown in Fig. 1.

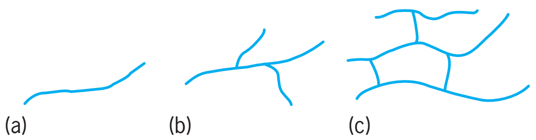


Fig. 1. Polymer chains. (*a*) Linear polymer chain. (*b*) Branched polymer chain. (*c*) Cross-linked polymer chain.

An example of addition polymerization is reaction (2). The

$$n\,H_2C{=}O \xrightarrow[\text{initiator (I)}]{\text{catalyst or}} [-CH_2-O-]_n \qquad (2)$$

Formaldehyde Polyoxymethylene

structure of the repeating unit is the difunctional monomeric unit, or "mer." In the presence of catalysts or initiators, the monomer yields a polymer by the joining together of *n* mers. If *n* is a small number, 2–10, the products are dimers, trimers, tetramers, or oligomers, and the materials are usually gases, liquids, oils, or brittle solids. In most solid polymers, *n* has values ranging from a few score to several hundred thousand, and the corresponding molecular weights range from a few thousand to several million. The end groups of this example of addition polymers are shown to be fragments of the initiator.

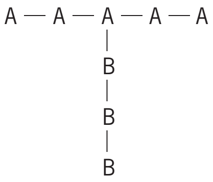
If only one monomer is polymerized, the product is called a homopolymer. The polymerization of a mixture of two monomers of suitable reactivity leads to the formation of a copolymer, a polymer in which the two types of mer units have entered the chain in a more or less random fashion. If chains of one homopolymer are chemically joined to chains of another, the product is called a block or graft copolymer:

A — B — A — A — B — B — B

Random copolymer

A — A — A — A — B — B — B — B — B

Block copolymer



$$\begin{array}{ccccccccc} A & - & A & - & A & - & A & - & A \\ & & & & | & & & & \\ & & & & B & & & & \\ & & & & | & & & & \\ & & & & B & & & & \\ & & & & | & & & & \\ & & & & B & & & & \end{array}$$

Graft polymer

Isotactic and syndiotactic (stereoregular) polymers are formed in the presence of complex catalysts, or by changing polymerization conditions, for example, by lowering the temperature. The groups attached to the chain in a stereoregular polymer are in a spatially ordered arrangement. The configuration of these ordered polymers and the disordered, atactic form is shown in Fig. 2. The regular structures of the isotactic and syndiotactic forms make them often capable of crystallization. The crystalline melting points of isotactic polymers are often substantially higher than the softening points of the atactic product.

In Fig. 2 each carbon atom to which a phenyl group is attached is asymmetrically substituted. For illustration, the heavily marked bonds are assumed to project up from the paper, and the dotted bonds down. Thus in a fully syndiotactic polymer, asymmetric carbons alternate in their left- or right-handedness (alternating *d*, *l* configurations), while in an isotactic polymer, successive carbons have the same steric configuration (*d* or *l*).

Among the several kinds of polymerization catalysis, free-radical initiation has been most thoroughly studied and is most widely employed. Atactic polymers are readily formed by free-radical polymerization, at moderate temperatures, of vinyl and diene monomers and some of their derivatives. *See* CATALYSIS; FREE RADICAL.

Some polymerizations can be initiated by materials, often called ionic catalysts, that contain highly polar reactive sites or complexes. The term heterogeneous catalyst is often applicable to these materials because many of the catalyst systems are insoluble in monomers and other solvents. These polymerizations are usually carried out in solution from which the polymer can be obtained by evaporation of the solvent or by precipitation on

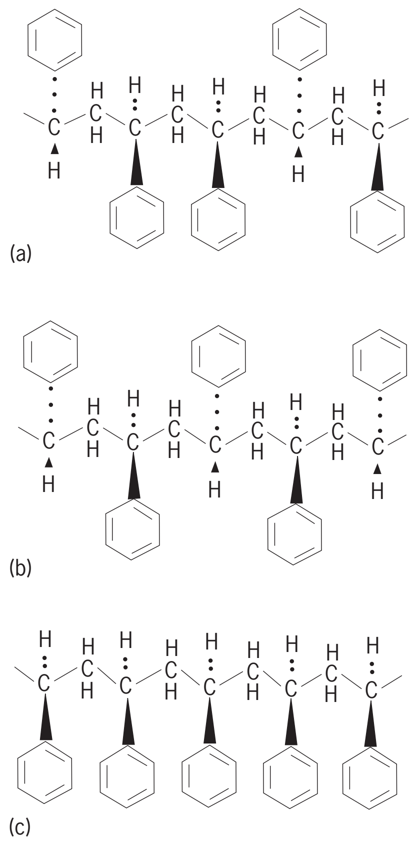


Fig. 2. Spatially oriented polymers. (*a*) Atactic (random; *dlldl* or *lddld*, and so on). (*b*) Syndiotactic (alternating; *dldl*, and so on). (*c*) Isotactic (right- or left-handed; *dddd*, or *llll*, and so on).

the addition of a nonsolvent. A distinguishing feature of complex catalysts is the ability of some representatives of each type to initiate stereoregular polymerization at ordinary temperatures or to cause the formation of polymers which can be crystallized. *See* CHAIN REACTION (CHEMISTRY); CHEMICAL DYNAMICS; HETEROGENEOUS CATALYSIS; INHIBITOR (CHEMISTRY); INORGANIC POLYMER; ORGANIC REACTION MECHANISM; PLASTICS PROCESSING; POLYMER. [J.A.M.]

Polymorphism (crystallography) The existence of different crystal structures with the same chemical composition. If only one chemical element is present, the forms are called allotropes. Graphite and diamond are allotropes of carbon, whereas quartz and cristobalite are polymorphs of silica (silicon dioxide, SiO_2). Although properties are different in these forms, reversible transformations, which involve small shifts in atom positions and no bulk transport of material, are common. The quartz transformation at 1063°F (573°C) is a reversible, atom-displacement transformation. *See* SILICA MINERALS.

In metals and ceramics, similar transformations are called martensitic. Advantage is taken of the localized nature of reversible transformation in steel by controlling the melting atmosphere, temperature, composition, mechanical working (alloying), and tempering and quenching operations. *See* HEAT TREATMENT (METALLURGY).

Control over transformations to achieve desirable properties as either devices or structural materials in extreme environments is a frequent objective. In the case of tin, reversibility on the atomic scale can have devastating consequences for bulk properties. Similar transformations may be beneficial in the right place and in the desired degree. Such transformation is attempted with metals and ceramics. *See* CERAMICS; CRYSTAL STRUCTURE. [D.Ev.]

Polymorphism (genetics) A form of genetic variation, specifically a discontinuous variation, occurring within plant and animal species in which distinct forms exist together in the same population, even the rarest of them being too common to be maintained solely by mutation. Thus the human blood groups are examples of polymorphism, while geographical races are not; nor is the diversity of height among humans, because height is “continuous” and does not fall into distinct tall, medium, and short types. *See* MUTATION.

Distinct forms must be controlled by some switch which can produce one form or the other without intermediates such as those arising from environmental differences. This clear-cut control is provided by the recombination of the genes. Each gene may have numerous effects and, in consequence, all genes are nearly always of importance to the organism by possessing an overall advantage or disadvantage. They are very seldom of neutral survival value, as minor individual variations in appearance often are. Thus a minute extra spot on the hindwings of a tiger moth is in itself unlikely to be of importance to the survival of the insect, but the gene controlling this spot is far from negligible since it also affects fertility. *See* RECOMBINATION (GENETICS).

Genes having considerable and discontinuous effects tend to be eliminated if harmful, and each gene of this kind is therefore rare. On the other hand, those that are advantageous and retain their advantage spread through the population so that the population becomes uniform with respect to these genes. Evidently, neither of these types of genes can provide the switch mechanism necessary to maintain a polymorphism. That can be achieved only by a gene which has an advantage when rare, yet loses that advantage as it becomes commoner.

Occasionally there is an environmental need for diversity within a species, as in butterfly mimicry. Mimicry is the resemblance of different species to one another for protective purposes, chiefly to avoid predation by birds. Sexual dimorphism falls within the definition of genetic polymorphism. In any species, males and females are balanced at optimum proportions which are generally near equality. Any tendency for one sex to increase relative to the other would be opposed by selection.

In general, a gene having both advantageous and disadvantageous effects may gain some overall advantage and begin to spread because one of the features it controls becomes useful in a new environment. A balance is then struck between the advantages and disadvantages of such a gene, ensuring that a proportion of the species carry it, thus giving rise to permanent discontinuous variation, that is, to polymorphism. *See* PROTECTIVE COLORATION.

Polymorphism is increasingly known to be a very common situation. Its existence is apparent whenever a single gene having a distinct recognizable effect occurs in a population too frequently to be due merely to mutation. Even if recognized by some trivial effect on the phenotype, it must in addition have important other effects. About 30% of the people in western Europe cannot taste as bitter the substance phenylthiourea. This is truly an insignificant matter; indeed, no one even had the opportunity of tasting it until the twentieth century. Yet this variation is important since it is already known that it can affect disease of the thyroid gland. *See* GENETICS; POPULATION GENETICS. [E.B.F.; J.R.Po.]

Polynomial systems of equations Systems of mathematical equations which have the form of system (1).

$$\begin{array}{c} f_1(x_1, x_2, \ldots, x_n) = 0 \\ f_2(x_1, x_2, \ldots, x_n) = 0 \\ \cdots\cdots\cdots\cdots\cdots\cdots \\ f_m(x_1, x_2, \ldots, x_n) = 0 \end{array} \tag{1}$$

Each $f_i(x_1, x_2, \ldots, x_n)$, $i = 1, 2, \ldots, m$, is a sum of terms of the form shown as expression (2), where the coefficient $a_{i_1 i_2 \cdots i_n}$ is a

$$a_{i_1 i_2 \ldots i_n} x_1^{i_1} x_2^{i_2} \ldots x_n^{i_n} \tag{2}$$

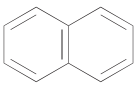
constant, or fixed number, and the exponent i_j of the variable x_j is a nonnegative whole number. An example of such a system in two variables is system (3). The expressions $f_i(x_1, x_2, \ldots, x_n)$ are called polynomials in several variables. The problem posed by system (1) is to find necessary and sufficient conditions that there exist values of the variables $x_1 = a_1, x_2 = a_2, \ldots, x_n = a_n$ which simultaneously satisfy each equation of the system, and to find all such sets of values, which are called solutions of the system. In example (3), a complete set of solutions is given by $x = 1$, $y = 0$; $x = 0$, $y = 1$; $x = 1$; $y = 1$; and $x = -1$, $y = -1$. *See* Equations, theory of; Linear systems of equations. [R.A.Be.]

$$\begin{gathered} x^2 - xy + y^2 - 1 = 0 \\ x^2 + xy - 3y^2 - 2x + 2y + 1 = 0 \end{gathered} \tag{3}$$

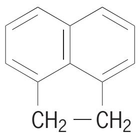
Polynuclear hydrocarbon

One of a class of hydrocarbons possessing more than one ring. The aromatic polynuclear hydrocarbons may be divided into two groups. In the first, the rings are fused, which means that at least two carbon atoms are shared between adjacent rings. Examples are naphthalene (**1**), which has two six-membered rings, and acenaphthene (**2**), which has two six-membered rings and one five-membered ring.

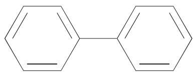
In the second group of polynuclear hydrocarbons, the aromatic rings are joined either directly, as in the case of biphenyl (**3**), or through a chain of one or more carbon atoms, as in 1,2-diphenylethane (**4**).



(**1**)



(**2**)



(**3**)

$C_6H_5CH_2CH_2C_6H_5$

(**4**)

The higher-boiling polynuclear hydrocarbons found in coal tar or in tars produced by the pyrolysis or incomplete combustion of carbon compounds are frequently fused-ring hydrocarbons, some of which may be carcinogenic. *See* Aromatic hydrocarbon; Steroid. [C.K.B.]

Polyol

A compound containing more than one hydroxyl group (—OH). Each hydroxyl is attached to separate carbon atoms of an aliphatic skeleton. This group includes glycols, glycerol, and pentaerythritol and also such products as trimethylolethane, trimethylolpropane, 1,2,6-hexanetriol, sorbitol, inositol, and poly(vinyl alcohol). Polyols are obtained from many plant and animal sources and are synthesized by a variety of methods.

Polyols such as glycerol, pentaerythritol, trimethylolethane, and trimethylolpropane are used in making alkyd resins for decorative and protective coatings. Glycols, glycerol, 1,2,6-hexanetriol, and sorbitol find application as humectants and plasticizers for gelatin, glue, and cork.

The polymeric polyols used in manufacture of the urethane foams represent a series of synthetic polyols. These polyols are generally poly(oxyethylene) or poly(oxypropylene) adducts of di-to octahydric alcohols. *See* Glycerol; Glycol. [P.C.J.]

Polyolefin resins

Polymers derived from hydrocarbon molecules that possess one or more alkenyl (or olefinic) groups. The term polyolefin typically is applied to polymers derived from ethylene, propylene, and other alpha-olefins, isobutylene, cyclic olefins, and butadiene, and other diolefins. *See* Alkene.

Polyethylene. Polyethylene is any homopolymer or copolymer in which ethylene is the major component monomer. It is a semicrystalline polymer of low to moderate strength and high toughness; its stiffness, yield strength, and thermal and mechanical properties increase with crystallinity. Toughness and ultimate tensile strength increase with molecular weight. Polyethylene shows excellent toughness at low temperatures. Polyethylene is relatively inexpensive, extremely versatile, and adaptable to a large array of fabrication techniques. It is chemically inert; resistant to solvents, acids, and alkalis; and has good dielectric and barrier properties. It is used in many housewares, films, molded articles, and coatings.

Low-density polyethylene has densities ranging from 0.905 to 0.936 g/cm^3. High-pressure low-density polyethylene is referred to simply as LDPE; linear low-density polyethylene (LLDPE) is a copolymer of polyethylene that is produced by a low-pressure polymerization process. High-density polyethylene (HDPE) covers the density range from 0.941 to 0.967 g/cm^3. HDPE generally consists of a polymethylene $(CH_2)_n$ chain with no, or very few, side chains to disrupt crystallization, while LLDPE contains side chains whose length depends on the comonomer used. *See* Copolymer.

LLDPE finds wide application in plastic films such as garbage bags and stretch cling films. Sheathing and flexible pipe are applications that take advantage of the flexibility and low-temperature toughness of LLDPE. HDPE is used in food packaging, grocery bags, pickup truck bedliners, and large containers. Fibers have been produced that approach the strength of spider silk, and is used in fishing lines and in medical applications.

Rubbery ethylene copolymers are used in compounded mixtures and range in comonomer content from 25 to 60% by weight, with propylene being the most widely used comonomer to form ethylene-propylene rubber. In addition to propylene, small amounts of a diene are sometimes included, forming a terepolymer. Products containing ethylene-propylene rubber and terepolymer have many automotive uses such as in bumpers, facia, dashboard panels, steering wheels, and assorted interior trim. *See* Rubber.

Ethylene copolymers are used to produce the polymer poly(ethylene-co-vinyl acetate) [EVA]. Applications include specialty film for heat sealing, adhesives, flexible hose and tubing, footwear components, bumper components, and gaskets. Foamed and cross-linked poly(ethylene-co-vinyl acetate) is used in energy-absorbing applications. Ionomers are ethylene copolymers that are produced from the copolymerization of ethylene with a comonomer containing a carboxylic group (COOH) such as methyl acrylic acid. Because of their toughness, ionomers are widely used in the covers for golf balls. [B.Be.]

Polypropylene. Commercial polypropylene (PP) homopolymers are isotactic, high-molecular-weight, semicrystalline solids having melting points around 160–165°C (320–329°F), low density (0.90–0.91 g/cm^3), and excellent stiffness and tensile strength. They have moderate impact strength (toughness), low density over a wide temperature range, excellent mechanical properties, and low electrical conductivity. Propylene, like ethylene, is produced in large quantities at low cost from the cracking of oil and other hydrocarbon feedstocks. Low-molecular-weight resins are used for melt spun and melt blown fibers and for injection-molding applications. Polypropylene resins are used in extrusion and blow-molding processes and to make cast, slit, and oriented films. Stabilizers are added to polypropylene to protect it from attack by oxygen, ultraviolet light, and thermal degradation; other additives improve resin clarity, flame retardancy, or radiation resistance.

Polypropylene homopolymers, random copolymers, and impact copolymers are used in such products as automotive parts, appliances, battery cases, carpeting, electrical insulation, fiber and fabrics, food packaging, and medical equipment. *See* Petroleum products.

Other poly(alpha-olefins). Poly(1-butene) is a tough and flexible resin that has been used in the manufacture of film and pipe. Poly(4-methyl-1-pentene) is used in the manufacture of chemical and medical equipment. High-molecular-weight polyisobutylenes are rubbery solids that are used as sealants, inner tubes, and tubeless tire liners. Low-molecular-weight polyisobutylenes are used in formulations for caulking, sealants, and lubricants. Butadiene and isoprene can be polymerized to give a number of polymer structures. The commercially important forms of polybutadiene and polyisoprene are similar in structure to natural rubber. *See* POLYACRYLONITRILE RESINS; POLYMER; POLYSTYRENE RESIN. [S.A.Co.]

Polyoma virus A papovavirus that infects rodents. The name derives from the capability of this virus to induce a wide variety of tumors when inoculated into newborn animals. The icosahedral viral particle consists of deoxyribonucleic acid (DNA) and protein only. The genome is a small, double-stranded, closed circular DNA molecule approximately 5300 base pairs in length. It encodes the T antigens expressed early in the productive cycle and in transformed cells, and the viral capsid proteins, expressed late in the productive cycle.

Polyoma virus is endemic in most wild populations of mice, but causes no disease. Tumors produced by this virus are unknown in the wild. Inoculation of large quantities of virus into newborn rodents, however, induces a number of tumor types, particularly many sarcomas and carcinomas. These tumors contain the viral genome but produce few infectious viral particles. Infected animals produce neutralizing antibodies directed against structural components of the virus; tumor-bearing animals produce antibodies to antigens (T antigens) which are present in tumor cells but not in the virus particle.

The virus is easily propagated to high titer in mouse embryo tissue culture, resulting in the lysis of the cells and the production of a hemagglutinin. This “productive infection” occurs only in mouse cells. Small numbers of “abortively infected” cells retain the viral genome and become transformed. Transformed cells are tumorigenic when injected into syngeneic animals, and contain the T antigens but produce no virus. The expression of the T antigens has been shown to be necessary and sufficient to induce cell transformation. *See* IMMUNOLOGY; ONCOLOGY; TUMOR VIRUSES; VIRUS. [S.M.D.]

Polyplacophora A class within the phylum Mollusca whose members are popularly called chitons, coat-of-mail shells, or sea cradles. All chitons are marine, and they typically live in the intertidal zone, although some live in deeper waters. They are found from subarctic to tropical latitudes but are most abundant in warmer waters. There are roughly 750 chiton species living today.

Polyplacophorans exhibit bilateral symmetry and are oval or elongate in outline. Chitons vary in length from a few millimeters ($^1/_{16}$ in.) to over 30 cm (12 in.), though most are a few centimeters (about 1 in.) long. They are flattened dorsoventrally and bear eight shell plates on their back. The plates, termed valves, are formed from crystals of the mineral aragonite, and the upper layer of the valves contains canals filled with sensory organs called esthetes. The larger of these structures serve as photoreceptors and hence act as eyes. *See* CHITON.

Chitons possess three valve types—head, intermediate, and tail. The valves are laterally embedded in the fleshy but tough girdle, which typically bears small aragonite spicules or scales of varying shapes. Ventrally, polyplacophorans possess a large foot which they use for moving about and for attaching to rocks in a manner similar to a limpet gastropod. The gills hang along both sides of the animal, in a deep groove between the foot and the shell. The anus is located near the posterior end of the foot. At the front of the foot is the head which bears the mouth with its associated rasping structure (the radula, which is characteristic of most mollusks). A unique feature of the chiton radula is that the largest teeth are hardened with magnetite, an iron mineral. Characters of the valves, the gills, and the radula typically have been used to differentiate major groups within the Polyplacophora. *See* LIMPET; MOLLUSCA. [M.V.]

Polyploidy The occurrence of related forms possessing chromosome numbers which are multiples of a basic number (n), the haploid number. Forms having $3n$ chromosomes are triploids; $4n$, tetraploids; $5n$, pentaploids, and so on. Autopolyploids are forms derived by the multiplication of chromosomes from a single diploid organism. As a result the homologous chromosomes come from the same source. These are distinguished from allopolyploids, which are forms derived from a hybrid between two diploid organisms. As a result, the homologous chromosomes come from different sources. About one-third of the species of vascular plants have originated at least partly by polyploidy, and as many more appear to have ancestries which involve ancient occurrences of polyploidy. The condition can be induced artificially with the drug colchicine and the production of polyploid individuals has become a valuable tool for plant breeding.

In animals, most examples of polyploidy occur in groups which are parthenogenetic, or in species which reproduce asexually by fission. *See* BREEDING (PLANT); CHROMOSOME ABERRATION; GENE; GENETICS; PLANT EVOLUTION; SPECIATION. [G.L.St.]

In addition to polyploid organisms in which all of the body cells contain multiples of the basic chromosome number, most plants and animals contain particular tissues that are polyploid or polytene. Both polyploid and polytene cells contain extra copies of DNA, but they differ in the physical appearance of the chromosomes. In polytene cells the replicated copies of the DNA remain physically associated to produce giant chromosomes that are continuously visible and have a banded pattern. The term polyploid has been applied to several types of cells: multinucleate cells; cells in which the chromosomes cyclically condense but do not undergo nuclear or cellular division (this process is termed endomitosis); and cells in which the chromosomes appear to be continually in interphase, yet the replicated chromosomes are not associated in visible polytene chromosomes. *See* CHROMOSOME; CHROMOSOME ABERRATION; GENETICS; MITOSIS. [T.L.O.W.]

Polypodiales The largest order of modern ferns, commonly called the true ferns, with approximately 250 genera and 9000 species; also known as Filicales. Although well represented in the temperate regions, they reach their greatest development in the moist tropics. They vary in habit from small filmy structures to large treelike plants. Many are epiphytic (live perched on other plants) and a number are climbing species. A few are aquatic. Perhaps the most striking species are the tropical tree ferns with their upright, unbranched stems and terminal clusters of large graceful leaves.

The Polypodiales differ from the other fem orders in being leptosporangiate—that is, their sporangium, or spore sac, arises from a single surface cell—and in having small sporangia with a definite number of spores. The wall of the sporangium is almost encircled with a ring of cells having unevenly thickened walls. This ring is called the annulus. When the sporangium is mature, the annulus, acting as a spring, causes the sporangium wall to rupture, thus discharging the spores. These plants are valued for their beauty and for the clues they give to the evolutionary history of the Polypodiales which extends back through the coal measures of the Paleozoic. *See* PALEOBOTANY.

The sporophyte is the conspicuous phase of the true ferns, and like other vascular plants it has true roots, stems, and leaves (Fig. 1). In most ferns, especially those of the temperate regions, the mature stem is usually a creeping rhizome (underground stem) without aerial branches. However, in several species the stems are branched, and in some they are erect. Whereas in the tropics the leaves are usually persistent and evergreen, in temperate regions the leaves of most species die back each year and are replaced by new ones the next growing season. Characteristic of this order is the apparent uncoiling of the leaves from the base toward the apex.

The internal structure of the blade of the leaf and of the root is very similar to that of these organs in the seed plants. The main

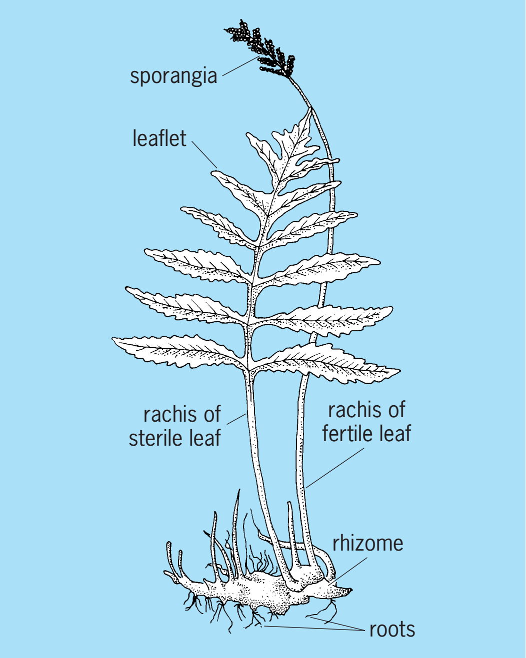


Fig. 1. **The sensitive fern (*Onoclea sensibilis*), a representative of the Polypodiopsida. (*After W. W. Rabbins, T. E. Weier, and C. R. Stocking, Botany: An Introduction to Plant Science, 3d ed., John Wiley and Sons, Inc., 1964*)**

difference is the presence of large intercellular spaces in the fern leaf and the frequent lack of apparent distinction between the spongy and palisade cells of the mesophyll, possibly because most ferns grow in the shade.

The life cycle of the fern consists of two independent (self-sustaining) alternating generations. The common leafy fern plant is the sporophytic (spore-producing) generation. When the mature spores are discharged and reach a suitable substrate, they germinate and produce a small, flat, green, heart-shaped structure known as the prothallium or gametophytic (gamete-producing) generation. The gametophyte produces the sex organs antheridia (male) and archegonia (female). The gametes (sperm and egg) unite in fertilization and the resultant cell, or zygote, develops into the spore-bearing (sporophytic) fern plant.

In all ferns, the spores are produced in special multicellular organs known as sporangia. Except for a few genera, the sporangia are arranged in groups or clusters called sori (Fig. 2). These are on the lower surface of the leaves or fertile fronds, either along the midrib of the pinnae, near the leaf margins, or scattered. Usually each sorus is covered by a flaplike structure called the indusium, which may be of various shapes and sizes. However, a few ferns have naked sori, and others have a false indusium formed by the folding or inrolling of the leaf margin. *See* POLYPODIOPHYTA; PSILOTOPHYTA. [P.A.V.]

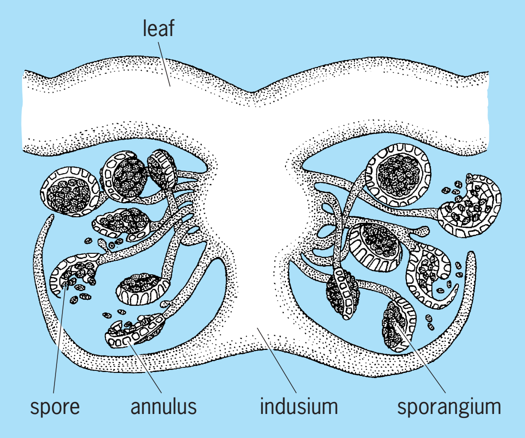

Fig. 2. **Diagram of section through a fern leaf, showing details of a sorus. (*After W. W. Robbins, T. E. Weier, and C. B. Stocking, Botany: An Introduction to Plant Science, 3d ed., John Wiley and Sons, Inc., 1964*)**

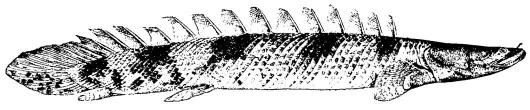
Polypodiophyta A division of the plant kingdom, commonly called the ferns, which is widely distributed throughout the world but is most abundant and varied in moist, tropical regions, The Polypodiophyta are sometimes treated as a class Polypodiopsida of a broadly defined division Tracheophyta (vascular plants). The group consists of five living orders (Ophioglossales, Marattiales, Polypodiales, Marsileales, and Salviniales), plus several orders represented only by Paleozoic fossils. The vast majority of the nearly 10,000 species belong to the single order Polypodiales, sometimes also called Filicales. *See* POLYPODIOPSIDA.

The Polypodiophyta ordinarily have well-developed roots, stems, and leaves that contain xylem and phloem as conducting tissues. The central cylinder of vascular tissue in the stem usually has well-defined parenchymatous leaf gaps where the leaf traces depart from it. The leaves are spirally arranged on the stem and are usually relatively large, with an evidently branching vascular system. In most kinds of ferns the leaves, called fronds, are compound or dissected. *See* LEAF; PHLOEM; ROOT (BOTANY); STEM; XYLEM.

The Polypodiophyta show a well-developed alternation of generations, both the sporophyte and the gametophyte generation being detached and physiologically independent of each other at maturity. The sporophyte is much the more conspicuous, and is the generally recognized fern plant. On some or all of its leaves it produces tiny sporangia which in turn contain spores. *See* COENOPTERIDALES; MARATTIALES ; POLYPODIALES; REPRODUCTION (PLANT). [A.Cr.]

Polypodiopsida A class (also known as Filicineae) of the plant division Polypodiophyta containing a large group of plants commonly called ferns. They are widely distributed throughout the world with their greatest development in the moist tropics. Polypodiopsida is an old class with a good representation in the Paleozoic flora. Some of the plant fossils resemble contemporary living species, *See* COENOPTERIDALES; MARATTIALES ; POLYPODIALES; POLYPODIOPHYTA. [P.A.V.]

Polypteriformes A distinctive and apparently ancient order of actinopterygian fishes, also called the Cladistia or the bichirs. Their characters include thick, rhombic, ganoid scales with an enamellike covering; a slitlike spiracle behind the eye; a well-ossified internal skeleton; a symmetrical caudal fin, basically heterocercal, with the upper part continuous with the dorsal fin (see illustration); a dorsal series of free, spinelike finlets, each supported by a radial bone; a distinctive pectoral fin base with three enlarged radial bones; and paired ventral lungs.



Bichir (*Polypterus endlicheri*), length to 3 ft (90 cm). (*After G. A. Boulenger, Catalogue of the Fresh Water Fishes of Africa in the British Museum, vol. 1, 1909*)

This order consists of a single family, the Polypteridae, that is known from the Eocene. The two Recent genera, *Polypterus*, with about 10 species, and *Erpetoichthys*, with 1 species, are confined to fresh waters of tropical Africa. *See* ACTINOPTERYGII; CHONDROSTEI. [R.M.B.]

Poly(p-xylylene) resins Linear, crystallizable resins based on an unusual polymerization of *p*-xylene and derivatives. The polymers are tough and chemically resistant, and may be deposited as adherent coatings by a vacuum process. The vapor deposition process makes it possible to coat small microelectronic parts with a thin layer of the polymer. [J.A.M.]

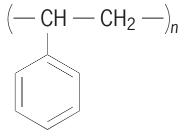
Polysaccharide A class of high-molecular-weight carbohydrates, colloidal complexes, which break down on hydrolysis to monosaccharides containing five or six carbon atoms. The polysaccharides are considered to be polymers in which monosaccharides have been glycosidically joined with the elimination of water. A polysaccharide consisting of hexose monosaccharide units may be represented by the reaction below.

$$nC_6H_{12}O_2 \rightarrow (C_6H_{10}O_5)_n + (n-1)H_2O$$

The term polysaccharide is limited to those polymers which contain 10 or more monosaccharide residues. Polysaccharides such as starch, glycogen, and dextran consist of several thousand D-glucose units. Polymers of relatively low molecular weight, consisting of two to nine monosaccharide residues, are referred to as oligosaccharides. *See* Dextran; Glucose; Glycogen; Monosaccharide; Starch.

Polysaccharides are often classified on the basis of the number of monosaccharide types present in the molecule. Polysaccharides, such as cellulose or starch, that produce only one monosaccharide type (D-glucose) on complete hydrolysis are termed homopolysaccharides. On the other hand, polysaccharides, such as hyaluronic acid, which produce on hydrolysis more than one monosaccharide type (*N*-acetylglucosamine and D-glucuronic acid) are named heteropolysaccharides. *See* Carbohydrate. [W.Z.H.]

Polystyrene resin A hard, transparent, glasslike thermoplastic resin. Polystyrene is characterized by excellent electrical insulation properties, relatively high resistance to water, high refractive index, clarity, and low softening temperature.



Polystyrene

High-molecular-weight homopolymers, copolymers, and polyblends are used as extrusion and molding compounds for packaging, appliance and furniture components, toys, and insulating panels. Styrene-butadiene copolymers are still used for automobile tires and in various rubber articles. The effects of blending small amounts of a rubbery polymer, such as butadiene-styrene rubber, with a hard, brittle polymer are most dramatic when the latter is polystyrene. The polyblend may have impact strength greater than ten times that of polystyrene. Various combinations of complex polyblends and interpolymers of acrylonitrile, styrene, and butadiene (ABS) resins are important as molding resins. ABS resins are also used as toughening agents for polymers such as polyvinyl chloride. Polystyrene is also used in combination with paints. The homopolymer and polyblends are used for panels or liners for refrigerator doors. Polystyrene may also be fabricated in the form of a rigid foam, which is used in packaging, food-service articles, and insulating panels. *See* Acrylonitrile; Copolymer; Plastics processing; Polyacrylonitrile resins; Polymer; Polymerization; Rubber; Styrene. [J.A.M.]

Polysulfide resins Resins that vary in properties from viscous liquids to rubberlike solids. Organic polysulfide resins are prepared by the condensation of organic dihalides with a polysulfide.

Compounding and fabrication of the rubbery polymers can be handled on conventional rubber machinery. The polysulfide rubbers are distinguished by their resistance to solvents such as gasoline, and to oxygen and ozone. The polymers are relatively impermeable to gases. The products are used to form coatings which are chemically resistant and special rubber articles, such as gasoline bags. The polysulfide rubbers were among the first polymers to be used in solid-fuel compositions for rockets. *See* Organosulfur compound; Polymerization; Rubber. [J.A.M.]

Polysulfone resins Polymers containing sulfone groups (—SO_2—) in the main chain, along with a variety of aromatic or aliphatic constituents. Polysulfones based on aromatic backbones constitute a useful class of engineering plastics, owing to their high strength, stiffness, and toughness together with high thermal and oxidative stability, low creep, transparency, and the ability to be processed by standard techniques for thermoplastics. The aromatic structural elements and the presence of sulfone groups are responsible for the resistance to heat and oxidation; ether and isopropylidene groups contribute some chain flexibility. Aromatic polysulfones can be used over wide temperature ranges. The high-temperature performance of poly(ethersulfones) to 200°C (390°F) is surpassed by few other polymers.

Because of the combination of properties discussed, aromatic polysulfone resins find many applications in electronic and automotive parts, medical instrumentation subject to sterilization, chemical and food processing equipment, and various plumbing and home appliance items. Coating formulations are also available, as well as grades reinforced with glass beads or fibers. Aliphatic polysulfones are less stable, for example, to hydrolysis. However, they have potential use in biomedical applications such as artificial membranes to remove carbon dioxide and perfuse with oxygen. *See* Copolymer; Heterocyclic polymer; Organosulfur compound. [J.A.M.]

Polytrichidae A subclass of the mosses (class Bryopsida), consisting of one family and 19 genera. The plants are acrocarpous and perennial, grow on soil, often in dry habitats, and are usually unbranched; annual increments often grow up through the male inflorescences, but do not give the appearance of forked stems. The plants are nearly always dioecious, with both male and female inflorescences terminal. The stems generally have well-developed vascular tissues. The long, narrow leaves are sheathed at the base; above the base the midrib often occupies most of the leaf. Stomata are usually present at or near the base of the capsule. *See* Bryophyta; Bryopsida; Dawsoniidae. [H.Cr.]

Polytropic process A process which occurs with an interchange of both heat and work between the system and its surroundings. The nonadiabatic expansion or compression of a fluid is an example of a polytropic process. The interrelationships between the pressure (P) and volume (V) and pressure and temperature (T) for a gas undergoing a polytropic process are given by Eqs. (1) and (2), where a and b are the polytropic

$$PV^a = \text{constant} \quad (1)$$

$$P^b/T = \text{constant} \quad (2)$$

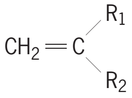
constants for the process of interest. These constants, which are usually determined from experiment, depend upon the equation of state of the gas, the amount of heat transferred, and the extent of irreversibility in the process. *See* Gas; Isentropic process; Isothermal process; Thermodynamic processes. [S.I.S.]

Polyurethane resins Polyurethane (or polyisocyanate) resins are produced by the reaction of a diisocyanate with a compound containing at least two active hydrogen atoms, such as a diol or diamine. Linear, fiber-forming polymers are formed by the addition of diisocyanates to diols, while cross-linking is made possible by the use of polyols or isocyanates having more than two functional groups. Unique elastomeric or stretch fibers can be made from polyester prepolymers, in which rubbery polyester blocks alternate with rigid urethane units and terminal isocyanate groups provide sites for further chain extension and cross-linking.

There are three major types of polyurethane elastomers. One type is based on ether- or ester-type prepolymers that are chain-extended and cross-linked using polyhydroxyl compounds or amines; alternately, unsaturated groups may be introduced to permit vulcanization with common curing agents such as peroxides. A second type is obtained by first casting a mixture of prepolymer with chain-extending and cross-linking agents, and then cross-linking further by heating. The third type is prepared by reacting a dihydroxy ester- or ether-type prepolymer, or a diacid, with a diisocyanate such as diphenylmethane dissocyanate and a diol.

Polyurethane resins can be produced in forms varying from hard, glossy, solvent-resistant coatings, to abrasion- and solvent-resistant rubbers, fibers, and flexible-to-rigid foams. The foams have found the widest use. The more flexible foams are employed as upholstery material for furniture, as rug backing, insulation, and crash pads. The more rigid foams are employed as the core in structural and insulating laminates and as insulation in refrigerated appliances and vehicles. Polyurethanes are also used as adhesives, for example, in the bonding of rubber and of nylon. The flexible polyurethanes may be used for coating rubber articles to give them additional resistance to abrasion and solvents. Wire insulated with polyurethane resin can be soldered directly without previously removing the coating because the polymer decomposes at the soldering temperature to yield a clean wire surface. *See* PLASTICS PROCESSING; POLYESTER RESINS; POLYETHER RESINS; POLYMERIZATION. [J.A.M.]

Polyvinyl resins Polymeric materials generally considered to include polymers derived from monomers having the structure



$$CH_2{=}C(R_1)(R_2)$$

in which R_1 and R_2 represent hydrogen, alkyl, halogen, or other groups. This article refers to polymers whose names include the term vinyl. For discussions of other vinyl-type polymers *see* POLYACRYLATE RESIN; POLYACRYLONITRILE RESINS; POLYFLUOROOLEFIN RESINS; POLYOLEFIN RESINS; POLYSTYRENE RESIN.

Many of the monomers can be prepared by addition of the appropriate compound to acetylene. For example, vinyl chloride, vinyl fluoride, vinyl acetate, and vinyl methyl ether may be formed by the reactions of acetylene with HCl, HF, CH_3OOH, and CH_3OH, respectively. Processes based on ethylene as a raw material have also become common for the preparation of vinyl chloride and vinyl acetate.

The polyvinyl resins may be characterized as a group of thermoplastics which, in many cases, are inexpensive and capable of being handled by solution, dispersion, injection molding, and extrusion techniques. The properties vary with chemical structure, crystallinity, and molecular weight.

Poly(vinyl acetals) are relatively soft, water-insoluble thermoplastic products obtained by the reaction of poly(vinyl alcohol) with aldehydes. Properties depend on the extent to which alcohol groups are reacted. Poly(vinyl butyral) is rubbery and tough and is used primarily in plasticized form as the inner layer and binder for safety glass. Poly(vinyl formal) is the hardest of the group; it is used mainly in adhesive, primer, and wire-coating formulations, especially when blended with a phenolic resin.

Poly(vinyl acetate) is a leathery, colorless thermoplastic material which softens at relatively low temperatures and which is relatively stable to light and oxygen. The polymers are clear and noncrystalline. The chief applications are as adhesives and binders for water-based or emulsion paints. *See* PAINT.

Poly(vinyl alcohol) is a tough, whitish polymer which can be formed into strong films, tubes and fibers that are highly resistant to hydrocarbon solvents. Although poly(vinyl alcohol) is one of the few water-soluble polymers, it can be rendered insoluble in water by drawing or by the use of cross-linking agents. Two groups of products are available, those formed by the essentially complete hydrolysis of poly(vinyl acetate), and those formed by incomplete hydrolysis.

The former may be plasticized with water or glycols and molded or extruded into films, tubes, and filaments which are resistant to hydrocarbons. These products are used for liners in gasoline hoses, for grease-resistant coating and paper adhesives, for treating paper and textiles, and as emulsifiers and thickeners.

Poly(vinyl carbazole) is a tough, glassy thermoplastic with excellent electrical properties and a relatively high softening temperature. Uses of the product has been limited to small-scale electrical applications requiring resistance to high temperatures.

Poly(vinyl chloride) [PVC] is a tough, strong thermoplastic material which has an excellent combination of physical and electrical properties. The products are usually characterized as plasticized or rigid types. Poly(vinyl chloride)[and copolymers] is the second most commonly used polyvinyl resin and one of the most versatile plastics. The plasticized types are somewhat elastic materials which are familiar in the form of shower curtains, floor coverings, raincoats, dishpans, dolls, bottle-top sealers, prosthetic forms, wire insulation, and films. Rigid products, which may consist of the homopolymer, copolymer, or polyblends, are commonly used in the manufacture of phonograph records, pipe, chemically resistant liners for chemical reaction vessels, and siding and window sashes.

Poly(vinylidene chloride) is a tough, hornlike thermoplastic with properties generally similar to those of poly(vinyl chloride). Because of its relatively low solubility and decomposition temperature, the material is most widely used in the form of copolymers with other vinyl monomers, such as vinyl chloride. The copolymers are employed as packaging film, rigid pipe, and as filaments for upholstery and window screens.

Poly(vinyl ethers) exist in several forms varying from soft, balsamlike semisolids to tough, rubbery masses, all of which are readily soluble in organic solvents. Polymers of the alkyl vinyl ethers are used in adhesive formulations and as softening or flexibilizing agents for other polymers.

Poly(vinyl fluoride) is a tough, partially crystalline thermoplastic material which has a higher softening temperature than poly(vinyl chloride). Films and sheets are characterized by high resistance to impact and cracking caused by flexing and temperature and by resistance to weathering.

Poly(vinyl pyrrolidone) is a water-soluble polymer of basic nature which has film-forming properties, strong absorptive or complexing qualities for various reagents, and the ability to form water-solubles salts which are polyelectrolytes. The main uses are as a water-solubilizing agent for medicinal agents such as iodine, and as a semipermanent setting agent in hair sprays. Certain synthetic textile fibers containing small amounts of vinylpyrrolidone as a copolymer have improved affinity for dyes. *See* PLASTICS PROCESSING; POLYMER; POLYMERIZATION. [J.A.M.]

Pomegranate A small deciduous tree, *Punica granatum*, belonging to the plant order Myrtales. Pomegranate is grown as an ornamental as well as for its fruit. The pomegranate is a native of Asia. It was originally known for its medicinal qualities, and cures for various ills were attributed to the fruit juice, the rind, and the bark of the roots. The fruit is a reddish, pomelike berry, containing numerous seeds imbedded in crimson pulp, from which an acid, reddish juice may be obtained. Limited quantities are grown in California and the Gulf states. *See* FRUIT, TREE; MYRTALES. [J.H.Cl.]

Poplar Any tree of the genus *Populus*, family Salicaceae, marked by simple, alternate leaves which are usually broader than those of the willow, the other American representative of this family. Poplars have scaly buds, bitter bark, flowers and fruit in catkins, and a five-angled pith. *See* SALICALES; WILLOW.

Some species are commonly called cottonwood because of the cottony hairs attached to the seeds. Other species, called aspens, have weak, flattened leaf stalks which cause the leaves to flutter in the slightest breeze. One of the important species in the United States is the quaking, or trembling, aspen (*P. tremuloides*). The soft wood of this species is used for paper pulp. The European aspen (*P. nigra*), which is similar to the quaking aspen, is sometimes planted, and its variety, *italica*, the Lombardy poplar of erect columnar habit, is used in landscape planting. The black cottonwood (*P. trichocarpa*) is the largest American poplar and is also the largest broad-leaved tree in the forests of the Pacific Northwest. The cottonwood or necklace poplar (*P. deltoides*) is native in the eastern half of the United States. In the balsam or tacamahac poplar (*P. balsamifera*), the resin is used in medicine as an expectorant. The wood is used for veneer, boxes, crates, furniture, paper pulp, and excelsior. [A.H.G./K.P.D.]

Poppy A plant, *Papaver somniferum* (Papaveraceae), which is probably a native of Asia Minor. It is cultivated extensively in China, India, and elsewhere. This plant is the source of opium, obtained by cutting into the fruits (capsules) soon after the petals have fallen. The white latex (juice) flows from the cuts and hardens when exposed to the air. This solidified latex is collected, shaped into balls or wafers, and often wrapped in the flower petals. This is the crude opium, which contains at least 20 alkaloids, including morphine and codeine. *See* MORPHINE; PAPAVERALES. [P.D.St./E.L.C.]

Population dispersal The process by which groups of living organisms expand the space or range within which they live. Dispersal operates when individual organisms leave the space that they have occupied previously, or in which they were born, and settle in new areas. Natal dispersal is the first movement of an organism from its birth site to the site in which it first attempts to breed. Adult dispersal is a subsequent movement when an adult organism changes its location in space. As individuals move across space and settle into new locations, the population to which they belong expands or contracts its overall distribution. Thus, dispersal is the process by which populations change the area they occupy.

Migration is the regular movement of organisms during different seasons. Many species migrate between wintering and breeding ranges. Such migratory movement is marked by a regular return in future seasons to previously occupied regions, and so usually does not involve an expansion of population range. Some migratory species show astounding abilities to return to the exact locations used in previous seasons. Other species show no regular movements, but wander aimlessly without settling permanently into a new space. Wandering (called nomadism) is typical of species in regions where the availibility of food resources are unpredictable from year to year. Neither migration nor nomadism is considered an example of true dispersal. *See* MIGRATORY BEHAVIOR.

Virtually all forms of animals and plants disperse. In most higher vertebrates, the dispersal unit is an entire organism, often a juvenile or a member of another young age class. In other vertebrates and many plants, especially those that are sessile (permanently attached to a surface), the dispersal unit is a specialized structure (disseminule). Seeds, spores, and fruits are disseminules of plants and fungi; trochophores and planula larvae are disseminules of sea worms and corals, respectively. Many disseminules are highly evolved structures specialized for movement by specific dispersal agents such as wind, water, or other animals.

A special case of zoochory (dispersal using animal agents) involves transport by humans. The movement of people and cargo by cart, car, train, plane, and boat has increased the potential dispersal of weedy species worldwide. Many foreign aquatic species have been introduced to coastal areas by accidental dispersal of disseminules in ship ballast water. The zebra mussel is one exotic species that arrive in this manner and is now a major economic problem throughout the Great Lakes region of North America. Some organisms have been deliberately introduced by humans into new areas. Domestic animals and plants have been released throughout the world by farmers. A few pest species were deliberately released by humans; European starlings, for example.

Some of the most highly coevolved dispersal systems are those in which the disseminule must be eaten by an animal. Such systems have often evolved a complex series of signals and investments by both the plant and the animal to ensure that the seeds are dispersed at an appropriate time and that the animal is a dependable dispersal agent. Such highly evolved systems are common in fruiting plants and their dispersal agents, which are animals called frugivores. Fruiting plants cover their seeds with an attractive, edible package (the fruit) to get the frugivore to eat the seed. To ensure that fruits are not eaten until the seeds are mature, plants change the color of their fruits as a signal to show that the fruits are ready for eating.

Many plants in the tropical rainforests are coevolved to have their seeds dispersed by specific animal vectors, including birds, mammals, and ants. Many tropical trees, shrubs, and herbaceous plants are specialized to have their seeds dispersed by a single animal species. Temperate forest trees, in contrast, often depend on wind dispersal of both pollen and seeds.

Dispersal barriers are physical structures that prevent organisms from crossing into new space. Oceans, rivers, roads, and mountains are examples of barriers for species whose disseminules cannot cross such features. It is believed that the creation of physical barriers is the primary factor responsible for the evolution of new species. A widespread species can be broken into isolated fragments by the creation of a new physical barrier. With no dispersal linking the newly isolated populations, genetic differences that evolve in each population cannot be shared between populations. Eventually, the populations may become so different that no interbreeding occurs even if dispersal pathways are reconnected. The populations are then considered separate species. *See* SPECIATION.

Dispersal is of major concern for scientists who work with rare and endangered animals. Extinction is known to be more prevalent in small, isolated populations. Conservation biologists believe that many species exist as a metapopulation, that is, a group of populations interconnected by the dispersal of individuals or disseminules between subpopulations. The interruption of dispersal in this system of isolated populations can increase the possibility of extinction of the whole metapopulation. Conservation plans sometimes propose the creation of corridors to link isolated patches of habitat as a way of increasing the probability of successful dispersal. *See* EXTINCTION (BIOLOGY); POPULATION DISPERSION. [J.B.D.]

Population dispersion The spatial distribution at any particular moment of the individuals of a species of plant or animal. Under natural conditions organisms are distributed either by active movements, or migrations, or by passive transport by wind, water, or other organisms. The act or process of dissemination is usually termed dispersal, while the resulting pattern of distribution is best referred to as dispersion. Dispersion is a basic characteristic of populations, controlling various features of their structure and organization. It determines population density, that is, the number of individuals per unit of area, or volume, and its reciprocal relationship, mean area, or the average area per individual. It also determines the frequency, or chance of encountering one or more individuals of the population in a particular sample unit of area, or volume. The ecologist therefore studies not only the fluctuations in numbers of individuals in a population but also the changes in their distribution in space. *See* POPULATION DISPERSAL.

Principal types of dispersion. The dispersion pattern of individuals in a population may conform to any one of several broad types, such as random, uniform, or contagious (clumped). Any pattern is relative to the space being examined; a population may appear clumped when a large area is considered, but may prove to be distributed at random with respect to a much smaller area.

Random or haphazard implies that the individuals have been distributed by chance. In such a distribution, the probability of finding an individual at any point in the area is the same for all points. Hence a truly random pattern will develop only if each individual has had an equal and independent opportunity to establish itself at any given point. Examples of approximately random dispersions can be found in the patterns of settlement by free-floating marine larvae and of colonization of bare ground by airborne disseminules of plants. Nevertheless, true randomness appears to be relatively rare in nature.

Uniform distribution implies a regularity of distance between and among the individuals of a population. Perfect uniformity exists when the distance from one individual to its nearest neighbor is the same for all individuals. Patterns approaching uniformity are most obvious in the dispersion of orchard trees and in other artificial plantings, but the tendency to a regular distribution is also found in nature, as for example in the relatively even spacing of trees in forest canopies, the arrangement of shrubs in deserts, and the distribution of territorial animals.

The most frequent type of distribution encountered is contagious or clumped, indicating the existence of aggregations or groups in the population. Clusters and clones of plants, and families, flocks, and herds of animals are common phenomena. The formation of groups introduces a higher order of complexity in the dispersion pattern, since the several aggregations may themselves be distributed at random, evenly, or in clumps. An adequate description of dispersion, therefore, must include not only the determination of the type of distribution, but also an assessment of the extent of aggregation if the latter is present.

Factors affecting dispersion. The principal factors that determine patterns of population dispersion include (1) the action of environmental agencies of transport, (2) the distribution of soil types and other physical features of the habitat, (3) the influence of temporal changes in weather and climate, (4) the behavior pattern of the population in regard to reproductive processes and dispersal of the young, (5) the intensity of intra- and interspecific competition, and (6) the various social and antisocial forces that may develop among the members of the population. Although in certain cases the dispersion pattern may be due to the overriding effects of one factor, in general populations are subject to the collective and simultaneous action of numerous distributional forces and the dispersion pattern reflects their combined influence. When many small factors act together on the population, a more or less random distribution is to be expected, whereas the domination of a few major factors tends to produce departure from randomness.

Optimal population density. The degree of aggregation which promotes optimum population growth and survival varies according to the species and the circumstances. Groups or organisms often flourish best if neither too few nor too many individuals are present; they have an optimal population density at some intermediate level. The concept of an intermediate optimal population density is sometimes known as Allee's principle. *See* ECOLOGICAL COMMUNITIES; POPULATION ECOLOGY; POPULATION GENETICS. [F.C.E.]

Population ecology The study of spatial and temporal patterns in the abundance and distribution of organisms and of the mechanisms that produce those patterns. Species differ dramatically in their average abundance and geographical distributions, and they display a remarkable range of dynamical patterns of abundance over time, including relative constancy, cycles, irregular fluctuations, violent outbreaks, and extinctions. The aims of population ecology are threefold: (1) to elucidate general principles explaining these dynamic patterns; (2) to integrate these principles with mechanistic models and evolutionary interpretations of individual life-history tactics, physiology, and behavior as well as with theories of community and ecosystem dynamics; and (3) to apply these principles to the management and conservation of natural populations.

In addition to its intrinsic conceptual appeal, population ecology has great practical utility. Control programs for agricultural pests or human diseases ideally attempt to reduce the intrinsic rate of increase of those organisms to very low values. Analyses of the population dynamics of infectious diseases have successfully guided the development of vaccination programs. In the exploitation of renewable resources, such as in forestry or fisheries biology, population models are required in order to devise sensible harvesting strategies that maximize the sustainable yield extracted from exploited populations. Conservation biology is increasingly concerned with the consequences of habitat fragmentation for species preservation. Population models can help characterize minimum viable population sizes below which a species is vulnerable to rapid extinction, and can help guide the development of interventionist policies to save endangered species. Finally, population ecology must be an integral part of any attempt to bring the world's burgeoning human population into harmonious balance with the environment. *See* ECOLOGY; MATHEMATICAL ECOLOGY; THEORETICAL ECOLOGY. [R.Hol.]

Population genetics The study of both experimental and theoretical consequences of mendelian heredity on the population level, in contradistinction to classical genetics which deals with the offspring of specified parents on the familial level. The genetics of populations studies the frequencies of genes, genotypes, and phenotypes, and the mating systems. It also studies the forces that may alter the genetic composition of a population in time, such as recurrent mutation, migration, and intermixture between groups, selection resulting from genotypic differential fertility, and the random changes incurred by the sampling process in reproduction from generation to generation. This type of study contributes to an understanding of the elementary step in biological evolution. The principles of population genetics may be applied to plants and to other animals as well as humans. *See* GENETICS; MENDELISM. [C.C.L.]

Population viability The ability of a population to persist and to avoid extinction. The viability of a population will increase or decrease in response to changes in the rates of birth, death, and growth of individuals. In natural populations, these rates are not stable, but undergo fluctuations due to external forces such as hurricanes and introduced species, and internal forces such as competition and genetic composition. Such factors can drive populations to extinction if they are severe or if several detrimental events occur before the population can recover. *See* ECOLOGY; POPULATION ECOLOGY.

One of the most important uses of population viability models comes from modern conservation biology, which uses these models to determine whether a population is in danger of extinction. This is called population viability analysis (PVA) and consists of demographic and genetic models that are used to make decisions on how to manage populations of threatened or endangered species. The National Research Council has called population viability analysis "the cornerstone, the obligatory tool by which recovery objectives and criteria [for endangered species] are identified." *See* ECOLOGICAL MODELING. [G.LeB.; T.E.M.]

Porcelain A high-grade ceramic ware characterized by high strength, a white color (under the glaze), very low absorption, good translucency, and a hard glaze. Equivalent terms are

European porcelain, hard porcelain, true porcelain, and hard paste porcelain. *See* GLAZING; POTTERY.

Porcelain is distinguished from other fine ceramic ware, such as china, by the fact that the firing of the unglazed ware (the bisque firing) is done at a lower temperature (1800–2200°F or 1000–1200°C) than the final or glost firing, which may be as high as 2700°F (1500°C). In other words, the ware reaches its final state of maturity at the maturing temperatures of the glaze.

The white color is obtained by using very pure white-firing kaolin or china clay and other pure materials, the low absorption results from the high firing temperature, and the translucency results from the glass phase. *See* CERAMICS. [J.F.McM.]

Porcupine Any of about 26 species of rodents which have spines or quills in addition to regular hair. These mammals are included in two families, the Hystricidae, or Old World porcupines, and the Erethizontidae, or New World porcupines. The spines are sharply pointed, erectile hairs which serve the animal as defensive structures and are controlled by powerful skin muscles. These animals have short limbs which terminate in five functional digits in the Old World species and four in the New World species. *See* MAMMALIA; RODENTIA. [C.B.C.]

Porifera The sponges, a phylum of the animal kingdom which includes about 5000 described species. The body plan of sponges is unique among animals. Currents of water are drawn through small pores, or ostia, in the sponge body and leave by way of larger openings called oscula. The beating of flagella on collar cells or choanocytes, localized in chambers on the interior of the sponge, maintains the water current. Support for the sponge tissues is provided by calcareous or siliceous spicules, or by organic fibers, or by a combination of organic fibers and siliceous spicules. Some species have a compound skeleton of organic fibers, siliceous spicules, and a basal mass of aragonite or calcite. The skeletons of species with supporting networks of organic fibers have long been used for bathing and cleaning purposes. Because of their primitive organization, sponges are of interest to zoologists as an aid in understanding the origin of multicellular animals. *See* ANIMAL KINGDOM; PARAZOA.

The Porifera have a fossil record extending from the Precambrian to Recent times. More than 1000 genera of fossil sponges have been described from the Paleozoic, Mesozoic, and Cenozoic eras.

The living Porifera are divided into four classes on the basis of their skeletal structures. A taxonomic scheme of the Porifera follows.

- Class Hexactinellida
  - Subclass Amphidiscophora
    - Order: Amphidiscosa
    - Hemidiscosa
    - Reticulosa
  - Subclass Hexasterophora
    - Order: Hexactinosa
    - Lynchniscosa
    - Lyssacinosa
- Class Calcarea
  - Subclass Calcinea
    - Order: Clathrinida
    - Leucettida
  - Subclass Calcaronea
    - Order: Leucosoleniida
    - Sycettida
  - Subclass Pharetronida
- Class Demospongiae
  - Subclass Tetractinomorpha
    - Order: Homosclerophorida
    - Choristida
    - Spirophorida
    - Hadromerida
    - Axinellida
  - Subclass Ceractinomorpha
    - Order: Dendroceratida
    - Dictyoceratida
    - Halichondrida
    - Haplosclerida
    - Poecilosclerida
    - (Permosphincta, extinct)
- Class Sclerospongiae

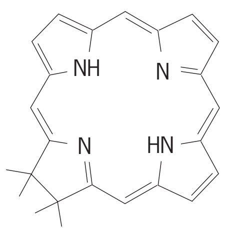
[J.K.Ri.]

Porocephalida One of two orders in the class Pentastomida of the phylum Arthropoda. In this order the larvae have four legs. The hooks on the adult articulate on a chitinous base or fulcrum and are arranged in a flattened trapezoidal pattern, or in a curved line or straight line. There are no podial or parapodial lobes. The two suborders are Porocephaloidea and Linguatuloidea.

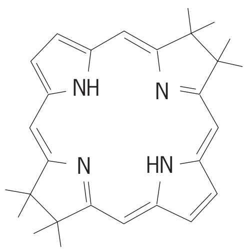
The Porocephaloidea comprise five families—Porocephalidae, Sebekidae, Armilliferidae, Sambonidae, and Subtriquetridae—and include most of the pentastomid species. These animals are cylindrical, with rounded ends. The hooks are sessile; the mouth is anterior between the hooks. Adults occur in the respiratory passages of snakes, lizards, turtles, and crocodiles; the larvae are encysted in fishes, snakes, lizards, crocodiles, and mammals.

Linguatuloidea contains a single family, with a single genus, *Linguatula*. Adults live in the nasal cavities of carnivorous mammals; the larvae are encysted in herbivorous mammals. The body is elongate, flattened ventrally, annulate, and attenuated posteriorly. *See* PENTASTOMIDA. [H.W.S.]

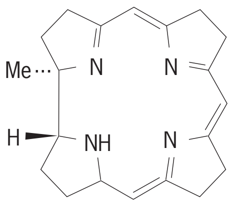
Porphyrin One of a class of cyclic compounds in which the parent macrocycle consists of four pyrrole-type units linked together by single carbon bridges. Several porphyrins with selected peripheral substitution and metal coordination carry out vital biochemical processes in living organisms. Chlorins, bacteriochlorins, and corrins are related tetrapyrrolic macrocycles that are also observed in biologically important compounds.



Chlorin

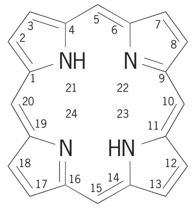


Bacteriochlorin



Corrin

Me = CH_3



Porphyrin nucleus

The complexity of porphyrin nomenclature parallels the complex structures of the naturally occurring derivatives. Hans Fischer used a simple numbering system for the porphyrin nucleus and a set of common names to identify the different porphyrins and their isomers. A systematic naming based on the 1–24 numbering system for the porphyrin nucleus was later developed by the International Union of Pure and Applied Chemistry (IUPAC) and the International Union of Biochemistry (IUB), and this system has gained general acceptance. The need for common names is clear after examination of the systematic names; for example, protoporphyrin IX has the systematic name 2,7,12,18-tetramethyl-3,8-divinyl-13,17-dipropanoic acid.

The aromatic character (hence stability) of porphyrins has been confirmed by measurements of their heats of combustion. In addition, x-ray crystallographic studies have established planarity of the porphyrin macrocycle which is a basic requirement for aromatic character. *See* DELOCALIZATION; X-RAY CRYSTALLOGRAPHY.

Most metals and metalloids have been inserted into the central hole of the porphyrin macrocycle. The resulting metalloporphyrins are usually very stable and can bind a variety of small molecules (known as ligands) to the central metal atom. Heme, the iron complex of protoporphyrin IX, is the prosthetic group of a number of major proteins and enzymes that carry out diverse biological functions. These include binding, transport, and storage of oxygen (hemoglobin and myoglobin), electron-transfer processes (cytochromes), activation and transfer of oxygen to substrates (cytochromes P450), and managing and using hydrogen peroxide (peroxidases and catalases). *See* COORDINATION COMPLEXES; CYTOCHROME; HEMOGLOBIN.

Chlorophylls and bacteriochlorophylls are magnesium complexes of porphyrin derivatives known as chlorins and bacteriochlorins, respectively. They are the pigments responsible for photosynthesis. Several chlorophylls have been identified, the most common being chlorophyll *a*, which is found in all oxygen-evolving photosynthetic plants. Bacteriochlorophyll *a* is found in many photosynthetic bacteria. *See* CHLOROPHYLL; PHOTOSYNTHESIS.

Porphyrins and metalloporphyrins exhibit many potentially important medicinal and industrial properties. Metalloporphyrins are being examined as potential catalysts for a variety of processes, including catalytic oxidations. They are also being examined as possible blood substitutes and as electrocatalysts for fuel cells and for the electrochemical generation of hydrogen peroxide. The unique optical properties of porphyrins make them likely candidates for photovoltaic devices and in photocopying and other optical devices. A major area where porphyrins are showing significant potential is in the treatment of a wide range of diseases, including cancer, using photodynamic therapy. *See* CATALYSIS. [T.W.D.]

Porphyroblast A relatively large crystal formed in a metamorphic rock. The presence of abundant porphyroblasts gives the rock a porphyroblastic texture. Minerals found commonly as porphyroblasts include biotite, garnet, chloritoid, staurolite, kyanite, sillimanite, andalusite, cordierite, and feldspar. Porphyroblasts are generally a few millimeters or centimeters across, but some attain a diameter of over 1 ft (30 cm). They may be bounded by well-defined crystal faces, or their outlines may be highly irregular or ragged. Very commonly they are crowded with tiny grains of other minerals that occur in the rock.

Most commonly, porphyroblasts develop in schist and gneiss during the late stages of recrystallization. As the rock becomes reconstituted, certain components migrate to favored sites and combine there to develop the large crystals. *See* GNEISS; METAMORPHIC ROCKS; SCHIST. [C.A.C.]

Porphyry An igneous rock characterized by porphyritic texture, in which large crystals (phenocrysts) are enclosed in a matrix of very fine-grained to aphanitic (not visibly crystalline) material. Porphyries are generally distinguished from other porphyritic rocks by their abundance of phenocrysts and by their occurrence in small intrusive bodies (dikes and sills) formed at shallow depth within the earth. In this sense porphyries are hypabyssal rocks. *See* IGNEOUS ROCKS; PHENOCRYST.

Porphyries occur as marginal phases of medium-sized igneous bodies (stocks, laccoliths) or as apophyses (offshoots) projecting from such bodies into the surrounding rocks. They are also abundant as dikes cutting compositionally equivalent plutonic rock, or as dikes, sills, and laccoliths injected into the adjacent older rocks. [W.I.R.]

Porulosida An order of Radiolaria. The central capsule shows many pores, more or less uniformly distributed over the surface of the thick and usually globular layer. The development of skeletal structures ranges from none at all through scattered spines to well-developed latticework shells. Colonial aggregates, in which the capsules of a number of organisms are embedded in a matrix, occur in several genera. *See* RADIOLARIA. [R.P.H.]

Positron An elementary particle with mass equal to that of the electron, and positive charge equal in magnitude to the electron's negative charge. The positron is thus the antiparticle (charge-conjugate particle) to the electron. The positron has the same spin and statistics as the electron. Positrons, like electrons, appear as decay products of many heavier particles; electron-positron pairs are produced by high-energy photons in matter. *See* ANTIMATTER; ELECTRON; ELECTRON-POSITRON PAIR PRODUCTION; ELEMENTARY PARTICLE.

A positron is, in itself, stable, but cannot exist indefinitely in the presence of matter, for it will ultimately collide with an electron. The two particles will be annihilated as a result of this collision, and photons will be created. However, a positron can first become bound to an electron to form a short-lived "atom" termed positronium. *See* POSITRONIUM.

Quantum field theory predicts the occurrence of a fundamental positron creation process in the presence of strong, static electric fields. For a bare nucleus with atomic number $Z > 173$, it becomes energetically favorable to transform the electron binding energy of larger than $2m_0c^2$, where m_0 is the electron rest mass and c is the speed of light, into simultaneously creating an electron bound to the nucleus and a positron that escapes from the nucleus. This process of spontaneous positron emission has not been observed since atoms with $Z > 173$ are not available in nature. However, with the introduction of heavy-ion accelerators, it has become possible to simulate such an atom for a short period in a high-energy collision between two stable heavy atoms such as uranium. Experiments have utilized a variety of such collision systems with total Z ranging from 180 to 188 to search for spontaneous positron emission. A number of these experiments reproduce the salient features expected for this process. However, some inconsistencies with the predictions of the theory have yet to be resolved before spontaneous positron emission is established experimentally. *See* NUCLEAR MOLECULE; QUASIATOM; SUPERCRITICAL FIELDS. [C.G.; J.Gre.]

Positronium An atomic-like system consisting of an electron and positron. Just as in the hydrogen atom, the energy levels of positronium are quantized, with the deepest levels bound by about 6.8 eV. The electron and positron spins can be aligned in the same direction (singlet states) or in opposite directions (triplet states). Annihilation of the positron and electron destroys the lowest-energy singlet state (parapositronium) in about 10^{-10} s, but the lowest triplet state (orthopositronium) survives longer, about 10^{-7} s. This allows sufficient time for precise measurement of the energy levels of triplet states. Because of the absence of nuclei in positronium, these measurements provide an accurate test of theories of the electromagnetic force (quantum electrodynamics) without interference from the strong force. *See* ATOMIC STRUCTURE AND SPECTRA; ELECTRON; FUNDAMENTAL INTERACTIONS; POSITRON.

Since the formation of positronium requires the close approach of a positron and an electron, beams of slow positrons can be used as probes of the electron density in gases, in insulating solids, or near surfaces. Since the singlet and triplet forms of positronium have very different lifetimes, and transitions between the two states can be induced by neighboring electrons, study of the decay of positronium can also provide information about electron densities on a microscopic scale. This is especially useful in the study of density fluctuations in gases near the critical point for condensation into liquids or solids. *See* CRITICAL PHENOMENA.

Annihilation radiation from positronium forms a component of the gamma-ray spectrum observed by astronomers, in particular from the galactic center. *See* GAMMA-RAY ASTRONOMY. [J.N.Ba.]

Posttraumatic stress disorder An anxiety disorder in some individuals who have experienced an event that poses a direct threat to the individual's or another person's life. The characteristic features of anxiety disorders are fear, particularly in the absence of a real-life threat to safety, and avoidance behavior.

A diagnosis of posttraumatic stress disorder requires that four criteria be met. First, the individual must have been exposed to an extremely stressful and traumatic event beyond the range of normal human experience. Second, the individual must periodically and persistently reexperience the event. This reexperiencing can take different forms, such as recurrent dreams and nightmares, an inability to stop thinking about the event, flashbacks during which the individual relives the trauma, and auditory hallucinations. Third, there is persistent avoidance of events related to the trauma, and psychological numbing that was not present prior to the trauma. Fourth, enduring symptoms of anxiety and arousal are present. These symptoms can be manifested in different forms, including anger, irritability, a very sensitive startle response, an inability to sleep well, and physiological evidence of fear when the individual is reexposed to a traumatic event.

Posttraumatic stress disorder symptoms appear to range over a continuum of severity, and it is unlikely that the disorder is an all-or-nothing phenomenon. The degree of the posttraumatic stress response is likely to be influenced by a complex interaction of personality, nature of the trauma, and posttraumatic events.

Physiological arousal responses in individuals with posttraumatic stress disorder include increases in heart rate, respiration rate, and skin conductivity upon reexposure to traumatic stimuli. Posttraumatic stress disorder may also be associated with structural and physiological changes in the brain. Stressful events also affect the activity level of the pituitary and adrenal glands. All these physiological changes are probably complexly related to the persistence and waxing and waning of symptoms in posttraumatic stress disorder. In addition, extreme and prolonged stress is associated with a variety of physical ailments, including heart attacks, ulcers, colitis, and decreases in immunological functioning. *See* NEUROBIOLOGY.

When an individual is diagnosed as having this disorder, particularly after it has been present for a number of years, it is common to also find significant depression, generalized anxiety, substance abuse and dependence, marital problems, and intense, almost debilitating anger. Although the primary symptoms of posttraumatic stress disorder are quite amenable to psychological treatment efforts, these secondary problems commonly associated with the chronic disorder are more difficult to treat.

Posttraumatic stress disorder can be treated by pharmacological means and with psychotherapy. Most psychological treatments for the disorder involve reexposure to the traumatic event. This reexposure is typically imaginal and can range from simply talking about the trauma to having the person vividly imagine reliving the traumatic event. This latter behavioral procedure is called implosion therapy or flooding. While flooding is not appropriate for all posttraumatic stress disorder cases, the procedure can dramatically decrease anxiety and arousal, intrusive thoughts, avoidance behavior, and emotional numbing. Along with specific behavior interventions, individuals with posttraumatic stress disorder should become involved in psychotherapeutic treatment for secondary problems. *See* NORADRENERGIC SYSTEM; PSYCHOPHARMACOLOGY; STRESS (PSYCHOLOGY). [R.W.But.]

Postulate In a formal deductive system, a proposition accepted without proof, from which other propositions are deduced by the conventional methods of formal logic. There is a certain arbitrariness as to which propositions are to be treated as postulates, because when certain proved propositions are treated as such, other propositions which were originally postulates often become proved propositions. In strict usage, the term postulate is nearly equivalent to axiom, although axiom is often loosely used to denote a truth supposed to be self-evident. *See* LOGIC. [P.W.Br./H.Ma.]

Postural equilibrium A lifeless object is said to be in equilibrium, or in a state of balance, when all forces acting upon it cancel. The result is a state of rest. In an actively moving animal, internal as well as external forces have to be considered, and the maintenance of a balanced attitude in a body consisting of a number of parts that are loosely connected by movable joints is complex.

The maintenance of equilibrium is relatively easy in limbless animals. When the animal is turned on its back, the lack of contact pressure on the creeping surface and the tactile stimulation of the back initiate movements which return the animal to its normal position. This is known as the righting reflex. Free-swimming and flying animals are often in a precariously poised state of equilibrium, so that the normal attitude can be maintained only by the continuous operation of corrective equilibrating mechanisms. The same applies to a lesser degree to long-legged quadrupeds, such as many mammals, and to bipeds, such as birds and some primates (including humans).

For most species, there is a specific orientation of the whole body or of body segments (such as the head) with respect to gravity. This orientation is based on multisensory inputs and on a set of inborn reflexes acting on the musculature. These postural reflexes also stabilize the genetically defined body orientation against external disturbances. The sensory information relies on a number of sources: (1) static and dynamic information from the eyes; (2) static and dynamic mechanoreceptors incorporated in the various types of statocysts in invertebrate animals and in the vestibular organ or labyrinth of vertebrates; (3) proprioceptor organs such as muscle spindles, Golgi endings in tendons, Pacinian corpuscles and similar encapsulated endings associated with tendons and joints, and other pressure receptors in supporting surfaces (for example, the soles of feet); and (4) sensory endings in the viscera, capable of being differentially stimulated by changes in the direction of visceral pull on mesenteries, and on other structures. *See* SENSATION; SENSE ORGAN.

In higher terrestrial vertebrates, during stance the center of mass is usually situated high above the ground due to the support of the body by the limbs. A critical aspect of posture in quadrupedal and bipedal stance is equilibrium maintenance which is preserved only when under static conditions the projection of the center of mass remains inside the support base. This positioning of the center of mass is based on two main controls. A "bottom up" control is based on the afferent nerve impulses, cutaneous and proprioceptive, from the feet and the ankle joint muscles. These nerve impulse serve in building up posture from the feet to the head. A "top down" control starts from the head, and is predominant during dynamic activities such as locomotion. Due to labyrinthine afferent nerve impulses, the head axis orientation remains stable with respect to space. The movement-related visual afferents recorded by the retina monitor the head displacements with respect to space and adjust the body posture as a function of these inputs.

Two levels of control are involved in maintaining balance. A first level includes the spinal cord and the brainstem, where a set of inborn reflexes are organized for stance regulation and head orientation. Most postural reflexes rely on networks at that level. The cerebellum is involved in the adaptation of these reflexes to the external constraints. *See* Reflex.

A second level of control includes cortical areas involved in multisensory integration and control as well as the basal ganglia. The postural body schema and the body orientation with respect to the external world are organized mainly at that level, with a predominant role in the right hemisphere. Coordination between balance control and locomotion or movements also depends on these higher levels. [J.Mas.]

Potassium A chemical element, K, atomic number 19, and atomic weight 39.102. It stands in the middle of the alkali metal family, below sodium and above rubidium. This lightweight, soft, low-melting, reactive metal (see table) is very similar to sodium in its behavior in metallic forms. *See* Alkali metals; Periodic table; Rubidium; Sodium.

Potassium chloride, KCl, finds its main use in fertilizer mixtures. It also serves as the raw material for the manufacture of other potassium compounds. Potassium hydroxide, KOH, is used in the manufacture of liquid soaps, and potassium carbonate in making soft soaps. Potassium carbonate, K_2CO_3, is also an important raw material for the glass industry. Potassium nitrate, KNO_3, is used in matches, in pyrotechnics, and in similar items which require an oxidizing agent. [M.Si.]

Potassium is a very abundant element, ranking seventh among all the elements in the Earth's crust, 2.59% of which is potassium in combined form. Seawater contains 380 parts per million, making potassium the sixth most plentiful element in solution.

Potassium is even more reactive than sodium. It reacts vigorously with the oxygen in air to form the monoxide, K_2O, and the peroxide, K_2O_2. In the presence of excess oxygen, it readily forms the superoxide, KO_2.

Potassium does not react with nitrogen to form a nitride, even at elevated temperatures. With hydrogen, potassium reacts slowly at 200°C (392°F) and rapidly at 350–400°C (662–752°F). It forms the least stable hydride of all the alkali metals.

The reaction between potassium and water or ice is violent, even at temperatures as low as −100°C (−148°F). The hydrogen evolved is usually ignited in reaction at room temperature. Reactions with aqueous acids are even more violent and verge on being explosive.

The potassium ion (K^+) is the most common intracellular cation and is essential for maintaining osmotic pressure and electrodynamic cellular properties in organisms. The intracellular potassium ion concentrations are typically high for most cells, whereas the potassium ion concentrations present in extracellular fluids are significantly lower. The hydrolysis of the coenzyme adenosine triphosphate (ATP) is mediated by the membrane-bound enzyme Na^+, K^+-ATPase. This enzyme is called the sodium pump and it is activated by both potassium and sodium ions; however, many enzymes are activated by potassium ions alone (for example, pyruvate kinase, aldehyde dehydrogenase, and phosphofructokinase).

Potassium deficiency may occur in several conditions, including malnutrition and excessive vomiting or diarrhea, and in patients undergoing dialysis; supplementation with potassium salts is sometimes required. *See* Osmoregulatory mechanisms. [D.M.DeF.]

Physical properties of potassium metal

Property	Temperature °C	Temperature °F	SI units	Customary (engineering) units
Density	100	212	0.819 g/cm^3	51.1 lb/ft^3
	400	752	0.747 g/cm^3	46.7 lb/ft^3
	700	1292	0.676 g/cm^3	42.2 lb/ft^3
Melting point	63.7	147		
Boiling point	760	1400		
Heat of fusion	63.7	147	14.6 cal/g	26.3 Btu/lb
Heat of vaporization	760	1400	496 cal/g	893 Btu/lb
Viscosity	70	158	5.15 millipoises	6.5 kinetic units
	400	752	2.58 millipoises	3.5 kinetic units
	800	1472	1.36 millipoises	2 kinetic units
Vapor pressure	342	648	1 mm	0.019 lb/in.^{2}
	696	1285	400 mm	7.75 lb/in.^{2}
Thermal conductivity	200	392	0.017 cal/(s)(cm^2)(cm)(°C)	26.0 Btu(h)(ft^2)(°F)
	400	752	0.09 cal/(s)(cm^2)(cm)(°C)	21.7 Btu/(h)(ft^2)(°F)
Heat capacity	200	392	0.19 cal/(g)(°C)	0.19 Btu/(lb)(°F)
	800	1472	0.19 cal/(g)(°C)	0.19 Btu/(lb)(°F)
Electrical resistivity	150	302	18.7 microhm-cm	
	300	572	28.2 microhm-cm	
Surface tension	100–150	212–302	About 80 dynes/cm	

Potato, Irish A plant of the genus *Solanum* in the nightshade family, Solanaceae; it is related to tomatoes and peppers. There are more than 2000 species of *Solanum*, of which about 150 bear tubers. The potato of commerce, *S. tuberosum*, originated in South America, probably in the highlands of Peru and Bolivia, where it has been cultivated for several thousand years. Potatoes were introduced into Europe by Spanish explorers in the late sixteenth century and into the United States from Ireland in 1719. The crop became a staple in Europe, was a primary source of food in Ireland, and is known even today as the Irish potato. *See* Solanales.

The potato plant is an annual, herbaceous dicotyledon that is grown primarily for its edible tubers, which are short, thick underground stems that form on the ends of stolons (lateral stems). Lateral buds (eyes) on the mature tuber are the growing points for a new crop, provided that whole tubers or pieces with at least one eye are planted.

There are 95–100 varieties certified for seed production in the United States and Canada. In the United States, seven varieties account for more than 70% of the commercial acreage planted. These are Russet Burbank, Norchip, Atlantic, Russet Norkotah, Superior, Centennial Russet, and Kennebec.

Potatoes are grown in more countries than any crop except for corn (maize), and they are the fourth-most important food crop in supplying energy in the human diet, following rice, wheat, and corn. The leading potato producers are Russia, China, Poland, and the United States, in descending order.

Chemical constituents can be affected by variety, production area, cultural practices, maturity at harvest, and storage conditions. The average composition of potatoes is 78–80% water, 14–18% starch, 2% protein, 1% minerals, 0.4% fiber, and 0.1% fat, with some sugars, organic acids, amino acids, and vitamins. The potato is very nutritious, serving as a nearly complete food itself, and it produces more food per acre than any other crop.

Starch constitutes about 65–80% of the dry weight of the potato and, calorically, is the most important component. Potatoes contain appreciable amounts of the B vitamins, and they are an excellent source of vitamin D. Potatoes contribute more vitamin C to the United States food supply than any other single food source. Inorganic constituents or minerals of potatoes are predominantly potassium, phosphorus, sulfur, chlorine, magnesium, and calcium. Potatoes contain sufficient quantities of iron to be a good nutritional source of this mineral as well. [J.C.Mi.]

Potato, sweet The fleshy root of the plant *Ipomoea batatas*. The sweet potato was mentioned as being grown in Virginia as early as 1648. In 1930 the selection of outstanding strains of the Porto Rico variety, which was introduced into Florida in 1908, was begun in Louisiana, and the best strain, Unit I Porto Rico, was released in 1934. The Unit I Porto Rico is now being replaced by the Centennial, a yam type which has three times its vitamin A content. More than 70% of the commercial crop in the United States is of the Centennial variety. Louisiana is the leading state for commercial production of both the canned and fresh products.

There are two principal types of sweet potato, the kind erroneously called yam and the Jersey type. The chief difference between the two is that in cooking or baking the yam, much of the starch is broken down into simple sugars (glucose and fructose) and an intermediate product, dextrin. This gives it a moist, syrupy consistency somewhat sweeter than that of the dry (Jersey) type. On cooking, the sugar in the dry type remains as sucrose.

The yam is produced largely in the Southern states; however, because of the breeding of more widely adapted varieties, it is now being grown farther north. The Jersey sweet potato is grown largely along the eastern shore of Virginia. Maryland, Delaware, and New Jersey, and also in Iowa and Kansas. [J.C.M.]

Technically, the sweet potato is a perennial plant, but in commerical production the growth is terminated by harvest due to impending change of seasons (cold or rainy) or by achievement of optimum storage root size. Plantings are established from sprouts obtained from stored roots or from vine cuttings. Production of storage roots does not require pollination, so that adverse conditions only delay or reduce harvests; crop failures are rare. A variety of soil types may be used; however, light sandy soils are preferred for ease of harvest.

A number of factors contribute to the worldwide importance of sweet potatoes. Perhaps foremost is the high energy yield, which exceeds that of Irish potatoes and grains. Sweet potato roots are also high in nutritional quality.

The sweet potato is a versatile crop that is used as a food, an ingredient in other foods, an animal feed, and a feedstock for the production of starch and ethanol. *See* Animal feeds; Potato, Irish; Starch. [J.C.Bo.]

Potential flow A fluid flow that is isentropic and that, if incompressible, can be mathematically described by Laplace's equation. For an ideal fluid, or a flow in which viscous effects are ignored, vorticity (defined as the curl of the velocity) cannot be produced, and any initial vorticity existing in the flow simply moves unchanged with the fluid. Ideal fluids, of course, do not exist since any actual fluid has some viscosity, and the effects of this viscosity will be important near a solid wall, in the region known as the boundary layer. Nevertheless, the study of potential flow is important in hydrodynamics, where the fluid is considered incompressible, and even in aerodynamics, where the fluid is considered compressible, as long as shock waves are not present. *See* Boundary-layer flow; Compressible flow; Isentropic flow.

In the absence of viscous effects, a flow starting from rest will be irrotational for all subsequent time. For an irrotational flow, the curl of the velocity is zero ($\nabla \times V = 0$). The curl of the gradient of any scalar function is zero ($\nabla \times \nabla\phi = 0$). It then follows mathematically that the condition of irrotationality can be satisfied identically by choosing the scalar function, ϕ, such that the velocity is the gradient of ϕ ($V = \nabla\phi$). For this reason, this scalar function ϕ has been traditionally referred to as the velocity potential, and the flow as a potential flow. *See* Calculus of vectors; Potentials.

By applying the continuity equation to the definition of the potential function, it becomes possible to represent the flow by the well-known Laplace equation ($\nabla^2\phi = 0$), instead of the coupled system of the continuity and nonlinear Euler equations. The linearity of the Laplace equation, which also governs other important physical phenomena such as electricity and magnetism, makes it possible to use the principle of superposition to combine elementary solutions in solving more complex problems. *See* Equation of continuity; Fluid flow; Laplace's differential equation; Laplace's irrotational motion. [P.E.R.]

Potentials Functions or sets of functions from whose first derivatives a vector can be formed. A vector is a quantity which has a magnitude and a direction, such as force.

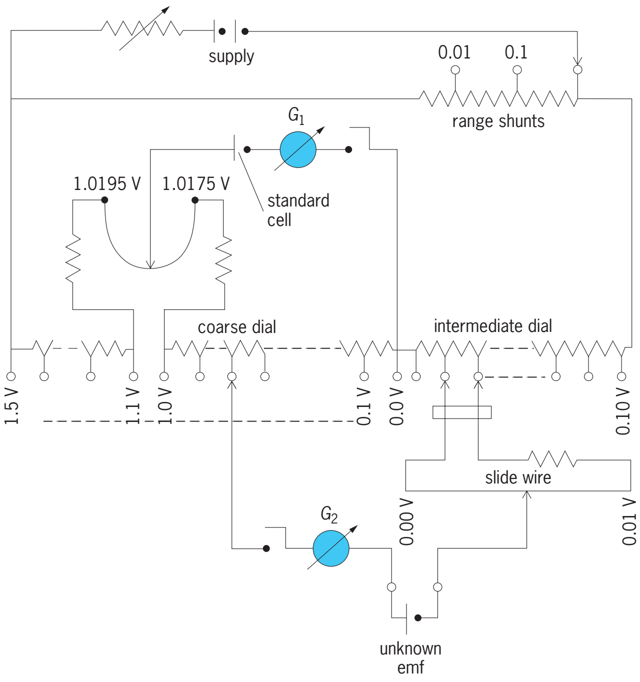
A single function, the scalar potential, is used in gravitation theory, electricity and magnetism, fluid mechanics, and other areas. The vectors obtained from it by partial differentiation are in these cases the gravitational, electric and magnetic field strengths, and the velocity, respectively. The vector potential is a set of three functions whose first derivatives give the magnetic induction. *See* Electric field; Gravitation; Laplace's irrotational motion. [F.Ro.]

Potentiometer An instrument that precisely measures an electromotive force (emf) or a voltage by opposing to it a known potential drop established by passing a definite current through a resistor of known characteristics. (A three-terminal resistive voltage divider is sometimes also called a potentiometer.) There are two ways of accomplishing this balance: (1) the current I may be held at a fixed value and the resistance R across which the IR drop is opposed to the unknown may be varied; (2) current may be varied across a fixed resistance to achieve the needed IR drop. *See* Electromotive force (emf); Resistor.

The essential features of a general-purpose constant-current instrument are shown in the illustration. The value of the current is first fixed to match an IR drop to the emf of a reference standard cell. With the standard-cell dial set to read the emf of the reference cell, and the galvanometer (balance detector) in position G_1, the resistance of the supply branch of the circuit is adjusted until the IR drop in 10 steps of the coarse dial plus the set portion of the standard-cell dial balances the known reference emf, indicated by a null reading of the galvanometer. This adjustment permits the potentiometer to be read directly in volts. Then, with the galvanometer in position G_2, the coarse, intermediate, and slide-wire dials are adjusted until the galvanometer again reads null. If the potentiometer current has not changed, the emf of the unknown can be read directly from the dial settings. There is usually a switching arrangement so that the galvanometer can be quickly shifted between positions 1 and 2 to check that the current has not drifted from its set value. *See* Electromotive force (cells); Galvanometer.

Potentiometer techniques may also be used for current measurement, the unknown current being sent through a known resistance and the IR drop opposed by balancing it at the voltage terminals of the potentiometer. Here, of course, internal heating and consequent resistance change of the current-carrying resistor (shunt) may be a critical factor in measurement accuracy; and the shunt design may require attention to dissipation of heat resulting from its I^2R power consumption. *See* Current measurement; Joule's law.

Potentiometer techniques have been extended to alternating-voltage measurements, but generally at a reduced accuracy level (usually 0.1% or so). Current is set on an ammeter which must have the same response on ac as on dc, where it may be



Circuit diagram of a general-purpose constant-current potentiometer, showing essential features.

calibrated with a potentiometer and shunt combination. Balance in opposing an unknown voltage is achieved in one of two ways: (1) a slide-wire and phase-adjustable supply; (2) separate in-phase and quadrature adjustments on slide wires supplied from sources that have a 90° phase difference. Such potentiometers have limited use in magnetic testing. *See* ALTERNATING CURRENT; ELECTRICAL MEASUREMENTS; VOLTAGE MEASUREMENT.

[F.K.H.; R.F.Dz.]

Pottery

Vessels made entirely or partly of clay, and fired to a strong, hard product; occasionally, the term refers to just the lower grades of such ware. Pottery may be glazed or unglazed. *See* CERAMICS; GLAZING.

Grades of pottery (such as china, stoneware, earthenware, and other special types) are distinguished by their color, strength, absorption (the weight of water soaked up when the piece is submerged, expressed as a percentage of the original weight), and translucency (ability to transmit light). All these properties refer to the material or "body" under any glaze present. *See* PORCELAIN.

Absorption is due to the presence of open pores or voids in the fired material into which water can penetrate; in general, the higher the firing temperature, the lower the absorption. Body color is determined mainly by raw-material purity. Strength depends on the porosity and also on the amount and type of glass and crystals developed in the body on firing. Translucency is obtained in products in which there is low porosity and little differences in index of refraction between the glass and crystals in the body. *See* CLAY.

[J.F.McM.]

Pottiales

An order of the true mosses (subclass Bryidae), consisting of three families and about 91 genera. The order is characterized by short, papillose leaf cells and deeply divided, commonly twisted peristome teeth. Members of the Pottiales typically grow erect, with stems simple or forked by subfloral innovation, and they often produce gemmae (asexual reproductive bodies) on leaves, stems, or rhizoids. The leaves have revolute margins, and are arranged in many rows. The single costa often ends in a hyaline hairpoint. *See* BRYIDAE; BRYOPHYTA; BRYOPSIDA.

[H.Cr.]

Poultry production

Poultry production comprises two major categories, meat production and egg production. Most poultry produced in North America is grown under close control on highly specialized farms. The evolution from small flocks to large commercial units after World War II was facilitated by rapid advances in the knowledge of nutrition, breeding, housing, disease control, and processing of poultry and eggs, and by improvements in transportation and refrigeration which made possible distant marketing of fresh products.

Incubation. Artificial incubation was a major advance in poultry production because it became possible to hatch large numbers of chicks of the same age for farmers to raise for meat or egg production. Modern incubators are constructed of materials that can be effectively cleaned and disinfected and that provide good insulation of the chamber. Eggs are set in specially designed plastic flats which fit into channels in egg racks that move on wheels. The egg racks are equipped with mechanical systems to tilt the eggs 45°; turning is usually done hourly. Eggs are transferred from the setting trays into hatching trays 3 days before expected hatch. After the hatch is completed, the chicks are transferred to a conveyer belt for processing or directly into plastic boxes with absorbent paper pads or into disposable paper boxes with wood fiber pads. Chick servicing often involves sexing, vaccination, and beak trimming. Usually, chicks are held at the hatchery prior to shipment to farms, starting early on the day after hatching. Specially designed delivery trucks or buses are used to provide adequate ventilation for chicks during shipment.

Breeding. The genetic stock used for modern poultry production is produced by highly specialized breeding companies. Meat poultry is selected for good meat type, fast growth, disease resistance, and efficient conversion of feed to meat. Different strains of chickens are used for table egg production. These are selected for high egg production, large egg size, and small body weight for better conversion of feed to eggs and good livability. The body weights of meat and egg production strains are dramatically different. *See* BREEDING (ANIMAL).

Brooding and rearing. Day-old chicks require an ambient temperature of 85–87°F (29–30°C) for normal growth and health during the first week of life. As the chicks grow and feather, they can tolerate lower temperatures. Brooding heat is often provided by a radiant gas brooder stove. Most chicks are started on floors that are covered with 2–4 in. (5–10 cm) of a litter material such as pine shavings, rice hulls, or peanut hulls. Feeding is usually done is small troughs or on plastic trays until the chicks learn to eat and drink. Chicks are quickly trained to eat from mechanical feeders and drink from closed water delivery systems to reduce labor.

Feeding and nutrition. Poultry diets consist of common grains and protein sources with mineral and vitamin supplements. Animal or vegetable fats may be added to increase energy and reduce dustiness. Corn, grain sorghum, wheat, oats, and barley are often used for poultry feeding in the United States. Soybean meal is widely used as a protein supplement. Other important protein supplements are meat meal, fish meal, safflower meal, feather meal, and canola meal. *See* ANIMAL FEEDS.

Housing. The purpose of a poultry house is to confine the birds; to protect them from predators and environmental extremes which would cause mortality or reduce growth, feed efficiency, immunocompetence, fertility or egg production; to facilitate light control; and to facilitate bird management. Poultry houses can be constructed from locally available building materials. Smooth interior surfaces are preferred for effective sanitation. Houses are usually a maximum of 40 ft (12 m) wide to facilitate more uniform ventilation. House length is approximately 500 ft (152 m); most houses are constructed with a gable roof.

Production systems. Chickens for table egg production are often housed in cages to provide cleaner eggs and protect the birds from disease agents which are recycled to birds from the manure. Meat chickens and turkeys are usually grown in litter-floor houses because heavier poultry experience more lameness, breast blisters, and weaker bones and joints when grown in cages.

Ducks and geese. With some modification of husbandry, ducks and geese can be successfully raised in confinement. They do not require water for swimming and can be grown in litter-floor houses similar to meat chickens or turkeys.

Health maintenance. The production of commercial poultry in large flocks requires well-designed disease-control programs. The first requirement is for maintenance of biosecurity in production units. This means that entrance of contaminated workers and visitors, birds, feed, and equipment must be prevented. Some poultry diseases are more effectively or economically controlled by vaccination. Examples are Marek's disease, Newcastle disease, infectious bronchitis, avian pox, infectious bursal disease, and often several others, depending on the disease history of the farm and the area where the poultry are raised. *See* NEWCASTLE DISEASE.

Processing and marketing. Shell eggs are often processed in plants located on the farm. A mechanical system can detect and separate cracked eggs. Egg processing machines can process up to 300 cases of eggs (360 eggs per case) per hour. Machines are also available to separate the yolk and albumen from the egg shell. Poultry are usually processed at large central plants under inspection by the U.S. Department of Agriculture. The meat birds are loaded on trucks at farms during the night, and processing typically begins at midnight, and is followed by extensive cleaning and disinfection of the plant. Poultry are removed from transport racks or coops and hung on shackles. After stunning, bleeding, scalding, and feather removal, the carcasses must be transferred to a second line or table in a different room for evisceration, chilling, cutting, and packaging. Many poultry processing plants cut up poultry before packaging, and they may also separate meat from bone or skin. *See* AGRICULTURAL SCIENCE (ANIMAL); EGG (FOWL). [R.A.E.]

Powder metallurgy

Powder metallurgy A metalworking process used to fabricate parts of simple or complex shape from a wide variety of metals and alloys in the form of powders. The process involves shaping of the powder and subsequent bonding of its individual particles by heating or mechanical working. Powder metallurgy is a highly flexible and automated process that is environmentally friendly, with a low relative energy consumption and a high level of materials utilization. Thus it is possible to fabricate high-quality parts to close tolerance at low cost. Powder metallurgy processing encompasses an extensive range of ferrous and nonferrous alloy powders, ceramic powders, and mixes of metallic and ceramic powders (composite powders). *See* METALLURGY.

Regardless of the processing route, all powder metallurgy methods of part fabrication start with the raw material in the form of a powder. A powder is a finely divided solid, smaller than about 1 mm (0.04 in.) in its maximum dimension. There are four major methods used to produce metal powders, involving mechanical comminution, chemical reactions, electrolytic deposition, and liquid-metal atomization. Metal powders exhibit a diversity of shapes ranging from spherical to acicular. Particle shape is an important property, since it influences the surface area of the powder, its permeability and flow, and its density after compaction. Chemical composition and purity also affect the compaction behavior of powders.

Powder metallurgy processes include pressing and sintering, powder injection molding, and full-density processing. *See* SINTERING.

Normally, parts made by pressing and sintering require no further treatment. However, properties, tolerances, and surface finish can be enhanced by secondary operations such as repressing, resintering, machining, heat treatment, and various surface treatments.

Powder injection molding is a process that builds on established injection molding technology used to fabricate plastics into complex shapes at low cost. It produces parts which have the shape and precision of injection-molded plastics but which exhibit superior mechanical properties such as strength, toughness, and ductility.

Parts fabricated by pressing and sintering are used in many applications. However, their performance is limited because of the presence of porosity. In order to increase properties and performance and to better compete with products manufactured by other metalworking methods (such as casting and forging), several powder metallurgy techniques have been developed that result in fully dense materials; that is, all porosity is eliminated. Examples of full-density processing are hot isostatic pressing, powder forging, and spray forming.

Powder metallurgy competes with several more conventional metalworking methods in the fabrication of parts, including casting, machining, and stamping. Characteristic advantages of powder metallurgy are close tolerances, low cost, net shaping, high production rates, and controlled properties. Other attractive features include compositional flexibility, low tooling costs, available shape complexity, and a relatively small number of steps in most powder metallurgy production operations.

Metal powders can be thermally unstable in the presence of oxygen. Very fine metal powders can burn in air (pyrophoricity) and are potentially explosive. Some respirable fine powders pose a health concern and can cause disease or lung dysfunction. Control is exercised by the use of protective equipment and safe handling systems such as glove boxes. *See* INDUSTRIAL HEALTH AND SAFETY. [A.La.]

Power

Power The time rate of doing work. Like work, power is a scalar quantity, that is, a quantity which has magnitude but no direction. Some units often used for the measurement of power are the watt (1 joule of work per second) and the horsepower (550 foot-pounds of work per second). *See* WORK.

Power is a concept which can be used to describe the operation of any system or device in which a flow of energy occurs. In many problems of apparatus design, the power, rather than the total work to be done, determines the size of the component used. Any device can do a large amount of work by performing for a long time at a low rate of power, that is, by doing work slowly. However, if a large amount of work must be done rapidly, a high-power device is needed. High-power machines are usually larger, more complicated, and more expensive than equipment which need operate only at low power. A motor which must lift a certain weight will have to be larger and more powerful if it lifts the weight rapidly than if it raises it slowly. An electrical resistor must be large in size if it is to convert electrical energy into heat at a high rate without being damaged. [P.W.S.]

Power amplifier

Power amplifier The final stage in multistage amplifiers, such as audio amplifiers and radio transmitters, designed to deliver appreciable power to the load. Power amplifiers may be called upon to supply power ranging from a few watts in an audio amplifier to many thousands of watts in a radio transmitter. In audio amplifiers the load is usually the dynamic impedance presented to the amplifier by a loudspeaker, and the problem is to maximize the power delivered to the load over a wide range of frequencies. The power amplifier in a radio transmitter operates over a relatively narrow band of frequencies with the load essentially a constant impedance. *See* AMPLIFIER. [H.F.K.]

Power factor

Power factor The ratio of watts average power (the average power measured in watts) to the apparent power of an alternating-current circuit. By definition, the equation below holds, which is the ratio of instrument readings.

$$\text{pf} = \frac{\text{watts average power}}{\text{rms volts} \times \text{rms amperes}}$$

A watt-meter indicates average power, and electrodynamometer or iron-vane instruments show rms voltage and current. For the steady-state ac circuit under sinusoidal voltage and current, $\mathrm{pf} = \cos\theta$, where θ is the phase angle between the voltage and current. This definition is restricted to sine waves of the same frequency. *See* Alternating-current circuit theory. [B.L.R.]

Power-factor meter An instrument used to indicate whether load currents and voltages are in time-phase with one another. *See* Power factor.

The single-phase meter contains a fixed coil that carries the load current, and crossed coils that are connected to the load voltage. There is no spring to restrain the moving system, which takes a position to indicate the angle between the current and voltage. The scale can be marked in degrees or in power factor.

The angle between the currents in the crossed coils is a function of frequency, and consequently each power-factor meter is designed for a single frequency and will be in error at all other frequencies. [H.So./E.C.St.]

Power integrated circuits Integrated circuits that are capable of driving a power load. The key feature of a power integrated circuit that differentiates it from other semiconductor technologies is its ability to handle high voltage, high current, or a combination of both.

In its simplest form, a power integrated circuit may consist of a level-shifting and drive circuit that translates logic-level input signals from a microprocessor to a voltage and current level sufficient to energize a load. For example, such a chip may be used to operate electronic display, where the load is usually capacitive in nature but requires drive voltages above 100 V, which is much greater than the operating voltage of digital logic circuits (typically 5 V). At the other extreme, the power integrated circuit may be required to perform load monitoring, diagnostic functions, self-protection, and information feedback to the microprocessor, in addition to handling large amounts of power to actuate the load. An example of this is an automotive multiplexed bus system with distributed power integrated circuits for control of lights, motors, air conditioning, and so forth. *See* Automotive electrical system; Electronic display; Microprocessor.

Power integrated circuits are expected to have an impact on all areas in which power semiconductor devices are presently being used. In addition, they are expected to open up new applications based upon their added features. The wide spectrum of voltages and currents over which power semiconductor devices are utilized are summarized in the table. *See* Integrated circuits. [B.J.Ba.]

Power plant A means for converting stored energy into work. Stationary power plants such as electric generating stations are located near sources of stored energy, such as coal fields or river dams, or are located near the places where the work is to be performed, as in cities or industrial sites. Mobile power plants for transportation service are located in vehicles, as the gasoline engines in automobiles and diesel locomotives for railroads. Power plants range in capacity from a fraction of a horsepower (hp) to over 10^6 kW in a single unit. Large power plants are assembled, erected, and constructed on location from equipment and systems made by different manufacturers. Smaller units are produced in manufacturing facilities.

Most power plants convert part of the stored raw energy of fossil fuels into kinetic energy of a spinning shaft. Some power plants harness nuclear energy. Elevated water supply or run-of-the-river energy is used in hydroelectric power plants. For transportation, the plant may produce a propulsive jet, as in some aircraft, instead of the rotary motion of a shaft. Other sources of energy, such as fuel cells, winds, tides, waves, geothermal, ocean thermal, nuclear fusion, photovoltaics, and solar thermal, have been of negligible commercial significance in the generation of power despite their magnitudes. *See* Energy sources.

There is no practical way of storing the mechanical or electrical output of a power plant in the magnitudes encountered in power plant applications, although several small-scale concepts have been researched. As of now, however, the output must be generated at the instant of its use. This results in wide variations in the loads imposed upon a plant. The capacity, measured in kilowatts or horsepower, must be available when the load is imposed. Much of the capacity may be idle during extended periods when there is no demand for output. Hence much of the potential output, measured as kilowatt-hours or horsepower-hours, cannot be generated because there is no demand for output. Kilowatts cannot be traded for kilowatt-hours, and vice versa. *See* Energy storage.

The efficiency of energy conversion is vital in most power plant installations. With thermal power plants the basic limitations of thermodynamics fix the efficiency of converting heat into work. The cyclic standards of Carnot, Rankine, Otto, Diesel, and Brayton are the usual criteria on which heat-power operations are variously judged. Performance of an assembled power plant, from fuel to net salable or usable output, may be expressed as thermal efficiency (%); fuel consumption (lb, pt, or gal per hp-h or per kWh); or heat rate (Btu supplied in fuel per hp-h or per kWh). American practice uses high or gross calorific value of the fuel for measuring heat rate or thermal efficiency and differs in this respect from European practice, which prefers the low or net calorific value.

In scrutinizing data on thermal performance, it should be recalled that the mechanical equivalent of heat (100% thermal efficiency) is 2545 Btu/hp-h and 3413 Btu/kWh (3.6 megajoules/kWh). Modern steam plants in large sizes (75,000–1,300,000 kW units) and internal combustion plants in modest sizes (1000–20,000 kW) have little difficulty in delivering a kilowatt-hour for less than 10,000 Btu (10.55 MJ) in fuel (34% thermal efficiency). For condensing steam plants, the lowest fuel consumptions per unit output (8200–9000 Btu/kWh or 8.7–9.5 MJ/kWh) are obtained in plants with the best vacuums, regenerative-reheat cycles using eight stages of extraction feed heating, two stages of reheat, primary pressures of 4500 lb/in.^{2} gage or 31 megapascals gage (supercritical), and temperatures of 1150°F (620°C). An industrial plant cogenerating electric power with process steam is capable of having a thermal efficiency of 5000 Btu/kWh (5.3 MJ/kWh).

Combustion turbines used in combined cycle configurations have taken a dominant role in new power generation capacity. The reason is the higher efficiency and lower emissions of the power plant in this arrangement. The rapid pace in advances in combustion turbine technology (such as higher firing temperatures that improve the Brayton cycle efficiency) has driven combined cycle efficiency to nearly 60% when using natural gas as fuel, while attaining low emission rates. Low fuel consumption (5700–6000 Btu/kWh or 6.0–6.3 MJ/kWh) is obtained by using higher firing temperatures, steam cooling on the combustor and gas turbine blades, a reheat steam cycle with a three-pressure heat recovery steam generator, and higher pressure and temperature of the steam cycle. These conditions are balanced with the need to keep the exhaust flue gas temperature as low as practical to achieve low emissions.

Gas turbines in simple cycle configuration are used mostly for peaking service due to their fast startup capabilities. The advances in the gas turbines have also increased the efficiency of simple cycle operations. Recuperation of the classic Brayton cycle gas turbine (simple cycle) is an accepted method of improving cycle efficiency that involves the addition of a heat exchanger to recover some portion of the exhaust heat that otherwise would be lost. *See* Gas turbine.

The nuclear power plant substitutes the heat of fission for the heat of combustion, and the consequent plant differs only in the method of preparing the thermodynamic fluid. It is otherwise similar to the usual thermal power plant. The pressure of a light-water reactor core is limited by material and safety considerations, while the temperature at which the steam is produced is determined by the core pressure. Because a nuclear reactor does not have the capability to superheat the steam above the core temperature, the steam temperature in a nuclear cycle is less than in a fossil cycle. *See* ELECTRIC POWER GENERATION; NUCLEAR REACTOR. [K.K.R.; R.S.G.]

Power shovel A power-operated digging machine consisting of a lower frame and crawlers, a machinery frame, and a gantry supporting a boom which in turn supports a dipper handle and dipper. The machines are powered by on-board diesel engines or by electric motors. Diesel-powered machines utilize a series of clutches and brakes that allow the operator to control various motions. Electric motor machines generally have individual motors for each motion, but occasionally clutches and brakes are used allowing one motor to drive two motions. *See* BULK-HANDLING MACHINES; CONSTRUCTION EQUIPMENT; HOISTING MACHINES. [E.W.S.]

Poynting's vector A vector, the outward normal component of which, when integrated over a closed surface in an electromagnetic field, represents the outward flow of energy through that surface. It is given by the equation below, where **E** is the electric field strength, **H** the magnetic field strength, **B**

$$\Pi = \mathbf{E} \times \mathbf{H} = \mu^{-1}\mathbf{E} \times \mathbf{B}$$

the magnetic flux density, and μ the permeability.

When an electromagnetic wave is incident on a conducting or absorbing surface, theory predicts that it should exert a force on the surface in the direction of the difference between the incident and the reflected Poynting's vector. *See* ELECTRIC FIELD; ELECTROMAGNETIC RADIATION; MAXWELL'S EQUATIONS; RADIATION PRESSURE. [W.R.Sm.]

Prairie dog A stout, fossorial rodent belonging to the family Sciuridae. Three species are recognized; the black-tailed prairie dog (*Cynomys ludovicianus*), once abundant on the prairies of the western United States, but now reduced in numbers; the white-tailed prairie dog (*C. gunnisoni*), discontinuously distributed in mountainous and high plains areas of Colorado, New Mexico, Utah, and Montana; and *C. mexicanus*, found in northern Mexico. All species have the same general features. The tail is short and flat, the ears are small, and the limbs are short and terminate in long claws which are used for burrowing. Prairie dogs are social animals and live in colonies. Their burrows are constructed with the main entrance surrounded by a mound of hard-packed dirt to protect against flooding. *See* RODENTIA. [C.B.C.]

Praseodymium A chemical element, Pr, atomic number 59, and atomic weight 140.91. Praseodymium is a metallic element of the rare-earth group. The stable isotope 140.907 makes up 100% of the naturally occurring element. The oxide is a black powder, the composition of which varies according to the method of preparation. If oxidized under a high pressure of oxygen it can approach the composition PrO_2. The black oxide dissolves in acid with the liberation of oxygen to give green solutions or green salts which have found application in the ceramic industry for coloring glass and for glazes. *See* PERIODIC TABLE; RARE-EARTH ELEMENTS. [F.H.Sp.]

Prasinophyceae A small class of mostly motile, photosynthetic, unicellular algae in the chlorophyll *a-b* phyletic line (Chlorophycota). It is segregated from the Chlorophyceae primarily on the basis of ultrastructural characters, especially the possession of one or more layers of polysaccharide scales outside the plasmalemma. Prasinophytes are mainly members of the marine plankton, but they are also found in brackish- and freshwater habitats. A few are benthic, with both coccoid and colonial forms known, while others live symbiotically within dinoflagellates, radiolarians, and turbellarian worms. Approximately 180 species are known in 13 genera. *See* ALGAE; CHLOROPHYCOTA; PHYTOPLANKTON. [P.C.Si.; R.L.Moe]

Preamplifier A voltage amplifier suitable for operation with a low-level input signal. It is intended to be connected to another amplifier with a higher input level. Preamplifiers are necessary when an audio amplifier is to be used with low-output transducers such as magnetic phonograph pickups. A preamplifier may incorporate frequency-correcting networks to compensate for the frequency characteristics of a given input transducer and to make the frequency response of the preamplifier-amplifier combination uniform. *See* AMPLIFIER; VOLTAGE AMPLIFIER. [H.F.K.]

Prebiotic organic synthesis The plausible pathways by which the molecular precursors of life may have formed on the primitive Earth. Amino acids, the nitrogenous bases, and ribose phosphates can be prepared under conditions that might have prevailed on the primitive Earth. The linking together of amino acids to form polypeptides, and of nucleotides to form polynucleotides, has in principle been established.

Harold C. Urey's model of the primordial Earth postulates an atmosphere rich in methane, ammonia, water, and hydrogen. When this gas mixture is subjected to an electrical spark, analogous to the way that lightning may have initiated such syntheses 4 billion years ago, the identified products included several amino acids (glycine, alanine, and aspartic acid), the building blocks of proteins. This novel result lent credibility to a theory in which the origin of life was viewed as a cumulative, stepwise process, beginning with the gaseous synthesis of small molecules, which rained down into oceans, lagoons, and lakes. With water as a ubiquitous solvent, organic molecules could then react with one another to form larger molecules (biopolymers) and finally to assemble into primitive cells. This general scenario has guided the design of prebiotic simulations.

However, an accumulation of geophysical data and computational models has cast doubt on the relevance of the synthesis of amino acids to the primordial Earth. Hydrogen probably escaped rapidly as the Earth cooled, leaving an atmosphere in which methane and ammonia were virtually absent. As the input of hydrogen is diminished, the formation of biomolecules is inhibited. This problem has led some scientists to look for extraterrestrial sources of organic matter. For example, meteorites are known to contain a rich source of amino acids and other small biomolecules, and perhaps the infall of such cosmic bodies onto the young Earth gave life its start. Alternatively, there may have been localized environments on the Earth where methane and other hydrogen-rich precursors were abundant, such as deep-ocean hydrothermal vents, which would have been favorable for the formation of life. *See* AMINO ACIDS; HYDROTHERMAL VENT. [W.J.Hag.]

Precambrian A major interval of geologic time between about 540 million years (Ma) and 3.8 billion years (Ga) ago, comprising the Archean and Proterozoic eons and encompassing most of Earth history. The Earth probably formed around 4.6 Ga and was then subjected to a period of intense bombardment by meteorites so that there are few surviving rocks older than about 3.8 billion years. Ancient rocks are preserved exclusively in continental areas. All existing oceanic crust is younger than about 200 million years, for it is constantly being recycled by the processes of sea-floor spreading and subduction. Development of techniques for accurate determination of the ages of rocks and minerals that are billions of years old has revolutionized the understanding of the early history of the Earth. *See* DATING METHODS; GEOCHRONOMETRY; GEOLOGIC TIME SCALE; ROCK AGE DETERMINATION.

Detailed sedimentological and geochemical investigations of Precambrian sedimentary rocks and the study of organic remains have facilitated understanding of conditions on the ancient Earth. Microorganisms are known to have been abundant in the early part of Earth history. The metabolic activities of such organisms played a critical role in the evolution of the atmosphere and oceans. There have been attempts to apply the concepts of plate tectonics to Precambrian rocks. These diverse lines of investigation have led to a great leap in understanding the early history of the planet. *See* PLATE TECTONICS.

Rocks of the Archean Eon (2.5–3.8 Ga) are preserved as scattered small "nuclei" in shield areas on various continents. The Canadian shield contains perhaps the biggest region of Archean rocks in the world, comprising the Superior province. Much of the Archean crust is typified by greenstone belts, which are elongate masses of volcanic and sedimentary rocks that are separated and intruded by greater areas of granitic rocks. The greenstones are generally slightly metamorphosed volcanic rocks, commonly extruded under water, as indicated by their characteristic pillow structures. These structures develop when lava is extruded under water and small sac-like bodies form as the lava surface cools and they are expanded by pressure from lava within. Such structures are common in Archean greenstone assemblages in many parts of the world. *See* ARCHEAN; METAMORPHIC ROCKS.

The Proterozoic Eon extends from 2.5 Ga until 540 Ma, the beginning of the Cambrian Period and Phanerozoic Eon. Proterozoic successions include new kinds of sedimentary rocks, display proliferation of primitive life forms such as stromatolites, and contain the first remains of complex organisms, including metazoans (the Ediacaran fauna). Sedimentary rocks of the Proterozoic Eon contain evidence of gradual oxidation of the atmosphere. Abundant and widespread chemical deposits known as banded iron formations (BIF) make their appearance in Paleo-Proterozoic sedimentary basins. *See* BANDED IRON FORMATION; PROTEROZOIC. [G.M.Y.]

Precast concrete

Precast concrete Concrete that has been cast into a form which is later incorporated into a structure. A concrete structure may be constructed by casting the concrete in place on the site, by building it of components cast elsewhere, or by a combination of the two. Concrete cast in other than its final position is called precast.

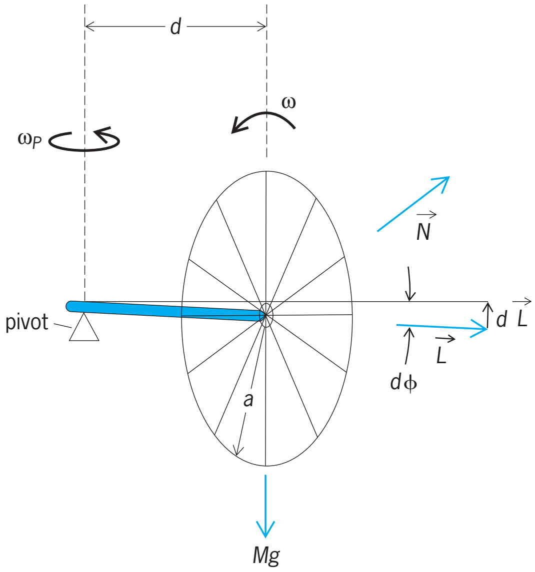
In contrast with cast-in-place concrete construction, in which columns, beams, girders, and slabs are cast integrally or bonded together by successive pours, precast concrete requires field connections to tie the structure together. These connections can be a major design problem.

Precast units can be standardized. Savings can then result from repeated reuse of forms and assembly-line production. Furthermore, high quality can be maintained because of the controls that can be kept on production under plant conditions. However, there is always the possibility that transportation, handling, and erection costs for the precast units will offset the savings. *See* CONCRETE; PRESTRESSED CONCRETE. [F.S.M.]

Precession

Precession The motion of an axis fixed in a body around a direction fixed in space. If the angle between the two is constant so that the axis sweeps out a circular cone, the motion is pure precession; oscillation of the angle is called nutation. An example of precession is the motion of the Earth's polar axis around the normal to the plane of the ecliptic; this is the precession of the equinoxes. A fast-spinning top, with nonvertical axis, which precesses slowly around the vertical direction, is another example. In both examples the precession is due to torque acting on the body. Another kind of precession, called free or fast precession, with a rate which is comparable to the rotation rate of the body, is seen, for instance, in a coin spun into the air. *See* NUTATION (ASTRONOMY AND MECHANICS); PRECESSION OF EQUINOXES.

As a simple example of gyroscopic motion, consider a rapidly spinning wheel with a horizontal axis supported at a distance d from the plane of the wheel (see illustration).



Simple precession of a rapidly spinning wheel with a horizontal axis supported by a pivot.

The angular momentum $\vec{L}$ is along the wheel symmetry axis and is approximately given by the angular momentum of the wheel about this axis; in the simple precession approximation to the motion, the angular momentum associated with precessional motion is neglected. The external torque $\vec{N}$ due to the gravitational force is perpendicular to the wheel axis in the horizontal plane. The change in the angular momentum $\vec{L}$ in an infinitesimal time interval dt is given by the rotational equation of motion in Eq. (1).

$$d\vec{L} = \vec{N}\,dt \tag{1}$$

See RIGID-BODY DYNAMICS.

Since $d\vec{L}$ and $\vec{L}$ are perpendicular, the length $\vec{L}$ is unchanged to first order in dt. The direction of $\vec{L}$ is rotated counterclockwise in the horizontal plane. The angular velocity of precession ω_P about the vertical axis is then given by Eq. (2), where g is the

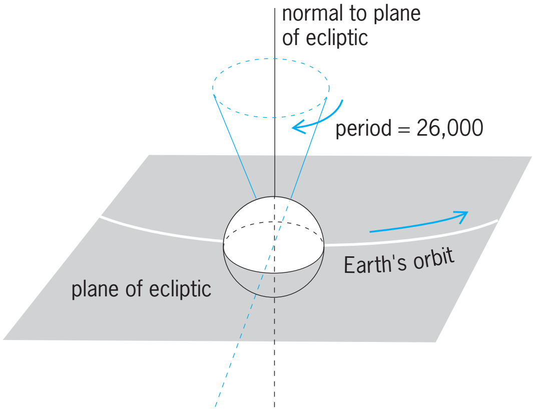
$$\omega_P = \frac{gd}{\omega a^2} \tag{2}$$

gravitational acceleration, ω is the spin angular velocity, and a is the radius of the wheel. Thus ω_P is independent of the mass of the wheel and inversely proportional to ω. For ω very large, the precession rate ω_P is quite slow. *See* GYROSCOPE. [V.D.B.]

Precession of equinoxes

Precession of equinoxes A slow change in the direction of orientation of Earth's axis of rotation which results in a gradual westward motion of the equinoxes. There are two types, known as lunisolar precession and planetary precession.

The lunisolar precession of the equinoxes is caused by the gravitational attraction of the Sun and the Moon which, as a result of the polar flattening of Earth and the inclination of Earth's axis, gives rise to a small turning moment, or torque, on the Earth in its orbit. As a result of this torque, Earth's axis describes



Conical motion of Earth's axis. One complete cycle of precession requires 26,000 years.

a cone about the normal to the plane of its orbit (see illustration); the period of this precession is approximately 26,000 years in a direction opposite to that of Earth's rotation.

The planetary precession is a comparatively small eastward motion of the equinoxes caused by the action of the other planets in altering the plane of Earth's orbit.

As a result of precession, Polaris will not always be the pole star. Vega will be nearer to the north celestial pole in about 12,000 years; α Draconis was the pole star about 4600 years ago. Another effect of precession is that the signs of the zodiac no longer correspond to their respective constellations. *See* PRECESSION. [J.A.Hy.]

Precious stones The materials found in nature that are used frequently as gemstones, including amber, beryl (emerald and aquamarine), chrysoberyl (cat's-eye and alexandrite), coral, corundum (ruby and sapphire), diamond, feldspar (moonstone and amazonite), garnet (almandite, demantoid, and pyrope), jade (jadeite and nephrite), jet, lapis lazuli, malachite, opal, pearl, peridot, quartz (amethyst, citrine, and agate), spinel, spodumene (kunzite), topaz, tourmaline, turquois and zircon. *See* GEM.

The terms precious and semiprecious have been used to differentiate between gemstones on a basis of relative value. Because there is a continuous gradation of values from materials sold by the pound to those valued at many thousands of dollars per carat, and because the same mineral may furnish both, a division is essentially meaningless. [R.T.L.]

Precipitation (chemistry) The process of producing a separable solid phase within a liquid medium. In analytical chemistry, precipitation is widely used to effect the separation of a solid phase in an aqueous solution. For example, the addition of a water solution of silver nitrate to a water solution of sodium chloride results in the formation of insoluble silver chloride. Quite often, one of the components in the solution is thus virtually completely separated in a relatively pure form. It can then be isolated from the solution phase by filtration or centrifugation, and the substance determined by weighing. This procedure is known as gravimetric analysis. Precipitation may also be used merely to effect partial or complete separation of a substance for purposes other than that of gravimetric analysis. Such purposes might involve either the isolation of a relatively pure substance or the removal of undesirable components of the solution. *See* GRAVIMETRIC ANALYSIS.

The extent to which a component can be separated from solution can be determined from the solubility-product constant obtained by determining the quantity of dissolved substance present in a known amount of saturated solution. This value is known as the solubility. The solubility can be drastically altered merely by adding to the solution any of the ions that make up the precipitate, for example, by adding varying quantities of either silver nitrate or sodium chloride to a saturated solution of silver chloride. Although solubility can be altered over a wide range, the solubility product itself remains practically constant over this same range. *See* SOLUBILITY PRODUCT CONSTANT.

Various techniques may be employed in order to reduce contamination by foreign ions. Precipitation from dilute solution is often effective. Heating the reaction mixture speeds recrystallization processes by which incorporated foreign ions may be returned to the solution phase. Precipitation from homogeneous solution results in the slow formation of large crystals of small surface area and hence lessens coprecipitation. If all these methods fail to reduce adequately the quantity of foreign ions incorporated in the solid phase, the precipitate is dissolved and reprecipitated by the previous procedure. *See* CHEMICAL SEPARATION TECHNIQUES; CRYSTALLIZATION; NUCLEATION. [L.Go./R.W.Mu.]

Precipitation (meteorology) The fallout of water drops or frozen particles from the atmosphere. Liquid types are rain or drizzle, and frozen types are snow, hail, small hail, ice pellets (also called ice grains; in the United States, sleet), snow pellets (graupel, soft hail), snow grains, ice needles, and ice crystals. In England sleet is defined as a mixture of rain and snow, or melting snow. Deposits of dew, frost, or rime, and moisture collected from fog are occasionally also classed as precipitation. *See* HAIL; SNOW.

All precipitation types are called hydrometeors, of which additional forms are clouds, fog, wet haze, mist, blowing snow, and spray. Whenever rain or drizzle freezes on contact with the ground to form a solid coating of ice, it is called freezing rain, freezing drizzle, or glazed frost; it is also called an ice storm or a glaze storm, and sometimes is popularly known as silver thaw or erroneously as a sleet storm. *See* CLOUD; FOG.

Rain, snow, or ice pellets may fall steadily or in showers. Steady precipitation may be intermittent though lacking sudden bursts of intensity. Hail, small hail, and snow pellets occur only in showers; drizzle, snow grains, and ice crystals occur as steady precipitation. Showers originate from instability clouds of the cumulus family, whereas steady precipitation originates from stratiform clouds.

The amount of precipitation, often referred to as precipitation or simply as rainfall, is measured in a collection gage. It is the actual depth of liquid water which has fallen on the ground, after frozen forms have been melted, and is recorded in millimeters or inches and hundredths. A separate measurement is made of the depth of unmelted snow, hail, or other frozen forms. *See* SNOW GAGE. For discussions of other topics related to precipitation; CLOUD PHYSICS; DEW; DEW POINT; HUMIDITY; HYDROLOGY; HYDROMETEOROLOGY; RAIN SHADOW; VAPOR PRESSURE; WEATHER MODIFICATION. [J.R.F.]

Precipitation measurement Instruments used to measure the amount of rain or snow that falls on a level surface. Such measurements are made with instruments known as precipitation gages. A precipitation gage can be as simple as an open container on the ground to collect rain, snow, and hail; it is usually more complex, however, because of the need to avoid wind effects, enhance accuracy and resolution, and make a measurement representative of a large area. Precipitation is measured as the depth to which a flat horizontal surface would have been covered per unit time if no water were lost by runoff, evaporation, or percolation. Depth is expressed in inches or millimeters, typically per day. The unit of time is often understood and not stated explicitly. Snow and hail are converted to equivalent depth of liquid water. *See* METEOROLOGICAL INSTRUMENTATION; PRECIPITATION (METEOROLOGY); SNOW SURVEYING. [F.V.B.]

Accurate quantitative precipitation measurement is probably the most important weather radar application. It is extremely valuable for hydrological applications such as watershed management and flash flood warnings. Radar can make rapid and spatially contiguous measurements over vast areas of a watershed at relatively low cost. *See* METEOROLOGICAL RADAR; PRECIPITATION (METEOROLOGY); RADAR METEOROLOGY. [R.J.Do.]

Precipitin The visible result of the chemical interaction of antigen and antibody. Not all antibodies will result in precipitation, yet they may participate in agglutination reactions or add onto particulate antigens, and evidence for their occurrence together with precipitating antibody can be obtained for most sera. Precipitins may be noted qualitatively or be quantified by noting the end-point dilution (titer) of serum required to give a precipitate at the threshold of visibility, or the amount of antibody may be determined in milligrams or micrograms by analysis of the precipitate with correction for the antigen contained therein. *See* ANTIBODY; ANTIGEN. [D.R.]

Precision agriculture The application of technologies and agronomic principles to manage spatial and temporal variability associated with all aspects of agricultural production for the purpose of improving crop performance and environmental quality. The intent of precision agriculture is to match agricultural inputs and practices to localized conditions within a field (site-specific management) and to improve the accuracy of their application. The finer-scale management of precision agriculture is in contrast to whole-field or whole-farm management strategies, where management decisions and practices are uniformly applied throughout a field or farmstead.

Successful implementation of precision agriculture requires three basic steps. First, farmers must obtain accurate maps of the spatial variability of factors (soils, plants, and pests) that determine crop yield and quality and/or factors that cause environmental degradation. Second, once known, variability can be managed using site-specific management recommendations and accurate input control technologies. Third, precision agriculture requires an evaluation component to understand the economic, environmental, and social impacts on the farm and adjacent ecosystems and to provide feedback on cropping system performance.

Precision agriculture is technology-enabled, information-based, and decision-focused, because it relies on an increasing level of detail in information acquired with technology to improve decision making in crop production. Consequently, precision agriculture will evolve as technology, information management, and decision tools emerge in this era of rapid technological advancement. *See* AGRICULTURAL SOIL AND CROP PRACTICES; AGRICULTURE; AGRONOMY; DECISION SUPPORT SYSTEM; INFORMATION SYSTEMS ENGINEERING. [F.J.P.; P.N.]

Precision approach radar (PAR) A tracking system that provides a ground control approach (GCA) air-traffic controller with a precise display of an aircraft's position relative to a runway final-approach course. To ensure absolute safety, precise information is displayed on a plan position indicator (PPI). This display provides the controller with aircraft position information for control of heading and rate of descent. To accomplish this and maintain the required precision for a final-approach aid, the display shows the aircraft position in relation to range, azimuth, and elevation. The information presented on the precision approach radar display allows an air-traffic controller to direct a pilot down along a runway approach course to a precision landing. Precision radar approaches are accomplished in most weather conditions and do not require any on-board avionics equipment, such as an instrument landing system (ILS).

There are two ways to provide the required range, azimuth, and elevation information on the plan position indicator: use of two antennas, one scanning elevation and the other azimuth; and a single computer-controlled phased-array antenna that can provide pencil-beam tracking for both elevation and azimuth positions. *See* ANTENNA (ELECTROMAGNETISM); RADAR. [M.A.DeP.]

Predator-prey interactions Predation occurs when one animal (the predator) eats another living animal (the prey) to utilize the energy and nutrients from the body of the prey for growth, maintenance, or reproduction. In the special case in which both predator and prey are from the same species, predation is called cannibalism. Sometimes the prey is actually consumed by the predator's offspring. This is particularly prevalent in the insect world. Insect predators that follow this type of lifestyle are called parasitoids, since the offspring grow parasitically on the prey provided by their mother.

Predation is often distinguished from herbivory by requiring that the prey be an animal rather than a plant or other type of organism (bacteria). To distinguish predation from decomposition, the prey animal must be killed by the predator. Some organisms occupy a gray area between predator and parasite. Finally, the requirement that both energy and nutrients be assimilated by the predator excludes carnivorous plants from being predators, since they assimilate only nutrients from the animals they consume. *See* FOOD WEB.

Population dynamics refers to changes in the sizes of populations of organisms through time, and predator-prey interactions may play an important role in explaining the population dynamics of many species. They are a type of antagonistic interaction, in which the population of one species (predators) has a negative effect on the population of a second (prey), while the second has a positive effect on the first. For population dynamics, predator-prey interactions are similar to other types of antagonistic interactions, such as pathogen-host and herbivore-plant interactions.

Community structure refers generally to how species within an ecological community interact. The simplest conception of a community is as a food chain, with plants or other photosynthetic organisms at the bottom, followed by herbivores, predators that eat herbivores, and predators that eat other predators. This simple conception works well for some communities. Nonetheless, the role of predator species in communities is often not clear. Many predators change their ecological roles over their lifetime. Many insect predators that share the same prey species are also quite likely to kill and devour each other. This is called intraguild predation, since it is predation within the guild of predators. Furthermore, many species are omnivores, feeding at different times as either predators or herbivores. Therefore, the role of particular predator species in a community is often complex.

Predator-prey interactions may have a large impact on the overall properties of a community. For example, most terrestrial communities are green, suggesting that predation on herbivores is great enough to stop them from consuming the majority of plant material. In contrast, the biomass of herbivorous zooplankton in many aquatic communities is greater than the biomass of the photosynthetic phytoplankton, suggesting that predation on zooplankton is not enough to keep these communities green. *See* POPULATION ECOLOGY. [A.R.I.]

Pregnancy The period during which a developing fetus is carried within the uterus. In humans, pregnancy averages 266 days (38 weeks) from conception to childbirth. Traditionally, pregnancy duration is counted from the woman's last menstrual period, which adds roughly 2 weeks to gestational age. This is how physicians arrive at a pregnancy length of 40 weeks (280 days).

The 9 months of pregnancy are typically divided into three periods (trimesters) of 3 months. The first sign of pregnancy is often the absence of an expected menstrual period. Common symptoms include nausea, breast tenderness, fatigue, and frequent urination. The diagnosis of pregnancy can be made as early as 10 days after fertilization by means of blood tests. By 6 weeks (from the last menstrual period), the uterus feels soft and is palpably enlarged. Pregnancy can be positively confirmed by observing cardiac motion of the fetus by ultrasound scanning (8 weeks) or by hearing fetal heart "tones" by using a Doppler detection instrument (10–12 weeks).

Early in the first trimester, the embryo's germ layers differentiate into organs and systems, a process that is nearly completed by the twelfth week. It is during this critical period of development that the fetus is most vulnerable to the adverse effects of drugs and other teratogenic influences. The second and third trimesters of pregnancy are characterized by increased fetal growth and gradual physiologic maturation of fetal organ systems. During this time, the maternal changes of pregnancy are greatest. The enlarging uterus encroaches on the abdominal region by the fourth month and at term nearly reaches the diaphragm. The breasts gradually enlarge in preparation for lactation. Striking cardiovascular changes, including nearly a 50% increase in cardiac output, provide the increased blood flow to accommodate the growing fetoplacental unit. Other changes in the renal, digestive, pulmonary, and endocrine systems reflect the numerous maternal adaptations that eventually must occur in a healthy pregnancy. *See* EMBRYOLOGY.

Early, regular prenatal care is associated with improved pregnancy outcome and seeks to identify risk factors in the pregnancy that may apply to mother or fetus. At 6–8 weeks, a complete physical examination, along with blood and urine analyses, should be performed. In addition to undergoing traditional tests, patients are now routinely screened for hepatitis B at the beginning of pregnancy, for fetal neural-tube defects such as open spine at 16 weeks, and for gestational diabetes at about 28 weeks. In addition to these blood tests, many physicians offer a sonogram at 16–18 weeks to establish gestational age, check for a multiple pregnancy, and screen for birth defects. During prenatal visits, a physician can evaluate nutrition, blood pressure, and fetal growth. *See* PRENATAL DIAGNOSIS.

Ideally, at the end of the third trimester, the process of labor begins. The muscles of the uterus contract, dilating the cervix and allowing the baby to begin moving into the vagina or birth canal. Continued contractions push the baby out of the mother's body. In the final stage of labor, the placenta detaches from the uterine walls and is expelled as the afterbirth. An alternative to vaginal delivery is the cesarean section, in which the baby is removed surgically through an abdominal incision.

The legal status of pregnancy termination (therapeutic abortion) varies from country to country, but about two-thirds of women in the world have access to legal abortion. Over 90% of abortions in the United States are performed in the first trimester by suction curettage, a technique that uses suctioning and removal of the uterine contents through the vagina with surgical instruments. Later pregnancies are terminated by a procedure called dilatation and evacuation (D&E) or by administration of drugs to stimulate uterine contractions. Medical and psychological sequelae to abortion are few, and are fewest for terminations in the first trimester. *See* PREGNANCY DISORDERS. [B.D.Sh.]

Pregnancy disorders Physical disorders that can arise as a consequence of pregnancy, ranging from mild to life-threatening. Extreme conditions can result in termination of the pregnancy or death of the mother.

The most common disorder of early pregnancy, persistent vomiting, is without known cause and usually subsides spontaneously within a few weeks. A more serious threat to pregnancy, vaginal bleeding (within the first 20 weeks), may be a sign of miscarriage (spontaneous abortion) or much less often, ectopic pregnancy (embryonic development outside the uterus, usually within the Fallopian tube). Over 50% of miscarriages are due to a spontaneous chromosomal abnormality in the sperm, egg, or developing embryo. Ectopics are nearly always removed surgically; the involved Fallopian tube usually can be preserved.

Some abnormal conditions in pregnancy are identified as a result of routine blood tests. Examples include rubella (German measles) and syphilis, both of which occur relatively infrequently and can cause birth defects. Rh disease is also uncommon because of prevention by prenatal blood tests and treatment with immunoglobulins in Rh-negative mothers. Routine screening is also recommended for hepatitis B. *See* HEPATITIS; PRENATAL DIAGNOSIS; RH INCOMPATIBILITY; RUBELLA; SYPHILIS.

Maternal conditions that may worsen during pregnancy include some forms of heart disease, seizure disorders, hypertensive disease, and acquired immune deficiency syndrome (AIDS). *See* ACQUIRED IMMUNE DEFICIENCY SYNDROME (AIDS).

Among the most important disorders during the second half of pregnancy are those associated with low birth weight due to either premature labor or fetal growth problems. Low birth weight is associated with twins, hypertensive disorders, smoking, and inadequate nutrition. The hypertensive disorders include pregnancy-induced hypertension (formerly known as toxemia) as well as chronic hypertension that exists before the pregnancy. Signs and symptoms of pregnancy-induced hypertension can include swelling of the hands and face, headaches, and a sudden weight gain of 5 lb (2 kg) or more in 1 week. Vaginal bleeding in late pregnancy, which is a potential emergency condition, often results from a placental problem; either the placenta is abnormally located near or over the cervix (placenta previa), or the placenta separates prematurely from the uterus (abruptio placenta). *See* HYPERTENSION.

Far less dramatic than these conditions, but equally important as a cause of fetal distress, is the "post dates" pregnancy, which occurs once pregnancy has extended 2 weeks beyond the date of expected delivery. When a pregnancy reaches 42 weeks, delivery is attempted as soon as possible as the aging placenta may lose its ability to provide adequate oxygen and nutrition.

Increased rest and proper nutrition are especially important in pregnancies complicated by high blood pressure, fetal growth problems, and twins. More immediate management often centers on the timing of delivery. *See* PREGNANCY. [B.D.Sh.]

Prehistoric technology The set of ideas that prescribe the manufacture and use of implements before written history. Technology is the principal means through which the human species has succeeded in occupying most of the world. Archeologists tend to use the term "artifact" for any material that was modified by ancient humans, whether this material was used or not, and the term "tool" for any material that was used by ancient humans, whether it was modified or not.

Archeological evidence has demonstrated that the human lineage has been making and using identifiable tools for at least 2.5–2.6 million years, beginning with stone implements and associated prehistoric remains. The advent of metalworking technologies, especially in the Old World, gradually brought about a decline in stone artifacts. By 2000 B.C., stone tools had been replaced by metal implements in much of Eurasia. Subsequent migrations of peoples and diffusion of ideas accelerated this replacement. *See* NEOLITHIC; PALEOLITHIC.

The archeological evidence for prehistoric technologies may be biased because of the nature of the raw materials that were used and the conditions of burial and preservation of these materials. In general, artifacts of stone, bone, pottery, and metal preserve fairly well in many areas, whereas artifacts of wood and other vegetable materials, skin, and horn tend to decay fairly rapidly and are normally found only in exceptional prehistoric contexts.

In 1816, C. Thompsen, director of the Danish National Museum, began to chronologically order the museum's prehistoric collections into three major groups, based upon technology, and now called the Three Age System. The earliest was a Stone Age, followed by a Bronze Age, and finally an Iron Age. As time went on, the prehistory of Europe was further divided, based on regional sequences that could be documented through excavation. In other places, such as the Americas, Australia, Oceania, and sub-Saharan Africa, different nomenclature was often used, since the regional technological sequences differed from that of western Europe.

New technological traits can be introduced into a society in a number of ways: (1) innovation or invention, which is the development of new ideas, including new technological characteristics; (2) diffusion, which involves the spread of ideas, including technological knowledge, from one group to another; and (3) migration, which is the spread of peoples, often with new technologies, into new areas. One of the goals of a prehistorian is to try to ascertain, based on archeological evidence, which factors best explain the technological changes seen in the archeological record. [N.To.; B.Bl.]

Prehnite A mineral with the formula $Ca_2(Al,Fe^{3+})(OH)_2$-$[Si_3AlO_{10}]$, with Al in parentheses in octahedral and Al in brackets in tetrahedral coordination by oxygens. The mineral usually occurs as stalactitic aggregates or as curved crystals, has a vitreous luster, and is yellowish green to pale green in color. Hardness is $6–6\frac{1}{2}$ on Mohs scale; specific gravity 2.8–2.9. Common occurrences include vesicular basalts such as the Keweenaw basalts in the Upper Peninsula of Michigan, and the Watchung basalts in New Jersey. *See* SILICATE MINERALS. [P.B.M.]

Prenatal diagnosis The identification of disease before the birth of a fetus. It often implies genetic diagnosis, but identification of anatomical defects as well as assessment of fetal functions and maturity are also considered. Some of the relatively common diseases that can be diagnosed prenatally are Tay-Sachs disease, cystic fibrosis, Duchenne's muscular dystrophy, hemophilia A, congenital adrenal hyperplasia, thalassemia, and sickle cell anemia.

Ultrasonic data have vastly improved the understanding of normal growth and development, thus permitting earlier and more accurate diagnosis of fetal disease. Fetal movements can also be observed, allowing assessment of functional well-being. *See* MEDICAL IMAGING; MEDICAL ULTRASONIC TOMOGRAPHY.

Obstetricians typically review the health history of the pregnant woman, the father-to-be, and their families in order to identify any possible heritable disorders in the families. Certain risks related to the patient's age, race, and geographic origin may be noted. Based on these assessments, genetic testing of the unborn child may be discussed or recommended. Using cells from the fetus, a prenatal genetic diagnosis can be made for at least 10% of those disorders that are known or assumed to result from a gene mutation. Such diagnosis is based on deoxyribonucleic acid (DNA) analysis or on detection of an abnormal enzyme or other protein produced by the defective gene. *See* HUMAN GENETICS. [D.McN.]

Press fit A force fit that has negative allowance; that is, the bore in the fitted member is smaller than the shaft which is pressed into the bore. Tight fits have slight negative allowance so that light pressure is required to assemble the parts; they are used for gears, pulleys, cranks, and rocker arms. Medium force fits have somewhat greater negative allowance and require considerable pressure for assembly; they are used for fastening locomotive wheels, car wheels, and motor armatures. *See* ALLOWANCE; FORCE FIT; SHRINK FIT. [P.H.B.]

Pressure The ratio of force to area. Atmospheric pressure at the surface of Earth is in the vicinity of 15 lbf/in.^{2} (1.0×10^5 Pa). Pressures in enclosed containers less than this value are spoken of as vacuum pressures; for example, the vacuum pressure inside a cathode-ray tube is 10^{-8} mmHg, meaning that the pressure is equal to the pressure that would be produced by a column of mercury, with no force acting above it, that is 10^{-8} mm high. This is absolute pressure measured above zero pressure as a reference level. Inside a steam boiler, the pressure may be 800 lbf/in.^{2} (5.5×10^6 Pa) or higher. Such pressure, measured above atmospheric pressure as a reference level, is gage pressure, designated psig. *See* PRESSURE MEASUREMENT. [F.H.R.]

Pressure measurement The determination of the magnitude of a fluid force applied to a unit area. Pressure measurements are generally classified as gage pressure, absolute pressure, or differential pressure. *See* PRESSURE.

Pressure gages generally fall in one of three categories, based on the principle of operation: liquid columns, expansible-element gages, and electrical pressure transducers.

Liquid-column gages include barometers and manometers. They consist of a U-shaped tube partly filled with a nonvolatile liquid. Water and mercury are the two most common liquids used in this type of gage. *See* BAROMETER; MANOMETER.

There are three classes of expansible metallic-element gages: bourdon, diaphragm, and bellows. Bourdon-spring gages, in which pressure acts on a shaped, flattened, elastic tube, are by far the most widely used type of instrument. These gages are simple, rugged, and inexpensive. In diaphragm-element gages, pressure applied to one or more contoured diaphragm disks acts against a spring or against the spring rate of the diaphragms, producing a measurable motion. In bellows-element gages, pressure in or around the bellows moves the end plate of the bellows against a calibrated spring, producing a measurable motion.

Electrical pressure transducers convert a pressure to an electrical signal which may be used to indicate a pressure or to control a process. Such devices as strain gages and resistive, magnetic, crystal, and capacitive pressure transducers are commonly used to convert the measured pressure to an electrical signal. *See* PRESSURE TRANSDUCER; STRAIN GAGE. [J.H.Z.]

Pressure seal A seal used to make pressure-proof the interface (contacting surfaces) between two parts that have frequent or continual relative rotational or translational motion; such seals are known as dynamic seals, as compared with static seals. While the pressure in seals is lower than that in gaskets, the motion hinders their effectiveness so that there are more types of seals than gaskets, each type attempting to serve its environment. The materials are leather, rubber, cotton, and flax, and for piston rings, cast iron. The forms of nonmetallic seals are rectangular, V-ring, and O-ring. Cartridge seals are available for rolling-contact bearings. Special seals include carbon ring and labyrinth seals for turbines and mechanical seals for pumps. *See* GASKET. [P.H.B.]

Pressure transducer An instrument component which detects a fluid pressure and produces an electrical, mechanical, or pneumatic signal related to the pressure. *See* TRANSDUCER.

In general, the complete instrument system comprises a pressure-sensing element such as a bourdon tube, bellows, or diaphragm element; a device which converts motion or force produced by the sensing element to a change of an electrical, mechanical, or pneumatic parameter; and an indicating or recording instrument. Frequently the instrument is used in an autocontrol loop to maintain a desired pressure. *See* PROCESS CONTROL.

Although pneumatic and mechanical transducers are commonly used, electrical measurement of pressure is often preferred because of a need for long-distance transmission, higher accuracy requirements, more favorable economics, or quicker response. Electrical pressure transducers may be classified by the operating principle as resistive transducers, strain gages, magnetic transducers, crystal transducers, capacitive transducers, and resonant transducers.

In resistive pressure transducers, pressure is measured by an element that changes its electrical resistance as a function of pressure. Many types of resistive pressure transducers use a movable contact, positioned by the pressure-sensing element. One form is a contact sliding along a continuous resistor, which may be straight-wire, wire- wound, or nonmetallic such as carbon.

Strain-gage pressure transducers might be considered to be resistive transducers, but are usually classified separately, They convert a physical displacement into an electrical signal. When a wire is placed in tension, its electrical resistance increases. The change in resistance is a measure of the displacement, hence of the pressure. Another variety of strain gage transducer uses integrated circuit technology. Resistors are diffused onto the surface of a silicon crystal within the boundaries of an area which is etched to form a thin diaphragm. *See* INTEGRATED CIRCUITS; STRAIN GAGE.

In magnetic pressure transducers, a change of pressure is converted into change of magnetic reluctance or inductance when one part of a magnetic circuit is moved by a pressure-sensing element—bourdon tube, bellows, or diaphragm.

Piezoelectric crystals produce an electric potential when placed under stress by a pressure-sensing element. Crystal transducers offer a high speed of response and are widely used for dynamic pressure measurements in such applications as ballistics and engine pressures. *See* PIEZOELECTRICITY.

Capacitive pressure transducers almost invariably sense pressure by means of a metallic diaphragm, which is also used as one plate of a capacitor.

The resonant transducer consists of a wire or tube fixed at one end and attached at the other (under tension) to a pressure-sensing element. The wire is placed in a magnetic field and allowed to oscillate. As the pressure is increased, the element increases the tension in the wire or tube, thus raising its resonant frequency. *See* PRESSURE MEASUREMENT. [J.H.Z.]

Pressure vessel A cylindrical or spherical metal container capable of withstanding pressures exerted by the material enclosed. Pressure vessels are important because many liquids and gases must be stored under high pressure. Special emphasis is placed upon the strength of the vessel to prevent explosions as a result of rupture. Codes for the safety of such vessels have been developed that specify the design of the container for specified conditions.

Most pressure vessels are required to carry only low pressures and thus are constructed of tubes and sheets rolled to form cylinders. Some pressure vessels must carry high pressures, however, and the thickness of the vessel walls must increase in order to provide adequate strength. Hydraulic and pneumatic cylinders are machine elements that are forms of pressure vessels. [J.J.R.]

Pressurized blast furnace A blast furnace operated under higher than normal pressure. The pressure is obtained by throttling the off-gas line, which permits a greater volume of air to be passed through the furnace at lower velocity and results in an increasing smelting rate. The process permits large increases in the weight of high-temperature air blown into the bottom of the furnace at lower gas velocities, thus increasing the rate of smelting and decreasing the rate of coke consumption, and also permitting smoother operation with less flue dust production through decreased pressure drop between bottom and top pressures. *See* FURNACE. [B.S.O.]

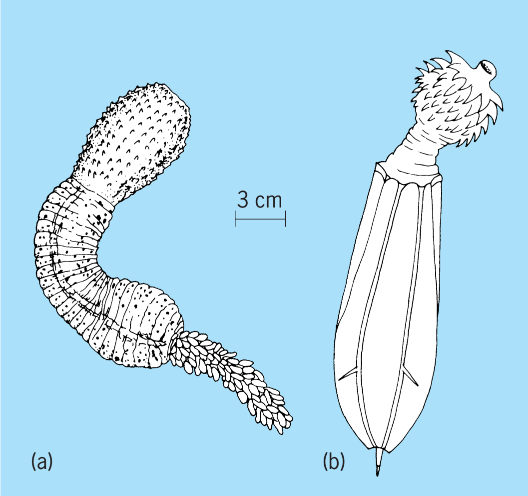
Prestressed concrete Concrete with stresses induced in it before use so as to counteract stresses that will be produced by loads. Prestress is most effective with concrete, which is weak in tension, when the stresses induced are compressive. One way to produce compressive prestress is to place a concrete member between two abutments, with jacks between its ends and the abutments, and to apply pressure with the jacks. The most common way is to stretch steel bars or wires, called tendons, and to anchor them to the concrete; when they try to regain their initial length, the concrete resists and is prestressed. The tendons may be stretched with jacks or by electrical heating.

Prestressed concrete is particularly advantageous for beams. It permits steel to be used at stresses several times larger than those permitted for reinforcing bars. It permits high-strength concrete to be used economically, for in designing a member with reinforced concrete, all concrete below the neutral axis is considered to be in tension and cracked, and therefore ineffective, whereas the full cross section of a prestressed concrete beam is effective in bending. *See* REINFORCED CONCRETE; STRESS AND STRAIN. [F.S.M.]

Priapulida One of the minor groups of wormlike marine animals, now regarded as a separate phylum of the animal kingdom with uncertain zoological affinities. The phylum is a small one with only two genera, *Priapulus* and *Halicryptus*.

Priapulida inhabit the colder waters of both hemispheres. They burrow in mud and sand of the sea floor, from the intertidal region to depths of 14,850 ft (4500 m).

Priapulids are small to medium-sized animals, the largest specimen attaining 6 in. (15 cm) in length. The body of *Priapulus* is made up of three distinct portions: proboscis, trunk, and caudal appendage (see illustration). Separated by a constriction from the trunk, the bulbous, introversible proboscis usually constitutes the anterior third of the body and is marked by 25 longitudinal ridges of papillae or spines. The mouth is located at the anterior end of the proboscis and is surrounded by concentric rows of teeth. The cylindrical trunk is annulated, but not segmented, and is often covered with irregularly dispersed spines and tubercles. At the posterior end of the trunk there are three openings: the anus and two urogenital apertures. [M.E.Ri.]



Priapulida. (*a*) *Priapulus* adult and (*b*) larva.

Prilling Solidification of droplets of molten material free-falling against an upward stream of air in a tower. It is a process used extensively in nitrogen fertilizer manufacturing. Melt is dispersed in the top of the tower at a temperature just above the solidification point of the material being processed. The dispersion arrangement, air flow, tower dimensions, and feed material are selected so the droplets approach a spherical shape and solidify before reaching the bottom of the tower. Prilling has long been a major way of agglomerating ammonium nitrate and urea because of its relative simplicity and economy. Prills of ammonium nitrate and urea are smooth, spherical, dust-free, and moderately rugged, but usually are smaller and more fragile than granulated fertilizers. *See* DRYING; FERTILIZER. [E.O.H.]

Primary vascular system (plant) The arrangement of conducting elements which serves for two-way transportation of substances between different parts of a plant. The conducting elements are of two principal kinds: xylem, which is mainly responsible for the conduction of water together with dissolved inorganic substances upward from the root to other plant organs; and phloem, which is mainly responsible for the conduction of food materials (assimilates), a flow which may take place in either direction. In the shoot region of the plant, xylem and phloem are usually associated into vascular bundles. In the root, however, they usually alternate with one another on different radii. *See* PHLOEM; XYLEM. [W.R.P.]

Primates The mammalian order to which humans belong. Primates are generally arboreal mammals with a geographic distribution largely restricted to the Tropics. Unlike most other mammalian orders, the primates cannot be defined by a diagnostic suite of specializations, but are characterized by a combination of primitive features and progressive trends. These include:

1. Increased dominance of vision over olfaction, with eyes more frontally directed, development of stereoscopic vision, and reduction in the length of the snout.
2. Eye sockets of the skull completely encircled by bone.
3. Loss of an incisor and premolar from each half of the upper and lower jaws with respect to primitive placental mammals.
4. Increased size and complexity of the brain, especially those centers involving vision, memory, and learning.

5. Development of grasping hands and feet, with a tendency to use the hands rather than the snout as the primary exploratory and manipulative organ.

6. Progressive elaboration of the placenta in conjunction with longer gestation period, small litter size (only one or two infants), and precocial young.

7. Increased period of infant dependency and more intensive parenting.

8. A tendency to live in complex, long-lasting social groups.

It has been recognized for a long time that many of these features are adaptations for living in trees. However, it has been proposed more recently that primates may have developed their specializations as a consequence of being visually directed predators, living among the smaller branches of the forest canopy or undergrowth, that captured insects with their hands.

Classification of the primates is as follows:

- Order Primates
  - Suborder Strepsirhini
    - Infraorder Lorisiformes
      - Superfamily Lorisoidea
        - Family: Lorisidae (lorises)
          - Galagidae (bushbabies)
    - Infraorder Lemuriformes
  - Superfamily Lemuroidea
        - Family: Cheirogaleidae (dwarf lemurs)
          - Lepilemuridae (sportive lemur)
          - Lemuridae (true lemurs)
          - Indriidae (sifakas, indri, woolly lemur)
          - Daubentoniidae (aye-aye)
  - Suborder Haplorhini
    - Hyporder Tarsiiformes
      - Superfamily Tarsioidea
        - Family Tarsiidae (tarsiers)
    - Hyporder Anthropoidea
      - Infraorder Platyrrhini
        - Superfamily Ceboidea
        - Family: Callitrichidae (marmosets, tamarins)
          - Cebidae (capuchins, squirrel monkeys, douroucoulis, titis)
          - Atelidae (sakis, uakaris, howler monkeys, spider monkeys, woolly monkeys)
    - Infraorder Catarrhini
      - Superfamily Cercopithecoidea
      - Family Cercopithecidae (Old World monkeys)
    - Superfamily Hominoidea
      - Family: Hylobatidae (gibbons, siamang)
        - Hominidae (orangutan, gorilla, chimpanzees, humans)

There are two major groups of primates: the strepsirhines or "lower" primates, and the haplorhines or "higher" primates. Strepsirhines have elongated and forwardly projecting lower front teeth that form a toothcomb, used for grooming the fur and for obtaining resins and gums from trees as a source of food. The digits of the hands and feet bear flattened nails, rather than claws, except for the second toe, which retains a sharp toilet claw for grooming. They also have a moist, naked rhinarium and cleft upper lip (similar to the wet noses of dogs). Most strepsirhines are nocturnal, with large eyes and a special reflective layer (the tapetum lucidum) behind the retina that intensifies images in low light. Compared with haplorhines, the brain size is relatively small and the snout tends to be longer.

The strepsirhines are subdivided into two major groups: the lorisoids, which are found throughout tropical Africa and Asia, and the lemuroids, which are restricted to Madagascar.

The lorisoids include the galagids or bushbabies (*Galago*, *Otolemur*, *Euoticus*, and *Galagoides*) and the lorisids or lorises (*Loris*, *Nycticebus*, *Perodicticus*, *Pseudopotto*, and *Arctocebus*). They are small nocturnal primates, in which the largest species, the greater bushbaby, weighs only about 1 kg (2 lb). Their diet consists mainly of a combination of insects, fruits, and gums. Lorisoids are semisolitary, living in small, dispersed social groups.

The greatest diversity of strepsirhines is found on Madagascar, where more than 30 species are represented, belonging to five different families.

Tarsiers, tiny primates (weighing only about 120 g) from the islands of Southeast Asia, all belong to a single genus, *Tarsius*. They are nocturnal with the largest eyes of any primate, and other adaptations for a specialized lifestyle as vertical clingers and leapers. In the past, tarsiers have been grouped together with the strepsirhines as prosimians, because they retain many primitive features lost in higher primates. However, tarsiers share a number of distinctive specializations with anthropoids that suggest that they are more closely related to each other than either is to the strepsirhines. For this reason, tarsiers and anthropoids are classified together as haplorhines.

The anthropoids include the platyrrhines or New World monkeys and the catarrhines or Old World monkeys, apes, and humans. Anthropoids are distinguished from strepsirhines and tarsiers in having a larger brain, relatively small eyes (all anthropoids are diurnal, active by day, except for the nocturnal douroucouli from South America), eye sockets almost completely enclosed by a bony septum, the two halves of the lower jaw fused in the midline rather than separated by a cartilage, small and immobile ears, the hands and feet bearing nails with no toilet claws (except for the callitrichids that have secondarily evolved claws on all fingers and toes), a single-chambered uterus rather than two-horned, and a more advanced placenta.

The platyrrhines from South and Central America are a diverse group of primates comprising more than 50 species and 16 genera. Primatologists have had a difficult time establishing a classification of platyrrhines that reflects their evolutionary interrelationships, and no consensus has been reached. There is agreement, however, that three distinct clusters can be defined: the callitrichids, the pitheciines, and the atelines. The last two groups appear to be closely related and are commonly included together in the family Atelidae. The relationships of the remaining platyrrhines are uncertain, and they are often placed together for convenience in the Cebidae.

All platyrrhines are arboreal, and they are widely distributed throughout tropical forests extending from Mexico to northern Argentina. They are small to medium-sized primates ranging from 100 g to 15 kg (0.2 to 33 lb). Platyrrhines exhibit a variety of quadrupedal locomotor types ranging from squirrellike scrambling, to leaping and forelimb suspension. Atelines and capuchin monkeys are unique among primates in having a specialized prehensile tail that can grasp around branches for extra support.

The catarrhines include all anthropoid primates from Africa, Asia, and Europe. There are two main groups: the cercopithecids or Old World monkeys, and the hominoids or apes and humans. Catarrhines are distinguished from platyrrhines by a reduction in the number of premolars from three to two in each half of the upper and lower jaw, and the development of a tubelike (rather than ringlike) tympanic bone to supports the eardrum.

Old World monkeys are widely distributed throughout sub-Saharan Africa and tropical Asia, and also occur in the extreme southwestern tip of the Arabian Peninsula, northwest Africa, Gibraltar (their only European record), and East Asia. They are a highly successful group comprising more than 80 species. They are distinguished from other anthropoids in having bilophodont molar teeth that bear a pair of transverse crests. They also have naked, roughened sitting pads on their rumps, called ischial callosities—a feature that they share with hylobatids. In addition, most Old World monkeys are highly sexually dimorphic, with males considerably larger than females.

Hominoidea is the superfamily to which apes and humans belong. Hominoids are distinguished from cercopithecoids in having primitive nonbilophodont molars, larger brains, longer arms than legs (except in humans), a broader chest, a shorter and less flexible lower back, and no tail. Many of these specializations relate to a more upright posture in apes, associated with a greater emphasis on vertical climbing and forelimb suspension.

Hominoids can be classified into two families: the Hylobatidae, which includes the gibbons and siamang, and the Hominidae, which includes the great apes and humans. The gibbons and siamang (*Hylobates*) are the smallest of the hominoids (4–11 kg or 9–24 lb), and for this reason they are sometimes referred to as the lesser apes. The nine or so species are common throughout the tropical forests of Asia. They are remarkable in having the longest arms of any primates, which are 30–50% longer than their legs. This is related to their highly specialized mode of locomotion, called brachiation, in which they swing below branches using only their forelimbs. Gibbons are fruit eaters, while the larger siamang incorporates a higher proportion of leaves in its diet. Hylobatids live in monogamous family groups in which males and females are similar in size.

The great apes include the orangutan (*Pongo*) from Asia and the gorilla (*Gorilla*) and chimpanzees (*Pan*) from Africa. These were formerly included together in their own family, the Pongidae, to distinguish them from humans, who were placed in the Hominidae. However, recent anatomical, molecular, and behavioral evidence has confirmed that humans are closely related to the great apes, especially to the African apes, and for this reason most scientists now classify them together in a single family, the Hominidae. The orangutan is restricted to the tropical rainforests of Borneo and northern Sumatra. They are large, arboreal primates that climb cautiously through the trees using all four limbs for support. Orangutans subsist mainly on fruits.

The gorilla, the largest of the hominoids, has a disjunct distribution in tropical Africa. Because of their great size, gorillas are almost entirely terrestrial, although females and young individuals frequently climb trees. Nests are often built on the ground. Gorillas move quadrupedally, and like chimpanzees, the hands are specialized for knuckle walking in which the weight of the animal is borne on the upper surface of the middle joints of the fingers. Mountain gorillas eat a variety of leaves, stems, and roots, while lowland gorillas eat a greater proportion of fruits. Groups consist of a dominant male, called a silverback, as well as several adult females, subadults, and infants.

There are two species of chimpanzees, the common chimpanzee (*Pan troglodytes*) and the bonobo or pygmy chimpanzee (*Pan panicus*). The common chimpanzee is widely distributed in the forests and woodlands stretching across equatorial Africa, while the pygmy chimpanzee is restricted to the tropical rainforests of the Congo. Both species nest and feed in trees, but they mostly travel on the ground. Common chimpanzees have eclectic diets, including meat, which they obtain by hunting small to medium-sized mammals. Tool-using behaviors are common, and more than a dozen simple tool types have been identified. Chimpanzees are gregarious and sociable, and they live in large multimale communities that divide into smaller subgroups for foraging. *See* APES; FOSSIL APES; FOSSIL HUMANS; FOSSIL PRIMATES; MAMMALIA; MONKEY. [T.Ha.]

Prime mover The component of a power plant that transforms energy from the thermal or the pressure form to the mechanical form. Mechanical energy may be in the form of a rotating or a reciprocating shaft, or a jet for thrust or propulsion. The prime mover is frequently called an engine or turbine and is represented by such machines as waterwheels, hydraulic turbines, steam engines, steam turbines, windmills, gas turbines, internal combustion engines, and jet engines. These prime movers operate by either of two principles: (1) balanced expansion, positive displacement, intermittent flow of a working fluid into and out of a piston and cylinder mechanism so that by pressure difference on the opposite sides of the piston, or its equivalent, there is relative motion of the machine parts; or (2) free continuous flow through a nozzle where fluid acceleration in a jet (and vane) mechanism gives relative motion to the machine parts by impulse, reaction, or both. *See* GAS TURBINE; HYDRAULIC TURBINE; IMPULSE TURBINE; INTERNAL COMBUSTION ENGINE; POWER PLANT; REACTION TURBINE; STEAM ENGINE; STEAM TURBINE; TURBINE. [T.Ba.]

Primer (surface coating) A material used for the first coat of paint or as the prime coat in a protective coating system. Primers are designed to promote adhesion of the coating system to the substrate, to furnish a good base for further coatings, and to prevent attack on the substrate by air, water, or other materials.

Wood primers are formulated to give maximum adhesion and to provide adequate flexibility for adjustment to dimensional changes that occur when wood swells or shrinks because of changes in moisture content. Primers used as the undercoat for enamels must provide a smooth film and permit easy sanding.

Metal primers must provide excellent adhesion by mechanical anchorage or chemical bonding. Modern corrosion-resistant coating systems applied over steel contain inorganic or organic zinc dispersed in a suitable vehicle. Zinc is attacked by the electrochemical corrosion process preferentially before steel, and protects the steel substrate by this sacrificial property. Prime coat materials for nonferrous metallic substrates usually are generically related to materials used in subsequent coats.

Primers for porous surfaces such as concrete must seal the surface adequately to provide a uniform base for future coatings.

Primers are always pigmented. In clear finishes the coat which performs this function is described as a sealer, an under-coater, or a wash coat. *See* CORROSION; PAINT; PIGMENT; SURFACE COATING. [C.R.Ma.; C.W.Si.]

Primitive gut The tubular structure in embryos which differentiates into the alimentary canal. The method by which the primitive gut arises depends chiefly on the yolk content of the egg.

Eggs with small or moderate amounts of yolk usually develop into spherical blastulae which invaginate at the vegetative pole to form double-walled gastrulae. The invaginated sac extends in length to become the primitive gut.

Animals such as fish, reptiles, and birds, having more yolk than can be cleaved, form flattened gastrulae consisting of three-layered blastoderms surmounting the yolk. Mammals also belong in this group, although the yolk has been lost secondarily in all except the monotremes. The head is formed by a folding of the blastoderm upon itself. The entodermal layer within the head fold becomes the pharynx. This foregut is extended by an anterior growth of the whole head and by the union of lateral entodermal folds at its posterior boundary. In most forms, the hindgut arises by a similar folding in the opposite direction, the tail fold, at the posterior end of the blastoderm. *See* CLEAVAGE (EMBRYOLOGY); GASTRULATION; OVUM. [H.L.Ha.]

Primulales An order of flowering plants, division Magnoliophyta (Angiospermae), in the subclass Dilleniidae of the class Magnoliopsida (dicotyledons). The order consists of three families: the Myrsinaceae, with about 1000 species; the Primulaceae, with about 1000 species; and the Theophrastaceae, with a little more than 100 species. These are plants with sympetalous flowers; that is, the petals are fused by their margins to form a corolla with a basal tube and terminal lobes. The functional stamens are opposite the corolla lobes, and there is a compound ovary that has a single style and two to numerous ovules which usually have two integuments and are on a free-central or basal placenta. The Myrsinaceae and Theophrastaceae are chiefly tropical and subtropical woody plants, but the Primulaceae are mostly herbaceous and are best developed in north temperate regions. Primrose (*Primula*) and cyclamen are familiar members of the Primulaceae. *See* DILLENIIDAE; MAGNOLIOPSIDA; PLANT KINGDOM. [A.Cr.; T.M.Ba.]

Printed circuit A conductive pattern that may or may not include printed components, formed in a predetermined design on the surface of an insulating base in an accurately repeatable manner. Printed circuits are fabricated by any of several graphic art processes. They greatly simplify mass production and increase equipment reliability. Their most important contribution, however, is the tremendous reduction achieved in size and weight of electronic devices and equipment. Printed circuits are used in practically all types of electronic equipment: toys, radio and television sets, telephone systems units, electrical wiring behind automobile dashboards, computers, and industrial control equipment.

Technology. The configuration in which electronic circuit elements are located and the routing of conductor paths between the circuit elements establish the precise circuit pattern. Location of the circuit elements can depend on a number of factors, including the form factor (outline of a printed wiring board in a piece of electronic equipment), signal criticality, and the power dissipation of the circuit elements. Conductor path routing is a function of the circuit element location, signal criticality, width and spacing of interconnection conductors, number of wiring channels per layer of interconnect structure, and number of interconnect layers allowed.

As a result of increased circuit complexity, sophisticated computer-aided engineering (CAE) programs have been developed to automate the design of printed circuits. Output from the computer-aided engineering database includes a circuit element parts list and schematic diagrams of the circuit interconnections. This computer-aided engineering database can be used as input to a computer-aided design (CAD) program that optimizes the location of circuit elements within the given form factor and automatically performs the conductor routing between circuit elements. *See* COMPUTER-AIDED DESIGN AND MANUFACTURING; COMPUTER-AIDED ENGINEERING.

Artwork masters are used to fabricate the screens and masks for the application of photoresistive materials in the actual formation of the required patterns on the finished parts. The computer-aided design database is also used in the preparation of numerous types of tooling, for example, drill templates, tapes for operation of numerical-tape-controlled drilling equipment, routing templates and dicing fixtures for trimming printed circuits or integrated-circuit dies to final configuration, laminating and holding fixtures, and string lists to drive automated test equipment. Numerous processes, including etching, screening, plating, laminating, vacuum deposition, diffusion, and application of protective coatings, are used in combination to produce various types of printed circuits. Completed printed circuits are inspected visually and dimensionally by using such techniques as microsectioning and infrared photospectrometer measurements in determining thicknesses of critical materials; in addition, they may be x-rayed and electrically tested to assure conformance to requirements. *See* PRINTING.

Printed wiring. Printed wiring is undoubtedly the most common type of printed circuit. The printed wiring board (PWB) is a copper-clad dielectric material with conductors etched on the external or internal layers. Printed wiring boards can be subdivided into single-sided, double-sided, and multilayer boards.

Single-sided boards contain all the interconnect structure on one of the external layers and are the least expensive to manufacture. Double-sided boards contain circuitry on both external layers. Plated through-holes and occasionally eyelets are used to provide electrical continuity between the sides. Double-sided boards are used in those applications in which the maximum number of interconnections (conductors) in a given area are required for minimum cost. Both single- and double-sided boards are commonly used in such commercial applications as automotive equipment, radio and television sets, and toys.

Multilayer boards contain circuitry on internal layers throughout the cross section of the board as well as on the external layers. Because of the reduced size of miniaturized microelectronic parts, these boards accommodate the increasing complexity and density of circuitry used in applications such as high-speed computers and signal processors. Multilayer printed wiring boards are manufactured by using two different methods: subtractive (print and etch) technology and additive (plate-up) technology.

Thick-film circuits. Thick-film circuits consist of such passive elements as resistors, capacitors, and inductors deposited on wafers or substrates of such dielectric materials as ceramic, glass, quartz, sapphire, and porcelain-coated metal. They are used for mass fabrication of passive networks for inclusion in linear microcircuits and large-signal digital and analog modules. Thick-film design and manufacture are usually based on film thicknesses of approximately 0.0005–0.0015 in. (12–38 μm).

Thin-film circuits. The deposition of thin films was the first application of printed circuit technology to microelectronics. The most important advantages to thin-film circuits are the following: (1) films with a uniform thickness in the range from 5×10^{-6} mm to 5×10^{-3} mm can be vacuum-deposited and controlled by measuring the resistance across a test pattern during deposition to ensure that final thicknesses are within design limits; (2) patterns formed during deposition or by selective etching afterward are much more precisely controlled than those which are printed, as in thick-film circuits; (3) more stable resistive materials can be used; and (4) thin films have less porous surface metallization, enabling faster rise times. Because of this precision and stability, thin-film circuits are frequently used in radio-frequency applications in avionics and industrial electronics.

Multichip devices. A multichip device, often referred to as a hybrid, is a combination of two or more electronic components mounted and interconnected via a substrate. The multichip device serves a customized electronic function and is packaged as a single device.

A multichip device serves the same function as a circuit card assembly; however, all the components are packaged together in a single hermetic case. Unlike printed wiring boards where all components are individually packaged and then mounted to the board, multichip devices may use bare, unpackaged dies. The advantages of multichip devices are the vast reduction in volume, area, and weight; improved thermal management; and increased functional densities, frequencies, and electrical performance. The disadvantage is the increased cost over that of equivalent printed wiring board assemblies. Multichip devices can be digital, analog, or a combination of both. [L.K.L.; V.J.B.; D.B.Ha.]

Printing A process in which an image is reproduced on a surface, such as paper. There are five general classes of printing processes: relief printing, which includes letterpress and flexography; planographic printing, which includes offset lithography, screenless lithography, collotype, and waterless printing; intaglio, which includes gravure, steel-die, and copper-plate engraving; stencil and screen printing; and electronic printing, which includes electrostatic, magnetographic, ion or electron deposition, and ink-jet printing.

In relief printing, the printing element consists of a raised surface of type, lines, and dots that are inked. Printing is done by transferring the ink directly from the image surface to the paper. The nonprinting areas are below the printing surface.

In planographic printing, the printing areas of the plate are on the same plane as the nonprinting areas. Lithographic printing is accomplished by using the principle that grease and water do not mix. Early lithography was done by using a grease crayon or greasy ink to draw letters, symbols, and pictures in reverse on a porous stone. The surface of the stone was then sponged with a solution of gum arabic in water to render the nonprinting portions receptive to moisture but repellent to greasy ink, and the printing portions receptive to grease and repellent to moisture. This process is still used as a fine-arts medium for making lithographic prints from drawings or lettering done manually on the stone and printed on a handpress.

Commercial lithography uses thin metal plates made photomechanically or digitally and mounted on a press that has means for inking and dampening the plates and prints indirectly by a method commonly known as offset. The inked image on the plate is first transferred to an intermediate rubber-covered blanket cylinder, which then transfers the image to the paper. Relief and intaglio printing can also be printed by the offset principle. Because almost all lithography is printed by the offset principle, the term offset has become synonymous with lithography. Another planographic process is waterless printing, which uses temperature-controlled offset lithographic presses and special silicone-coated plates that can be printed without dampening. Collotype and screenless printing are planographic processes that print illustrations without the need of halftone images.

Intaglio printing, also known as gravure printing, is accomplished by cutting or engraving and etching various sizes or depths of minute cells (or wells) below the surface of a plate or cylinder to form the images. The cells are flooded and loaded with ink, the excess ink is scraped off the surface of the plate by a doctor blade, and the ink left in the cells is transferred to the substrate. The depth and size of each cell determine the amount of ink that is transferred to the printed surface. The nature of the process permits a heavy laydown of ink, which accounts for the rich, saturated colors typical of the gravure process.

In stencil and screen printing, also known as porous printing, ink is brushed or squeezed through a stencil image on a fine screen onto paper or other surface such as metal, glass, or textile. The screen holds the image area, which may carry either pictorial or typographic material. Although this process accounts for a comparatively small part of the total volume of printing, mechanization has made it more useful commercially. Because of the heavy laydown of ink, strong colors can be obtained by this process, making it suitable for posters and signs as well as fine art.

Conventional printing processes use printing plates and presses to produce quantities of the same image. Electronic printing processes use digital imaging systems that produce an image in each cycle of the imaging device. The images can be the same or can be changed from cycle to cycle. Electronic printing is especially suited to printed products requiring variable information such as utility bills, personalized mail, insurance policies, and customized books.

Electrostatic or electrophotographic printing is similar to photocopying. The processes use a photoconductor that is charged, exposed by lasers, and imaged with dry powder or liquid toners. They are used extensively for on-demand printing. Color electrophotographic printing systems are used for short-run variable and on-demand printing. Magnetographic printing is similar to electrophotographic printing except that magnetic toners are used. It is used for single- and spot-color short-run and on-demand printing.

In ion or electron deposition printing, a latent image is formed by ions or electrons on a heated dielectric coated cylinder, toned with a magnetic toner, and transferred and fixed to paper under pressure. The system is used for on-demand variable short-run single- or spot-color printing.

Ink-jet printing uses jets of ink droplets controlled by computer signals to print variable information. It is used extensively in packaging, and in mailing and distribution of magazines and catalogs. Color ink-jet is used for color proofing and short-run printed displays and billboards.

All the individual printing processes use a sequence of procedures. There are two types of processes in use: plate and plateless. The plate processes are the conventional printing processes—letterpress, flexography, lithography, gravure, screen printing, and others—which use a plate or other type of image carrier such as a cylinder or screen, and a printing press on which the image carrier is mounted, ink is applied, and the image is transferred to paper or other substrate. The plateless processes are the electronic or digital printing processes—electrophotographic, magnetographic, ion or electron deposition, and ink-jet—in which the images are produced digitally by lasers or other devices using special toners or inks.

The sequence of steps in both processes is prepress, press or print, and postpress. The prepress and postpress operations are similar for both processes: that is, the design, preparation, and assembly of images for reproduction, the finishing operations to give the final product such as a leaflet, book, or package, and their distribution, are essentially the same. The two differ in the means used to convert the imaging information into the imaged page, sheet, or board that must be converted to the final printed product for distribution.

The prepress operations for the conventional plate processes have consisted of typesetting, layout and design, process photography, image assembly, and platemaking. These were traditionally manual, labor-intensive operations, but electronics and computers have gradually replaced many manual operations. Phototypesetting and electronic scanning were the first computerized systems to replace manual operations. These were followed by other digital systems. The phototypesetter became the imagesetter. Page layout was accomplished by computer software programs. The scanner was enhanced by color electronic prepress systems. Personal computers developed into desktop publishing systems that emulated color electronic prepress systems, and imagesetters produced films for platemaking.

The conventional printing systems require plates. These plates are traditionally made from photographic negatives or positives. The availability of imagesetters that could produce the films for plates spurred the development of high-speed printing plates that could be exposed by lasers directly in the imagesetter. Also, the introduction of high-speed imagesetters with large memory capacity encouraged the development of digital printing systems that give printed products directly without the use of printing plates or presses.

Each conventional printing process has specific requirements for its printing plates or image carriers. The printing press unit has a cylinder for mounting the plate; an inking system to feed ink to the plate; and on an offset lithographic press, a cylinder covered with a rubber blanket to which the image is transferred from the plate and which transfers the image to the paper feeding over an impression cylinder. The press has a means for feeding paper or other substrate into the printing units, and a delivery device for collecting the printed sheets. The press has as many printing units as the number of colors that it can print (a four-color press has four printing units).

Digital printing uses different printing engines, depending on the process. Electrophotographic printing systems are like high-speed copiers, with a photoconductor-coated cylinder, means for charging the photoconductor, a device for laser exposure of the image on the photoconductor, and means for toning and fixing the image on the substrate. Ink-jet printing systems use an engine for ejecting selected droplets of dyed inks through small orifices in glass or stainless steel nozzles onto paper or other substrate.

After the sheets are printed, most must be put through some finishing operations to make a functional product. Sheets for books or booklets must be folded, collated, bound into covers, and stacked. They must also be prepared for distribution to the customer. [M.H.B.]

Prion disease Transmissible spongiform encephalopathies in both humans and animals. Scrapie is the most common form in animals, while in humans the most prevalent form is Creutzfeldt-Jakob disease. This group of disorders is characterized at a neuropathological level by vacuolation of the brain's gray matter (spongiform change). They were initially considered to be examples of slow virus infections. Experimental work has consistently failed to demonstrate detectable nucleic acids—both ribonucleic acid (RNA) and deoxyribonucleic acid (DNA)—as constituting part of the infectious agent. Contemporary understanding suggests that the infectious particles are composed predominantly, or perhaps even solely, of protein, and from this concept was derived the acronym prion (proteinaceous infectious particles). Also of interest is the apparent paradox of how these disorders can be simultaneously infectious and yet inherited in an autosomal dominant fashion (from a gene on a chromosome other than a sex chromosome).

Disorders. Scrapie, which occurs naturally in sheep and goats, was the first of the spongiform encephalopathies to be described. An increasing range of animal species have been recognized as occasional natural hosts of this type of disease. Bovine spongioform encephalopathy, commonly known as mad cow disease, has been epidemic in British cattle. The first confirmed cases were reported in late 1986. By early 1995 it had been identified in almost 150,000 cattle and more than half of all British herds. Its exact origin is not known, but claims that it came from sheep are now discredited.

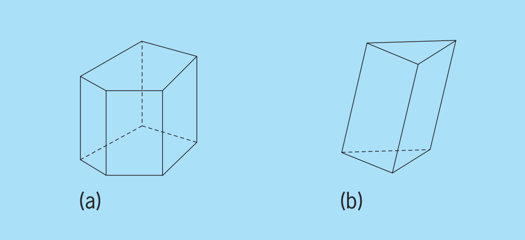
So far, animal models have indicated that only central nervous system tissue has been shown to transmit the disease after oral ingestion—a diverse range of other organs, including udder, skeletal muscle, lymph nodes, liver, and buffy coat of blood (white blood cells) proving noninfectious.

The currently recognized spectrum of human disorders encompasses kuru, Creutzfeldt-Jakob disease, Gerstmann-Straussler-Scheinker disease, and fatal familial insomnia. All, including familial cases, have been shown to be transmissible to animals and hence potentially infectious; all are invariably fatal with no effective treatments currently available.

Human-to-human transmission. A variety of mechanisms of human-to-human transmission have been described. Transmission is due in part to the ineffectiveness of conventional sterilization and disinfection procedures to control the infectivity of transmissible spongiform encephalopathies. Numerically, pituitary hormone–related Creutzfeldt-Jakob disease is the most important form of human-to-human transmission of disease. However, epidemiological evidence suggests that there is no increased risk of contracting Creutzfeldt-Jakob disease from exposure in the form of close personal contact during domestic and occupational activities. Incubation periods in cases involving human-to-human transmission appear to vary enormously, depending upon the mechanism of inoculation. Current evidence suggests that transmission of Creutzfeldt-Jakob disease from mother to child does not occur. Two important factors pertaining to transmissibility are the method of inoculation and the dose of infectious material administered. A high dose of infectious material administered by direct intracerebral inoculation is clearly the most effective method of transmissibility and generally provides the shortest incubation time. *See* BRAIN; MUTATION; NERVOUS SYSTEM DISORDERS; SCRAPIE; VIRUS INFECTION, LATENT, PERSISTENT, SLOW. [C.L.Mas.; S.J.Co.]

Prism

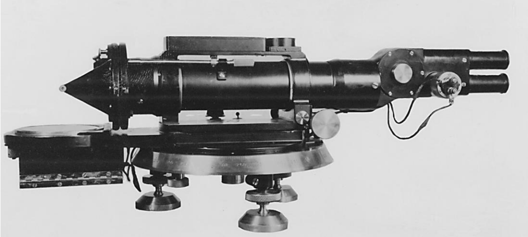
A polyhedron of which two faces are congruent polygons in parallel planes, and the other faces are parallelograms (see illustration). The bases B are the congruent polygons; the lateral faces are the parallelograms; the lateral edges are the edges not lying in the bases; and the perpendicular distance between the bases is the altitude h. Sections parallel to the bases are congruent to the bases. A prism is a right prism if its lateral edges are perpendicular to the bases; an oblique prism otherwise. A prism is called a triangular prism if its bases are triangles; a pentagonal prism if its bases are pentagons; and a parallelepiped if its bases are parallelograms. The volume of any prism is equal to the area of its base times its altitude ($V = Bh$). *See* POLYHEDRON. [J.S.F.]



Prism configurations. (*a*) Right. (*b*) Oblique.

Prismatic astrolabe

A surveying instrument used to make the celestial observations needed in establishing an astronomical position. The instrument (see illustration) consists of an accurate prism, a small pan of mercury to serve as an artificial horizon, an observing telescope with two eyepieces of different power, level bubbles and leveling screws, a magnetic compass and azimuth circle, adjusting screws, flashlight-battery power source, light, and a rheostat to control the intensity of illumination.



A prismatic astrolabe, used to make celestial observations. (*U.S. Naval Oceanographic Office*)

By using a fixed prism, the instrument measures a fixed altitude, usually 45°. As a rising star increases altitude past that for which the instrument was constructed, the direct image appears to move upward from the bottom of the field of vision to the top. The image reflected by the mercury horizon appears to move downward from top to bottom. At the established altitude the rays produce images at the center of the field of view. A fixed altitude is used to minimize error due to variations from standard atmospheric refraction. Each accurately timed observation provides one line of position. [A.B.M.]

Private branch exchange

A telecommunications switching system physically located at a customer's place of business. The private branch exchange (PBX) provides internal station-to-station communications for a well-defined set of users. It also provides access to outside telephone lines, called trunks, which connect the private branch exchange to the telephone company's central office. A typical private branch exchange has more stations than trunks (often as many as 10 stations for each trunk) because the stations share the use of the trunks. *See* TELEPHONE SERVICE.

CENTREX service, a leased business telephone service provided by the local telephone operating company, provides many of the same station features and functions as a private branch exchange. However, the main switching vehicle for CENTREX is located at the telephone company central office rather than the customer's premises. Conceptually, however, it is similar to a private branch exchange because station users must access the public switched network (PSN) on a contention basis, whereby stations share trunks.

Three distinct generations of private branch exchanges have appeared. In the first generation (1900–1930), a human operator manually set up calls. Second-generation private branch exchanges (mid-1930s to mid-1970s) used mechanical relays to establish the call path. The third generation of private branch exchanges is the stored-program microprocessor-controlled system. Introduced in the mid-1970s, these systems use computer instructions to perform the call set-up and tear-down. Because the private branch exchange is software-based, features and upgrades can often be added without disturbing its operation and the system can be expanded modularly as necessary. The third-generation private branch exchange is physically much smaller than electromechanical models, uses less power, and generates less heat. *See* DIGITAL COMPUTER; MICROPROCESSOR.

One significant development of this generation is the rise of digital transmission as the predominant method of signal transmission within the private branch exchange. The analog voice signal can be encoded into a string of digital pulses by a coder/decoder (codec). After it is switched through the private branch exchange, the signal is reconverted to analog format. *See* ANALOG-TO-DIGITAL CONVERTER; DIGITAL-TO-ANALOG CONVERTER; ELECTRICAL COMMUNICATIONS; PULSE MODULATION.

Telephone instruments have also evolved, becoming more intelligent and versatile. The trend is toward proprietary electronic digital multibutton telephone sets with their own microprocessors, which support enhanced features and functions. Many private branch exchanges permit transmission of data as well as voice conversations. Integrated voice-data terminals, data adapters mounted within the telephone, and stand-alone data units allow the user to conduct voice and data calls simultaneously. *See* TELEPHONE.

Data transmissions switched through the private branch exchange can communicate with another data device or computer connected to the system or, via the public switched network, with a wide variety of remote data devices and computers. Communications between two data devices attached to the same private branch exchange is usually end-to-end digital. Completely digital transmission between two private branch exchanges is also possible by using public switched network digital trunk facilities, called T1 or DS1 trunks. However, in most cases when transmission through the public switched network is required, the originating location must convert the digital signal to analog format by using a modem. *See* DATA COMMUNICATIONS; MODEM.

Modern private branch exchanges have extensive and virtually identical feature complements, which include several types of call forwarding, least-cost routing, station message detail recording (SMDR), conferencing, hunting, and calling restrictions. In addition to these features, many private branch exchanges interface with outboard applications processors, which enhance the call-processing function of the private branch exchange. [B.W.Ba.; V.F.R.]

Probability Although probability theory derives its notion and terminology from intuition, a vague statement such as "John will probably come" is as remote from it as the statement "John is forceful and energetic" is remote from mechanics. Probability theory constructs abstract models, mostly of a qualitative nature, and only experience can show whether these reasonably describe laws of nature or life. As always in mathematics, only logical relations and implications enter the theory, and the notion of probability is just as undefinable (and as intuitive) as are the notions of point, line, or mass.

The sample space. One speaks of probabilities only in connection with conceptual (not necessarily performable) experiments and must first define the possible outcomes. It is necessary to distinguish between elementary (indivisible) and compound outcomes or events. Each elementary outcome is called sample point; their aggregate is the sample space. The conceptual experiment is defined by the sample space, and it must be introduced and established at the outset.

Events. In examining a bridge hand, one may ask whether it contains an ace or satisfies some other condition. In principle each such event may be described by specifying the sample points which do satisfy the stipulated condition. Thus every compound event is represented by an aggregate of sample points, and in probability theory these terms are synonymous. The standard notations of set theory are used to describe relations among events. *See* SET THEORY.

Given an event A one may consider the case that A does not occur. This is the negation or complement of A, denoted by A'; it consists of those sample points that do not belong to A. Given two events A and B, the event C that either A or B or both occur is the union of A and B and denoted by $C = A \cup B$. In particular $A \cup A'$ is the whole sample space $\mathfrak{S}$ which therefore represents certainty. The event D, both A and B occur, is the intersection of A and B and written $D = A \cap B$. It consists of the points common to A and B.

Probabilities in finite spaces. If the sample space $\mathfrak{S}$ contains only N points $E_1, \ldots, E_N$ their probabilities may be any numbers such that $P\{E_j\} \geqq 0$ and $P\{E_1\} + \cdots + P\{E_N\} = 1$.

The probability $P\{A\}$ of an event A is the sum of the probabilities of all points contained in A; thus $P\{\mathfrak{S}\} = 1$.

Frequently considerations of symmetry lead one to consider all E_j as equally likely; that is, to set $P(E_j) = 1/N$. In this case $P(A) = n/N$ where n is the number of points in A; for a gambler betting on A, these represent the "favorable cases." For example, in throwing a pair of "perfect" dice, one naturally assumes that the 36 possible outcomes are equally likely. This model does not lose its justification or usefulness by the fact that actual dice do not live up to it. The assumption of perfect randomness in games, card shuffling, industrial quality control, or sampling is rarely realized, and the true usefulness of the model stems from the experience that noticeable departures from the ideal scheme lead to the detection of assignable causes and thus to theoretical or experimental improvements.

Conditional probability–independence. Suppose that a population of N people includes N_A color-blind persons and N_H females. To the event A "a randomly chosen person is color-blind" can be ascribed probability $P\{A\} = N_A/N$, and similarly for the event H that a person be female one has $P\{B\} = N_H/N$. If N_{AH} is the number of color-blind females, the ratio N_{AH}/N_H may be interpreted as probability that a randomly chosen female is color-blind; here the experiment "random choice in the population" is replaced by a selection from the female subpopulation. In the original experiment, N_{AH}/N is the probability of the simultaneous occurrence of both A and H, so that $N_{AH}/N_H = P\{A \cap H\}/P\{H\}$. Similar situations occur so frequently that it is convenient to define the conditional probability of the event A relative to H by Eq. (1).

$$P\{A \mid H\} = \frac{P\{A \cap H\}}{P\{H\}} \tag{1}$$

This concept is useful whenever it is desired to restrict the consideration to those cases where the event H occurs (or where the hypothesis H is fulfilled). Thus, in betting on an event A the knowledge that H occurred would induce one to replace $P\{A\}$ by $P\{A \mid H\}$.

Independent trials. The intuitive frequency interpretation of probability is based on the concept of experiments repeated under identical conditions; a theoretical model for this concept can be developed.

Consider an experiment described by a sample space $\mathfrak{S}$; for simplicity of language it can be assumed that $\mathfrak{S}$ consists of finitely many sample points $E_1, \ldots, E_N$. When the same experiment is performed twice in succession, the thinkable outcomes are the N^2 pairs of sample points $(E_1, E_1), (E_1, E_2), \ldots, (E_N, E_N)$, and these now constitute the new sample space. It is called the combinatorial product of $\mathfrak{S}$ by itself and denoted by $\mathfrak{S} \times \mathfrak{S}$.

Probabilities must be assigned to the events in $\mathfrak{S} \times \mathfrak{S}$. If the second trial is independent of the first, the probabilities in $\mathfrak{S} \times \mathfrak{S}$ follow the productive rule $P\{E_i, E_j\} = P\{E_i\}P\{E_j\}$.

In the case of n tossings of a coin, this rule leads to the probability 2^{-n} for each sample point in agreement with the requirement of equally likely cases. In the more general case of Bernoulli trials, each trial results in success S or failure F, and $P\{S\} = p$, $P\{F\} = q$ where $p + q = 1$. (This may be considered as the model of a skew coin.) A succession of n independent trials of this kind leads to the sample space of n-tuples $(SFFS \cdots FS)$, and the probability of such a point is the product $(pqqp \cdots qp)$ obtained on replacing each S by p and each F by q.

Markov chains. Markov chains represent an important scheme for dependent trials. Suppose that at each trial the possible outcomes are $E_1, \ldots, E_N$ and that whenever E_i occurs the conditional probability of E_j at the next trial is p_{ij}, independently of what happened at the preceding trials. Here, of course, $p_{ij} \geqq 0$ and $p_{i1} + p_{i2} + \cdots + p_{iN} = 1$ for each i. The p_{ij} are called transition probabilities. The whole process is now determined if the initial probabilities, π_i, at the first trial are known. For example, $P\{E_a\, E_b\, E_c\} = \pi_a p_{ab} p_{bc}$. The probability of the event "E_c at the third trial" is obtained by summation over all a and b, and so on. Markov chains, and their analog with continuous time, represent the simplest type of stochastic process. *See* STOCHASTIC PROCESS.

Random variables and their distributions. The theory of probability traces its origin to gambling, and the gambler's gain may still serve as the simplest example of a random variable. With every possible outcome (sample point) there is associated a number, namely, the corresponding gain. In other words, the gain is a function on the sample space, and such functions are called random variables. With the same experiment, one may associate many random variables.

Every random variable X has a distribution function $F(t) = P\{X \leqq t\}$. If X assumes only finitely many values, then $F(t)$ is a step function. The notion of independence carries over: Two random variables X and Y are independent if $p(X \leqq x, Y \leqq t\} = P(X \leqq s\} \cdot P\{Y \leqq t)$.

Expectations. Given a random variable X one may interpret its distribution function $F(t)$ as describing the distribution of a unit mass along the real axis such that the interval $a < x \leqq b$ carries mass $F(b) - F(a)$. In the case of a discrete variable assuming the values $x_1, x_2, \ldots$ with probabilities $p_1, p_2, \ldots$ the entire mass is concentrated at the points x_i; if $F'(x) = f(x)$ exists, it represents the ordinary mass density as defined in mechanics. The center of gravity of this mass distribution is called the expectation of X; the usual symbol for it is $E(X)$, but physicists and engineers use notations such as $\langle X \rangle$, $\langle X \rangle_{Av}$, or X. In the cases mentioned, $E(X)$ is given by Eqs.(2) and (3).

$$E(X) = \Sigma P_i x_j \tag{2}$$

$$E(X) = \int_{-\infty}^{+\infty} x f(x)\, dx \tag{3}$$

Before discussing the significance of the new concept, a few frequently used definitions are appropriate. Put $m = E(X)$. Then $(X - m)^2$ is, of course, a random variable. In mechanics, its expectation represents the moment of inertia of the mass distribution. In probability, it is called variance of X, given by Eq. (4). Its positive root is the standard deviation.

$$\mathrm{Var}(X) = E(X - m)^2 = E(X^2) - m^2 \tag{4}$$

The variance is a measure of spread: It is zero only if the entire mass is concentrated at the point m, and it increases as the mass is moved away from m. In the case of two variables X_1 and X_2 with expectations m_l and m_2 it is necessary to consider not only the two variances $s_i^2 = E[(X_i - m_i)^2]$ but also the covariance $\mathrm{Cov}(X_1, X_2) = E[(X - m_1)(X_2 - m_2)] = E(X_1 X_2) = m_1 m_2$. The covariance divided by $s_1 s_2$ is called the correlation coefficient of X_1, and X_2. If it vanishes, X_1 and X_2 are called uncorrelated. Every pair of independent variables is uncorrelated, but the converse is not true.

Laws of large numbers. To explain the meaning of the expectation and, at the same time, to justify the intuitive frequency interpretation of probability, consider a gambler who at each trial may gain the amounts $x_1, x_2, \ldots, x_n$ with probabilities $p_1, p_2, \ldots, p_n$. The gains at the first and second trials are independent random variables X_1, X_2 with the indicated distribution and the common expectation $m = \Sigma p_i x_i$. The event that an individual gain equals x, as probability p_i, and the frequency interpretation of probability leads one to expect that in a large number n of trials this event should happen approximately np_i times. If this is true, the total gain $S_n = X_1 + X_2 + \cdots + X_n$ should be approximately nm; that is, the average gain $(l/n)S_n$ should be close to m. The law of large numbers in its simplest form asserts this to be true. *See* GAME THEORY; STATISTICS. [W.F.]

Proboscidea An order of placental mammals derived from conservative (that is, primitive or ancient) hooved mammal stock (sometimes informally referred to as condylarths), the oldest members known from Paleocene sediments of North Africa. At one point, proboscideans had a wide distribution, having reached every continent except Australia and Antarctica. They included an astonishing variety of forms. However, currently this order consists of only two forms, belonging to the family Elephantidae: the African elephant (*Loxodonta africana*) and the Asian elephant (*Elephas maximus*). Features commonly associated with the proboscideans include large body size, enlarged incisors that form paired tusks (relatively small lower tusks were present in the jaws in the majority of extinct forms in addition), and a proboscis (often referred to informally as a trunk). It is important to realize that the very early forms lacked both significant tusks and a proboscis, though they are still formally considered proboscideans. Unlike most modern hooved mammals which have reduced the toe number to four or more often fewer, proboscideans have retained five toes. Throughout their known history, proboscideans have been strictly herbivorous.

Early elephant evolution mostly occurred in Africa during the Eocene and Oligocene. Near the beginning of the Miocene, proboscideans exited Africa and spread all over Europe and Asia, and by the middle Miocene they reached North America. The proboscideans were highly successful in North America, and between 2 and 1.5 million years ago they entered South America across the Panamanian landbridge. Between 12,000 and 10,000 years ago, most of the world's proboscideans became extinct, with only the African and Asian elephants surviving.

There has been considerable debate by paleontologists as to which animals are actually proboscideans, in part because some members of the order bear little or no superficial resemblance to modern forms. Two suborders in the classification below, Deinotherioidea and Barytherioidea, represent such sometimes disputed groups.

Order Proboscidea
  Suborder: Deinotherioidea
    Barytherioidea
    Moeritheriodea
    Elephantoidea
      Infraorder Mammutoidea
        Family Mammutidae
      Infraorder Gomphotherioidea
        Family: Gomphotheriidae
          Elephantidae

The conservative proboscideans consist of the members of the suborders Deinotherioidea, Barytherioidea, and Moeritherioidea. Though these animals are considered to be proboscideans, they mostly bear little or no resemblance to elephants. In fact, such typically elephantine characters as tusks and a proboscis do not strictly define the order Proboscidea. Instead, proboscideans are characterized by relatively obscure features in the teeth, shoulder, and ankle. The relationship of these suborders to the advanced suborder Elephantoidea (which includes the living elephants) is not well understood. *See* ELEPHANT; MAMMALIA. [W.D.L.]

Procellariiformes A large order of strictly marine birds found far offshore except when breeding. The procellariforms, or tube-nosed swimmers, are most closely related to their descendant group, the penguins. The Procellariiformes comprise four families: Diomedeidae (albatrosses; 13 species); Procellariidae (shearwaters, petrels, and fulmars; 66 species); Hydrobatidae (storm petrels; 21 species); and Pelecanoididae (diving petrels; 4 species).

The tube-nosed swimmers are characterized by having their nostrils enclosed in a tube, which is paired in albatrosses; dense plumage; webbed feet; and long wings. They range in size from the sparrow-sized storm petrels to large albatrosses, which have the greatest wingspan of all living birds, up to 12 ft (3.7 m). The procellariiforms are excellent fliers, as evidenced by the migratory—actually nomadic wandering—flights of many thousands of miles. Procellariiforms swim well, but only the pelecanoidids dive under water, using their wings for propulsion. They are highly pelagic and feed on fish, squids, and crustaceans. Procellariiforms have a well-developed olfactory sense to locate food and apparently to locate their nesting burrows at night. The larger species mature slowly; some albatrosses begin breeding only after reaching 6 to 8 years of age. Tight pair bonds are formed during courtship, which can take elaborate forms, as is seen in albatrosses. *See* AVES. [W.J.B.]

Process control

Process control A field of engineering dealing with ways and means by which conditions of processes are brought to and maintained at desired values, and undesirable conditions are avoided as much as possible. In general, a process is understood to mean any system where material and energy streams are made to interact and to transform each other. Examples are the generation of steam in a boiler; the separation of crude oil by fractional distillation into gas, gasoline, kerosine, gas-oil and residue; the sintering of iron ore particles into pellets; and the polymerization of propylene molecules for the manufacture of polypropylene. In the wide sense, process control also encompasses determining the desired values.

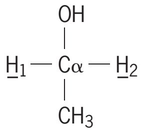
Process control includes a number of functions, which can be arranged in a hierarchy, as follows:

Scheduling
Mode setting
Quality control
Regulatory control/Sequence control
Coping with faults

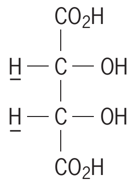
Computerized instrumentation has revolutionized the interaction with plant personnel, in particular the process operators. Traditionally, the central control room was provided with long panels or consoles, on which alarm lights, indicators, and recorders were mounted. Costs were rather high, and surveyability was poor. In computerized instrumentation, visual display units can provide information in a concise and flexible way, adapted to human needs and capabilities. *See* AUTOMATION; CONTROL SYSTEMS. [J.E.R.]

Process engineering A branch of engineering in which a process effects chemical and mechanical transformations of matter, conducted continuously or repeatedly on a substantial scale. Process engineering constitutes the specification, optimization, realization, and adjustment of the process applied to manufacture of bulk products or discrete products. Bulk products are those which are homogeneous throughout and uniform in properties, are in gaseous, liquid, or solid form, and are made in separate batches or continuously. Examples of bulk product processes include petroleum refining, municipal water purification, the manufacture of penicillin by fermentation or synthesis, the forming of paper from wood pulp, the separation and crystallization of various salts from brine, the production of liquid oxygen and nitrogen from air, the electrolytic beneficiation of aluminum, and the manufacture of paint, whiskey, plastic resin, and so on. Discrete products are those which are separate and individual, although they may be identical or very nearly so. Examples of discrete product processes include the casting, molding, forging, shaping, forming, joining, and surface finishing of the component piece parts of end products or of the end products themselves. Processes are chemical when one or more essential steps involve chemical reaction. Almost no chemical process occurs without many accompanying mechanical steps such as pumping and conveying, size reduction of particles, classification of particles and their separation from fluid streams, evaporation and distillation with attendant boiling and condensation, absorption, extraction, membrane separations, and mixing. *See* DIALYSIS; DISTILLATION; EVAPORATION; EXTRACTION; ION-SELECTIVE MEMBRANES AND ELECTRODES; MECHANICAL CLASSIFICATION; MECHANICAL SEPARATION TECHNIQUES; MIXING; OPTIMIZATION; PRODUCTION ENGINEERING. [E.F.L.]

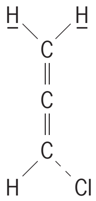
Prochirality The property displayed by a prochiral molecule or a prochiral atom (prostereoisomerism). A molecule or atom is prochiral if it contains, or is bonded to, two constitutionally identical ligands (atoms or groups), replacement of one of which by a different ligand makes the molecule or atom chiral. Examples are shown below.



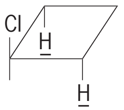
(1)



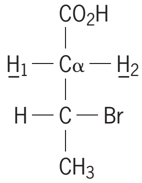
(2)



(3)



(4)



(5)

None of molecules **1–4** is chiral, but if one of the underlined pair of hydrogens is replaced, say, by deuterium, chirality results in all four cases. In compound **1**, ethanol, a prochiral atom or center can be discerned ($C\alpha{:}CH_2$); upon replacement of H by D, a chiral atom or center is generated, whose configuration depends on which of the two pertinent atoms (H_1 or H_2) is replaced. Molecule **5** is chiral to begin with, but separate replacement of H_1 and H_2 (say, by bromine) creates a new chiral atom at $C\alpha$ and thus gives rise to a pair of chiral diastereomers. No specific prochiral atom can be discerned in molecules **2–4**, which are nevertheless prochiral (**3** has a prochiral axis).

Faces of double bonds may also be prochiral (and give rise to prochiral molecules), namely, when addition to one or other of the two faces of a double bond gives chiral products.

Although the term prochirality is widely used, especially by biochemists, a preferred term is prostereoisomerism. This is because replacement of one or other of the two corresponding ligands (called heterotopic ligands) or addition to the two heterotopic faces often gives rise to achiral diastereomers without generation of chirality. Thus not all compounds which display prostereoisomerism also display prochirality. *See* MOLECULAR ISOMERISM; STEREOCHEMISTRY. [E.L.E.]

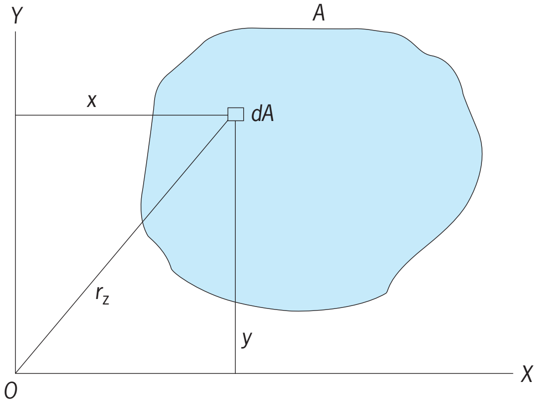
Prochlorophyceae A class of prokaryotic organisms coextensive with the division Prochlorophycota in the kingdom Monera. Because prochlorophytes carry out oxygen-evolving photosynthesis, they may be considered algae. They are distinguished from Cyanophyceae, the only other prokaryotic algae, by the presence in their photosynthetic lamellae of chlorophyll *b* in addition to chlorophyll *a* and the absence of phycobilin pigments. Otherwise, they resemble Cyanophyceae biochemically and ultrastructurally. The class comprises a single genus, *Prochloron*, with one species. *See* ALGAE; CYANOPHYCEAE. [P.C.Si.; R.L.Moe]

Procyon The brightest star in the constellation Canis Minor, apparent magnitude +0.36. Procyon (α Canis Minoris) is among the stars nearest to the Earth, at a distance of only 3.5 parsecs (1.08×10^{14} km or 6.7×10^{13} mi). Its spectral type is F5, but Procyon is slightly overluminous compared to a main-sequence star of the same spectral type, which indicates that Procyon has already begun to evolve off the main sequence. Its intrinsic luminosity is about seven times that of the Sun. *See* SPECTRAL TYPE; STELLAR EVOLUTION.

Procyon has a faint 11th-magnitude companion, Procyon B, a white dwarf in the final stages of its evolution, with a luminosity only 1/2000 that of the Sun. From the astrometric orbit the masses of the primary and its companion have been computed as 1.75 and 0.62 solar masses, respectively. The progenitor of the white dwarf was originally the more massive of the two stars and underwent the final stages of its stellar evolution sooner than the original secondary, which is now seen as Procyon A. *See* BINARY STAR; STAR; WHITE DWARF STAR. [D.W.L.]

Product design The determination and specification of the parts of a product and their interrelationship so that they become a unified whole. The design must satisfy a broad array of requirements in a condition of balanced effectiveness. A product is designed to perform a particular function or set of functions effectively and reliably, to be economically manufacturable, to be profitably salable, to suit the purposes and the attitudes of the consumer, and to be durable, safe, and economical to operate. For instance, the design must take into consideration the particular manufacturing facilities, available materials, know-how, and economic resources of the manufacturer. The product may need to be packaged; usually it will also need to be shipped so that it should be light in weight and sturdy of construction. The product should appear significant, effective, compatible with the culture, and appear to be worth more than the price. *See* PRODUCTION ENGINEERING; PRODUCTION PLANNING. [R.I.F.]

Product of inertia The product of inertia of area A relative to the indicated XY rectangular axes is $I_{XY} = \int xy\, dA$ (see illustration). The product of inertia of the mass contained in volume V relative to the XY axes is $I_{XY} = \int xy\rho\, dV$—similarly for I_{YZ} and I_{ZX}.



Product of inertia of an area.

Relative to principal axes of inertia, the product of inertia of a figure is zero. If a figure is mirror symmetrical about a YZ plane, $I_{ZX} = I_{XY} = 0$. *See* MOMENT OF INERTIA. [N.S.F.]

Product quality The collection of features and characteristics of a product that contribute to its ability to meet given requirements. Early work in controlling product quality was on creating standards for producing acceptable products. By the mid-1950s, mature methods had evolved for controlling quality, including statistical quality control and statistical process control, utilizing sequential sampling techniques for tracking the mean and variance in process performance. During the 1960s, these methods and techniques were extended to the service industry. During 1960–1980, there was a major shift in world markets, with the position of the United States declining while Japan and Europe experienced substantial growth in international markets. Consumers became more conscious of the cost and quality of products and services. Firms began to focus on total production systems for achieving quality at minimum cost. This trend has continued, and today the goals of quality control are largely driven by consumer concerns and preferences.

There are three views for describing the overall quality of a product. First is the view of the manufacturer, who is primarily concerned with the design, engineering, and manufacturing processes involved in fabricating the product. Quality is measured by the degree of conformance to predetermined specifications and standards, and deviations from these standards can lead to poor quality and low reliability. Efforts for quality improvement are aimed at eliminating defects (components and subsystems that are out of conformance), the need for scrap and rework, and hence overall reductions in production costs. Second is the view of the consumer or user. To consumers, a high-quality product is one that well satisfies their preferences and expectations. This consideration can include a number of characteristics, some of which contribute little or nothing to the functionality of the product but are significant in providing customer satisfaction. A third view relating to quality is to consider the product itself as a system and to incorporate those characteristics that pertain directly to the operation and functionality of the product. This approach should include overlap of the manufacturer and customer views. *See* MANUFACTURING ENGINEERING.

Quality control (QC) is the collection of methods and techniques for ensuring that a product or service is produced and delivered according to given requirements. This includes the development of specifications and standards, performance measures, and tracking procedures, and corrective actions to maintain control. The data collection and analysis functions for quality control involve statistical sampling, estimation of parameters, and construction of various control charts for monitoring the processes in making products. This area of quality control is formally known as statistical process control (SPC) and, along with acceptance sampling, represents the traditional perception of quality management. Statistical process control focuses primarily on the conformance element of quality, and to somewhat less extent on operating performance and durability. *See* PROCESS CONTROL; QUALITY CONTROL.

Concurrent engineering, quality function deployment, and total quality management (TQM) are modern management approaches for improving quality through effective planning and integration of design, manufacturing, and materials management functions throughout an organization. Quality improvement programs typically include goals for reducing warranty claims and associated costs because warranty data directly or indirectly impact most of the product quality dimensions. *See* ENGINEERING DESIGN. [M.U.T.]

Product usability A concept in product design, sometimes referred to as ease of use or user-friendliness, that is related directly to the quality of the product and indirectly to the productivity of the work force. Customer surveys show that product quality is broken down into six components (in descending order of importance): reliability, durability, ease of maintenance, usability, trusted or brand name, and price. Ease of maintenance and usability both relate to product usability. Reliability also has a component of usability to it. If a product is too difficult to use and thus appears not to work properly, the customer may think that it has malfunctioned. Consequently, the customer may return the product to the store not because it is unreliable but because it does not work the way the customer thinks it should. *See* HUMAN-COMPUTER INTERACTION.

There are five criteria by which a product's usability can be measured, including time to perform a task, or the execution time; learnability; mental workload, or the mental effort required to perform a task; consistency in the design; and errors. The usability of a product usually cannot be optimized for all five criteria at the same time. Trade-offs will occur. As an example, a product that is highly usable in terms of fast execution times will often have poor usability in terms of the time needed to learn how to use the product. A product designer must be aware that it may not be possible for a product to be highly usable by all usability criteria, and so design according to the criteria that are most important to potential customers. Casual users of a product will have different demands on a product compared to expert users. *See* CONTROL SYSTEMS; HUMAN-FACTORS ENGINEERING; HUMAN-MACHINE SYSTEMS.

Many companies, especially computer or consumer electronics companies, have laboratories in which to test the usability of their products. The methods of usability testing are formal experimentation, informal experimentation, and task analyses. Although laboratory methods for improving usability can increase the cost of the product design, the benefits (market share, productivity) will outweigh the costs. *See* METHODS ENGINEERING; OPTIMIZATION. [R.Eb.]

Production engineering A branch of engineering that involves the design, control, and continuous improvement of integrated systems in order to provide customers with high-quality goods and services in a timely, cost-effective manner. It is an interdisciplinary area requiring the collaboration of individuals trained in industrial engineering, manufacturing engineering, product design, marketing, finance, and corporate planning. In many organizations, production engineering activities are carried out by teams of individuals with different skills rather than by a formal production engineering department.

In product design, the production engineering team works with the designers, helping them to develop a product that can be manufactured economically while preserving its functionality. Features of the product that will significantly increase its cost are identified, and alternative, cheaper means of obtaining the desired functionality are investigated and suggested to the designers. The process of concurrently developing the product design and the production process is referred to by several names such as design for manufacturability, design for assembly, and concurrent engineering. *See* ACTIVITY-BASED COSTING; DESIGN STANDARDS; PROCESS ENGINEERING; PRODUCT DESIGN; PRODUCTION PLANNING.

The specification of the production process should proceed concurrently with the development of the product design. This involves selecting the manufacturing processes and technology required to achieve the most economical and effective production. The technologies chosen will depend on many factors, such as the required production volume, the skills of the available work force, market trends, and economic considerations. In manufacturing industries, this requires activities such as the design of tools, dies, and fixtures; the specification of speeds and feeds for machine tools; and the specification of process recipes for chemical processes.

Actual production of physical products usually begins with a few prototype units being manufactured in research and development or design laboratories for evaluation by designers, the production engineering team, and sales and marketing personnel. The goal of this pilot phase is to give the production engineering team hands-on experience making the product, allowing problems to be identified and remedied before investing in additional production equipment or shipping defective products to the customer. The pilot production process involves changes to the product design and fine-tuning of unit manufacturing processes, work methods, production equipment, and materials to achieve an optimal trade-off between cost, functionality, and product quality and reliability. *See* PILOT PRODUCTION; PROTOTYPE.

The production facility itself can be designed around the sequence of operations required by the product, referred to as a product layout. General-purpose production machinery is used, and often must be set up for each individual job, incurring significant changeover times while this takes place. This type of production facility is usually organized in a process layout, where equipment with similar functions is grouped together. *See* HUMAN-MACHINE SYSTEMS; PRODUCTION METHODS.

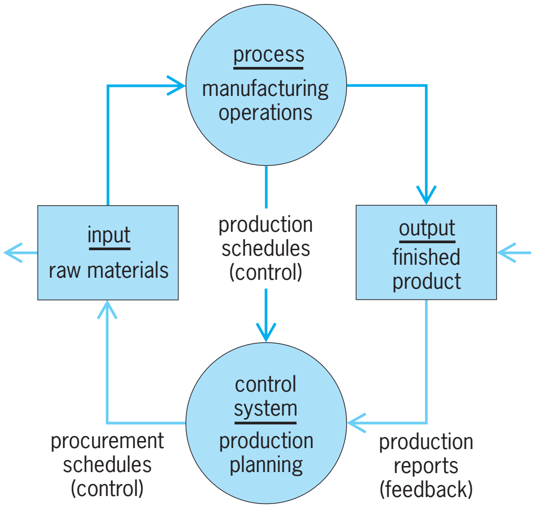
The production engineering process does not stop once the product has been put into production. A major function of production engineering is continuous improvement—continually striving to eliminate inefficiencies in the system and to incorporate and advance the frontier of the best existing practice. The task of production engineering is to identify potential areas for improving the performance of the production system as a whole, and to develop the necessary solutions in these areas. *See* PRODUCT QUALITY. [R.M.U.]

Production methods Processes and techniques that are used to manufacture a product. Production methods can vary greatly, depending on the specifications of the product and the quantity required. Determining the production methods is typically part of the process-planning phase of design, that is, the steps related to converting the design into a final product. Production methods must be considered carefully and planned properly because the production cycle generally represents a large investment of time and money. *See* PROCESS ENGINEERING; PRODUCT DESIGN; PRODUCTION PLANNING.

The two basic forms of production systems are job-shop production (for applications where the products are made either in single units or in limited production runs) and mass production. A third production form, specific process production, is normally restricted to industries such as the chemical process industry where the processing is the product, such as distilling and refining. *See* DISTILLATION; PETROLEUM PROCESSING AND REFINING; UNIT PROCESSES.

In spite of the many advances that have been made in the methods and equipment used in manufacturing, the basic categories of manufacturing processes have remained relatively unchanged. These can be divided into seven general categories: casting and molding, shearing and forming, machining/material removal, heat treating, finishing, assembly, and inspection. However, none of these processes is totally exclusive. *See* HEAT TREATMENT (METALLURGY); METAL CASTING; METAL FORMING; PLASTICS PROCESSING. [E.G.Ho.]

Production planning The function of a manufacturing enterprise responsible for the efficient planning, scheduling, and



The production process as an input-output process.

coordination of all production activities. The planning phase involves forecasting demand and translating the demand forecast into a production plan that optimizes the company's objective, which is usually to maximize profit while in some way optimizing customer satisfaction. These twin objectives are not always synonymous. During the scheduling phase the production plan is translated into a detailed, usually day-by-day, schedule of products to be made. During the coordination phase actual product output is compared with scheduled product output, and this information is used to adjust production plans and production schedules. *See* OPTIMIZATION.

If the production or manufacturing process is viewed as an input-output process, then the production planning function can be viewed as a control process with feedback (see illustration). The control is in the form of schedules and plans, while the feedback results from the comparison of the production reports with the production schedules. *See* CONTROL SYSTEMS; INVENTORY CONTROL; PRODUCTION ENGINEERING; PRODUCTION METHODS. [J.E.Bi.]

Productivity In a business or industrial context, the ratio of output production to input effort. The productivity ratio is an indicator of the efficiency with which an enterprise converts its resources (inputs) into finished goods or services (outputs). If the goal is to increase productivity, this can be done by producing more output with the same level of input. Productivity can also be increased by producing the same output with fewer inputs. One problem with trying to measure productivity is that a decision must be made in terms of identifying the inputs and outputs and how they will be measured. This is relatively easy when productivity of an individual is considered, but it becomes difficult when productivity involves a whole company or a nation.

Industry and government officials have adopted three common types of productivity measures. Partial productivity is the simplest type of productivity measure; a single type of input is selected for the productivity ratio. The company or organization selects an input factor that it monitors in daily activity. Direct labor hours is a factor that most companies monitor because they pay their employees based on hours worked.

Total factor productivity is a productivity measure combines that labor and capital, two of the most common input factors used in the partial productivity measure. This measure is often used at the national level, because many governments collect statistics on both labor and capital. In calculating at the national level, the gross national product (GNP) is used as the output.

Total productivity is a productivity measure that incorporates all the inputs required to make a product or provide a service. The inputs could be grouped in various categories as long as they determine the total inputs required to produce an output.

Many factors affect productivity. Some general categories for these factors are product, process, labor force, capacity, external influences, and quality.

There are many different plans that companies develop in an attempt to improve productivity. Wage incentive plans and changes in management structure are two ways that companies focus on the labor force. Investment in research and development allows companies to develop new products and processes that are more productive. Quality improvement programs can reduce waste and provide more competitive products at a lower cost. *See* METHODS ENGINEERING; OPERATIONS RESEARCH; PRODUCTION PLANNING. [G.L.To.]

Progesterone A steroid hormone produced in the corpus luteum and placenta. The hormone has an important physiological role in the luteal phase of the menstrual cycle and in the maintenance of pregnancy. In addition, progesterone produced in the testis and adrenals has a key role as an intermediate in the biosynthesis of androgens, estrogens, and the corticoids (adrenal cortex steroids). *See* ANDROGEN; CHOLESTEROL; ESTROGEN; MENSTRUATION; PREGNANCY; STEROID; STEROL. [R.I.D.]

Programmable controllers Electronic computers that are used for the control of machines and manufacturing processes through the implementation of specific functions such as logic, sequencing, timing, counting, and arithmetic. They are also known as programmable logic controllers (PLCs). Historically, process control of a single or a few related devices has been implemented through the use of banks of relays and relay logic for both the control of actuators and their sequencing. The advent of small, inexpensive microprocessors and single-chip computers, or microcontroller units, brought process control from the age of simple relay control to one of electronic digital control while neither losing traditional design methods such as relay ladder diagrams nor restricting their programming to that single paradigm. The computational power of programmable controllers and their integration into networks has led to capabilities approaching those of distributed control systems, and plantwide control is now a mixture of distributed control systems and programmable controllers. Applications for programmable controllers range from small-scale, local process applications in which as few as 10 simple feedback control loops are implemented, up to large-scale, remote supervisory process applications in which 50 or more process control loops spread across the facility are implemented. Typical applications include batch process control and materials handling in the chemical industry, machining and test-stand control and data acquisition in the manufacturing industry, wood cutting and chip handling in the lumber industry, filling and packaging in food industries, and furnace and rolling-mill controls in the metal industry. *See* DIGITAL COMPUTER; DISTRIBUTED SYSTEMS (CONTROL SYSTEMS); MICROPROCESSOR.

Although programmable controllers have been available since the mid-1970s, developments—such as the ready availability of local area networks (LANs) in the industrial environment, standardized hardware interfaces for manufacturer interchangability, and computer software to allow specification of the control process in both traditional (ladder logic) and more modern notations such as that of finite-state machines—have made them even more desirable for industrial process control. *See* LOCAL-AREA NETWORKS.

Programmable logic controllers are typically implemented by using commonly available microprocessors combined with standard and custom interface boards which provide level conversion, isolation, and signal conditioning and amplification. Microprocessors used in programmable controllers are similar or the same as those used in personal computers. The software of a programmable controller must respond to interrupts and be a real-time operating system, characteristics which the typical operating system of a personal computer does not possess. *See* MICROCOMPUTER; OPERATING SYSTEM; REAL-TIME SYSTEMS; SOFTWARE.

Perhaps the biggest benefit of programmable controllers is their small size, which allows computational power to be placed immediately adjacent to the machinery to be controlled, as well as their durability, which allows them to operate in harsh environments. This proximity of programmable controllers to the equipment that they control allows them to effect the sensing of the process and control of the machinery through a reduced number of wires, which reduces installation and maintenance costs. The proximity of programmable controllers to processes also improves the quality of the sensor data since it reduces line lengths, which can introduce noise and affect sensor calibration. [K.J.Hi.]

Programming languages The different notations used to communicate algorithms to a computer. A computer executes a sequence of instructions (a program) in order to perform some task. In spite of much written about computers being electronic brains or having artificial intelligence, it is still necessary for humans to convey this sequence of instructions to the computer before the computer can perform the task. The set of instructions and the order in which they have to be performed is known as an algorithm. The result of expressing the algorithm in a programming language is called a program. The process of writing the algorithm using a programming language is called programming, and the person doing this is the programmer. *See* ALGORITHM.

In order for a computer to execute the instructions indicated by a program, the program needs to be stored in the primary memory of the computer. Each instruction of the program may occupy one or more memory locations. Instructions are stored as a sequence of binary numbers (sequences of zeros and ones), where each number may indicate the instruction to be executed (the operator) or the pieces of data (operands) on which the instruction is carried out. Instructions that the computer can understand directly are said to be written in machine language. Programmers who design computer algorithms have difficulty in expressing the individual instructions of the algorithm as a sequence of binary numbers. To alleviate this problem, people who develop algorithms may choose a programming language. Since the language used by the programmer and the language understood by the computer are different, another computer program called a compiler translates the program written in a programming language into an equivalent sequence of instructions that the computer is able to understand and carry out. *See* COMPUTER STORAGE TECHNOLOGY.

Machine language. For the first machines in the 1940s, programmers had no choice but to write in the sequences of digits that the computer executed. For example, assume we want to compute the absolute value of $A + B - C$, where A is the value at machine address 3012, B is the value at address 3013, and C is the value at address 3014, and then store this value at address 3015.

It should be clear that programming in this manner is difficult and fraught with errors. Explicit memory locations must be written, and it is not always obvious if simple errors are present. For example, at location 02347, writing 101... instead of 111... would compute $|A + B + C|$ rather than what was desired. This is not easy to detect.

Assembly language. Since each component of a program stands for an object that the programmer understands, using its name rather than numbers should make it easier to program. By naming all locations with easy-to-remember names, and by using symbolic names for machine instructions, some of the difficulties of machine programming can be eliminated. A relatively simple program called an assembler converts this symbolic notation into an equivalent machine language program.

The symbolic nature of assembly language greatly eased the programmer's burden, but programs were still very hard to write. Mistakes were still common. Programmers were forced to think in terms of the computer's architecture rather than in the domain of the problem being solved.

High-level language. The first programming languages were developed in the late 1950s. The concept was that if we want to compute $|A + B - C|$, and store the result in a memory location called D, all we had to do was write $D = |A + B - C|$ and let a computer program, the compiler, convert that into the sequences of numbers that the computer could execute. FORTRAN (an acronym for Formula Translation) was the first major language in this period.

FORTRAN statements were patterned after mathematical notation. In mathematics the = symbol implies that both sides of the equation have the same value. However, in FORTRAN and some other languages, the equal sign is known as the assignment operator. The action carried out by the computer when it encounters this operator is, "Make the variable named on the left of the equal sign have the same value as the expression on the right." Because of this, in some early languages the statement would have been written as $-D \rightarrow D$ to imply movement or change, but the use of → as an assignment operator has all but disappeared.

The compiler for FORTRAN converts that arithmetic statement into an equivalent machine language sequence. In this case, we did not care what addresses the compiler used for the instructions or data, as long as we could associate the names A, B, C, and D with the data values we were interested in.

Structure of programming languages. Programs written in a programming language contain three basic components: (1) a mechanism for declaring data objects to contain the information used by the program; (2) data operations that provide for transforming one data object into another; (3) an execution sequence that determines how execution proceeds from start to finish.

Data declarations. Data objects can be constants or variables. A constant always has a specific value. Thus the constant 42 always has the integer value of forty-two and can never have another value. On the other hand, we can define variables with symbolic names. The declaration of variable A as an integer informs the compiler that A should be given a memory location much like the way the variable A in example (2) was given the machine address 03012. The program is given the option of changing the value stored at this memory location as the program executes.

Each data object is defined to be of a specific type. The type of a data object is the set of values the object may have. Types can generally be scalar or aggregate. An object declared to be a scalar object is not divisible into smaller components, and generally it represents the basic data types executable on the physical computer. In a data declaration, each data object is given a name and a type. The compiler will choose what machine location to assign for the declared name.

Data operations. Data operations provide for setting the values into the locations allocated for each declared data variable. In general this is accomplished by a three-step process: a set of operators is defined for transforming the value of each data object, an expression is written for performing several such operations, and an assignment is made to change the value of some data object.

For each data type, languages define a set of operations on objects of that type. For the arithmetic types, there are the usual operations of addition, subtraction, multiplication, and division. Other operations may include exponentiation (raising to a power), as well as various simple functions such as modula or remainder (when dividing one integer by another). There may be other binary operations involving the internal format of the data, such as binary *and*, *or*, *exclusive or*, and *not* functions. Usually there are relational operations (for example, equal, not equal, greater than, less than) whose result is a boolean value of *true* or *false*. There is no limit to the number of operations allowed, except that the programming language designer has to decide between the simplicity and smallness of the language definition versus the ease of using the language.

Execution sequence. The purpose of a program is to manipulate some data in order to produce an answer. While the data operations provide for this manipulation, there must be a mechanism for deciding which expressions to execute in order to generate the desired answer. That is, an algorithm must trace a path through a series of expressions in order to arrive at an answer. Programming languages have developed three forms of execution sequencing: (1) control structures for determining execution sequencing within a procedure; (2) interprocedural communication between procedures; and (3) inheritance, or the automatic passing of information between two procedures.

Corrado Böhm and Giuseppi Jacopini showed in 1966 that a programming language needs only three basic statements for control structures: an assignment statement, an IF statement, and a looping construct. Anything else can simplify programming a solution, but is not necessary. If we add an input and an output statement, we have all that we need for a programming language. Languages execute statements sequentially with the following variations to this rule.

IF statement. Most languages include the IF statement. In the IF-THEN statement, the expression is evaluated, and if the value is *true*, then Statement_1 is executed next. If the value is *false*, then the statement after the IF statement is the next one to execute. The IF-THEN-ELSE statement is similar, except that specific true and false options are given to execute next. After executing either the THEN or ELSE part, the statement following the IF statement is the next one to execute.

The usual looping constructs are the WHILE statement and the REPEAT statement. Although only one is necessary, languages usually have both.

Inheritance is the third major form of execution sequencing. In this case, information is passed automatically between program segments. This is the basis for the models used in the object-oriented languages C++ and Java.

Inheritance involves the concept of a class object. There are integer class objects, string class objects, file class objects, and so forth. Data objects are instances of these class objects. Objects inherit the properties of the objects from which they were created. Thus, if an integer object were designed with the methods (that is, functions) of addition and subtraction, each instance of an integer object would inherit those same functions. One would only need to develop these operations once and then the functionality would pass on to the derived object.

All objects are derived from one master object called an Object. An Object is the parent class of objects such as magnitude, collection, and stream. Magnitude now is the parent of objects that have values, such as numbers, characters, and dates. Collections can be ordered collections such as an array or an unordered collection such as a set. Streams are the parent objects of files. From this structure an entire class hierarchy can be developed.

If we develop a method for one object (for example, *print* method for *object*), then this method gets inherited to all objects derived from that object. Therefore, there is not the necessity to always define new functionality. If we create a new class of integer that, for example, represents the number of days in a year (from 1 to 366), then this new integerlike object will inherit all of the properties of integers, including the methods to add, subtract, and print values. It is this concept that has been built into C++, Java, and current object-oriented languages.

Once we build concepts around a class definition, we have a separate package of functions that are self-contained. We are able to sell that package as a new functionality that users may be willing to pay for rather than develop themselves. This leads to an economic model where companies can build add-ons for existing software, each add-on consisting of a set of class definitions that becomes inherited by the parent class. *See* Object-oriented programming.

Current programming language models. C was developed by AT&T Bell Laboratories during the early 1970s. At the time, Ken Thompson was developing the UNIX operating system. Rather than using machine or assembly language as in (2) or (3) to write the system, he wanted a high-level language. *See* Operating system.

C has a structure like FORTRAN. A C program consists of several procedures, each consisting of several statements, that include the IF, WHILE, and FOR statements. However, since the goal was to develop operating systems, a primary focus of C was to include operations that allow the programmer access to the underlying hardware of the computer. C includes a large number of operators to manipulate machine language data in the computer, and includes a strong dependence on reference variables so that C programs are able to manipulate the addressing hardware of the machine.

C++ was developed in the early 1980s as an extension to C by Bjarne Stroustrup at AT&T Bell Labs. Each C++ class would include a record declaration as well as a set of associated functions. In addition, an inheritance mechanism was included in order to provide for a class hierarchy for any program.

By the early 1990s, the World Wide Web was becoming a significant force in the computing community, and web browsers were becoming ubiquitous. However, for security reasons, the browser was designed with the limitation that it could not affect the disk storage of the machine it was running on. All computations that a web page performed were carried out on the web server accessed by web address (its Uniform Resource Locator, or URL). That was to prevent web pages from installing viruses on user machines or inadvertently (or intentionally) destroying the disk storage of the user.

Java bears a strong similarity to C++, but has eliminated many of the problems of C++. The three major features addressed by Java are:

1. There are no reference variables, thus no way to explicitly reference specific memory locations. Storage is still allocated by creating new class objects, but this is implicit in the language, not explicit.
2. There is no procedure call statement; however, one can invoke a procedure using the member of class operation. A call to *CreateAddress* for class *address* would be encoded as *address.CreateAddress*( ).
3. A large class library exists for creating web-based objects.

The Java bytecodes (called applets) are transmitted from the web server to the client web site and then execute. This saves transmission time as the executing applet is on the user's machine once it is downloaded, and it frees machine time on the server so it can process more web "hits" effectively. *See* Client-server system.

Visual Basic, first released in 1991, grew out of Microsoft's GW Basic product of the 1980s. The language was organized around a series of events. Each time an event happened (for example, mouse click, pulling down a menu), the program would respond with a procedure associated with that event. Execution happens in an asynchronous manner.

Although Prolog development began in 1970, its use did not spread until the 1980s. Prolog represents a very different model of program execution, and depends on the resolution principle and satisfaction of Horn clauses of Robert A. Kowalski at the University of Edinburgh. That is, a Prolog statement is of the form p:- q, r which means p is true if both q is true or r is true.

A Prolog program consists of a series Horn clauses, each being a sequence of relations concerning data in a database. Execution proceeds sequentially through these clauses. Each relation can invoke another Horn clause to be satisfied. Evaluation of a relation is similar to returning a procedure value in imperative languages such as C or C++.

Unlike the other languages mentioned, Prolog is not a complete language. That means there are algorithms that cannot be programmed in Prolog. However, for problems that are amenable for searching large databases, Prolog is an efficient mechanism for describing those algorithms. *See* Software; Software engineering. [M.V.Z.]

Progression (mathematics) Ordered, countable sets of numbers, $x_1, x_2, x_3, \ldots$, not necessarily all different. In general such sets are called sequences, whereas the term progression is usually confined to the special types: the arithmetic, in which the difference $x_k - x_{k-1}$ between successive terms is constant; the geometric, in which the ratio x_k/x_{k-1} is constant; and the harmonic, in which the reciprocals of the terms are in arithmetic progression.

If the first term of an arithmetic progression is a and the common difference b, then the terms of the progression are given by Eqs. (1). The sum of the first n terms S_n is given by Eq. (2).

$$x_1 = a, x_2 = a + b, x_3 = a + 2b, \ldots, x_n = a + (n-1)b, \ldots \qquad (1)$$

$$S_n = n\frac{x_1 + x_n}{2} = n\left(a + \frac{n-1}{2}b\right) \qquad (2)$$

If the first term of a geometric progression is a and the common ratio r, then the terms of the progression are given by Eqs. (3). Excluding the case $r = 1$ (when all terms are the same), the sum S_n of the first n terms is given by Eq. (4).

$$x_1 = a, x_2 = ar, x_3 = ar^2, \ldots, x_n = ar^{n-1}, \ldots \quad (3)$$

$$S_n = a\frac{1 - r^n}{1 - r} \quad (4)$$

The arithmetic mean A and the geometric mean G of n positive numbers are defined by Eqs. (5) and(6).

$$A = \frac{x_1 + x_2 + \cdots + x_n}{n} \quad (5)$$

$$G = \sqrt{x_1 x_2 \cdots x_n} \quad (6)$$

The reciprocals of sequence (1) form a harmonic progression. There is no compact expression for the sum of n terms.

If x_1, x_2, x_3 are in harmonic progression, then Eq. (7) is called

$$x_2 = \frac{2x_1 x_3}{x_1 + x_3} \quad (7)$$

their harmonic mean. [L.B.]

Projective geometry A geometry that investigates those properties of figures that are unchanged (invariant) when the figures are projected from a point to a line or plane.

Two features of plane projective geometry are (1) introduction of an ideal line that each ordinary line g intersects (the intersection being common to all lines parallel to g), and (2) the principle of duality, according to which any statement that is obtained from a valid one (theorem) by substituting for each concept involved, its dual, is also valid. ("Line" and "point" are dual, "connecting two points by a line" is dual to "intersecting two lines," and so on.) The subject has been developed both synthetically (as a logical consequence of a set of postulates) and analytically (by the introduction of coordinates and the application of algebraic processes). *See* CONFORMAL MAPPING; EUCLIDEAN GEOMETRY. [L.M.Bl.]

Prokaryotae A group of predominantly unicellular microorganisms or infectious agents of cells (the viruses), lacking nuclei, and having asexual and chromonemal reproduction and unidirectional recombination. The Prokaryotae may be considered to include a kingdom for viruses, although such "organisms" are considered acellular or noncellular (even nonliving) by many authorities, and one for the typical moneran forms, the many kinds of bacteria plus the cyanobacteria (the blue-green algae) and the Prochlorophycota. *See* VIRUS.

Bacteria, viruses, and blue-green algae possess little in common, besides such superficial characters as microscopic (or ultramicroscopic) size and frequent involvement in causing diseases in other organisms, including human beings, and such negative characters as not being eukaryotic, not possessing any mouth opening, and not being multicellular (or, in the case of viruses, even cellular) in their organization. In the smallest dimension, prokaryotes measure from 0.2 to 10 micrometers; viruses show a diameter of 10 to 300 nanometers, the largest, therefore, just barely overlapping in width with the smallest bacterium.

Monerans (above the virus level) are generally solitary, unicellular forms; but some species are filamentous, colonial, or mycelial. Some are also motile, either by gliding or by the action of bacterial flagella containing the protein flagellin. Modes of nutrition are diverse: absorptive, chemosynthetic, photoheterotrophic, and photoautotrophic. Respiration is anaerobic or aerobic, or facultatively either one. Respiratory and photosynthetic functions are both generally associated with the plasma membrane system: there are no specialized organelles such as mitochondria or plastids, although thylakoids are present in cyanobacteria and in Prochlorophycota.

Virus particles can survive in a dried, crystalline, metabolically inert state. Bacteria may produce endospores of great resistance to a variety of environmental stresses; the trophic forms occur ubiquitously in aquatic or moist habitats, including cells and tissues of hosts belonging to all other groups of organisms. Complex viruses have an envelope surrounding the nucleocapsid; many bacteria possess rigid cell walls, and some produce outer sheaths. *See* ALGAE; BACTERIA; CYANOBACTERIA; EUKARYOTAE; PROCHLOROPHYCEAE. [J.O.C.]

Promethium A chemical element, Pm, atomic number 61. Promethium is the "missing" element of the lanthanide rare-earth series. The atomic weight of the most abundant separated radioisotope is 147. *See* PERIODIC TABLE.

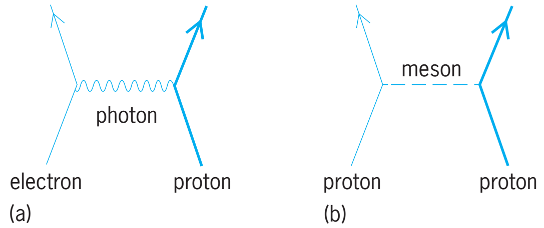
Although a number of scientists have claimed to have discovered this element in nature as a result of observing certain spectral lines, no one has succeeded in isolating element 61 from naturally occurring materials. It is produced artificially in nuclear reactors, since it is one of the products that results from the fission of uranium, thorium, and plutonium.

All the known isotopes are radioactive. Its principal uses are for research involving tracers. Its main application is in the phosphor industry. It has also been used to manufacture thickness gages and as a nuclear-powered battery in space applications. *See* RARE-EARTH ELEMENTS. [F.H.Sp.]

Pronghorn An antelopelike animal, *Antilocapra americana*, the sole representative of the family Antilocapridae, and of uncertain taxonomic affinities. This animal is reputed to be the fastest ungulate in North America and is the only hollow-horned ungulate with branched horns present in both sexes. Like the deer, the pronghom sheds its horns each fall; the new growth is complete by midsummer.

The pronghorn live in small herds in rather wild, rocky desert country. They feed on cactus, sagebrush, and other vegetation. In late summer, a buck begins to accumulate a harem of about 10–15 does. Two young are usually born in the spring after a gestation period of 35 weeks. Average life-span for a pronghorn is about 8 years. *See* ARTIODACTYLA. [C.B.C.]

Propagator (field theory) The probability amplitude for a particle to move or propagate to some new point of space and time when its amplitude at some point of origination is known. The propagator occurs as an important part of the probability in reactions and interactions in all branches of modern physics. Its properties are best described in the framework of quantum field theory for relativistic particles, where it is written in terms of energy and momentum. Concrete examples for electron-proton and proton-proton scattering are provided in the illustration. The amplitude for these processes contains the propagators for the exchanged proton and meson, which actually specify the dominant part of the probability of each process when the scattering occurs at small angles. In similar fashion, for any electromagnetic process, a propagator for each internal line of the Feynman diagram (each line not connected directly to the outside world) enters the probability amplitude.



Feynman diagrams for scattering processes. (*a*) Electron-proton scattering via photon exchange. (*b*) Proton-proton scattering via meson exchange.

See Feynman diagram; Quantum electrodynamics; Quantum field theory; Quantum mechanics. [K.E.L.]

Propellant Usually, a combustible substance that produces heat and supplies ejection particles, as in a rocket engine. A propellant is both a source of energy and a working substance; a fuel is chiefly a source of energy, and a working substance is chiefly a means for expending energy. Because the distinction is more decisive in rocket engines, the term propellant is used primarily to describe chemicals carried by rockets for propulsive purposes. *See* Aircraft fuel; Rocket propulsion; Thermodynamic cycle.

Propellants are classified as liquid or as solid. Even if a propellant is burned as a gas, it may be carried under pressure as a cryogenic liquid to save space. For example, liquid oxygen and liquid hydrogen are important high-energy liquid bipropellants.

Liquid propellants. A liquid propellant releases energy by chemical action to supply motive power for jet propulsion. The three principal types of propellants are monopropellant, bipropellant, and hybrid propellant. Monopropellants are single liquids, either compounds or solutions. Bipropellants consist of fuel and oxidizer carried separately in the vehicle and brought together in the engine. Hybrid propellants use a combination of liquid and solid materials to provide propulsion energy and working substance. Typical liquid propellants are listed in the table. *See* Metal-base fuel.

The availability of large quantities and their high performance led to selection of liquefied gases such as oxygen for early liquid-propellant rocket vehicles. Liquids of higher density with low vapor pressure (see table) are advantageous for the practical requirements of rocket operation under ordinary handling conditions. Such liquids can be retained in rockets for long periods ready for use and are convenient for vehicles that are to be used several times. The high impulse of the cryogenic systems is desirable for rocket flights demanding maximum capabilities, however, such as space exploration or transportation of great weights for long distances. [S.Si.]

Solid propellants. A solid propellant is a mixture of oxidizing and reducing materials that can coexist in the solid state at ordinary temperatures. When ignited, a propellant burns and generates hot gas. Although gun powders are sometimes called propellants, the term solid propellant ordinarily refers to materials used to furnish energy for rocket propulsion.

A solid propellant normally contains three essential components: oxidizer, fuel, and additives. Oxidizers commonly used in solid propellants are ammonium and potassium perchlorates, ammonium and potassium nitrates, and various organic nitrates, such as glyceryl trinitrate (nitroglycerin). Common fuels are hydrocarbons or hydrocarbon derivatives, such as synthetic rubbers, synthetic resins, and cellulose or cellulose derivatives. The additives, usually present in small amounts, are chosen from a wide variety of materials and serve a variety of purposes. Catalysts or suppressors are used to increase or decrease the rate of burning; ballistic modifiers may be used for a variety of reasons, as to provide less change in burning rate with pressure (platinizing agent); stabilizers may be used to slow down undesirable changes that may occur in tong-term storage.

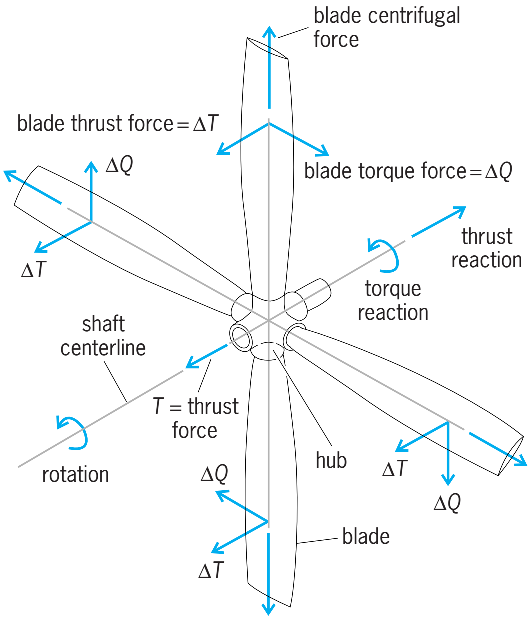
Physical properties of liquid propellants

Propellant	Boiling point, °F (°C)	Freezing point, °F (°C)	Density g/ml	Specific impulse,* s
Monopropellants				
Acetylene	−119 (−84)	−115 (−82)	0.62	265
Hydrazine	236 (113)	35 (2)	1.01	194
Ethylene oxide	52 (11)	−168 (−111)	0.88	192
Hydrogen peroxide	288 (142)	13 (−11)	1.39	170
Bipropellants				
Hydrogen	−423 (−253)	−433 (−259)	0.07	
Hydrogen-fluorine	−306 (−188)	−360 (−218)	1.54	410
Hydrogen-oxygen	−297 (−183)	−362 (−219)	1.14	390
Nitrogen tetroxide	70 (21)	12 (−11)	1.49	—
Nitrogen-tetroxide-hydrazine	236 (113)	35 (2)	1.01	290
Red nitric acid	104 (40)	−80 (−62)	1.58	
Red fuming nitric acid–*uns*-dimethyl hydrazine	146 (63)	−71 (−57)	0.78	275

*Maximum theoretical specific impulse at 1000 psi (6.895 megapascals) chamber pressure expanded to atmospheric pressure.

Solid propellants are classified as composite or double base. The composite types consist of an oxidizer of inorganic salt in a matrix of organic fuels, such as ammonium perchlorate suspended in a synthetic rubber. The double-base types are usually high-strength, high-modulus gels of cellulose nitrate (guncotton) in glyceryl trinitrate or a similar solvent. [H.W.R.]

Propeller (aircraft) A hub-and-multiblade device for changing rotational power of an aircraft engine into thrust power for the purpose of propelling an aircraft through the air (see illustration). An air propeller operates in a relatively thin medium compared to a marine propeller, and is therefore characterized by a relatively large diameter and a fairly high rotational speed. It is usually mounted directly on the engine drive shaft in front of or behind the engine housing. *See* Propeller (marine craft).



Typical four-bladed propeller system.

Usually propellers have two, three, or four blades; for high-speed or high-powered airplanes, six or more blades are used. In some cases these propellers have an equal number of opposite rotating blades on the same shaft, and are known as dual-rotation propellers.

A propeller blade advances through the air along an approximate helical path which is the result of its forward and rotational velocity components. This action is similar to a screw being turned in a solid surface, except that in the case of the propeller a slippage occurs because air is a fluid. Because of the similarity to the action of a screw, a propeller is also known as an airscrew. To rotate the propeller blade, the engine exerts a torque force. This force is reacted on by the blade in terms of lift and drag force components produced by the blade sections in the opposite direction. As a result of the rational forces reacting on the air, a rotational velocity remains in the propeller wake with the same rotational direction as the propeller. This rotational velocity times the mass of the air is proportional to the power input. The sum of all the lift and drag components of the blade sections in the direction of flight are equal to the thrust produced. These forces react on the air, giving an axial velocity component opposite to the direction of flight. By the momentum theory, this velocity times the mass of the air going through the propeller is equal to the thrust.

A propeller blade must be designed to withstand very high centrifugal forces. The blade also must withstand the thrust force produced plus any vibratory forces generated, such as those due to uneven flow fields. To withstand the high stresses due to rotation, propeller blades have been made from a number of materials, including wood, aluminum, hollow steel, and plastic composites. The most common material used has been solid aluminum. However, the composite blade constructions are being used for new turboprop installations because of their very light weight and high strength characteristics.

For a small, low-power airplane, very simple, fixed-pitch, single-piece, two-blade propellers are used. The rotational speed of these propellers depends directly on the power input and forward speed of the airplane. Because of the fixed-blade angle of this type of propeller, it operates near peak efficiency only at one condition. To overcome the limitations of the simple fixed-pitch propeller, configurations that provide for variable blade angles are used. The blades of these propellers are retained in their hub so that they can be rotated about their centerline while the propeller rotates. For the normal range of operation, the blade angle varies from the low blade angle needed for takeoff to the high blade angle needed for the maximum speed of the airplane. *See* AIRCRAFT PROPULSION; AIRPLANE; HELICOPTER. [H.V.B.]

Propeller (marine craft)

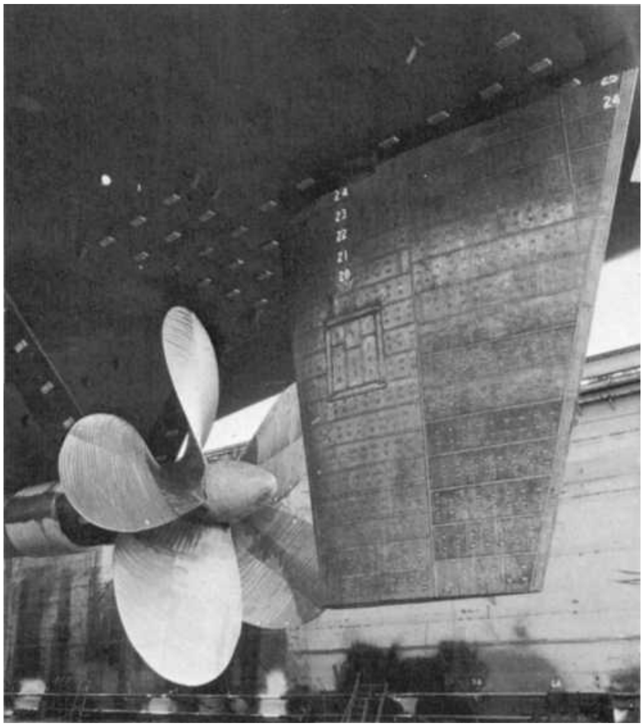
A component of a ship-propulsion power plant which converts engine torque into propulsive force or thrust, thus overcoming a ship's resistance to forward motion by creating a sternward accelerated column of water. Since 1860 the screw propeller has been the only propeller type used in ocean transport, mainly because of the evolution of the marine engine toward higher rotative speed.

The advantages of a screw propeller include light weight, flexibility of application, good efficiency at high rotative speed, and relative insensitivity to ship motion. The fundamental theory of screw propellers is applicable to all forms of marine propellers. In its present form a screw propeller consists of a streamlined hub attached outboard to a rotating engine shaft, on which are mounted two to seven blades. The blades are either solid with the hub, detachable, or movable. The screw propeller has the characteristic motion of a screw; it revolves about the axis along which it advances. The screw blades are approximately elliptical in outline.

One or more screw propellers are usually fitted as low as possible at the ship's stern to act as thrust-producing devices (see illustration). The low position of the propellers affords good protection and sufficient immersion during the pitching movements of the ship. The choice of the number of propellers to incorporate into a vessel design is based upon several factors. In general, a single-screw arrangement yields a higher propulsive efficiency than multiple screws, particularly when most of the propeller is operating in the boundary layer of the ship and can recover some of the energy loss. In addition, single-screw propulsion systems generally result in savings in machinery cost and weight in comparison to multiple-screw arrangements.

The formation and collapse of vapor-filled bubbles, or cavities, causes noise, vibration, and often rapid erosion of the propeller material, especially in fast, high-powered vessels. This phenomenon is known as cavitation. As long as the rotational and translational speeds of the propeller are not too high, the onset of cavitation can be delayed or limited to an acceptable amount by clever design of blade sections. *See* CAVITATION.

Supercavitating and superventilated propellers are designed to have fully developed blade cavities which spring from the leading edge of the blade, cover the entire back of the blade, and collapse well downstream of the blade trailing edge. The blade of such propellers has unique sections which usually are wedge-shaped with a sharp leading edge, blunt trailing edge, and concave face. Supercavitating propellers have cavities filled with water vapor and small amounts of gases dissolved in the fluid media. Superventilated propellers have cavities filled primarily with air from the water surface or gases other than water vapor from a gas supply system through the propeller shaft.



Stern view of *Great Land* in drydock, showing screw propeller. (*From E. Schorsch, R. T. Bicicchi, and J. W. Fu, Hull experiments on 24-knot RO/RO vessels directed toward fuel-saving application of copper-nickel, Soc. Nav. Archit. Mar. Eng. Trans., 86:254–276, 1978*)

For ships which normally operate at widely varying speeds and propeller loadings (towboats, rescue vessels, trawlers, and ferryboats), the application of controllable-pitch (rotatable-blade) propellers permits the use of full engine power at rated rpm under all operational conditions, ensuring maximum thrust production, utmost flexibility, and maneuverability. Since these propellers are also reversible, they permit the use of nonre-versible machinery (gas turbines). *See* MARINE ENGINE; MARINE MACHINERY. [J.B.H.]

Proprioception

The sense of position and movement of the limbs and the sense of muscular tension. The awareness of the orientation of the body in space and the direction, extent, and rate of movement of the limbs depend in part upon information derived from sensory receptors in the joints, tendons, and muscles. Information from these receptors, called proprioceptors, is normally integrated with that arising from vestibular receptors (which signal gravitational acceleration and changes in velocity of movements of the head), as well as from visual, auditory, and tactile receptors. Sensory information from certain proprioceptors, particularly those in muscles and tendons, need not reach consciousness, but can be used by the motor system as feedback to guide postural adjustments and control of well-practiced or semiautomatic movements such as those involved in walking.

Receptors for proprioception are the endings of peripheral nerve fibers within the capsule or ligaments of the joints or within muscle. These endings are associated with specialized end organs such as Pacinian corpuscles, Ruffini's cylinders, and Golgi organs (the latter resembling histologic Golgi structures in the skin), and muscle spindles. *See* CUTANEOUS SENSATION; SENSATION; SOMESTHESIS. [R.LaM.]

Propulsion The process of causing a body to move by exerting a force against it. Propulsion is based on the reaction principle, stated qualitatively in Newton's third law, that for every action there is an equal and opposite reaction. A quantitative description of the propulsive force exerted on a body is given by Newton's second law, which states that the force applied to any body is equal to the rate of change of momentum of that body, and is exerted in the same direction as the momentum change. *See* NEWTON'S LAWS OF MOTION.

In the case of a vehicle moving in a fluid medium, such as an airplane or a ship, the required change in momentum is generally produced by changing the velocity of the fluid (air or water) passing through the propulsive device or engine. In other cases, such as that of a rocket-propelled vehicle, the propulsion system must be capable of operating without the presence of a fluid medium; that is, it must be able to operate in the vacuum of space. The required momentum change is then produced by using up some of the propulsive device's own mass, which is called the propellant. *See* AERODYNAMIC FORCE; AIRFOIL; FLUID FLOW; FLUID MECHANICS; PROPELLANT.

The two terms most generally used to describe propulsion efficiency are thrust specific fuel consumption for engines using the ambient fluid (air or water), and specific impulse for engines which carry all propulsive media on board. *See* SPECIFIC FUEL CONSUMPTION; SPECIFIC IMPULSE.

The energy source for most propulsion devices is the heat generated by the combustion of exothermic chemical mixtures composed of a fuel and an oxidizer. An air-breathing chemical propulsion system generally uses a hydrocarbon such as coal, oil, gasoline, or kerosine as the fuel, and atmospheric air as the oxidizer. A non-air-breathing engine, such as a rocket, almost always utilizes propellents that also provide the energy source by their own combustion.

Where nuclear energy is the source of propulsive power, the heat developed by nuclear fission in a reactor is transferred to a working fluid, which either passes through a turbine to drive the propulsive element such as a propeller, or serves as the propellant itself. Nuclear-powered ships and submarines are accepted forms of transportation. *See* TURBINE PROPULSION. [J.Gr.]

Prosobranchia The largest and most diverse subclass of the molluscan class Gastropoda. The group includes mostly marine snails but with a few fresh-water and land genera, all retaining an anterior mantle cavity and internal evidence of torsion. Adult prosobranchs always retain the streptoneurous (twisted-commissure) condition of the central nervous system, with the commissures to the visceral ganglia in the characteristic figure-eight pattern. This pattern reflects the torsion through 180° during larval (or embryonic) development which has brought the mantle cavity to a position above the head and facing forward. This contrasts with conditions in the other two gastropod subclasses, Opisthobranchia and Pulmonata, in which the effects of torsion are reduced or obscured in adults by secondary processes of development and growth. *See* GASTROPODA; OPISTHOBRANCHIA; PULMONATA.

The diversity of functional morphology exhibited by the prosobranchs is not equaled by any comparable subclass in the entire animal kingdom. From two-gilled forms with symmetrical cardiac and renal structures (the "Diotocardia") which can be numbered among the most primitive of all living mollusks, evolution within prosobranch stocks has involved increasing asymmetry of pallial, cardiac, and renal systems and greater hydrodynamic efficiencies. Torsion and the anterior mantle cavity create locomotory, circulatory, sanitary, and hydraulic problems which have been solved in a variety of ways in different prosobranchs. Four orders are commonly recognized in subclass Prosobranchia: Archaeogastropoda, Neritacea, Mesogastropoda, and Neogastropoda. *See* NEOGASTROPODA. [W.D.R.H.]

Prospecting Exploration for mineral deposits. The result of prospecting is the discovery of potentially economic mineralization, that is, the prospect. Mineral exploration continues beyond prospecting to include the delineation and evaluation of the prospect to determine its minability as an orebody or economic mineral deposit. A successful prospect is developed into a mine. *See* MINING.

Prospecting generally pertains to the search for deposits of metallic ore minerals, but it also includes the search for nonmetallic or industrial minerals and rocks such as sulfur, potash, and limestone, and mineral fuels such as petroleum, coal, and oil shale.

With much of the Earth's readily accessible surface having been investigated for minerals, prospecting is increasingly directed toward the discovery of deeper mineralization in recognized mining districts; mineralization hidden beneath overlying rocks, sediments, and soils; and mineralization in the less-known jungle, arctic, and offshore parts of the world. *See* MARINE MINING; OIL AND GAS, OFFSHORE.

Prospecting is done on the basis of the guides to ore associated with a conceptual image of the anticipated orebody. The image is referred to as an exploration model, and it is drawn from the characteristics of known orebodies in similar terrain. The exploration model and its guides to ore are expressed in terms of the regional and local geologic pattern; it has a certain diagnostic mineralogical character, it will commonly have a halo or envelope of associated guide minerals, and it will be expected to have a recognizable geochemical and geophysical expression. *See* ORE AND MINERAL DEPOSITS.

The topography itself may give evidence of abrupt depressions related to the leaching and collapse of sulfide ore minerals, or it may show boldly exposed silicified zones associated with ore. Some of the latter expressions of ore mineralization represent outcrops of siliceous iron formation host rocks, quartz-filled breccia pipes, and the prospector's classic quartz reefs that indicate vein deposits. Aerial photography and satellite imagery are valuable in searching for the topographic expression of potential ore mineralization.

Outcrops of gossan (the residue of red, brown, and yellow iron oxides and silica that remains from the weathering and near-surface leaching of sulfide ore minerals) are examined in the field for evidence of underlying ore mineralization, and trains of float (fragments of ore and gossan) are traced toward their apparent topographic origin. In glaciated terrain, trains of ore boulders are mapped and traced systematically toward their apparent sources.

Placer gold and placer accumulations of other minerals such as platinum, cassiterite, rutile, and diamonds are sought as economic deposits in themselves and are used as guides to upstream deposits of associated minerals. In addition, resistant and relatively dense minerals in stream gravels and residual heavy minerals in soil are collected by the long-established prospector's method of panning the loose material, and these are traced to a source area.

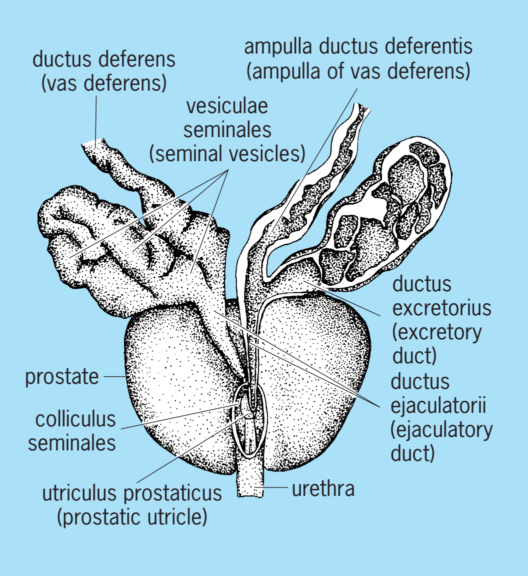
Geochemical prospecting is based on two characteristics of orebodies: an association with anomalous concentrations of chemical elements within primary halos in the surrounding rock, and an association with secondary dispersal patterns of chemical elements in the surficial products of their weathering and erosion. Geochemical methods involve the field and laboratory analysis of sampled rock, soil, vegetation, and other natural materials for trace amounts (in parts per million or billion) of the principal indicator elements of an orebody and of the related pathfinder elements that provide more recognizable or farther-reaching anomalies. *See* GEOCHEMICAL PROSPECTING.

Imagery provided by remote sensing from aircraft and orbiting satellites is of fundamental importance in prospecting and in the patterns of exploration data associated with geographical information systems. Aerial photography in spectral bands of the near-infrared and near-ultraviolet frequencies is also used in photogeology for discriminating between types of exposed rock and soil and for emphasizing the appearance of bleached and stained areas as well as geobotanical anomalies. Airborne remote-sensing systems have provided radar imagery of terrain in the prospecting of cloud-covered jungle regions, and they have furnished thermal-band infrared surveys for recognizing anomalously warm areas that may be associated with mineralization. Airborne multispectral sensors with the capability of identifying some of the specific kinds of minerals in altered zones have been tested for use in prospecting. *See* AERIAL PHOTOGRAPH; GEOGRAPHIC INFORMATION SYSTEMS; REMOTE SENSING.

Geophysical exploration is based on the measurement of physical properties associated with geologic features. As a means of both airborne and ground prospecting for mineral deposits, it involves the recognition of contrasts in properties between the deposit and the adjacent rock, generally to depths on the order of 330–660 ft (100– 200 m), and the definition of deeper structural and lithologic features to be used as guides to ore mineralization. Magnetic, electrical, electromagnetic, and radioactive methods are the most widely used in prospecting for ore and industrial minerals deposits. Geophysical surveys are often made by several methods, so that more than one physical property can be taken into account. *See* GEOMAGNETISM; GEOPHYSICAL EXPLORATION; ROCK, ELECTRICAL PROPERTIES OF.

Drilling is the principal method of subsurface prospecting where evidence of ore mineralization and geophysical or geochemical anomalies indicates a target for prospecting at a depth of more than a few feet. Geophysical information is obtained by the probing or logging of drill holes. Electrical and electromagnetic logging is done in holes drilled in search of metallic orebodies; with these methods, the radius of search is extended considerably beyond that of the small-diameter cylinder of sampled rock. Gamma-ray methods of geophysical drill-hole logging have become standard practice in prospecting for uranium ore. *See* ENGINEERING GEOLOGY; WELL LOGGING. [W.C.Pe.]

Prostate gland A triangular body in men, the size and shape of a chestnut, that lies immediately in front of the bladder with its apex directed down and forward. It is found only in the male, having no female counterpart. The prostatic portion of the urethra extends through it, passing from the bladder to the penis. This organ contains 15–20 branched, tubular glands which form lobules. The gland ducts open into the urethra. Between the gland clusters, or alveoli, there is a dense, fibrous, connecting tissue, the stroma, which also forms a tough capsule around the gland, continuous with the bladder wall. Penetrating the prostate to empty into the urethra are the ejaculatory ducts from the seminal vesicles which are located above and behind the organ (see illustration). The prostatic gland secretes a viscid, alkaline fluid which aids in sperm motility and in neutralizing the acidity of the vagina, thus enhancing fertilization. After middle age, the prostate is sometimes subject to new tissue growth, usually benign, that may result in interference with urine flow through the compressed urethra. [W.J.B.]



Prostate gland and seminal vesicles. (*After Eycleshymer and Jones, in W. A. N. Darland, ed., American Illustrated Medical Dictionary, 19th ed., Saunders, 1942*)

Prosthesis An artificial replacement of a body part. It may be an internal replacement such as an artificial joint or an external replacement such as an artificial limb. Prostheses of all types are lighter and more functional than their predecessors; the broad field of prosthetics has benefited from advances in materials, miniaturization, and computer-generated fabrication.

Limb prosthetics. A standard nomenclature is used to refer to level of amputation and related prostheses. The term trans is used when an amputation goes across the axis of a long bone, such as transtibial (across the tibia of the leg) or transhumeral (across the humerus of the arm). When there are two bones together such as the tibia and fibula, the primary bone is identified. Amputations between long bones or through a joint are referred to as disarticulations and identified by the major body part, such as knee disarticulation. The term partial is used to refer to a part of the foot or hand distal to the ankle or wrist that may be amputated.

Socket design varies with the level of amputation and the configurations of the individual residual limb. The prosthetic socket must support body weight and hold the residual limb firmly and comfortably during all activities. Additionally, the socket needs to grip the residual limb firmly to reduce movement between the socket and the skin. Sockets are individually constructed for each client from a cast made of the residual limb. Sockets may be hard and rigid, or flexible and supported by a rigid frame.

There are several methods of suspending each type of prosthesis. Suction sockets allow suspension without belts, sleeves, or cuffs. In the transtibial prosthesis a rubber sleeve or a cuff that fits on the thigh may be used. In the transfemoral prosthesis a belt around the pelvis provides suspension.

Foot and ankle function is complex, and a variety of prosthetic feet are designed to respond dynamically to the pressure of walking and running. They store energy at the moment of heel contact, then return it at toe-off.

Of paramount importance is the prosthetic component, called a terminal device, that will substitute for the missing hand. There is no device that completely replaces the appearance or function of the anatomic hand. The two types of terminal device are the hand and the hook. Either is secured to a plastic socket encasing the forearm.

The hand may be active or passive: passive hands have no moving parts; active hands have a mechanism that permits the client to control finger position by appropriate action in the proximal part of the amputated limb. The most popular active hand is operated myoelectrically. The individual wears a socket with one or more skin electrodes that contact appropriate muscle groups.

A hook is made either of aluminum or steel, hooks have two fingers that the client can open and close. Myoelectrically controlled hooks are available; however, most individuals who wear hooks have cable-operated ones that are either voluntary-opening or voluntary-closing.

Joint replacements. Artificial replacements of joints, such as hip, knee, or shoulder, are another type of prosthesis. The knee and hip joints are the most frequently replaced. Lower limb joint replacements must have load-bearing capabilities and are fabricated in different sizes of metal. Joint replacements may sometimes be secured by polymer adhesive. A high degree of restoration of function is usually obtained with hip and knee joint replacements.

In the upper extremity, shoulder and metacarpal phalangeal joints are most frequently replaced. The joint replacement in the upper limb needs to be light and to allow a great range of movement.

Other prostheses. There are a great variety of other types of replacements of body parts. Women who lose a breast to cancer are fitted with a prosthesis that can be fabricated of a number of lightweight materials and molded to resemble in shape and texture the remaining breast. Prosthodontics are devices used to replace teeth. The cardiac pacemaker is a form of a prosthesis replacing the natural electrical stimulation of the heart with a battery-operated device inserted within the body. Damaged heart valves are replaced with artificial valves attached directly to the heart muscle and to the major blood vessels. Prosthetic eyes, fabricated to resemble the remaining eye in color and configuration, serve a cosmetic function only. [B.J.Ma.]

Biologic-prosthetic systems. Although mechanical or electromechanical prosthetic devices represent the main option in many situations, regeneration of destroyed or resected tissue is the preferred goal. The use of inert materials to provide a basis for regenerated tissue growth offers intermediate options for reconstruction. *See* BIOMEDICAL ENGINEERING; SURGERY. [W.R.]

Protactinium A chemical element, Pa, atomic number 91. Isotopes of mass numbers 216, 217, and 222–238 are known, all of them radioactive. Only ^{231}Pa, the parent of actinium, ^{234}Pa, and ^{233}Pa occur in nature. The most important of these is ^{231}Pa, an α-emitter with a half-life of 32,500 years. The artificial isotope, ^{233}Pa, is important as an intermediary in the production of fissile ^{233}U. Both ^{231}Pa and ^{233}Pa can be synthesized by neutron irradiation of thorium. *See* ACTINIUM; PERIODIC TABLE; RADIOACTIVITY; URANIUM.

Protactinium is, formally, the third member of the actinide series of elements and the first in which a 5*f* electron appears, but its chemical behavior in aqueous solution resembles that of tantalum and niobium more closely than that of the other actinides. *See* NIOBIUM; TANTALUM.

Metallic protactinium is silver in color, malleable, and ductile. The crystal structure is body-centered tetragonal. Samples exposed to air at room temperature show little or no tarnishing over a period of several months. The numerous compounds of protactinium that have been prepared and characterized include binary and polynary oxides, halides, oxyhalides, sulfates, oxysulfates, double sulfates, oxynitrates, selenates, carbides, organometallic compounds, and noble metal alloys. *See* ACTINIDE ELEMENTS. [H.W.Ki.]

Protandry That condition in which an animal is first a male and then becomes a female. It occurs in many groups, including oysters and cyclostomes. The reverse condition is protogyny. *See* PROTOGYNY. [T.I.S.]

Proteales An order of flowering plants, division Magnoliophyta, in the eudicots. Consisting of three families, the order is one of the most controversial in current classifications, with a lack of obvious morphological characters linking the family Nelumbonaceae (two species) to the other two families, Platanaceae (seven species) and Proteaceae (about 1350 species). However, DNA sequences indicate that the three families form a natural group. *See* MAGNOLIOPHYTA; MAGNOLIOPSIDA; WOOD ANATOMY.

Nelumbonaceae are aquatic, rhizomatous herbs with peltate leaves held above the water on long petioles, and have often been thought to be related to the true waterlilies (Nymphaeales). *Nelumbo* (sacred lotus and American lotus) is used as a source of food, as an ornamental, and as a sacred plant in several Asian countries.

Platanaceae, from the Northern Hemisphere, are deciduous, monoecious trees with simple, palmately lobed leaves, flaking bark, and branched hairs. Plane trees (*Platanus*) are common street trees, due to the regular loss of bark (which gives some resistance to pollution), and they also provide timber. *See* BARK; DECIDUOUS PLANTS; FRUIT; LEAF; NYMPHAEALES.

Proteaceae (predominantly tropical and subtropical, in the Southern Hemisphere) are evergreen shrubs and trees that often accumulate aluminum. Several genera (including *Banksia*, *Protea*, and *Leucospermum*) are widely cultivated for cut flowers; *Grevillea* and other genera are used for timber; and *Macadamia* yields edible nuts. *See* EVERGREEN PLANTS; ROOT (BOTANY). [M.F.F.]

Protective coloration A strategy that organisms use to avoid or deflect the attacks of predators by misleading the latter's visual senses.

Protective coloration can be classified according to whether the functioning or malfunctioning of the vertebrate visual system is exploited. Exploiting the malfunction of the system means simply "not being seen": the prey fails to attract the attention of the predator, usually because it is the same color as the general background or because it fails to cast a shadow. The organism avoids producing shadow by flattening itself against the substrate, or by countershading, in which the lower parts of a cylindrical prey such as a caterpillar are more lightly colored than the upper parts. As shadows normally form on the underside of cylinders, the shading cancels the shadow and makes the caterpillar optically flat. Animals that match their background often have an ability to select the appropriate background to rest on, or much less frequently can change their own color to match (as in the case of the chameleon).

Exploiting the functioning of the vertebrate perceptual system takes many forms. The vertebrate visual cortex decodes the image on the retina in a hierarchical process starting with the detection of edges. A moth may counter this by possessing strikingly contrasted patches of color on its wings, arranged in a random way. The outline of the moth is thus broken up, and the predator cannot decode it as a significant shape. The prey may also exploit the learning capacity of the predator. For example, insectivorous birds see leaves but do not attack them because they have learned (or perhaps know innately) that these are not edible. Resemblances to leaves, twigs, thorns, flowers, parts of flowers, and more bizarre objects like fresh turds (usually bird droppings) are very widespread. This type of camouflage is termed mimetic camouflage. Camouflage in general is often termed cryptic coloration.

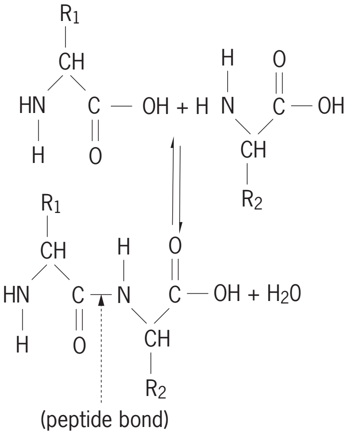
Coloration may be considered mimetic if protection is achieved by a resemblance to some other existing object, which is recognized by the predator but not associated in its mind with feeding. Usually this negative or neutral association is learned, but in a minority of instances it is almost certainly innate. Small birds have an innate flight response to large eyes in close-up (which normally indicate that a cat or a predatory bird is dangerously close). This reaction is exploited by many moths and other insects, which have eyelike markings, sometimes very convincing in their shading and highlighting, on concealed parts of the wings. Attack by a bird causes such a moth to change its posture rapidly to reveal the fake eyes, thus frightening away the attacker. Motmots (birds which habitually prey on snakes) have a similar innate fear of the red, black, and yellow striping patterns of the deadly coral snakes. These patterns are mimicked by various nonvenomous snakes, and even some caterpillars.

Flash coloration describes the phenomenon in which the prey is cryptic when at rest, but reveals brilliantly colored parts while escaping. This behavior seems to function simply by startling the predator. Very small eye marks at the tips of the wings, or a false head at the wrong end of the body (shown by some coral reef fish, for example) may cause the predator to misdirect its attack.

Protection through the possession of a chemical or physical defense that is dangerous to one's potential predator, accompanied by a strikingly conspicuous pattern known as warning coloration (often black, red, yellow, and white), is widespread—the ensemble of defense and color is termed aposematic. The actual defense ranges from toxic venoms through stings (in wasps, for example), to the oozing of noxious foams or hemolymph (as in ladybirds), to the possession of toxic chemicals (cyanides, cardiac glycosides, alkaloids) that will poison the predator or simply produce a revolting taste. The function of the warning color is to remind the predator of its previous unpleasant experience.

Sometimes the term mimicry is restricted to resemblances between edible species and actively defended and warningly colored models (as opposed to inedible objects such as thorns). Much is known about the evolution of this kind of mimicry in butterflies (and to a lesser extent, in bees and flies). If the mimic is entirely edible, the relationship is parasitic; the mimic benefits from the resemblance, but as every encounter with a mimic reduces the predator's aversion, the model suffers some increase in the rate of attack. Such mimicry has traditionally been termed Batesian mimicry. Alternatively, the mimic may be almost or fully as defended as the model, leading to a mutualistic relationship known as Müllerian mimicry, in which both the model and the mimic species suffer a decreased rate of predation. [J.R.G.T.]

Protein A biological macromolecule made up of various α-amino acids that are joined by peptide bonds. A peptide bond is an amide bond formed by the reaction of an α-amino group ($—NH_2$) of one amino acid with the carboxyl group (—COOH) of another, as shown below. Proteins generally contain from 50 to 1000 amino acid residues per polypeptide chain.



See PEPTIDE.

Occurrence. Proteins are of importance in all biological systems, playing a wide variety of structural and functional roles. They form the primary organic basis of structures such as hair, tendons, muscle, skin, and cartilage. All of the enzymes, the catalysts in biochemical transformations, are protein in nature. Many hormones, such as insulin and growth hormone, are proteins. The substances responsible for oxygen and electron transport (hemoglobin and the cytochromes, respectively) are conjugated proteins that contain a metalloporphyrin as the prosthetic group. Chromosomes are highly complex nucleoproteins, that is, proteins conjugated with nucleic acid. Viruses are also nucleoprotein in nature. Of the more than 200 amino acids that have been discovered either in the free state or in small peptides, only 20 amino acids are present in mammalian proteins. Thus, proteins play a fundamental role in the processes of life. *See* AMINO ACIDS.

Specificity. The linear arrangement of the amino acid residues in a protein is termed its sequence (primary structure). The sequence in which the different amino acids are linked in any given protein is highly specific and characteristic for that particular protein.

This specificity of sequence is one of the most remarkable aspects of protein chemistry. The number of possible permutations of sequence in even so small a protein as insulin, of molecular weight 5732 and with 51 amino acid residues, is astronomic: 1051 permutations. Yet it has been established that the pancreatic cell of a given species has only one of these possible sequences. The elucidation of the mechanism conferring such a high degree of specificity on the biosynthetic reactions by which proteins are built up from free amino acids has been one of the key problems of modern biochemistry. *See* MOLECULAR BIOLOGY.

Proteins are not stretched polymers; rather, the polypeptide backbone of the molecule can fold in several ways by means of hydrogen bonds between the carbonyl oxygen and the amide nitrogen. The folding of each protein is determined by its particular sequence of amino acids. The long polypeptide chains of proteins, particularly those of the fibrous proteins, are held together in a rather well-defined configuration. The backbone is coiled in a regular fashion, forming an extended helix. As a result of this coiling, peptide bonds separated from one another by several amino acid residues are brought into close spatial approximation. The stability of the helical configuration can be attributed to hydrogen bonds between these peptide bonds. *See* FIBROUS PROTEIN.

In addition to hydrogen bonds, there are electrostatic interactions, such as those between COO^- and NH_3^+ groups of the side chains, and van der Waals forces, that is, hydrophobic interactions, which help to determine the configuration of the polypeptide chain. The term secondary structure is used to refer to all those structural features of the polypeptide chain determined by noncovalent bonding interactions.

In addition to the α-helical sections of proteins, there are segments that contain β-structures in which there are hydrogen bonds between two polypeptide chains that run in parallel or antiparallel fashion.

The tertiary structure (third level of folding) of a protein comes about through various interactions between different parts of the molecule. Disulfide bridges formed between cysteine residues at different locations in the molecule can stabilize parts of a three-dimensional structure by introducing a primary valence bond as a cross-link. Hydrogen bonds between different segments of the protein, hydrophobic bonds between nonpolar side chains of amino acids such a phenylalanine and leucine, and salt bridges such as those between positively charged lysyl side chains and negatively charged aspartyl side chains all contribute to the individual tertiary structure of a protein.

Finally, for those proteins that contain more than one polypeptide chain per molecule, there is usually a high degree of interaction between each subunit, for example, between the α- and β-polypeptide chains of hemoglobin. This feature of the protein structure is termed its quarternary structure.

Properties. The properties of proteins are determined in part by their amino acid composition. As macromolecules that contain many side chains that can be protonated and unprotonated depending upon the pH of the medium, proteins are excellent buffers. The fact that the pH of blood varies only very slightly in spite of the numerous metabolic processes in which it participates is due to the very large buffering capacity of the blood proteins.

Biosynthesis. The processes by which proteins are synthesized biologically have become one of the central themes of molecular biology. The sequence of amino acid residues in a protein is controlled by the sequence of the DNA as expressed in messenger RNA at ribosomes. *See* DEOXYRIBONUCLEIC ACID (DNA); RIBONUCLEIC ACID (RNA); RIBOSOMES. [G.E.Pe.; J.M.Ma.]

Degradation. As with many other macromolecular components of the organism, most body proteins are in a dynamic state of synthesis and degradation (proteolysis). During proteolysis, the peptide bond that links the amino acids to each other is hydrolyzed, and free amino acids are released. The process is carried out by a diverse group of enzymes called proteases.

During proteolysis, the energy invested in generation of the proteins is released. *See* ENZYME.

Distinct proteolytic mechanisms serve different physiological requirements. Proteins can be divided into extracellular and intracellular, and the two groups are degraded by two distinct mechanisms. Extracellular proteins such as the plasma immunoglobulins and albumin are degraded in a process known as receptor-mediated endocytosis. Ubiquitin-mediated proteolysis of a variety of cellular proteins plays an important role in many basic cellular processes such as the regulation of cell cycle and division, differentiation, and development; DNA repair; regulation of the immune and inflammatory responses; and biogenesis of organelles. [A.J.Ci.]

Molecular chaperones. Molecular chaperones are specialized cellular proteins that bind nonnative forms of other proteins and assist them to reach a functional conformation. The role of chaperone proteins under conditions of stress, such as heat shock, is to protect proteins by binding to misfolded conformations when they are just starting to form, preventing aggregation; then, following return of normal conditions, they allow refolding to occur. Chaperones also play essential roles in folding under normal conditions, providing kinetic assistance to the folding process, and thus improving the overall rate and extent of productive folding. [A.Ho.]

Protein engineering. The amino acid sequences, sizes, and three-dimensional conformations of protein molecules can be manipulated by protein engineering, in which the basic techniques of genetic engineering are used to alter the genes that encode proteins. These manipulations are used to generate proteins with novel activities or properties for specific applications, to discover structure-function relationships, and to generate biologically active minimalist proteins (containing only those sequences necessary for biological activity) that are smaller than their naturally occurring counterparts.

Many subtle variations in a particular protein can be generated by making amino acid replacements at specific positions in the polypeptide sequence. For example, at any specific position an amino acid can be replaced by another to generate a mutant protein that may have different characteristics by virtue of the single replaced amino acid. Amino acids can also be deleted from a protein sequence, either individually or in groups. These proteins are referred to as deletion mutants. Deletion mutants may or may not be missing one or more functions or properties of the full, naturally occurring protein. Moreover, part or all of a protein sequence can be joined or fused to that of another protein. The resulting protein is called a hybrid or fusion protein, which generally has characteristics that combine those of each of the joined partners. [P.Sc.]

Protein metabolism

The transformation and fate of food proteins from their ingestion to the elimination of their excretion products. Proteins are of exceptional importance to organisms because they are the chief constituents, aside from water, of all the soft tissue of the body. Special proteins have unique roles as structural and functional elements of cells and tissues. Examples are keratin of skin, collagen of tendons, actin and myosin of muscle, the blood proteins, enzymes in all tissues, and protein hormones of the hypophysis. *See* BLOOD; ENZYME; HORMONE; MUSCLE.

Isotopic labeling experiments have established that body proteins are in a dynamic state, constantly being broken down and replaced. This is a rapid process in organs active in metabolism, such as liver, kidney, intestinal mucosa, and pancreas, much slower in skeletal muscle, and extremely slow in connective tissue elements and skin.

Protein is digested to amino acids in the gastrointestinal tract. These are absorbed and distributed among the different tissues, where they form a series of amino acid pools that are kept equilibrated with each other through the medium of the circulating blood. The needs for protein synthesis of the different organs are supplied from these pools. Excess amino acids in the tissue pools lose their nitrogen by a combination of transamination and deamination. The nitrogen is largely converted to urea and excreted in the urine. The residual carbon products are then further metabolized by pathways common to the other major foodstuffs—carbohydrates and fats. *See* CARBOHYDRATE; LIPID.

Ingestion of protein is needed primarily to supply amino acids for the formation of new and depleted body protein and as a source of various other body constituents derived from the amino acids. The amino acids of proteins fall into two nutritional categories: essential or indispensable, and nonessential or dispensable. For a number of amino acids, the category to which they belong changes between the periods of body growth and adulthood and changes also in different animal species. Eight essential amino acids are needed for maintenance of nitrogen equilibrium in healthy young men. The remaining amino acids can be formed in the body from other materials. *See* AMINO ACIDS.

Protein digestion occurs to a limited extent in the stomach and is completed in the duodenum of the small intestine. The main proteolytic enzyme of the stomach is pepsin, which is secreted in an inactive form, pepsinogen. Its transformation to the active pepsin, initiated by the acidity of the gastric juice, involves liberation of a portion of the pepsinogen molecule as a peptide. Pepsin preferentially hydrolyzes peptide bonds containing an aromatic amino acid, and it requires an acid medium to function. *See* DIGESTIVE SYSTEM; PEPSIN.

The acid chyme is discharged from the stomach, containing partially degraded proteins, into a slightly alkaline fluid in the small intestine. This fluid is composed of pancreatic juice and succus entericus, the intestinal secretion. The pancreas secretes three known proteinases, trypsin, chymotrypsin, and carboxypeptidase. All three are secreted as inactive zymogens. Activation starts with the transformation of the inactive trypsinogen into the active trypsin. Trypsin, in turn, activates chymotrypsin and carboxypeptidase. *See* PEPTIDE.

Trypsin and chymotrypsin are endopeptidases; that is, they cleave internal peptide bonds. The so-called peptidases are exopeptidases; they cleave terminal peptide bonds. Trypsin has a predilection for those containing the basic amino acid residues of lysine and arginine. These two proteinases perform the major share in hydrolyzing proteins to small peptides. Digestion to amino acids is completed by the exopeptidases. Carboxypeptidase acts on peptides from the free carboxyl end; aminopeptidases from the free amino end. Other peptidases act on di- or tripeptides, or peptides containing such special amino acids as proline.

The amino acid digestion products of the proteins are absorbed by the small intestine as rapidly as they are liberated. The absorbed amino acids are carried by the portal blood system to the liver, from which they are distributed to the rest of the body. Small amounts of the peptides formed during digestion escape further hydrolysis and may also enter the circulation from the intestine. This is shown by a rise in the peptide nitrogen in the blood.

The unabsorbed food residue in the small intestine is passed into the cecum, then the colon, and finally is eliminated as feces.

The absorbed amino acids that escape decomposition become part of the amino acid pools of the body. From these amino acids, new tissue proteins are synthesized to meet body needs. The rate of tissue replacement varies greatly for different tissues. In humans, it has been estimated that the average half-life of the total body protein is 80 days; that of lung, brain, bone, skin, and most muscle combined is 158 days; while that of liver and serum proteins combined is only 10 days.

The major organ of plasma protein synthesis is the liver. It forms all of the plasma albumin and fibrinogen and a considerable proportion of the globulins. (A portion of the total plasma globulin is synthesized in other tissues containing reticuloendothelial cells. The hormones and enzymes present in blood plasma are derived in the main from nonhepatic sources.) *See* ALBUMIN; FIBRINOGEN; LIVER.

The plasma proteins have numerous important physiological functions. The albumin is the major factor in the regulation of the blood volume through its osmotic action, which counteracts the fluid expulsion effect of the hydrostatic pressure resulting from the contractions of the heart. Fibrinogen is one component of a sequential process essential for coagulation of the blood. Other plasma components include the blood platelets and prothrombin. The globulins include fractions that are carriers of phospholipids and sterols and certain essential metal ions, iron, and copper. Other fractions, chiefly γ-globulin, contain the antibodies that are the defenses against numerous diseases.

Synthesis and utilization of the plasma proteins is a rapid process. There is a complete turnover of the major plasma proteins in a period of a few days. The difference from normal in the turnover times in a variety of diseases provides an insight into the nature of the disease processes. [D.M.G.]

Proteins, evolution of Proteins are large organic molecules that are involved in all aspects of cell structure and function. They are made up of polypeptide chains, each constructed from a basic set of 20 amino acids, covalently linked in specific sequences. Each amino acid is coded by three successive nucleotide residues in deoxyribonucleic acid (DNA); the sequence of amino acids in a polypeptide chain, which determines the structure and function of the protein molecule, is thus specified by a sequence of nucleotide residues in DNA. *See* GENE; PROTEIN.

Sequence analyses of polypeptides which are shared by diverse taxonomic groups have provided considerable information regarding the genetic events that have accompanied speciation. Interspecies comparison of the amino acid sequences of functionally similar proteins has been used to estimate the amount of genetic similarity between species; species that are genetically more similar to each other are considered to be evolutionarily more closely related than those that are genetically less similar.

The study of functionally related proteins from different animal species has suggested that single amino acid substitutions are the predominant type of change during evolution of such proteins. Insertions or deletions of one or more amino acids have also been reported. In proteins that serve the same function in dissimilar species small differences in the amino acid sequence will often not affect overall functioning of the protein molecule.

In taxonomic protein sequence analysis, the amino acid sequence of a protein from one species is compared with the amino acid sequence of the protein from another species, and the minimum number of nucleotide replacements (in DNA) required to shift from one amino acid to another is calculated. Peptide "genealogies" can be constructed from many such comparisons in a related group of organisms.

Classical versus protein-derived phylogenies. It has been recognized for a long time that the amino acid sequences of a protein are species-specific. Protein sequencing has been used widely since the mid-1960s to examine taxonomic relationships. Results indicate that, in general, genealogical relationships (phylogenies) based on sequence analyses correspond fairly well with the phylogeny of organisms as deduced from more classical methods involving morphological and paleontological data.

Evolutionary biologists are turning increasingly to the new nucleic acid sequencing technology as an alternative to determining the amino acid sequence of proteins. Knowing the actual nucleotide sequences of genes rather than having to infer them from protein sequence data allows more accurate data to be used in determining genealogical relationships of organisms. For example, silent nucleotide substitutions (that is, base changes in DNA codons that do not result in amino acid changes) can be detected.

Orthologous and paralogous sequences. The reconstruction of phylogenies from analysis of protein sequences is based on the assumption that the genes coding for the proteins are homologous, that is, descendants of a common ancestor. Those sequences whose evolutionary history reflects that of the species in which they are found are referred to as orthologous. The cytochrome *c* molecules (present in all eukaryotes) are an example of an orthologous gene family. Organisms as diverse as humans and yeast have a large proportion of the amino acids in these molecules in common; they derive from a single ancestral gene present in a species ancestral to both these organisms and to numerous others.

Sequences which are descendants of an ancestral gene that has duplicated are referred to as paralogous. Paralogous genes evolve independently within each species. The genes coding for the human α, β, γ, δ, ϵ, and ζ hemoglobin chains are paralogous. Their evolution reflects the changes that have accumulated since these genes duplicated. Analysis of paralogous genes in a species serves to construct gene phylogenies, that is, the evolutionary history of duplicated genes within a given lineage.

Rate of evolution. Sequence data from numerous proteins have shown that different proteins evolve at different rates. Some proteins show fewer amino acid substitutions, or more conservation, than others. Proteins such as immunoglobulins, snake venom toxins, and albumins have changed extensively. Their function apparently requires relatively less specificity of structure and therefore has relatively greater tolerance for variance. By contrast, certain proteins, such as various histones, have changed relatively little over long periods of time. Histone H4 shows extreme conservation; it has essentially the same sequence in all eukaryotes examined. Such extensive sequence conservation is generally interpreted to indicate that the functions of H4 are extremely dependent on its entire structure; thus little or no change is tolerated in its structure. The rates at which different proteins evolve are therefore thought to be due to different functional constraints on the structure of the proteins—the more stringent the conditions that determine the function of a protein molecule, the smaller the chance that a random change will be tolerated in its structure.

Each protein generally has a nearly constant evolutionary rate (the rate of acceptance of mutations) in each line of descent. Exceptions to this rule have been reported, however, and much effort has been spent on determining whether these anomalies are genuine. Some anomalies have been shown to be due to comparison of nonhomologous proteins, and others due to sequencing errors. Other deviations from constant rate of sequence evolution remain to be explained; once uncovered, these may provide useful information about the mechanisms of evolution at the molecular level. [P.K.M.]

Proteocephaloidea An order of tapeworms of the subclass Cestoda. With one exception, these worms are intestinal parasites of fresh-water fishes, amphibians, and reptiles. The holdfast organ bears four suckers and, frequently, an apical organ which may be suckerlike. The segmental anatomy is very similar to that of the Tetraphyllidea. Most authorities recognize two families, the Proteocephalidae and the Monticellidae. *See* CESTODA. [C.P.R.]

Proteomyxidia A subclass of Actinopodea including protozoan organisms without protective coverings (tests) or skeletal elements. Pseudopodia are fine, branched, and interconnected (reticulopodia), or filamentous (filopodia). Many are invaders of algae and other plants. There is one order, Proteomyxida, which contains two families, Pseudosporidae and Vampyrellidae. *See* ACTINOPODEA. [R.P.H.]

Proterozoic A major division of geologic time spanning from 2500 to 543 million years before present (Ma). The beginning of Proterozoic time is an arbitrary boundary that roughly coincides with the transition from a tectonic style dominated by extensive recycling of the Earth's continental crust to a style characterized by preservation of the crust as stable continental platforms. The end of the Proterozoic coincides with the Precambrian-Cambrian boundary, which is formally defined on the basis of the first appearance of diverse coelomate invertebrate animals. Proterozoic Earth history testifies to several remarkable biogeochemical events, including the formation and dispersal of the first supercontinent, the maturation of life and evolution of animals, the rise of atmospheric oxygen, and the decline of oceanic carbonate saturation. Tremendous iron and lead-zinc mineral deposits occur in Proterozoic rocks, as do the first preserved accumulations of oil and gas. *See* CAMBRIAN; PRECAMBRIAN.

Many of the Earth's Archean cratons are blanketed by little-deformed sequences of Proterozoic sedimentary rocks, which indicate that vigorous recycling of the Earth's crust, characteristic of Archean time, had slowed markedly by the beginning of Proterozoic time. This decrease in crustal recycling is attributed to the development of thick continental roots, which stabilized the cratons, and the decrease in heat that was escaping from the Earth's interior, believed to drive thermal convection in the Earth's mantle and recycling of the crust. Most of the Earth's Archean cratons appear to have participated in the formation of a supercontinent in Mesoproterozoic time, about 1200 Ma. This supercontinent, called Rodinia, seems to have assembled with the North American craton (Laurentia) at its center. Rodinia persisted until the latest part of the Neoproterozoic, about 600 Ma. *See* ARCHEAN; CONTINENTS, EVOLUTION OF; EARTH, CONVECTION IN; EARTH, HEAT FLOW IN; EARTH CRUST; EARTH INTERIOR; PLATE TECTONICS.

Giant iron oxide deposits were formed by precipitation from seawater about 2000 Ma, whereupon oxygen was free to accumulate in the atmosphere and shallow ocean. During most of Paleoproterozoic time the oceans and atmosphere were reducing and ferrous iron was abundant in seawater. *See* ATMOSPHERE, EVOLUTION OF.

The partial pressure of carbon dioxide on the early Earth was very high. During Proterozoic time, much of the mass of carbon shifted from the ocean and atmosphere to the solid Earth. Enormous volumes of limestone [$CaCO_3$] and dolostone [$CaMg(CO_3)_2$] were deposited and testify to this shift. *See* DOLOMITE ROCK; LIMESTONE; SEDIMENTARY ROCKS.

Glaciers covered significant parts of the Earth during two widely separated times in Proterozoic history. The first episode occurred about 2200 Ma, and glacial deposits of that age cover various parts of North America and Scandinavia. The second episode consisted of at least two different pulses spanning from 750 to 600 Ma during Neoproterozoic time. Glaciers formed at that time were of almost global extent, and were thought to have extended from the poles to the Equator, according to the snowball Earth hypothesis. *See* GLACIAL EPOCH.

A number of significant events in the evolution of life occurred during Proterozoic time. The record of biological activity is rich, consisting of actual body fossils, in addition to organism traces and impressions, and complex chemical biomarkers. Eukaryotic microbes appear to have evolved by about 1900 Ma, when they became major players in ecosystems present at that time. By the beginning of Neoproterozoic time, about 1000 Ma, multicellular eukaryotic algae are present in numerous sedimentary basins around the world. *See* EUKARYOTAE; RIBONUCLEIC ACID (RNA).

The evolution of animals did not take place until the close of Neoproterozoic time. Why these organisms evolved at this particular time in Earth history remains unanswered. General opinion proposes that it was likely the result of the confluence of a number of environmental factors, such as the rise in oxygen. Whatever the cause of their origin, these existed until at least 543 Ma, when another major evolutionary adaptive radiation began which marks the onset of Cambrian time and the end of the Proterozoic Eon. *See* ANIMAL EVOLUTION; EXTINCTION (BIOLOGY); GEOLOGIC TIME SCALE. [J.P.Gr.]

Protista The kingdom comprising all single-celled forms of living organisms in both the five-kingdom and six-kingdom systems of classification. Kingdom Protista encompasses both Protozoa and Protophyta, allowing considerable integration in the classification of both these animallike and plantlike organisms, all of whose living functions as individuals are carried out within a single cell membrane. Among the kingdoms of cellular organisms, this definition can be used to distinguish the Protista from the Metazoa (sometimes named Animalia) for many-celled animals, or from the Fungi and from the Metaphyta (or Plantae) for many-celled green plants. *See* METAZOA.

The most significant biological distinction is that which separates the bacteria and certain other simply organized organisms, including blue-green algae (collectively, often designated Kingdom Monera), from both Protista and all many-celled organisms. The bacteria are described as prokaryotic; both the Protista and the cells of higher plants and animals are eukaryotic. Structurally, a distinguishing feature is the presence of a membrane, closely similar to the bounding cell membrane, surrounding the nuclear material in eukaryotic cells, but not in prokaryotic ones. *See* EUKARYOTAE; PROKARYOTAE; PROTOZOA.

The definition that can separate the Protista from many-celled animals is that the protistan body never has any specialized parts of the cytoplasm under the sole control of a nucleus. In some protozoa, there can be two, a few, or even many nuclei, rather than one, but no single nucleus ever has separate control over any part of the protistan cytoplasm which is specialized for a particular function. In contrast, in metazoans there are always many cases of nuclei, each in control of cells of specialized function.

Most authorities would agree that the higher plants, the Metazoa, and the Parazoa (or sponges) almost certainly evolved (each independently) from certain flagellate stocks of protistans. [W.D.R.H.]

Protobranchia A subclass of bivalve mollusks characterized by a foot with a sole that is divided sagittally and longitudinally and has papillate margins. The Protobranchia are divided into two orders, Solemyoida and Nuculoida. The Solemyoida have an edentulous shell, and if teeth are present, they are not chevron-shaped. The palps are small, triangular, and without palp proboscides. This is in contrast to the Nuculoida, which have well-developed, chevron-shaped hinge teeth and large palps with palp proboscides. The Nuculoida are subdivided into two superfamilies, Nuculacea and Nuculanacea.

The Protobranchia are found throughout the seas of the world, and they are particularly common in the deep sea, where they may form up to 10% of the invertebrate infauna. The subclass has one of the longest geological records within the animal kingdom, dating from the Early Ordovician if not the Late Cambrian. *See* BIVALVIA; MOLLUSCA. [J.A.A.]

Protococcida An order of the protozoan subclass Coccidia in the class Telosporea, subphylum Sporozoa. This is a very small group containing perhaps six species in perhaps three genera. All are parasites of marine invertebrates. Only sexual reproduction is known. *See* COCCIDIA. [N.D.L.]

Protogyny A condition in hermaphroditic or dioecious animals in which the female reproductive structures mature before the male structures. It is of rare occurrence. Botanically, protogyny occurs in some plant species in which the stigma develops, withers, and dies before the anthers mature. *See* PROTANDRY. [T.I.S.]

Protolepidodendrales An extinct order of the class Lycopodiopsida (clubmosses) of the Devonian Period. Most of these clubmosses are poorly preserved and not well understood; the notable exception is the widespread *Leclercqia complexa*, which has been largely reconstructed from fragmentary fossils.

Leclercqia (Early to Middle Devonian) was a medium-sized herb; its horizontal rhizomes generated vertical axes up to 0.4 in. (1 cm) in diameter. The vascular tissue formed a star-shaped actinostele, with inward maturation of the metaxylem tracheids. Additional structural support was provided in the cortical cylinder by thickened hypodermal fibers. The micro-phyllous leaves were not routinely shed. Most branched into five unequal, needlelike lobes, each supplied by a lateral branch of the median vascular trace, and arranged three-dimensionally. Zones of sterile leaves alternated with zones of fertile sporophylls; both sterile and fertile leaves bore a small ligule on the upper surface. The stomata-bearing sporangia were located on the same surface of the sporophyll, somewhat closer to the stem than the ligule. The sporangia were elliptical and released spores of the same size; thus, *Leclercqia* is primitively homosporous.

Complex leaf morphologies are important characteristics in assigning genera to the Protolepidodendrales, even though it may be that they represent multiple independent evolutionary events. The presence of a ligule has been demonstrated only in *Leclercqia*; yet it is the combination of homosporous reproduction and the presence of a ligule that delimits the order and testifies to its evolutionary intermediacy between the eligulate homosporous Lycopodiales and the ligulate heterosporous Selaginellales. *See* LYCOPODIALES; SELAGINELLALES. [R.M.Ba.; W.A.DiM.]

Proton A positively charged particle that is the nucleus of the lightest chemical element, hydrogen. The hydrogen atom consists of a proton as the nucleus, to which a single negatively charged electron is bound by an attractive electrical force (since opposite charges attract). The proton is about 1836 times heavier than the electron, so that the proton constitutes almost the entire mass of the hydrogen atom. Most of the interior of the atom is empty space, since the sizes of the proton and the electron are very small compared to the size of the atom. *See* ATOMIC STRUCTURE AND SPECTRA; ELECTRIC CHARGE; HYDROGEN.

For chemical elements heavier than hydrogen, the nucleus can be thought of as a tightly bound system of Z protons and N neutrons. An electrically neutral atom will then have Z electrons bound comparatively loosely in orbits outside the nucleus. *See* NEUTRON; NUCLEAR STRUCTURE.

The numerical values of some overall properties of the proton can be summarized as follows: charge, 1.602×10^{-19} coulomb; mass, 1.673×10^{-27} kg; spin, $(^1/_2)\hbar$ (where $\hbar$ is Planck's constant h divided by 2π); magnetic dipole moment, 1.411×10^{-26} joule/tesla; radius, about 10^{-15} m. *See* FUNDAMENTAL CONSTANTS; NUCLEAR MOMENTS; SPIN (QUANTUM MECHANICS).

It is instructive to contrast the proton's properties with those of the electron. All of the electron's properties have been found to be those expected of a spin-$^1/_2$ particle which is described by the Dirac equation of quantum mechanics. Such a Dirac particle has no internal size or structure. *See* ELECTRON; RELATIVISTIC QUANTUM THEORY.

By contrast, although it also has a spin of $^1/_2$, the proton's magnetic moment, which is different from that for a Dirac particle, and its binding with neutrons into nuclei strongly suggest that it has some kind of internal structure, rather than being a point particle. Two different kinds of high-energy physics experiments have been used to study the internal structure of the proton. An example of the first type of experiment is the scattering of high-energy electrons, above say 1 GeV, from a target of protons. The angular pattern and energy distribution of the scattered electrons give direct information about the size and structure of the proton. The second type of high-energy experiment involves the production and study of excited states of the proton, often called baryonic resonances. It has been found that the spectrum of higher-mass states which are produced in high-energy collisions follows a definite pattern. *See* BARYON.

In 1963, M. Gell-Mann and, independently, G. Zweig pointed out that this pattern is what would be expected if the proton were composed of three spin-$^1/_2$ particles, quarks, with two of the quarks (labeled u) each having a positive electric charge of magnitude equal to $^2/_3$ of the electron's charge (e), and the other quark (labeled d) having a negative charge of magnitude of $^1/_3 e$. Subsequently, the fractionally charged quark concept was developed much further, and has become central to understanding every aspect of the behavior and structure of the proton. *See* QUARKS.

An important class of fundamental theories, called grand unification theories (GUTs), makes the prediction that the proton will decay. The predicted lifetime of the proton is very long, about 10^{30} years or more—which is some 10^{20} times longer than the age of the universe—but this predicted rate of proton decay may be detectable in practical experiments. *See* GRAND UNIFICATION THEORIES.

If the proton is observed to decay, this new interaction will also have profound consequences for understanding of cosmology. The very early times of the big bang (about 10^{-30} s) are characterized by energies so high that the same grand unified interaction which would allow proton decay would also completely determine the subsequent evolution of the universe. This could then explain the remarkable astrophysical observation that the universe appears to contain only matter and not an equal amount of antimatter. *See* COSMOLOGY; ELEMENTARY PARTICLE. [T.H.F.]

Proton-induced x-ray emission (PIXE) A highly sensitive analytic technique for determining the composition of elements in small samples. Proton-induced x-ray emission (PIXE) is a nondestructive method capable of analyzing many elements simultaneously at concentrations of parts per million in samples as small as nanograms. PIXE is the preferred technique for surveying the environment for trace quantities of such toxic elements as lead and arsenic. There has also been a rapid development in the use of focused proton beams for PIXE studies in order to produce two-dimensional maps of the elements at spatial resolutions of micrometers.

The typical PIXE apparatus uses a small Van de Graaff machine to accelerate the protons which are then guided to the sample. Nominal proton energies are between 1 and 4 MeV; too low an energy gives too little signal while too high an energy produces too high a background. The energetic protons ionize some of the atoms in the sample, and the subsequent filling of empty inner orbits results in the characteristic x-rays. These monoenergetic x-rays emitted by the sample are then efficiently counted in a high-resolution silicon (lithium) detector which is sensitive to the x-rays of all elements heavier than sodium. *See* JUNCTION DETECTOR; X-RAYS.

The advantages of PIXE over electron-induced x-ray techniques derive from the heaviness of the proton which permits it to move through matter with little deflection. The absence of scattering results in negligible continuous radiation (bremsstrahlung). As a result, proton-induced x-ray techniques are two to three orders of magnitude more sensitive to trace elements than are techniques based on electron beams. *See* BREMSSTRAHLUNG. [L.Gro.]

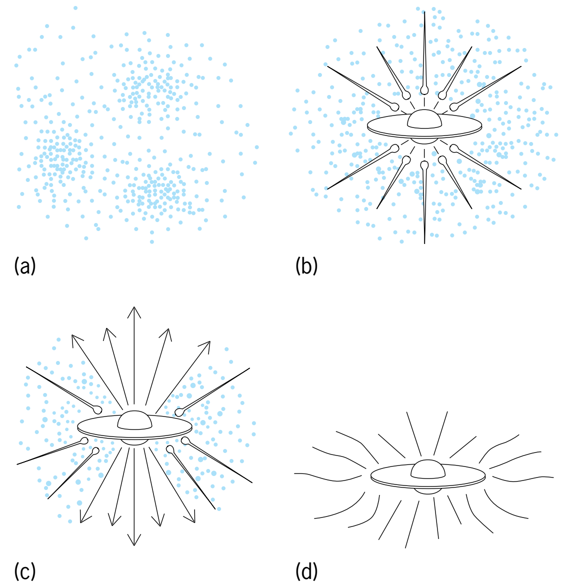
Proton-proton chain A group of nuclear reactions involving fusion of light nuclei that converts hydrogen into helium. It is believed to be the principal source of energy in main sequence stars of a little more than a solar mass and of less massive stars. Completion of a chain results in the consumption of four protons (hydrogen-1 nuclei, designated ^{1}H), and the production of a helium (^{4}He) nucleus plus two positrons (e^+) and two neutrinos (ν). The two positrons are annihilated along with two electrons (e^-), and the total energy release is 26.73 MeV. Approximately 0.58 MeV is released as neutrino energy and is not available as thermal energy in a star. The chain can be thought of as the conversion of four hydrogen atoms into a helium atom plus energy in the form of photons or neutrinos, or the kinetic energy of particles. The energy $E = 26.73$ MeV arises from the mass difference between four hydrogen atoms and the helium atom, and is calculated from the Einstein mass-energy equation $E = \Delta mc^2$, where Δm is the mass difference and c^2 is the square of the velocity of light. Because hydrogen is the fuel consumed in the process, it is referred to as hydrogen burning by means of the proton-proton chain. *See* NUCLEAR FUSION; NUCLEAR REACTION; STELLAR EVOLUTION. [G.R.C.; D.H.H.]

Protorosauria An order of primitive diapsid reptiles in the infraclass Archosauria, known from the upper Permian to the end of the Triassic Series. Protorosaurs (also known as prolacertiforms) are the earliest and most primitive known reptiles that show modifications of the rear limb for a more upright posture and a fore-and-aft movement that culminated in bipedal dinosaurs and birds. Protorosaurs are characterized by elongate neck vertebrae, reduction of the lower temporal bar, and emargination of the quadrate to support a tympanum.

Protorosaurus, from the upper Permian of Europe, was up to 6 ft (2 m) in length. Both the neck and the limbs were long. *Protorosaurus* may have resembled a large varanid lizard in life, although the ankle bones were specialized in a much different way than those of lizards. The most distinctive protorosaur was *Tanystropheus* from the Middle Triassic Series of Europe. It reached 9 ft (3 m) in length, most of which consisted of a bizarrely elongated neck, at least three times the length of the trunk region. *Tanystropheus* was apparently an aquatic animal, as was the related North American genus Tanytrachelus. *See* ARCHOSAURIA; DIAPSIDA; REPTILIA. [R.L.C.]

Protostar A dense condensation of material that is still in the process of accreting matter to form a star. Protostars are expected in dense interstellar complexes of gas and dust. Since the gas is mostly in the form of molecules, especially molecular hydrogen (H_2), these complexes are called molecular clouds. *See* INTERSTELLAR MATTER; MOLECULAR CLOUD.

Molecular clouds contain clumps of material with relatively low temperatures, typically 10 to 50 K (−442 to −370°F), and densities significantly higher than in the surrounding medium, between 10,000 and 100,000 atoms per cubic centimeter (illus. *a*). Such condensations will collapse under the effect of gravity if they are more massive than a certain value, now called the Jeans mass. The protostar is the central core that forms as a cloud condensation contracts.



Stages of protostellar evolution. (*a*) Dense cores occur in a large molecular cloud. (*b*) A protostar surrounded by a disk has formed in a collapsing core. (*c*) A well-collimated wind has broken through at the opposite poles of the system. (*d*) A visible star with a circumstellar disk is revealed. (*After F. H. Shu, F. C. Adams, and S. Lizano, Star formation in molecular clouds: Observations and theory, Annu. Rev. Astron. Astrophys., 25:23–84, 1987*)

Because the collapsing core is also rotating, its outer parts are flattened into a disk (illus. *b*). At this stage, the protostar's mass is very small, perhaps only 1/1000 of the mass of the present Sun. Over a period of 10^4–10^6 years it continues to accrete material from the infalling envelope and eventually attains a stellarlike mass. Core collapse is checked, leaving a central protostar, when the gravitational heating produced by the contraction can no longer be radiated away as quickly as it is generated. Eventually, the core becomes sufficiently hot that the nuclear reactions that sustain stars can begin.

Much of this description of protostellar evolution is based on theoretical considerations. Although the velocity patterns of the gas around many objects have been measured, infalling material has not been detected. By contrast, in many cases (illus. *c*), gas is seen emanating from an embedded source in two well-collimated and oppositely directed outflows. The objects at the cores of these bipolar outflows are loosely referred to as protostars. *See* STELLAR EVOLUTION; T TAURI STAR. [A.I.S.]

Prototheria One of the four subclasses of the class Mammalia. Prototheria contains a single order, the Monotremata. No ancestral genera of fossil monotremes are known, and the structure of the living monotremes is so specialized that the affinities of the Prototheria are largely conjectural. Most mammalogists believe that the prototheres arose from a different stock of therapsid reptiles than the one that gave rise to the Theria.

No fossils earlier than the Pleistocene are known, and these come from Australia. The duckbilled platypus and several species of the echidnas are living representatives of this group. Everything indicates that the Prototheria represent a very small and relatively unsuccessful group that has miraculously survived in an isolated corner of the Earth. *See* MAMMALIA; MONOTREMATA; THERAPSIDA. [D.D.D.; F.S.S.]

Prototype A first or original model of hardware or software. Prototyping involves the production of functionally useful and trustworthy systems through experimentation with evolving systems. Generally, this experimentation is conducted with much user involvement in the evaluation of the prototype.

A primary use for prototyping is the acquisition of information that affects early product development. For example, if requirements for human-computer interfaces are ambiguous or inadequate, prototyping is frequently used to define an acceptable functional solution. It is a method for increasing the utility of user knowledge for purposes of continuing development to a final product. Information obtained through prototyping is important to designers, managers, and users in identifying issues and problems. Prototyping conserves time and resources prior to the commitment of effort to construct a final product.

In many hardware and software development projects, the first prototype product built is barely usable. It is usually too slow, too big, too awkward in use. Hence, the term throwaway prototype is generally applied to describe this early use of prototyping. Usually this is due to lack of understanding of user requirements. There is no alternative but to start again and build a redesigned version in which these problems are solved.

A developmental prototyping approach for incremental design of subsystems is often used to reduce the risk involved in building a system-level prototype. In this prototyping environment an incremental approach to rapid prototyping of subsystems development is used. This provides for management oversight of the entire process to assure that resource usage is effective and efficient. Product assurance is implemented throughout the process to make certain that the prototype operation contains the necessary components to satisfy subsystem requirements. Requirements analysis is performed and reviewed, then incremental specifications are developed and reviewed, followed by design of the approved specifications, and completed by implementation of the product. *See* Model theory; Software engineering; Systems engineering. [J.D.P.]

Protozoa A group of eukaryotic microorganisms traditionally classified in the animal kingdom. Although the name signifies primitive animals, some Protozoa (phytoflagellates and slime molds) show enough plantlike characteristics to justify claims that they are plants.

Protozoa are almost as widely distributed as bacteria. Free-living types occur in soil, wet sand, and in fresh, brackish, and salt waters. Protozoa of the soil and sand live in films of moisture on the particles. Habitats of endoparasites vary. Some are intracellular, such as malarial parasites in vertebrates, which are typical Coccidia in most of the cycle. Other parasites, such as *Entamoeba histolytica*, invade tissues but not individual cells. Most trypanosomes live in the blood plasma of vertebrate hosts. Many other parasites live in the lumen of the digestive tract or sometimes in coelomic cavities of invertebrates, as do certain gregarines. *See* Coccidia; Gregarinia; Trypanosomatidae.

Many Protozoa are uninucleate, others are binucleate or multinucleate, and the number of nuclei also may vary at different stages in a life cycle. Protozoa range in size from 1 to 10^6 micrometers. Colonies are known in flagellates, ciliates, and Sarcodina. Although marked differentiation of the reproductive and somatic zooids characterizes certain colonies, such as *Volvox*, Protozoa have not developed tissues and organs.

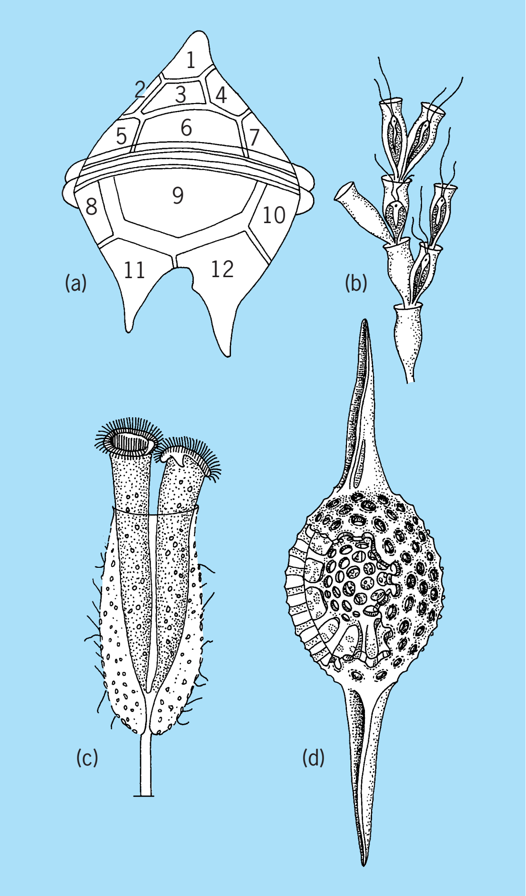


Fig. 1. External coverings of Protozoa. (*a*) Theca of dinoflagellate (*Peridinium*), showing separate plates. (*b*) Lorica of a colonial chrysomonad, *Dinobryon.* (*c*) Two zooids within a lorica of a peritrich, *Cothurnia.* (*d*) A radiolarian skeleton, siliceous type. (*After L. H. Hyman, The Invertebrates, vol. 1, McGraw-Hill, 1940*)

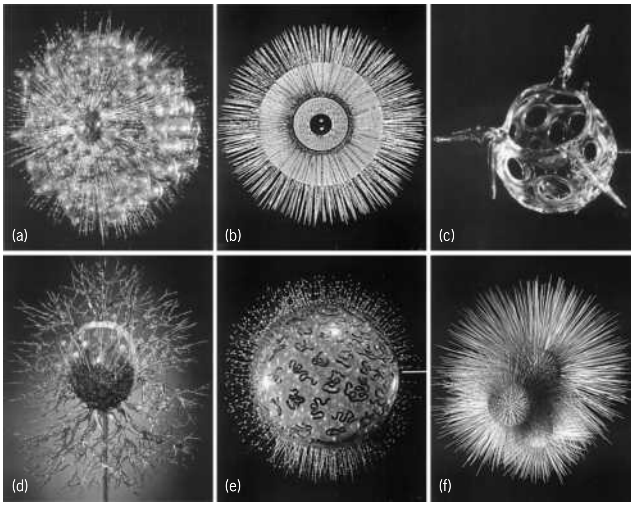

Fig. 2. Glass models of marine Protozoa. Radiolarian types: (*a*) *Trypanosphaera transformata* Haeckel (Indian Ocean); (*b*) *Actissa princeps* Haeckel (Indian and Pacific oceans); (*c*) *Peridium spinipes* Haeckel (Pacific Ocean); (*d*) *Lithocircus magnificus* Haeckel (Atlantic Ocean); (*e*) *Collozoum serpentinum* Haeckel (Atlantic Ocean). (*f*) Foraminiferan type: the pelagic *Globigerina bulloides* d'Orbigny (which is found in all seas). (*American Museum of Natural History*)

Morphology. A protozoan may be a plastic organism (ameboid type), but changes in form are often restricted by the pellicle. A protective layer is often secreted outside the pellicle, although the pellicle itself may be strengthened by incorporation of minerals. Secreted coverings may fit closely, for example, the cellulose-containing theca of Phytomonadida and Dinoflagellida, analogous to the cell wall in higher plants. The dinoflagellate theca (Fig. 1*a*) may be composed of plates arranged in a specific pattern. Tests, as seen in Rhizopodea (Arcellinida, Gromiida, Foraminiferida), may be composed mostly of inorganic material, although organic (chitinous) tests occur in certain species. Siliceous skeletons, often elaborate, characterize the Radiolaria (Figs. 1*d* and 2*c*). A vase-shaped lorica, from which the anterior part of the organism or its appendages may be extended, occurs in certain flagellates (Fig. 1*b*) and ciliates (Fig. 1*c*). Certain marine ciliates (Tintinnida) are actively swimming loricate forms.

Flagella occur in active stages of Mastigophora and flagellated stages of certain Sarcodina and Sporozoa. A flagellum consists of a sheath enclosing a matrix in which an axoneme extends from the cytoplasm to the flagellar tip. In certain groups the sheath shows lateral fibrils (mastigonemes) which increase the surface area and also may modify direction of the thrust effecting locomotion. Although typically shorter than flagella, cilia are similar in structure. *See* Cilia and flagella.

Two major types of pseudopodia have been described, the contraction-hydraulic and the two-way flow types. The first are lobopodia with rounded tips and ectoplasm denser than endoplasm. The larger ones commonly contain granular endoplasm and clear ectoplasm. Two-way flow pseudopodia include reticulopodia of Foraminiferida and related types, filoreticulopodia of Radiolaria, and axopodia of certain Heliozoia.

In addition to nuclei, food vacuoles (gastrioles) in phagotrophs, chromatophores and stigma in many phytoflagellates, water-elimination vesicles in many Protozoa, and sometimes other organelles, the cytoplasm may contain mitochondria, Golgi material, pinocytotic vacuoles, stored food materials, endoplasmic reticulum, and sometimes pigments of various kinds.

Nutrition. In protozoan feeding, either phagotrophic (holozoic) or saprozoic (osmotrophic) methods predominate in particular species. In addition, chlorophyll-bearing flagellates profit from photosynthesis; in fact, certain species have not been grown in darkness and may be obligate phototrophs.

Phagotrophic ingestion of food, followed by digestion in vacuoles, is characteristic of Sarcodina, ciliates, and many flagellates. Digestion follows synthesis of appropriate enzymes and their transportation to the food vacuole. Details of ingestion vary. Formation of food cups, or gulletlike invaginations to enclose prey, is common in more or less ameboid organisms, such as various Sarcodina, many flagellates, and at least a few Sporozoa. Entrapment in a sticky reticulopodial net occurs in Foraminiferida and certain other Sarcodina. A persistent cytostome and gullet are involved in phagotrophic ciliates and a few flagellates. Many ciliates have buccal organelles (membranes, membranelles, and closely set rows of cilia) arranged to drive particles to the cytostome. Particles pass through the cytostome into the cytopharynx (gullet), at the base of which food vacuoles (gastrioles) are formed. Digestion occurs in such vacuoles.

By definition saprozoic feeding involves passage of dissolved foods through the cortex. It is uncertain to what extent diffusion is responsible, but enzymatic activities presumably are involved in uptake of various simple sugars, acetate and butyrate. In addition, external factors, for example, the pH of the medium, may strongly influence uptake of fatty acids and phosphates.

Reproduction. Reproduction occurs after a period of growth which ranges, in different species, from less than half a day to several months (certain Foraminiferida). General methods include binary fission, budding, plasmotomy, and schizogony. Fission, involving nuclear division and replication of organelles, yields two organisms similar in size. Budding produces two organisms, one smaller than the other. In plasmotomy, a multinucleate organism divides into several, each containing a number of nuclei. Schizogony, characteristic of Sporozoa, follows repeated nuclear division, yielding many uninucleate buds.

Simple life cycles include a cyst and an active (trophic) stage undergoing growth and reproduction. In certain free-living and parasitic species, no cyst is developed. Dimorphic cycles show two active stages; polymorphic show several. The former include adult and larva (Suctoria); flagellate and ameba (certain Mastigophora and Sarcodina); flagellate and palmella (nonflagellated; certain Phytomonadida); and ameba and plasmodium (Mycetozoia especially).

Parasitic protozoa. Parasites occur in all major groups. Sporozoa are exclusively parasitic, as are some flagellate orders (Trichomonadida, Hypermastigida, and Oxymonadida), the Opalinata, Piroplasmea, and several ciliate orders (Apostomatida, Astomatida, and Entodiniomorphida). Various other groups contain both parasitic and free-living types. Protozoa also serve as hosts of other protozoa, certain bacteria, fungi, and algae.

Relatively few parasites are distinctly pathogenic, causing amebiasis, visceral leishmaniasis (kala azar), sleeping sickness, Chagas' disease, malaria, tick fever of cattle, dourine of horses, and other diseases. *See* Ciliophora; Cnidospora; Malaria; Sarcomastigophora; Sporozoa. [R.P.H.]

Protura An order of ancestrally wingless insects (subclass Apterygota). The order is usually classified into four families in two suborders (Eosentomoidea and Acerentomoidea), and about 500 species are recognized.

The insects are under 0.08 in. (2 mm) in length and have an elongated body with a small head, relatively large abdomen, and three pairs of functional legs. The first pair of legs is normally held out in front of the head, antennalike. They serve to replace the sensory role of true antennae, which are absent. Paired pseudoculi (probably chemosensory) occupy eyelike positions on the head. The mouthparts include an elongate and styliform mandible, a maxilla, and a two-part labium. All parts are enclosed within a pocket in the head, so that only their tips are exposed. The thorax bears five-segmented legs, each with an apical claw. In the adult, the abdomen has 12 segments; the anus is terminal, and cerci (segmented sensory appendages on the last abdominal segment) are lacking. The sterna of the first, second, and third segments bear short styli, probably representing vestigial limbs. A large gland opens at the rear of the eighth dorsal plate, which sometimes has a comblike lid. The genitalia are enclosed within a ventral pouch between the eleventh and twelfth segments, and have paired protrusible stylets (slender, elongated appendages).

Protura live in forest soil, leaf litter, and similar places, and are thought to feed on mycorrhizal fungi. They are distributed globally but unevenly in temperate and tropical climates, and they sometimes occur in enormous numbers, as in some Oregon fir forests in the United States. *See* Apterygota; Insecta. [W.L.Bro.]

Proustite A mineral having composition Ag_3AsS_3. It occurs in prismatic crystals terminated by steep ditrigonal pyramids, but is more commonly massive or in disseminated grains. Hardness is 2–2.5 (Mohs scale) and specific gravity is 5.55. The luster is adamantine and the color ruby red. It is called light ruby silver in contrast to pyrargyrite, dark ruby silver. Proustite and pyrargyrite are found together in silver veins. Noted localities are at Chañiarcillo, Chile; Freiberg, Germany; Guanajuato, Mexico; and Cobalt, Ontario, Canada. *See* Pyrargyrite. [C.S.Hu.]

Provenance (geology) In sedimentary geology, all characteristics of the source area from which clastic (detrital) sediments and sedimentary rocks are derived, including relief, weathering, and source rocks. *See* Weathering processes.

The goal of most provenance studies of sedimentary rocks is the determination of source characteristics of the mountains or hills from which the constituent sediment was derived. Such determinations are difficult to make because sediment composition and texture are continually modified during erosion, transport, deposition, and diagenesis (postdepositional modification). It is most straightforward to determine provenance in situations in which these modifying effects are minimal; provenance may be indeterminate or ambiguous in situations involving extensive modification of sediment composition and texture. The former situation is most common in tectonically active areas, resulting in rapid uplift and erosion of mountains, rapid transport and deposition, and slight diagenetic modification after deposition. In contrast, stable continental areas (for example, cratons) provide ample opportunity for intense weathering so that chemical, mineralogical, and textural characteristics of sediment are intensely modified. *See* Diagenesis; Erosion; Sedimentary rocks.

Clastic sediment is commonly recycled during multiple episodes of mountain building, erosion, sedimentation, lithification, and renewed mountain building. This process constitutes the rock cycle, within which igneous, sedimentary, and metamorphic rocks are created and modified. During this process, it is common for older sedimentary rocks to be uplifted and eroded, so that individual sedimentary particles (clasts) are recycled to form new sediment, which may be lithified to form new sedimentary rock. Provenance studies must determine the proportion of a sedimentary rock derived directly from indicated source rocks versus the proportion derived directly from another sedimentary rock (that is, rocks exposed during previous cycles of sedimentation). This determination is essential, but commonly difficult to accomplish because the multicyclic nature of sediment may be difficult to recognize. *See* Metamorphic rocks.

Fundamentally different methods of study are utilized, depending on what aspect of provenance is emphasized, what type of sediment is studied, and what scale of sampling and study is attempted. Grain size of detrital sediment is a dominant control over what methods may be employed.

Methods of determining provenance include direct determination of rock types (primarily used for coarse to medium grains); direct determination of mineralogy (used for all grain sizes); whole-rock geochemistry (used for medium to fine grains); geochemistry of individual mineral species (used for all grain sizes, but especially for medium grains); and radiometric dating of individual mineral species (primarily for medium grains). *See* GEOCHEMISTRY; MINERALOGY; ROCK AGE DETERMINATION. [R.V.I.]

Prymnesiophyceae A class of algae (also known as Haptophyceae) in the chlorophyll *a-c* phyletic line (Chromophycota). In protozoological classification these organisms constitute an order, Prymnesiida or Haptomonadida, in the class Phytamastigophora. Most of the approximately 300 species of prymnesiophytes are biflagellate monads. *See* CHROMOPHYCOTA.

This class has been segregated from the Chrysophyceae, with which it shares many biochemical and ultrastructural characters. Prymnesiophytes differ from chrysophytes, however, in several significant characters: (1) the typical monad bears a filiform organelle, the haptonema, between the two flagella; (2) except in the order Pavlovales, the flagella are of equal length and smooth; (3) organic scales, which may be calcified, cover most mottle cells.

Calcified scales (cellulosic scales impregnated with calcite) are characteristic of many prymnesiophytes. These scales, which are given the general term coccoliths, were discovered in marine sediment before they were observed on living cells. Coccoliths are classified into several morphological types (such as rhabdoliths, discoliths, zygoliths, and ceratoliths), which are of great diagnostic value in the taxonomy of the prymnesiophytes that bear them (coccolithophorids).

In most prymnesiophytes a nonmotile phase alternates with a motile phase. The nonmotile phase is a free-living unicell or a palmelloid or pseudofilamentous colony. In some cases the alternation is mediated by sexual reproduction. Usually, however, reproduction is effected by binary fission or the production of zoospores.

Prymnesiophytes are primary marine, with coccolithophorids constituting one of the three major components of phytoplankton (the others being diatoms and dinoflagellates). *See* ALGAE; COCCOLITHOPHORIDA; PHYTOPLANKTON; PROTOZOA. [P.C.Si; R.L.Moe]

Pseudoborniales An order of fossil plants found in Middle and Upper Devonian rocks. The group is related to Sphenophyllales and includes a single family and two monotypic genera. *Pseudobornia ursina* is known from Bear Island (north of Norway), Alaska, and Germany. *Prosseria grandis* is found in New York State. Sphenopsid characters are more firmly established in this order than in Hyeniales. *See* HYENIALES; SPHENOPHYLLALES. [H.P.B.]

Pseudomonas A genus of gram-negative, nonsporeforming, rod-shaped bacteria. Motile species possess polar flagella. They are strictly aerobic, but some members do respire anaerobically in the presence of nitrate. Some species produce acids oxidatively from carbohydrates; none is fermentative and none photosynthetic.

Members of the genus *Pseudomonas* cause a variety of infective diseases; some species cause disease of plants. One species, *P. mallei*, is a mammalian parasite, and is the causative agent of glanders, an infectious disease of horses that occasionally is transmitted to humans by direct contact. *Pseudomonas aeruginosa* is the most significant cause of hospital-acquired infections, particularly in predisposed patients with metabolic, hematologic, and malignant diseases. The spectrum of clinical disease ranges from urinary tract infections to septicemia, pneumonia, meningitis, and infections of postsurgical and posttraumatic wounds. *See* GLANDERS; HOSPITAL INFECTIONS; MENINGITIS; PNEUMONIA. [G.L.Gi.]

Pseudophyllidea An order of tapeworms of the subclass Cestoda, parasitic in the intestine of all classes of vertebrates. Typically, the head is simple in structure with two groovelike attachment organs, the bothria. Most pseudophyllideans are segmented and polyzoic with replication of the reproductive systems, although there are a number which do not show such replication and are monozoic.

Dibothriocephalus latus, the broad or fish tapeworm of humans and certain piscivorous mammals, is a pseudophyllidean. In humans, this worm sometimes precipitates a pernicious anemia by competing with the host for vitamin B_{12}. Larval pseudophyllideans are occasionally found as parasites in the extraintestinal tissues of humans, producing a condition known as sparganosis. *See* CESTODA. [C.P.R.]

Pseudoscorpionida An order of terrestrial Arachnida having the general appearance of miniature scorpions without the postabdomen and sting. The body length is seldom greater than 0.2 in. (5.0 mm). Typically, each finger of the anterior appendages, or chelicerae, has a serrula composed of a row of ligulate plates. Ducts of silk glands open near the end of the movable finger, often in connection with a simple or branched spinneret. The second pair of appendages, or palpi, are large and conspicuous, usually with glands that discharge venom through a terminal tooth on one or both of the chelal fingers. The four pairs of legs are ambulatory.

Pseudoscorpions feed chiefly on small arthropods and, although frequently found on birds, mammals, and insects, are considered nonparasitic. Pseudoscorpions are common in the nests of mammals, birds, and social insects, in woody debris and forest litter, under stones, and in crevices in the bark of trees. About 2000 species have been described. *See* ARACHNIDA. [C.C.Ho.]

Pseudosphaeriales (lichenized) An order of the class Ascolichenes. The order is also called the Pleosporales. They resemble the typical pyrenomycetous lichens except for the structure of the ascocarp, which is not a true perithecium. It is flask-shaped and lined with a layer of interwoven, branched pseudoparaphyses. The asci, with bitunicate walls, are located in scattered locules.

There are two major families: the larger one, Arthophyreniaceae, is a widespread family with at least five genera; the Mycoporaceae is a small family with two well-known genera, *Dermatina* and *Mycoporellum*. All of the species in this order are crustose and many lack a well-defined thallus. [M.E.H.]

Pseudotuberculosis A disease of rodents and birds caused by the bacterium *Pasteurella pseudotuberculosis*. The disease is occasionally transmitted to humans.

This sporadic, or epizootic, plaguelike disease in rodents and animals causes small abscesses in the liver, spleen, and intestinal wall. In humans, the infection has been reported as an acute fatal septicemia in some cases. The organisms may localize in mesenteric lymph nodes of the ileocecal region and cause acute appendicitis and gastrointestinal symptoms. [K.F.M.]

Psilophytales A group long recognized as an order of fossil plants (subdivision Psilopsida) collected in rocks of Late Silurian and Devonian age. It has been subdivided into three categories whose descriptions include the chief kinds of plants formerly included in Psilophytales. They are given in this Encyclopedia as three classes of the division Rhyniophyta: Rhyniopsida, Zosterophyllopsida, and Trimerophytopsida. *See* EMBRYOBIONTA; PALEOBOTANY; RHYNIOPHYTA; RHYNIOPSIDA; TRIMEROPHYTOPSIDA; ZOSTEROPHYLLOPSIDA. [H.P.B.]

Psilotophyta A division of the plant kingdom consisting of only two genera with three living species, *Psilotum nudum*, *P. complanatum*, and *Tmesipteris tannensis*. *Psilotum* is widespread in tropical and subtropical regions of both hemispheres, but *Tmesipteris* is confined to Australia and some of the Pacific islands. The Psilotophyta have the typical life cycle of vascular cryptograms, with an alteration of sporophyte and gametophyte generations, the sporophyte being much the larger and more complex. The Psilotophyta have no economic importance, but they are interesting as possible remnants of an ancient (Silurian and Devonian) group of plants, the Rhyniophyta, which is regarded as ancestral to all other vascular plants. *See* Polypodiophyta; Psilophytales; Rhyniophyta. [A.Cr.]

Psittaciformes The parrots, a large order of land birds found worldwide but with most species concentrated in the landmasses of the Southern Hemisphere, particularly Australasia, the Neotropics, Africa, and southern Asia. Only a few species are found in the northern temperate regions. The parrots are most closely allied to pigeons, from which they have probably evolved. *See* Columbiformes.

Although the parrots are generally placed in a single family, the Psittacidae, they are divided into a number of distinct subfamilies, which are listed below; the largest subfamily is the Psittacinae, with 247 species of parrots.

Order Psittaciformes
  Family Psittacidae
    Subfamily: Psittacinae (parrots)
      Cacatuinae (cockatoos)
      Micropsittinae (pygmy parrots)
      Strigopinae (owl parrot)
      Nestorinae (keas)
      Loriinae (lories)
      Psittrichadinae (Pesquet's parrot)
      Loriculinae (hanging parrots)

Parrots have a characteristic strong hooked bill. The tongue is large and fleshy. A short neck connects the large head to the stocky body. The wings are of medium length, varying from pointed to rounded. The legs are short and stout with strong, clawed toes arranged in a zygodactyl pattern, two pointing forward and two backward. The tail varies from short to long. Parrots fly well and can attain high speeds, but even those few parrots that are migratory journey only short distances. One species, the owl parrot, is flightless. Parrots can walk well but not rapidly. The parrot's plumage is variable; most often it is green, but red, orange, yellow, blue, black, and white in bold, bright patterns are also common. Parrots are mainly vegetarians, eating seeds, nuts, fruit, nectar, or pollen; a few consume animal food.

Parrots are social birds and usually live in flocks. Almost all species have a strong pair bond, remaining together year-round for life. Parrots are found mainly in the tropics and in the southern continents, and the center of parrot radiation is the Australia-New Zealand region. Many parrots in captivity have an excellent ability to mimic words, and some can be taught a large vocabulary. However, parrots are not known to mimic the calls of other birds in the wild. Their vocalizing ability is probably important for the constant communication between mates.

Parrots are the most important birds in the avicultural and pet trade, with most species kept in captivity. Because the demand for parrots is so great, many countries have imposed exportation bans on native birds or importation restrictions on wild-trapped parrots. *See* Aves. [W.J.B.]

Psocoptera An order of insects frequently referred to as the Corrodentia, or Copeognatha. Common names for members of this order are book lice, bark lice, and psocids, the latter a general term for all members of the order. They are usually less than 0.25 in. (0.6 cm) long, though rarely some may reach about 0.5 in. (1.2 cm). Wings may be absent, and when present are of differing distinctive venational types. Tarsi are two- or three-segmented, cerci are absent and metamorphosis is gradual. Chewing mouthparts usually have a much enlarged clypeus; the lacinia of the maxilla is usually elongate and chisellike, and the antennae have 13 or more segments.

Book lice are most common among old papers on dusty shelves, in cereals, or other domestic situations. They are usually pale, wingless types of insects. Many bark lice, the majority winged, occur on the bark or foliage of trees, and some are found under dead bark or beneath stones. Nymphs of a few species occur on tree trunks as clusters of gregarious individuals, but disperse when mature.

Psocoptera are worldwide, especially in warm countries, and some 1300 species are known. Current classification now lists about 27 families for this group. About 150 species, in 11 families, have been found in the United States. *See* Insecta. [A.B.Gu.]

Psychoacoustics All of the psychological interactions between humans (and animals) and the world of sound. It encompasses all studies of the perception of sound, as well as the production of speech. *See* Hearing (human); Speech. [L.E.M.]

Psychoanalysis Psychoanalysis may be defined as (1) a psychological theory; (2) a form of psychotherapy, especially for the treatment of neurotic and character or personality disorders; and (3) a method for investigating psychological phenomena. Psychoanalysis was created and developed by Sigmund Freud, who presented his method, clinical observations, and theory in *Interpretation of Dreams* and other major works, including *The Psychopathology of Everyday Life* and *Three Essays on the Theory of Sexuality*, as well as in many of his case studies.

Psychoanalytic theory. Generally, psychoanalysis is concerned with the causal role of wishes and beliefs in human life. More specifically, it attempts to explain mental or behavioral phenomena that do not appear to make sense as the effects of unconscious wishes and beliefs. Such phenomena include dreams, disturbances in functioning such as slips of the tongue or pen and transient forgetting, and neurotic symptoms. Typically, unconscious wishes and beliefs are constituents of conflicts.

The term unconscious in psychoanalysis does not mean simply that mental contents are out of awareness. Its psychodynamic meaning is that the person does not want to be aware of these contents, and takes active steps to avoid being aware of them. A fundamental hypothesis of psychoanalysis is that because a mental entity is dynamically unconscious it has the causal power to produce the phenomena that are of interest to psychoanalysis.

At first, the dynamic unconscious was thought to consist of traumatic memories. Later, it was believed to consist of impulses or wishes—especially sexual (and aggressive) impulses or wishes. Psychoanalysis now emphasizes that the dynamic unconscious consists of fantasies, which have a history reaching back to childhood. These fantasies are internal scenarios in which sexual (and aggressive) wishes are imagined as fulfilled.

Psychoanalysis is distinct in attributing causal powers to unconscious sexual wishes. Such attribution depends on extending the meaning of sexual to encompass the quest for sensual pleasure in childhood (so-called infantile sexuality) and choices of objects and aims. One theme that is thought to have particular importance is the Oedipus complex, in which the child rivals one parent in seeking sensual gratifications of various kinds from the other parent.

When an unconscious fantasy is activated, it manifests itself in conscious mental states or in actions—importantly, in emotions; in interpretations of the significance of events or states of affairs; in attributions of motives to others; and in daydreams, dreams, and neurotic symptoms.

Unconscious fantasies, as distinct from both conscious reality-oriented imagining and conscious day-dreaming, are constructed when imagination functions under very special conditions.

This emphasis on fantasy underscores the fact that psychoanalysis gives priority to the relation between wishes (including wishes a person knows could not conceivably be gratified in reality) and imagination (functioning under very special conditions).

Psychotherapy. Free association is the method of psychoanalysis. Patients are encouraged not to talk about some particular problem or aspect of their lives but rather to suspend any conscious purposive organization of what they say, speaking freely. Both psychoanalyst and patient follow the patient's productions: conscious purposes are replaced by unconscious purposes, which, under these conditions, can determine the direction of the patient's mental processes with less interference.

Interventions are predominantly interpretative; psychoanalysts do not seek primarily to tell their patients what to do, to educate them about the world, to influence their values, or to reassure them in one way or another that everything is or will be all right. Psychoanalysts look for patterns in what each patient says and for signs of feelings of which the patient is more or less unaware. They then engage their patients (who are increasingly aware of these patterns and able to experience and articulate these feelings) in an inquiry about the reasons for them or motives behind them. The focus is on what the patients do not know—and do not want to know—about themselves and their inner life, including strategies for avoiding such knowledge and the consequences of these strategies.

The goal of psychoanalytic psychotherapy is to extend the realm of what patients permit themselves to experience. It tries to mitigate the misery that patients with a neurotic, character, or personality disorder inflict on themselves.

The case-study method is characteristic of psychoanalytic research. The arguments that can be used in case studies are analogy (the use of familiar or homely models in which postulated causes and mechanisms can be shown to exist); consilience (the convergence of inferences from different kinds of information on a common cause); and abduction (inference to the best explanation). *See* PSYCHOTHERAPY. [M.Ed.]

Psycholinguistics An area of study which draws from linguistics and psychology and focuses upon the comprehension and production of language. Although psychologists have long been interested in language, and the field of linguistics is an older science than psychology, scientists in the two fields have had little contact until the work of Noam Chomsky was published in the late 1950s. Chomsky's writing had the effect of making psychologists acutely aware of their lack of knowledge about the structure of language, and the futility of focusing attention exclusively upon the surface structure of language. As a result, psycholinguists, who have a background of training in both linguistics and psychology, have been attempting since the early 1960s to gain a better understanding of how the abstract rules which determine human language are acquired and used to communicate appropriately created meaningful messages from one person to another via the vocal-auditory medium. Research has been directed to the evolutionary development of language, the biological bases of language, the nature of the sound system, the rules of syntax, the nature of meaning, and the process of language acquisition. [D.S.P.]

Psychology The study of human behavior and mental processes. Psychology is sharply divided into applied and experimental areas. However, many fields are represented in both research and applied psychology.

Researchers in psychology study a wide range of areas. Cognitive research is often included as part of subdiscipline called cognitive science. This area examines central issues such as how mental process work, the relation between mind and brain, and the way in which biological transducing systems can convert physical regularities into perceptions of the world. Cognitive science is carved from the common ground shared by computer science, cognitive psychology, philosophy of mind, linguistics, neuropsychology, and cognitive anthropology. The study of human attention is a cognitive area that is central in the field. *See* COGNITION.

The study of consciousness involves such basic questions as the physiological basis of mental activity, the freedom of will, and the conscious and unconscious uses of memory. The latter topic can be classified under the rubric of implicit memory. *See* INSTINCTIVE BEHAVIOR; MEMORY; PSYCHOLINGUISTICS; SENSATION.

Social psychology includes the study of interactions between individuals and groups, as well as the effects of groups on the attitudes, opinions, and behavior of individuals. The field covers such topics as persuasion, conformity, obedience to authority, stereotyping, prejudice, and decision making in social contexts. *See* MOTIVATION; PERSONALITY THEORY.

Developmental psychology has three subfields: life-span development, child development, and aging. Most research in the area concentrates on child development, which examines the development of abilities, personality, social relations, and, essentially, every attribute and ability seen in adults. *See* AGING; INTELLIGENCE.

A clinical psychologist is usually known by the term psychologist, which in some states is a term that can be used only by a registered practitioner. A psychiatrist is a physician with a specialty in psychiatric treatment and, in most states, with certification as a psychiatrist by a board of medical examiners. A psychoanalyst is typically trained by a psychoanalytic institute in a version of the Freudian method of psychoanalysis. A large number of practitioners qualify both as psychoanalysts and psychiatrists. *See* PSYCHOANALYSIS.

Neuropsychologists are usually psychologists, who may come from an experimental or a clinical background but who must go through certification as psychologists. They treat individuals who have psychological disorders with a clear neurological etiology, such as stroke.

Clinical practice includes individual consultation with clients, group therapy, and work in clinics or with teams of health professionals. Psychological therapists work in many settings and on problems ranging from short-term crises and substance abuse, to psychosis and major disorders. While there are definite biases within each field, it is possible for a practitioner with any background to prefer behavior therapy, a humanistic approach, a Freudian (dynamic) approach, or an eclectic approach derived from these and other areas.

Nonclinical professional work in psychology includes the human-factors element, which traditionally is applied to the design of the interface between a machine and its human operator. Cognitive engineering is a branch of applied psychology that deals mainly with software and hardware computer design. Industrial psychology also includes personnel selection and management and organizational planning and consulting.

The use of psychology in forensic matters is a natural result of the fact that much of law is based on psychology. Psychologists have been involved in jury selection, organization of evidence, evaluation of eyewitness testimony, and presentation of material in court cases. Psychiatrists and psychologists are also called on to diagnose potential defendants for mental disorders and the ability to stand trial. [W.P.B.]

Psychoneuroimmunology The study of the interactions among behavioral, neural and endocrine, and immune functions. This convergence of disciplines has evolved to achieve a more complete understanding of adaptive processes. At one time, the immune system was considered an independent agency of defense that protected the organism against foreign material (that is, proteins that were not part of one's "self"). Indeed, the immune system is capable of considerable self-regulation. However, converging data from the behavioral and brain sciences indicate that the brain plays a critical role in the regulation or modulation of immunity. Thus, psychoneuroimmunology emphasizes the study of the functional significance of the relationship between these systems—not in place of, but in addition to, the more traditional analysis of the mechanisms governing the functions within a single system—and the significance of these interactions for health and disease. *See* NEUROIMMUNOLOGY.

Brain–immune system interactions. Evidence for nervous system–immune system interactions exists at several biological levels. Primary and secondary lymphoid organs are innervated by the sympathetic nervous system, and lymphoid cells bear receptors for many hormones and neurotransmitters. These substances, secreted by the pituitary gland, are thus able to influence lymphocyte function. Moreover, lymphocytes themselves can produce neuropeptide substances. Thus, there are anatomical and neurochemical channels of communication that provide a structural foundation for the several observations of functional relationships between the nervous and immune systems.

Stress and immunity. The link between behavior and immune function is suggested by experimental and clinical observations of a relationship between psychosocial factors, including stress, and susceptibility to or progression of disease processes that involve immunologic mechanisms. Abundant data document an association between stressful life experiences and changes in immunologic reactivity. The death of a family member and other, less severe, stressful experiences (such as taking examinations) result in transient impairments in several parameters of immune function. *See* DISEASE; STRESS (PSYCHOLOGY).

In animals, a variety of stressors can influence a variety of immune responses. Since immune responses are themselves capable of altering levels of circulating hormones and neurotransmitters, these interactions probably include complex feedback and feedforward mechanisms. *See* ENDOCRINOLOGY.

The direction, magnitude, and duration of stress-induced alterations of immunity are influenced by (1) the quality and quantity of stressful stimulation; (2) the capacity of the individual to cope effectively with stressful events; (3) the quality and quantity of immunogenic stimulation; (4) the temporal relationship between stressful stimulation and immunogenic stimulation; (5) the sampling times and the particular aspect of immune function chosen for measurement; (6) the experiential history of the individual and the existing social and environmental conditions upon which stressful and immunogenic stimulation are superimposed; (7) a variety of host factors such as species, strain, age, sex, and nutritional state; and (8) interactions among these variables.

Conditioning. Central nervous system involvement in the modulation of immunity is dramatically illustrated by the classical (Pavlovian) conditioning of the acquisition and extinction of suppressed and enhanced antibody- and cell-mediated immune responses. In a one-trial taste-aversion conditioning situation, a distinctively flavored drinking solution (the conditioned stimulus) was paired with an injection of the immunosuppressive drug cyclophosphamide (the unconditioned stimulus). When subsequently immunized with sheep red blood cells, conditioned animals reexposed to the conditioned stimulus showed a reduced antibody response compared to nonconditioned animals and conditioned animals that were not reexposed to the conditioned stimulus. *See* CONDITIONED REFLEX.

The acquisition and the extinction (elimination of the conditioned response by exposures to the conditioned stimulus without the unconditioned stimulus) of the conditioned enhancement and suppression of both antibody- and cell-mediated immune responses—and nonimmunologically specific host defense responses as well—have been demonstrated under a variety of experimental conditions.

Prospects. An elaboration of the integrative nature of neural, endocrine, and immune processes and the mechanisms underlying behaviorally induced alterations of immune function is likely to have clinical and therapeutic implications that will not be fully appreciated until more is known about the extent of these interrelationships in normal and pathophysiological states. *See* ENDOCRINE SYSTEM (VERTEBRATE); IMMUNOLOGY; NERVOUS SYSTEM (VERTEBRATE). [R.Ad.]

Psychopharmacology A discipline that merges the subject matter of psychology, which studies cognition, emotion, and behavior, and pharmacology, which characterizes different drugs. Thus, psychopharmacology focuses on characterizing drugs that affect thinking, feeling, and action. In addition, psychopharmacology places particular emphasis on those drugs that affect abnormalities in thought, affect, and behavior, and thus has a relationship to psychiatry. Psychopharmacology is predominantly, but not exclusively, concerned with four major classes of drugs that are of clinical significance in controlling four major categories of psychiatric disorder: anxiety, depression, mania, and schizophrenia.

Anxiety is an emotional state that can range in intensity from mild apprehension and nervousness to intense fear and even terror. It has been estimated that 2–4% of the general population suffer from an anxiety disorder at some time. Although anxiety in some form is a common experience, it can become so intense and pervasive as to be debilitating; it may therefore require psychiatric attention and treatment with an anxiolytic drug. There are three major groups of anxiolytics. Members of the first group are called propanediols; meprobamate is the most widely used. The second group is the barbiturates, of which phenobarbital is the most generally prescribed. The third group, most frequently prescribed, is the benzodiazepines, the best known of which is diazepam.

A major advance in understanding the benzodiazepines was the identification of the cellular sites at which these drugs act (so-called benzodiazepine receptors). The distribution of these receptors in the brain has also been found to have a striking parallel to the distribution of the receptors for a naturally occurring substance called gamma-amino butyric acid (GABA). Furthermore, it is known that GABA has a ubiquitous inhibitory role in modulating brain function. Most importantly, it is now clear that benzodiazepines share a biochemical property in that all augment the activity of GABA. *See* ANXIETY DISORDERS; SEROTONIN; TRANQUILIZER.

The symptoms of depression can include a sense of sadness, hopelessness, despair, and irritability, as well as suicidal thoughts and attempts, which are sometimes successful. In addition, physical symptoms such as loss of appetite, sleep disturbances, and psychomotor agitation are often associated with depression. When depression becomes so pervasive and intense that normal functioning is impaired, antidepressant medication may be indicated. It has been estimated that as much as 6% of the population will require antidepressant medication at some time in their lives.

There are two major groups of antidepressant drugs. Members of the first group are called heterocyclics because of their characteristic chemical structures. Members of the second group, which are less often prescribed, are called monoamine oxidase inhibitors. *See* MONOAMINE OXIDASE.

The antidepressants typically require at least several weeks of chronic administration before they become effective in alleviating depression. This contrasts with the anxiolytics, which are effective in reducing anxiety in hours and even minutes. Another difference between these two classes of drugs is that the anxiolytics are more likely to be efficacious: anxiolytics are effective in the vast majority of nonphobic, anxious patients, whereas the antidepressants are effective in only about 65–70% of depressed patients. *See* AFFECTIVE DISORDERS.

Manic episodes are characterized by hyperactivity, grandiosity, flight of ideas, and belligerence; affected patients appear to be euphoric, have racing thoughts, delusions of grandeur, and poor if not self-destructive judgment. Periods of depression follow these episodes of mania in the majority of patients. The cycles of this bipolar disorder are typically interspersed among periods of normality that are, in most cases, relatively protracted.

Mania can usually be managed by chronic treatment with lithium salts and can be expected to be effective in 70–80% of the individuals treated. Furthermore, the period of depression that typically follows the manic episode can usually be prevented, or at least attenuated, if lithium treatment is maintained after the manic phase has subsided. Any periods of depression that do occur can be managed by antidepressant drugs. Lithium is no longer the only drug used in the management of mania. Carbamazepine, an anticonvulsant that is used in the treatment of epilepsy, is also useful in the treatment of periods of mania.

Schizophrenia is a form of psychosis; it incorporates a broad range of symptoms that can include bizarre delusions, hallucinations, incoherence of thought processes, inappropriate affect, and grossly disorganized movements. It affects 1–2% of the population. The symptoms of schizophrenia can be controlled, in varying degrees, by a large group of drugs called antipsychotics. Symptom management requires chronic medication and can be expected in about 80% or more of the schizophrenics treated. However, management is only partially successful in that normal functioning is not completely restored in most patients.

The antipsychotics have a broad range of side effects among which are disturbances of movement that fall into two general classes. The first class includes an array of symptoms very like those characteristic of Parkinson's disease. The second class of movement disorder is called tardive dyskinesia. Signs of this disturbance typically include involuntary movements that most often affect the tongue and facial and neck muscles but can also include the digits and trunk.

Although different antipsychotic drugs have different kinds and degrees of side effects, all share a single biochemical action: they all attenuate the activity of dopamine, a naturally occurring substance in the brain. The reduction in dopamine activity produced by the antipsychotics directly accounts for their effects on motor behavior. It is to be expected, therefore, that disrupted dopamine activity in this system would produce disturbances of movement. It is less clear, however, whether reduced dopamine function is also a factor in the process by which these drugs control psychotic (including schizophrenic) symptoms. *See* SCHIZOPHRENIA. [P.L.C.]

Psychophysical methods Methods for the quantitative study of the relations between physical stimulus magnitudes and the corresponding magnitudes of sensation, for example, between the physical intensity of a light and its perceived brightness or the concentration of a sugar solution and its observed sweetness. To establish these relations, measurement scales are needed, not only for physical magnitudes but also for subjective magnitudes. Subjective scales are not obtained directly from observation but are theoretical models which summarize observed relations between stimuli and responses. *See* SENSATION.

The term psychophysical methods is sometimes extended to include certain scaling techniques which are most often used with subjective dimensions to which there correspond no simple physical dimensions, for example, food preferences. *See* MULTIDIMENSIONAL SCALING.

In 1860, G. Fechner designed psychophysical methods to measure the absolute threshold, defined as the minimum stimulus energy that an organism can detect, and the differential threshold, defined as the minimum detectable change in a stimulus. Both quantities had to be defined as statistical averages. To obtain reliable measurements for these averages, Fechner devised the method of limits (also called the method of minimal changes) and the method of constant stimuli.

In the method of limits, the experimenter begins with a stimulus which is too weak for the subject to detect. In successive presentations, the stimulus intensity is increased in small, equal steps, the subject reporting after each presentation whether the stimulus was perceived until it has been detected. The descending series is then begun, the stimulus intensity beginning at an above-threshold value and decreasing in steps until the subject signals the disappearance of the stimulus. Many such series are given.

In measuring the difference threshold, essentially the same procedure is involved, except that the subject now signals the relation of a comparison stimulus to a standard stimulus. After a large number of such trials, the average of each of these four threshold values is computed.

To measure the absolute threshold by the method of constant stimuli, the experimenter selects a small number of stimulus values in the neighborhood of the absolute threshold (previously roughly located by informal use of the method of limits) and presents them to the subject a large number of times each, in an irregular order unknown to the subject. Each time a stimulus is presented, the subject reports the presence or absence of sensation.

The data provide the proportion of times that each stimulus resulted in a report of sensation by the subject. One can then estimate the stimulus value that has a probability of .50 of producing sensation, this value being defined as the absolute threshold. An analogous procedure is followed in obtaining difference thresholds.

Fechner proposed to use the results of threshold measurement in developing a subjective metric or scale. He defined the difference threshold, or just noticeable difference (jnd), as the subjective unit and the absolute threshold as the zero point of the subjective scale. Thus the subjective intensity of a particular brightness of light, for example, would be specified when it was given as 100 jnd's above threshold. The subjective scale so defined is not a linear function of the physical stimulus scale since jnd's, though defined as subjectively equal units, are not of physically equal magnitude throughout the intensity scale. The size of the jnd is approximately proportional to physical stimulus intensity. To the extent that this relation holds, Fechner deduced that subjective intensity should be proportional to the logarithm of the stimulus intensity.

Rather than requiring of the subject merely either yes-no or ordinal judgments, some methods require the subject to make direct-ratio discriminations. For instance, he or she may be presented with a moderately loud tone, and then required, by turning a knob, to adjust the loudness of a comparison tone until it is half as loud, or twice as loud, as the first. The first case illustrates the method of fractionation, the second the method of multiplication. In the method of magnitude estimation, the subject is given a stimulus, such as the brightness of a light, to serve as a modulus with a value assigned to it, for example, 10. The task, as other lights of different intensities are presented, is to assign them numbers which shall stand in the same ratio to 10 as their brightness stands to that of the modulus. One twice as bright is given the designation 20; one half as bright is 5. In these and other similar methods, whether the subject's task is to estimate or to produce the prescribed ratio or the prescribed fraction, there are certain common characteristics. Direct-ratio assessments are obtained from the subject; there can be experimental checks on internal consistency of the results, and since the individual judgments are not of high precision, repetition is required if stable averages are to be obtained.

The empirical results obtained by the various methods are in fairly good agreement. They agree in that, to at least a first approximation, subjective magnitudes on a variety of dimensions are found to be power functions of suprathreshold stimulus intensity; that is to say, subjective magnitude is proportional to the suprathreshold stimulus magnitude raised to a power. The powers have a range from 0.3 for auditory loudness to 3.5 for subjective intensity of alternating current that is applied to the skin.

In direct-matching methods the subject is not required to produce or assess the ratio of one subjective magnitude to another, but only to adjust a comparison stimulus until some attribute appears to match that of a standard stimulus. For example, the subject might be asked to adjust the physical intensities of tones of various frequencies until their loudness matched that of a 1000-Hz tone of fixed intensity. The result would be an equal-loudness contour, showing the intensities to which tones of various frequencies must be set to produce sensations of equal loudness. These data are of use in acoustics. *See* Loudness.

The method of average error, the third of the three methods devised by Fechner, is a special application of direct-matching methods to cases in which the point of interest is in discrepancies between perception and stimulation. The subject adjusts a comparison stimulus to match a standard stimulus; the average of a number of such settings gives the point of subjective equality, and the difference between this point and the standard stimulus is the average error. Two illustrative uses of the method are the measurement of accuracy of distance perception and the measurement of the magnitude of so-called optical illusions. *See* Hearing (human); Psychology. [J.F.H.]

Psychosis Any disorder of higher mental processes of such severity that judgments pertaining to the reality of external events are significantly impaired. A wide range of conditions can bring about a psychotic state. They include schizophrenia, mania, depression, ingestion of drugs, withdrawal from drugs, liver or kidney failure, endocrine disorders, metabolic disorders, and Alzheimer's disease, epilepsy, and other neurologic dysfunctions. The dreams of normal sleep are a form of psychosis.

Psychotic alterations of beliefs are called delusions. Psychotic alterations of perception are referred to as hallucinations. Psychotic states that are due to alcoholism, metabolic diseases, or other medical conditions are frequently accompanied by general mental confusion. On the other hand, psychiatric illnesses and drugs can produce hallucinations and delusions in the absence of general confusion. Few of those symptoms are unique to a particular illness, which can make proper diagnosis difficult and challenging. Correct diagnosis, however, is critical so that appropriate treatment can be provided. *See* Addictive disorders; Affective disorders; Alzheimer's disease; Neurotic disorders; Paranoia; Psychotomimetic drug; Schizophrenia. [R.E.Ho.]

Psychosomatic disorders Disorders characterized by physiological changes that originate, at least in part, from emotional factors. The classical psychosomatic symptoms and their theorized causes are shown in the table.

Psychological states influence body organs through a combination of three interrelated mechanisms: neural, hormonal, and immunologic. Voluntary movements (for example, clenching the teeth) are mediated through the motor neurons by the conscious command of the brain. In stress, clenching of the teeth, mediated by the same motor neurons, may also occur, but the act may not be voluntary and conscious. Stress usually causes an activation of the sympathetic nervous system and the hypothalamo-pituitary-adrenal axis followed by a decrease in immunocompetence. Immune mechanisms may be suppressed in part through corticosteroid activation, but a decrease in T-lymphocyte activity in stress may not be mediated by hormones. Individual specific, but inadvertent, conditioning of specific conflict or stress to specific bodily malfunction may be an important psychosomatic mechanism. *See* Conditioned reflex; Neuroimmunology.

Theorized psychological factors in classical psychosomatic disorders

Symptom (disease)	Psychological factors	Presumed psychosomatic mechanism
Hyperacidity (peptic ulcer)	Inhibited dependence; general stress	Increased acid secretion
Essential hypertension	Conflict over hostility; general stress	Vasoconstriction
Bronchial asthma	Conflict over wish for protection or separation; anxiety; general stress	Bronchospasm Bronchospasm
Migraine	Conflict over control; general stress	Vasoconstriction and vasodilatation
Thyrotoxicosis (Graves' disease)	Conflict over premature self-sufficiency	Increased thyroid-stimulating hormone secretion
Diarrhea (ulcerative colitis)	Conflict over an obligation	Gastrointestinal cholinergic activation

Conversion disorders refer to physical symptoms referrable to the somatosensory nervous system or special sensory organs that cannot be explained on the basis of a medical or neurologic disease. Common symptoms include paralysis, blindness, ataxia, aphonia, and numbness of the feet (stocking anesthesia). The symptoms may represent a psychological conflict or may be a form of body-language communication. The treatment of choice is psychotherapy.

In somatization disorder (also known as Briquet's syndrome), the patient recurrently complains of multiple somatic symptoms that are referrable to practically every organ system in the body and which, upon medical investigation, turn out not to be a diagnosable physical disease. This disorder is distinguished from conversion disorder by the chronicity and multiplicity of its symptoms. The symptoms do not usually symbolize psychological conflicts but may represent general dysphoria and distorted illness behavior. There is no definitive treatment; patients should be managed by one physician who coordinates all diagnostic and treatment plans and who provides ongoing support and follow-up without unnecessary invasive procedures.

Specific psychological conflicts often characterize patients with classical psychosomatic symptoms or disorders they represent; however, only one aspect of a multifactorial or heterogeneous disorder is not considered to be etiologic. Genetic factors are known to play important roles in the pathogenesis of most of these diseases. Some of the psychological difficulties demonstrated by these patients may in fact be a result of the disease. Psychotherapy is often helpful in resolving the conflicts when they are severe enough to warrant it, but it does not necessarily ameliorate the physical symptoms or the course of disease. *See* Psychotherapy. [H.Lei.]

Psychotherapy Any treatment or therapy that is primarily psychological in nature. In recent years, counseling also has been included in this categorization.

Psychodynamic therapies. Historically, psychoanalysis—created by Sigmund Freud—has played an important role in the growth and development of psychotherapy. Central to Freud's theories was the importance of unconscious conflicts in producing the symptoms and defenses of the patient. The goal of therapy is to help the patient attain insight into the repressed conflicts which are the source of difficulty. Since patients resist these attempts bring to consciousness the painful repressed material, therapy must proceed slowly. Consequently, psychoanalysis is a long-term therapy requiring several years for completion and almost daily visits. Since Freud's time, there have been important modifications associated with former disciples such as Alfred Adler and Carl Jung. Self psychology and ego psychology are among more recent emphases. However, the popularity of psychoanalysis has waned. *See* Psychoanalysis.

Experiential therapies. A number of related therapies are included in this group. Probably best known was the patient-centered therapy of Carl Rogers appearing in the 1940s. In Rogers' therapy, a major emphasis is placed on the ability of the patient to change when the therapist is empathic and genuine and conveys nonpossessive warmth. The therapist is nondirective in the interaction with the patient and attempts to facilitate the growth potential of the patient. Other therapeutic approaches considered as experiential include Gestalt therapy, existential approaches, and transpersonal approaches. The facilitation of experiencing is emphasized as the basic therapeutic task, and the therapeutic relationship is viewed as a significant potentially curative factor.

Cognitive, behavioral, and interpersonal therapies. In behavioral therapies, therapists play a more directive role. The emphasis is on changing the patient's behavior, using positive reinforcement, and increasing self-efficacy. More recently, cognitive therapies such as those of A. T. Beck have tended to be combined with behavioral emphases. The cognitive-behavioral therapies have focused on changing dysfunctional attitudes into more realistic and positive ones and providing new information-processing skills. *See* Cognition.

Most of the developments in interpersonal therapy have occurred in work with depressed patients. The goal of interpersonal therapy (a brief form of therapy) is centered on increasing the quality of the patient's interpersonal interactions. Emphasis is placed on enhancing the patient's ability to cope with stresses, improving interpersonal communications, increasing morale, and helping the patient deal with the effects of the depressive disorder. *See* Personality theory.

Eclectic and integrative therapies. The largest number of psychotherapists consider themselves to be eclectics. They do not adhere strictly to one theoretical orientation or school but use any procedures that they believe will be helpful for the individual patient. Eclecticism has been linked with the development of a movement for integration in psychotherapy. The emphasis in this new development is on openness to the views of other approaches, a less doctrinaire approach to psychotherapy, and an attempt to integrate two or more different theoretical views or systems of psychotherapy.

Group, family, and marital therapy. Most psychotherapy is conducted on a one-to-one basis—one therapist for one patient—and the confidentiality of these sessions is extremely important. However, there are other instances where more than one patient is involved because of particular goals. These include marital, family, and group therapy. Outpatient groups have been used for smoking cessation, weight loss, binge eating, and similar problems as well as for what were traditionally viewed as psychoneurotic problems. Inpatient group therapy was frequently employed in mental hospital settings.

There has been research on the combined use of medication and psychotherapy. In general, where two highly successful treatments are combined in cases with depressive or anxiety disorders, there appears to be little gain in effectiveness. However, in several studies of hospitalized patients with schizophrenia where individual psychotherapy has been ineffective, a combination of psychotherapy and medication has produced better results than medication alone. *See* Affective disorders; Psychopharmacology; Schizophrenia. [S.L.G]

Psychotomimetic drug A class of drugs reliably inducing temporary states of altered perception, often with symptoms similar to those of psychosis. The drug experiences are clearly perceived, vivid, and remembered. Sensory input is heightened and subjective experience is intensified, but control is diminished. The subject's feelings and momentary perceptions gain an independence from the normal corrections of logic; whatever stray item occupies the attention (a sensation or an unguarded and unevaluated memory or thought) becomes at the moment compellingly significant. Thinking and perceiving of this order coexist with the capacity for, but not an interest in, normal thought and function.

These drugs have been called psychedelic (or mind-manifesting) because of the convincing clarity with which a normally suppressed, more sensory, plastic, and primitive part of the mind is revealed to the drugged subject, contrasting sharply with the capacity to focus, discriminate, and judge.

The two drugs of chief interest, mescaline and LSD-25 (lysergic acid diethylamide), are of ancient lineage. Mescaline, used in highly structured Amerindian tribal religious rituals, is derived from peyote buttons, which are the dried tops of a cactus found in the southwestern United States. LSD has been synthesized with compounds derived from ergot, which infests such grasses as rye. (Some ergot derivatives are useful in the treatment of migraine and in obstetrics for the postpartum constriction of the uterus and blood vessels.) *See* Ergot.

There are a number of other psychotomimetics (less potent than LSD but similar), such as those from mushrooms (psilocybin and psilocin) and those synthesized in the laboratory. Ring-substituted amphetamines resembling mescaline's structure (for example, "STP") have been produced in profusion. There are subtle differences among these newer compounds, some producing more or less euphoria and more or less dyscontrol and anxiety. [D.X.F.]

Psychrometer An instrument consisting of two thermometers which is used in the measurement of the moisture content of air or other gases. The bulb or sensing area of one of the thermometers either is covered by a thin piece of clean muslin cloth wetted uniformly with distilled water or is otherwise coated with a film of distilled water. The temperatures of both the bulb and the air contacting the bulb are lowered by the evaporation which takes place when unsaturated air moves past the wetted bulb. An equilibrium temperature, termed the wet-bulb temperature (T_W), will be reached; it closely approaches the lowest temperature to which air can be cooled by the evaporation of water into that air. The water-vapor content of the air surrounding the wet bulb can be determined from this wet-bulb temperature and from the air temperature measured by the thermometer with the dry bulb (T_D by using an expression of the form $e = e_{SW} - aP\ (T_D - T_W)$. Here e is the water-vapor pressure of the air, e_{SW} is the saturation water-vapor pressure at the wet-bulb temperature, P is atmospheric pressure, and a is the psychrometric constant, which depends upon properties of air and water, as well as on speed of ventilation of air passing the wet bulb. *See* Psychrometrics. [R.M.Sch.]

Psychrometrics A study of the physical and thermodynamic properties of the atmosphere. The properties of primary concern in air conditioning are (1) dry-bulb temperature, (2) wet-bulb temperature, (3) dew-point temperature, (4) absolute humidity, (5) percent humidity, (6) sensible heat, (7) latent heat, (8) total heat, (9) density, and (10) pressure.

The dry-bulb temperature is the ambient temperature of the air and water vapor as measured by a thermometer or other temperature-measuring device in which the thermal element is dry and shielded from radiation. *See* Air temperature; Temperature.

If the bulb of a dry-bulb thermometer is covered with a silk or cotton wick saturated with distilled water and the air is drawn over it at a velocity not less than 1000 ft/min (5 m/s), the resultant temperature will be the wet-bulb temperature. Where the dry-bulb and wet-bulb temperatures are the same, the atmosphere is saturated.

The dew-point temperature is the temperature at which the water vapor in the atmosphere begins to condense. This is also the temperature of saturation at which the dry-bulb, wet-bulb, and dew-point temperatures are all the same. *See* Dew point.

The actual quantity of water vapor in the atmosphere is designated as the absolute humidity. Percentage or relative humidity is the ratio of the actual water vapor in the atmosphere to the quantity of water vapor the atmosphere could hold if it were saturated at the same temperature. *See* Humidity.

Sensible heat, or enthalpy of dry air, is heat which manifests itself as a change in temperature. *See* Enthalpy.

Latent heat, or enthalpy of vaporization, is the heat required to change a liquid into a vapor without change in temperature.

Latent heat is sometimes referred to as the latent heat of vaporization and varies inversely as the pressure.

The total heat, or enthalpy, of the atmosphere is the sum of the sensible heat, latent heat, and superheat of the vapor above the saturation or dew-point temperature. Total heat is relatively constant for a constant wet-bulb temperature, deviating only about 1.5–2% low at relative humidities below 30%.

The density of the atmosphere varies with both altitude and percentage humidity. The higher the altitude the lower the density, and the higher the moisture content the lower the density. *See* DENSITY.

Atmospheric pressure is usually referred to as barometric pressure. Pressure varies inversely as elevation, as temperature, and as percentage saturation. *See* MOISTURE-CONTENT MEASUREMENT; PSYCHROMETER. [J.Ev.]

Pteraspidomorpha The subclass of Agnatha that includes the jawless vertebrates with paired nostrils. Pteraspidomorphi, sometimes called Diplorhina, includes only the extinct ostracoderm order Heterostraci and some or all of the problematical fossil genera now referred to the order Thelodonti. *See* HETEROSTRACI. [R.H.De.]

Pteridosperms A group of extinct seed plants characterized by fernlike leaves that produced naked seeds. The discovery of the seed ferns was a major contribution to the study of plant evolution because it demonstrated the existence of a group of vascular plants that is today extinct. Although the seed ferns probably have their ultimate origin within the progymnosperm order Aneurophytales, the best evidence of the group comes from lower Carboniferous (Mississippian) and younger sediments. Some seed ferns are reconstructed as trees with stout stems, while perhaps the majority were vines or lianas that supported massive fernlike fronds. The seed ferns consist of six Paleozoic orders (Calamopityales, Buteoxylonales, Lyginopteridales, Medullosales, Callistophytales, Glossopteridales) and three orders (Peltaspermales, Corystospermales, Caytoniales) found in Mesozoic rocks. *See* CAYTONIALES; PALEOBOTANY. [T.N.T.]

Pterobranchia A group of small sessile hemichordates that may be colonial (*Rhabdopleura*), pseudocolonial (*Cephalodiscus*), or solitary (*Atubaria*). Each individual, or zooid, lives inside a nonchitinous tube secreted by the protosome, except for *Atubaria*; an aggregation of zooids is called a coenecium and can vary in shape. The protosome, or oral shield, is disciform, closes the mouth ventrally, and secretes the tube. The protocoel has symmetrical pores at the base of the first pair of arms. The mesosome, or collar, has an anteroventral mouth and one to nine pairs of dorsally ciliated tentaculated arms, which are used to collect small organisms for food. The mesocoels extend into both arms and tentacles.

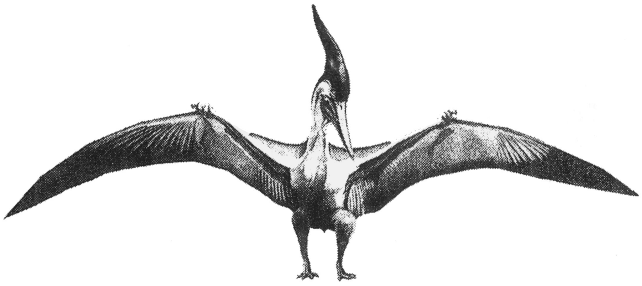
The metasome is divided into a sacciform trunk and a slender ventral stalk that may be free at its end. The trunk contains the U-shaped digestive tract, with the pharynx having a single pair of gills, except in *Rhabdopleura*. The stomach is a sacciform expansion of the gut, and the tubular intestine curves dorsally and opens behind the arms by a middorsal anus.

The nervous system is very simple and lacks a neurochord. The buccal diverticulum is hollow, with an anteroventral heart vesicle and central sinus. The glomerulus is poorly developed, and the circulatory system is simpler that in enteropneusts. *See* HEMICHORDATA. [J.Ben.]

Pteropsida A large group of vascular plants characterized by having parenchymatous leaf gaps in the stele and by having leaves which are thought to have originated in the distant past as branched stem systems. Some botanists regard the Pteropsida as a natural group which they recognize as a class, subdivision, or division. Others regard it as an artificial assemblage of plants that have undergone certain similar changes from a rhyniophyte ancestry. The various components of the Pteropsida are here treated as three separate divisions under the names Magnoliophyta, Pinophyta, and Polypodiophyta. *See* MAGNOLIOPHYTA; PINOPHYTA; POLYPODIOPHYTA. [A.CR.]

Pterosauria The "winged reptiles" of the Mesozoic Era, constituting the closest major group to Dinosauria and sharing many features with them. Their common ancestor was a small, bipedal, agile archosaur similar to *Scleromochlus* with a large, lightly built skull, short body, long hindlimbs, and digitigrade feet with four long metatarsals. Pterosaurs inherited all these features, and further evolved the power of flight. Pterosaurs had a wing of skin that was internally supported by long, fine, possibly collagenous stiffening fibers and braced by the forelimb, including a greatly elongated fourth finger (the first three remained small). Their brains were large and birdlike. Their bone walls were the thinnest of all tetrapods; *See* ORNITHISCHIA; SAURISCHIA.

The earliest pterosaurs are known from the Late Triassic, about the time that the first dinosaurs appeared: they include *Eudimorphodon, Peteinosaurus*, and *Preondactylus*, all from marine rocks of Italy. Pterodactyloids ("wing-fingers") were a subgroup of Late Jurassic and Cretaceous pterosaurs that replaced the early pterosaurs. The best-known members of this group include the small *Pterodactylus* and the *Pteranodon* with 7-m (23-ft) wing span (see illustration).



***Pteranodon* (reconstruction).**

Most pterosaurs are known from shallow marine sediments, and ecologically resemble shorebirds and seabirds. *See* ARCHOSAURIA; DINOSAUR; REPTILIA. [K.Pa.]

Pterygota The larger of two subclasses of Insecta. All have wings in the adult stage or have been derived from winged ancestors; that is, if wingless, they are secondarily so. The primitive pterygotes make up the section Paleoptera; the mayflies, dragonflies, and damselflies are in this category. All other pterygotes constitute the section Neoptera. The more primitive Neoptera have exopterygote development, as in the grasshoppers, true bugs, and others, whereas the more specialized Neoptera have endopterygote development, as in the butterflies, moths, beetles, wasps, and so on. *See* APTERYGOTA; ENDOPTERYGOTA; EXOPTERYGOTA; INSECTA. [F.M.C.]

Ptychodactiaria An order of the zoantharian anthozoans of the phylum Coelenterata. This group of solitary sea anemones is known only from two genera, *Ptychodactis* and *Dactylanthus* from the Arctic and Antarctic. *See* ANTHOZOA; COELENTERATA. [C.H.]

Public health An effort organized by society to protect, promote, and restore the people's health. It is the combination of sciences, skills, and beliefs that is directed to the maintenance and improvement of health through collective or social actions. The programs, services, and institutions of public health emphasize the prevention of disease and the health needs of the population as a whole. Additional goals include the reduction of the amount of disease, premature death, disability, and discomfort in the population.

The basic sciences of public health include epidemiology and vital statistics, which measure health status and assess health trends in the population. Epidemiology is also a powerful research method, used to identify causes and calculate risks of acquiring or dying of many conditions. Many sciences, including toxicology and microbiology, are applied to detect, monitor, and correct physical, chemical, and biological hazards in the environment. Such applications are being used to address concerns about a deteriorating global environment. The social and behavioral sciences have become more prominent in public health since the recognition that such factors as indolence, loneliness, personality type, and addiction to tobacco contribute to the risk of premature death and chronic disabling diseases. *See* EPIDEMIOLOGY.

In most industrial nations, public health services are organized nationally, regionally, and locally. National public health services are usually responsible for setting, monitoring, and maintaining health standards, for promoting good health, for collecting and compiling national health statistics, and for supporting and performing research on diseases important to public health. Regional (for example, state) public health services deal mainly with major health protection activities such as ensuring safe water and food supplies; they may also operate screening programs for early detection of disease and are responsible for health care of certain groups such as chronic mentally ill persons. Local public health services (in cities, large towns, and some rural communities) conduct a variety of personal public health services, such as immunization programs, health education, health surveillance and advice for mothers and newborn babies, and personal care of vulnerable groups such as the elderly and housebound long-term sick. Local health services also investigate and control epidemics and other communicable conditions such as sexually transmitted diseases.

National public health services communicate with each other in efforts to control diseases of international importance, and they collaborate worldwide under the auspices of the World Health Organization (WHO). While much of the work of WHO has been concentrated in the developing nations, it has also been involved in global efforts to control major epidemic diseases and to set standards for hazardous environmental and occupational exposures. [J.M.La.]

Pulley A wheel with a flat, crowned, or grooved rim used with a flat belt, V-belt, or a rope to transmit motion and energy. Pulleys for use with V-belt and rope drives have grooved surfaces and are usually called sheaves. A combination of ropes, pulleys, and pulley blocks arranged to gain a mechanical advantage, as for hoisting a load, is referred to as block and tackle. *See* BELT DRIVE; BLOCK AND TACKLE.

Pulleys for flat belts are made of cast iron, fabricated steel, wood, and paper. A particular pulley design must be based on such considerations as the ability to resist shock, to conduct heat, and to resist corrosive environments. The face must be smooth enough to minimize belt wear; yet there must be adequate friction between belt and pulley face to carry the load.

The two common types of V-belt pulley are pressed-steel and cast-iron. The pressed-steel pulleys are suitable for single-belt drives. For multiple-belt drives, or in single-belt drives where pulley mass should be high to get a flywheel effect, cast-iron pulleys are used. [J.R.Z.]

Pulmonata A subclass of the molluscan class Gastropoda, containing about 23,500 species of snails that are grouped into three superorders: Systellommatophora, Basommatophora, and Stylommatophora. Pulmonates include most of the common snails found on land or in freshwaters, although a few prosobranchs have invaded both habitats. Certain pulmonates are intertidal to subtidal on rocky shores of tropical and temperate regions. *See* BASOMMATOPHORA; STYLOMMATOPHORA; SYSTELLOMMATOPHORA.

Fresh-water pulmonates belong to the superorder Basommatophora and are adapted to make use of accidental transport on birds or insects from one isolated body of water to another. Mostly they have short life-spans, and their numbers vary dramatically with the seasons.

Land pulmonates belong to the superorder Stylommatophora and are marginally terrestrial in that they can be active only when the humidity in their microhabitat is 90% or above. Thus many are cryptic or nocturnal in both feeding and reproduction. They can survive in deserts by estivating for up to 6 years. *See* GASTROPODA. [G.A.S.]

Pulsar A celestial radio source producing intense short bursts of radio emission. Since the discovery of pulsars in 1968, about 1300 pulsars have been found (as of May 2001), and it has become clear that 100,000 pulsars must exist in the Milky Way Galaxy—most of them too distant to be detected with existing radio telescopes. *See* RADIO ASTRONOMY.

Pulsars are distinguished from most other types of celestial radio sources in that their emission, instead of being constant over time scales of years or longer, consists of periodic sequences of brief pulses. The interval between pulses, or pulse period, is nearly constant for a given pulsar, but for different sources ranges from 0.0016 to 8.5 s. The bursts of emission are generally confined to a window whose width is a few percent of the interpulse period. Individual pulses can vary widely in intensity.

The association of pulsars with neutron stars, the collapsed cores left behind when moderate- to high-mass stars become unstable and collapse, is supported by many arguments. The standard model for pulsars is a spinning neutron star with an intense dipole magnetic field (surface field of 10^{12} gauss or 10^{8} teslas) misaligned with the rotation axis. The off-axis rotating dipole field develops a huge voltage difference between the neutron star surface and the surrounding matter. Charges accelerate in this voltage and generate an avalanche of electrons and positrons, a relativistic current leaving the polar zones of the star. Highly directive radio emission is formed in this current, which is observed as pulses, one per rotation, just like a rotating searchlight. *See* ELECTRON; POSITRON.

A fundamental observation that supports the rotating neutron star model is the remarkable stability of the basic pulsation periods, which typically remain constant to a few tens of nanoseconds over a year. This stability is natural to the free rotation of a compact, rigid object like a neutron star, but is extremely difficult to produce by any other known physical process.

Pulsars have provided a unique set of probes for the investigation of the diffuse gas and magnetic fields in interstellar space. Measurement of absorption at 1420 MHz, the frequency of the hyperfine transition in ground-state neutral hydrogen atoms, gives information on the structure of gas clouds, and in many cases provides an estimate of the pulsar distance. The index of refraction for radio waves in the ionized interstellar gas is strongly frequency-dependent, and low-frequency signals propagate more slowly than those at high frequencies. The broadband, pulsed nature of pulsar signals makes them ideal for measurements of this dispersion.

The first pulsar in a binary, PSR B1913+167, was found in 1975. About 50 binary pulsars are now known. The binary pulsar PSR B1913+167 has an orbital speed near one-thousandth the speed of light. This large speed and the intense gravitational field of the nearby companion neutron star, when combined with the accurate clock mechanism provided by the pulsations, make this system an ideal testing ground for relativistic gravitation theories. One especially important prediction of the general theory of relativity is that a close binary star system should gradually lose energy by the radiation of gravitational waves, and consequently the two stars should slowly spiral closer together. Observations of Doppler shifts of the pulsar signals have established that the two masses in the PSR B1913+167 system are each approximately 1.4 times the mass of the Sun. The quantitative prediction of general relativity is, then, that the orbital period should diminish by about 10^{-7} s per orbit, amounting to a cumulative orbital phase shift of 8 s after 14 years. Just such an effect has been found, and the observations provide the first (and only) experimental evidence in support of the existence of gravitational waves. *See* Gravitation; Gravitational radiation; Relativity. [D.C.Ba.]

Pulse demodulator A device that recovers the modulating signal from a pulse-modulated wave. This recovery may or may not require a two-stage demodulation. Pulse-duration-modulated (PDM) or pulse-amplitude-modulated (PAM) signals may be completely recovered by a conventional detector in amplitude-modulation (AM) radio or a phase-quadrature-type demodulator in frequency-modulation (FM) radio. The reason is that the pulse area is proportional to the modulating-signal amplitude at the time of each pulse, and the low-pass demodulator output filter removes the pulse-frequency components as well as the carrier-frequency components and leaves only the original modulating-frequency components in the filter output. *See* Amplitude-modulation detector; Frequency-modulation detector.

Pulse-position-modulated (PPM) and pulse-code-modulated (PCM) signals require a two-stage demodulation because the pulse train must be processed before the original modulation can be recovered. The pulse-train modulation may be recovered from a radio-frequency (rf) carrier by any appropriate AM or FM detector, provided that the low-pass filter in the detector output passes the significant frequency components of the pulse. *See* Pulse modulation. [C.L.A.]

Pulse generator An electronic circuit capable of producing a waveform that rises abruptly, maintains a relatively flat top for an extremely short interval, and then rapidly falls to zero. A relaxation oscillator, such as a multivibrator, may be adjusted to generate a rectangular waveform having an extremely short duration, and as such it is referred to as a pulse generator. However, there is a class of circuits whose exclusive function is generating short-duration, rectangular waveforms. These circuits are usually specifically identified as pulse generators. An example of such a pulse generator is the triggered blocking oscillator, which is a single relaxation oscillator having transformer-coupled feedback from output to input. *See* Multivibrator.

Pulse generators sometimes include, but are usually distinguished from, trigger circuits. Trigger circuits generate a short-duration, fast-rising waveform for initiating or triggering an event or a series of events in other circuits. In the pulse generator, the pulse duration and shape are of equal importance to the rise and fall times. *See* Trigger circuit.

The term pulse generator is often applied not only to an electronic circuit generating prescribed pulse sequences but to an electronic instrument designed to generate sequences of pulses with variable delays, pulse widths, and pulse train combinations, programmable in a predetermined manner, often microprocessor-controlled.

A network, formed in such a way as to simulate the delay characteristics of a lossless transmission line, and appropriate switching elements to control the duration of a pulse form the basis for a variety of types of pulse generators. Some delay-line-controlled pulse generators are capable of generating pulses containing considerable amounts of power for such applications as modulators in radar transmitters. *See* Delay line; Wave-shaping circuits. [G.M.G.]

Pulse jet A type of jet engine characterized by periodic surges of thrust. The pulse jet engine was widely known for its use during World War II on the German V-l missile (see illustration). The basic engine cycle was invented in 1908. The inlet end of the engine is provided with a grid to which are attached flap valves. These valves are normally held by spring tension against the grid face and block the flow of air back out of the front of the engine. They can be sucked inward by a negative differential pressure to allow air to flow into the engine. Downstream from the flap valves is the combustion chamber. A fuel injection system is located at the entrance to the combustion chamber. The chamber is also fitted with a spark plug. Following the combustion chamber is a long exhaust duct which provides an inertial gas column.

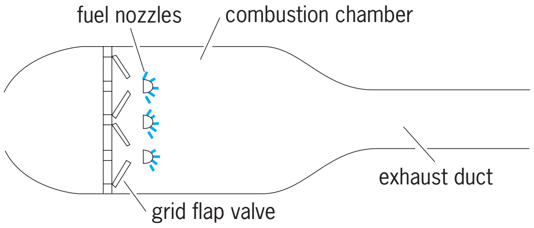


Diagram of a pulse jet.

Pulse jets have also been used to propel radio-controlled target drones and experimental helicopters. In the latter case, they were mounted on the blade tips for directly driving the rotor. The high fuel consumption, noise, and vibrations generated by the pulse jet limit its scope of applications. *See* Propulsion. [B.Pi.]

Pulse modulation A set of techniques whereby a sequence of information-carrying quantities occurring at discrete instances of time is encoded into a corresponding regular sequence of electromagnetic carrier pulses. Varying the amplitude, polarity, presence or absence, duration, or occurrence in time of the pulses gives rise to the four basic forms of pulse modulation: pulse-amplitude modulation (PAM), pulse-code modulation (PCM), pulse-width modulation (PWM, also known as pulse-duration modulation, PDM), and pulse-position modulation (PPM).

Analog-to-digital conversion. An important concept in pulse modulation is analog-to-digital (A/D) conversion, in which an original analog (time- and amplitude-continuous) information signal $s(t)$ is changed at the transmitter into a series of regularly occurring discrete pulses whose amplitudes are restricted to a fixed and finite number of values. An inverse digital-to-analog (D/A) process is used at the receiver to reconstruct an approximation of the original form of $s(t)$. Conceptually, analog-to-digital conversion involves two steps. First, the range of amplitudes of $s(t)$ is divided or quantized into a finite number of predetermined levels, and each such level is represented by a pulse of fixed amplitude. Second, the amplitude of $s(t)$ is periodically measured or sampled and replaced by the pulse representing the level that corresponds to the measurement. *See* Analog-to-digital converter; Digital-to-analog converter.

According to the Nyquist sampling theorem, if sampling occurs at a rate at least twice that of the bandwidth of $s(t)$, the latter can be unambiguously reconstructed from its amplitude values at the sampling instants by applying them to an ideal low-pass filter whose bandwidth matches that of $s(t)$.

Quantization, however, introduces an irreversible error, the so-called quantization error, since the pulse representing a sample measurement determines only the quantization level in which the measurement falls and not its exact value. Consequently, the process of reconstructing $s(t)$ from the sequence of pulses yields only an approximate version of $s(t)$.

Pulse-amplitude modulation. In PAM the successive sample values of the analog signal $s(t)$ are used to effect the amplitudes of a corresponding sequence of pulses of constant duration occurring at the sampling rate. No quantization of the samples normally occurs (Fig. 1*a*, *b*). In principle the pulses may occupy the entire time between samples, but in most practical systems the pulse duration, known as the duty cycle, is limited to a

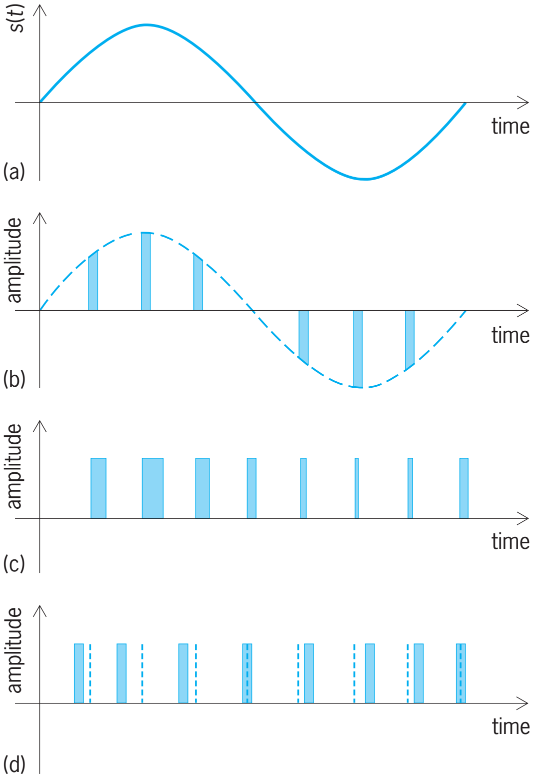

Fig. 1. Forms of pulse modulation for the case where the analog signal, *s*(*t*), is a sine wave. (*a*) Analog signal, *s*(*t*). (*b*) Pulse-amplitude modulation. (*c*) Pulse-width modulation. (*d*) Pulse-position modulation.

fraction of the sampling interval. Such a restriction creates the possibility of interleaving during one sample interval one or more pulses derived from other PAM systems in a process known as time-division multiplexing (TDM). *See* MULTIPLEXING AND MULTIPLE ACCESS.

Pulse-width modulation. In PWM the pulses representing successive sample values of *s*(*t*) have constant amplitudes but vary in time duration in direct proportion to the sample value. The pulse duration can be changed relative to fixed leading or trailing time edges or a fixed pulse center. To allow for time-division multiplexing, the maximum pulse duration may be limited to a fraction of the time between samples (Fig. 1*c*).

Pulse-position modulation. PPM encodes the sample values of *s*(*t*) by varying the position of a pulse of constant duration relative to its nominal time of occurrence. As in PAM and PWM, the duration of the pulses is typically a fraction of the sampling interval. In addition, the maximum time excursion of the pulses may be limited (Fig. 1*d*).

Pulse-code modulation. Many modern communication systems are designed to transmit and receive only pulses of two distinct amplitudes. In these so-called binary digital systems, the analog-to-digital conversion process is extended by the additional step of coding, in which the amplitude of each pulse representing a quantized sample of *s*(*t*) is converted into a unique sequence of one or more pulses with just two possible amplitudes. The complete conversion process is known as pulse-code modulation.

Figure 2*a* shows the example of three successive quantized samples of an analog signal *s*(*t*), in which sampling occurs every T seconds and the pulse representing the sample is limited to $T/2$ seconds. Assuming that the number of quantization levels is limited to 8, each level can be represented by a unique sequence of three two-valued pulses. In Fig. 2*b* these pulses are of amplitude V or 0, whereas in Fig. 2*c* the amplitudes are V and $-V$.

PCM enjoys many important advantages over other forms of pulse modulation due to the fact that information is represented by a two-state variable. First, the design parameters of a PCM transmission system depend critically on the bandwidth of the original signal *s*(*t*) and the degree of fidelity required at the point of reconstruction, but are otherwise largely independent of the information content of *s*(*t*). This fact creates the possibility of deploying generic transmission systems suitable for many types of information. Second, the detection of the state of a two-state variable in a noisy environment is inherently simpler than the precise measurement of the amplitude, duration, or position of a pulse in which these quantities are not constrained. Third, the binary pulses propagating along a medium can be intercepted and decoded at a point where the accumulated distortion and attenuation are sufficiently low to assure high detection accuracy. New pulses can then be generated and transmitted to the next such decoding point. This so-called process of repeatering significantly reduces the propagation of distortion and leads to a quality of transmission that is largely independent of distance.

Time-division multiplexing. An advantage inherent in all pulse modulation systems is their ability to transmit signals from multiple sources over a common transmission system through the process of time-division multiplexing. By restricting the time duration of a pulse representing a sample value from a particular analog signal to a fraction of the time between successive samples, pulses derived from other sampled analog signals can be accommodated on the transmission system.

One important application of this principle occurs in the transmission of PCM telephone voice signals over a digital transmission system known as a T1 carrier. In standard T1 coding, an original analog voice signal is band-limited to 4000 hertz by passing it through a low-pass filter, and is then sampled at the Nyquist rate of 8000 samples per second, so that the time between successive samples is 125 microseconds. The samples are quantized to 256 levels, with each of them being represented by a sequence of 8 binary pulses. By limiting the duration of a single pulse to 0.65 microsecond, a total of 193 pulses can be accommodated in the time span of 125 microseconds between

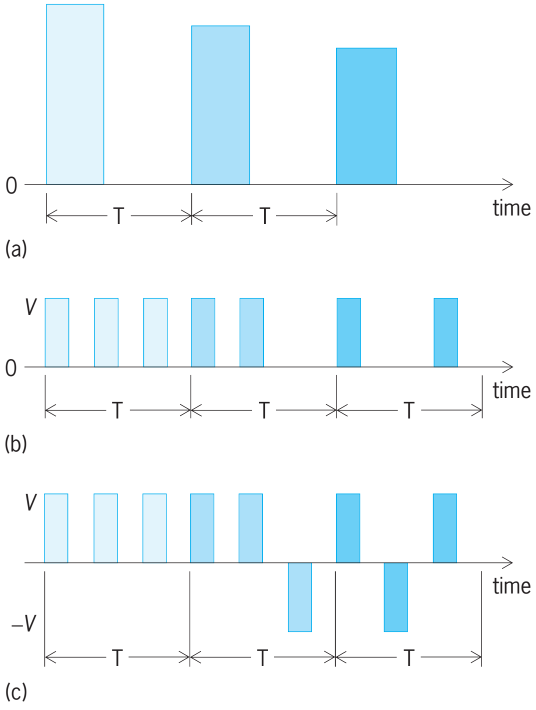

Fig. 2. Pulse-code modulation. (*a*) Three successive quantized samples of an analog signal. (*b*) With pulses of amplitude *V* or 0. (*c*) With pulses of amplitude *V* or −*V*.

samples. One of these serves as a synchronization marker that indicates the beginning of such a sequence of 193 pulses, while the other 192 pulses are the composite of 8 pulses from each of 24 voice signals, with each 8-pulse sequence occupying a specified position. T1 carriers and similar types of digital carrier systems are in widespread use in the world's telephone networks.

Bandwidth requirements. Pulse modulation systems may incur a significant bandwidth penalty compared to the transmission of a signal in its analog form. An example is the standard PCM transmission of an analog voice signal band-limited to 4000 hertz over a T1 carrier. Since the sampling, quantizing, and coding process produces 8 binary pulses 8000 times per second for a total of 64,000 binary pulses per second, the pulses occur every 15.625 microseconds. Depending on the shape of the pulses and the amount of intersymbol interference, the required transmission bandwidth will fall in the range of 32,000 to 64,000 hertz. This compares to a bandwidth of only 4000 hertz for the transmission of the signal in analog mode.

Applications. PAM, PWM, and PPM found significant application early in the development of digital communications, largely in the domain of radio telemetry for remote monitoring and sensing. They have since fallen into disuse in favor of PCM.

Since the early 1960s, many of the world's telephone network providers have gradually, and by now almost completely, converted their transmission facilities to PCM technology. The bulk of these transmission systems use some form of time-division multiplexing, as exemplified by the 24-voice channel T1 carrier structure. These carrier systems are implemented over many types of transmission media, including twisted pairs of telephone wiring, coaxial cables, fiber-optic cables, and microwave. *See* Coaxial cable; Communications cable; Microwave; Optical communications; Optical fibers; Switching systems (communications); Telephone service.

The deployment of high-speed networks such as the Integrated Service Digital Network (ISDN) in many parts of the world has also relied heavily on PCM technology. PCM and various modified forms such as delta modulation (DM) and adaptive differential pulse-code modulation (ADPCM) have also found significant application in satellite transmission systems. *See* Communications satellite; Data communications; Electrical communications; Integrated services digital network (ISDN); Modulation. [H.J.He.]

Pulse modulator A device for the pulse modulation of a radio-frequency carrier signal. In pulse modulation, information is transmitted by generating a train of discrete pulses whose amplitude, duration, position, or mere presence is controlled in accordance with the signal. *See* Pulse modulation.

Pulse-amplitude modulation. In pulse-amplitude modulation (PAM) the desired signal to be transmitted is sampled periodically (Fig. 1). PAM may be accomplished by the use of a multiplier circuit. The signal that contains the intelligence to be transmitted is applied to one of the multiplier inputs, and the train of pulses known as the sampling signal is applied to the other multiplier input. If this train of pulses has an amplitude of one during the pulse and zero elsewhere, the multiplier output will consist of a train of pulses, each having an amplitude equal to the signal amplitude at the time of sampling (Fig. 1). The main reason for using PAM is that several signals may be transmitted over a single communication channel by a technique known as multiplexing. *See* Multiplexing and multiple access.

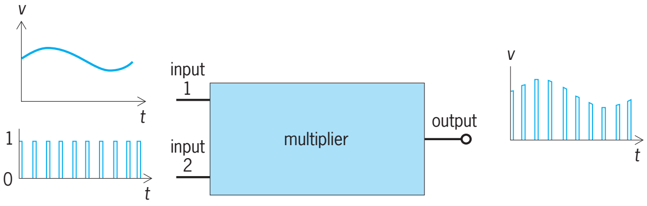

Fig. 1. Pulse-amplitude modulation by means of a multiplier circuit.

The most simple technique for multiplexing several signals onto a single channel is to use a rotating multipole switch known as a commutator. The commutator may serve as the sampler, or modulator, as well as the multiplexer. A commutator must be used on the receiving end as well as the transmitting end of the multiplexed channel in order to unscramble the signals. These commutators must be synchronized so that each message is sent to its proper destination at the receiving end. For example, several telephone conversations might be sampled and multiplexed onto a single telephone line. An easily identifiable synchronizing signal must also be sent to synchronize the commutators at the two ends of the system. A low-pass filter is used in each message line at the receiving end to pass only the desired message frequencies and remove the higher frequencies of the pulses. *See* Electric filter.

Pulse-width and pulse-position modulation. PAM is a satisfactory method of communication when transmission distances are short enough to maintain high signal-to-noise ratios. However, when transmission distances become long, such as many miles, the atmospheric noise from lightning and other electrical sources that is induced into either a hard-wire line or a radio antenna may degrade the signal-to-noise ratio sufficiently to at least cause annoyance and at worst render the message unintelligible. Both pulse-width modulation (PWM) and pulse-position modulation (PPM) have been used in the past with the hope of improving the signal-to-noise ratio. *See* Electrical interference; Electrical noise; Signal-to-noise ratio.

PWM may be obtained from the PAM pulse by charging a small capacitor to the peak voltage of each pulse as it comes along, and then discharging the capacitor through a constant current source before the next pulse arrives. Then the capacitor voltage decreases linearly to zero during a time that is proportional to the pulse amplitude. These triangular pulses may then be passed through a Schmitt trigger circuit to square them up and provide constant amplitude pulses of varying width.

PPM may then be obtained by differentiating the PWM signals to produce narrow pulses at both the leading and trailing edges of the PWM pulses. The leading-edge pulse is used as the reference pulse, and the time difference between it and the trailing-edge pulse represents the modulation amplitude. These sharp PPM pulses may be squared up by the use of either a Schmitt trigger circuit or a one-shot multivibrator. Both the PWM and PPM signals are subject to noise modulation so their use may or may not improve the signal-to-noise ratio in comparison with a PAM system. *See* Multivibrator.

Pulse-code modulation. A signal transmission system of any type may become essentially immune to atmospheric and other induced noise when pulse-code modulation (PCM) is used. In this type of modulation, the modulating signal is first sampled (Fig. 2*a*). The resulting PAM signals are then quantized by a circuit that compares each pulse amplitude with a set of predetermined levels and produces a stepwise-varying replica of the original signal having only the predetermined voltage levels. In Fig. 2*b*, eight equally spaced levels were chosen to represent signals limited to the range from approximately 0 to 7 V peak amplitude. Thus the quantizing levels are separated by 1 V. Each quantized level is then represented by a sequence of pulses known as a code. Any of many different coding systems may be used, but the binary code is basic and is very commonly used (Fig. 2*c*). Analog-to-digital converters are available in integrated-circuit form. *See* Analog-to-digital converter; Integrated circuits.

If the transmission path is very long, one or more repeater stations may be needed at intermediate points. These repeaters receive the signal while it is still larger than the noise, remove the noise, amplify the signal, and retransmit it along the channel.

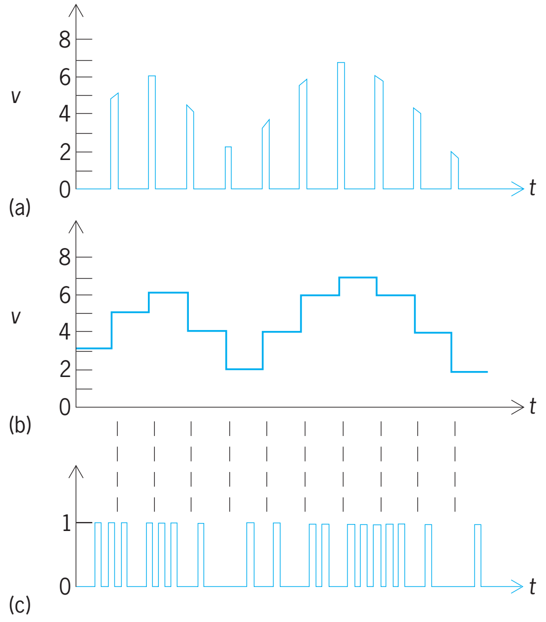

Fig. 2. Pulse-code modulation. (*a*) Signal sampling. (*b*) Quantization. (*c*) Binary pulse coding.

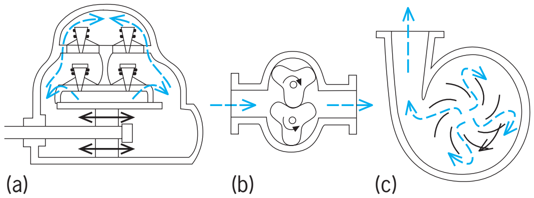
In fact, PCM signals that are weaker than the noise may be received and the noise rejected if a phase-locked loop is used as the demodulator in the receiver. *See* Phase-locked loops.

The signal-to-noise ratio of PCM voice communication decreases if the signal level decreases significantly from its maximum permissible value because some of the quantization levels are then not used. In order to overcome this problem, signal compression is used prior to modulation. This compression is accomplished by amplifying the weak signals more than the strong ones so the variation in signal level is greatly reduced. In order to restore the original relative signal levels at the receiving end of the system after demodulation, a circuit known as an expander is used to amplify the stronger signals more than the weak ones. A circuit that will serve as either a compressor or expander is known as a compander. [C.L.A.]

Pumice A rock froth, formed by the extreme puffing up of liquid lava by expanding gases liberated from solution in the lava prior to and during solidification. Some varieties will float in water for many weeks before becoming waterlogged. Typical pumice is siliceous (rhyolite or dacite) in composition, but the lightest and most vesicular pumice (known also as reticulite and thread-lace scoria) is of basaltic composition. *See* Lava; Volcanic glass. [G.A.M.]

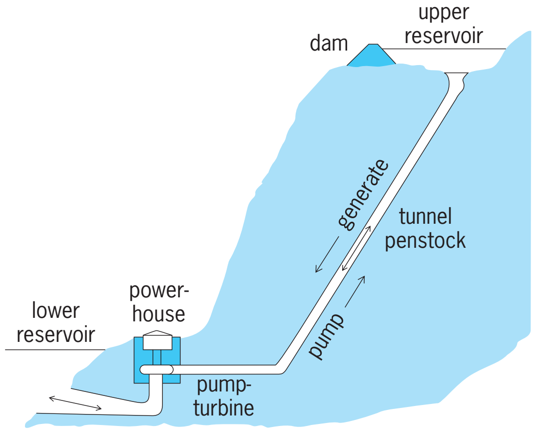
Pump A machine that draws a fluid into itself through an entrance port and forces the fluid out through an exhaust port (see illustration). A pump may serve to move liquid, as in a cross-country pipeline; to lift liquid, as from a well or to the top of a tall building; or to put fluid under pressure, as in a hydraulic brake. These applications depend predominantly upon the discharge characteristic of the pump. A pump may also serve to empty a container, as in a vacuum pump or a sump pump, in which case the application depends primarily on its intake characteristic. *See* Centrifugal pump; Compressor; Displacement pump; Fan; Fuel pump; Pumping machinery; Vacuum pump. [E.F.W.]



Pumps. (*a*) Reciprocating. (*b*) Rotary. (*c*) Centrifugal.

Pumped storage A process, also known as hydroelectric storage, for converting large quantities of electrical energy to potential energy by pumping water to a higher elevation, where it can be stored indefinitely and then released to pass through hydraulic turbines and generate electrical energy. An indirect process is necessary because electrical energy cannot be stored effectively in large quantities. Storage is desirable, as the consumption of electricity is highly variable between day and night, between weekday and weekend, as well as among seasons. Consequently, much of the generating equipment needed to meet the greatest daytime load is unused or lightly loaded at night or on weekends. During those times the excess capability can be used to generate energy for pumping, hence the necessity for storage.

A typical pumped-storage development is composed of two reservoirs of essentially equal volume situated to maximize the difference in their levels. These reservoirs are connected by a system of waterways along which a pumping-generating station is located (see illustration). Under favorable geological conditions, the station will be located underground, otherwise it will be situated on the lower reservoir. The principal equipment of the station is the pumping-generating unit. In United States practice, the machinery is reversible and is used for both pumping and generating; it is designed to function as a motor and pump in one direction of rotation and as a turbine and generator in opposite rotation. *See* Electric power generation; Pumping machinery; Waterpower. [D.L.G.]



Schematic of a conventional pumped-storage development.

Pumping machinery Devices which convey fluids, chiefly liquids, from a lower to a higher elevation or from a region of lower pressure to one of higher pressure. Pumping machinery may be broadly classified as mechanical or as electromagnetic.

In mechanical pumps ghe fluid is conveyed by direct contact with a moving part of the pumping machinery. The two basic types are (1) velocity machines, centrifugal or turbine pumps, which impart energy to the fluid primarily by increasing its velocity, then converting part of this energy into pressure or head, and (2) displacement machines with plungers, pistons, cams, or other confining forms which act directly on the fluid, forcing it to flow against a higher pressure. *See* Centrifugal pump; Displacement pump.

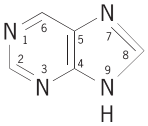
Where direct contact between the fluid and the pumping machinery is undersirable, as in atomic energy power plants for circulating liquid metals used as reactor coolants or as solvents for reactor fuels, electromagnetic pumps are used. There are no moving parts in these pumps; no shaft seals are required. The liquid metal passing through the pump becomes, in effect, the rotor circuit of an electric motor. [E.F.W.]

Pumpkin The term commonly applied to the larger, organe-colored fruit of the *Cucurbita* species, used when ripe as a table vegetable, in pies, or for autumn decoration. Although some taxonomists would restrict the term pumpkin to the species *Cucurbita* pepper and *C. moschata*, it is also used in referring to *C. mixta*. New Jersey, Illionis, and California are important producing states. *See* VIOLALES. [H.J.C.]

Puna An alpine biological community in the central portion of the Andes Mountains of South America. Sparsely vegetated, treeless stretches cover high plateau country (altiplano) and slopes of central and southern Peru, Bolivia, northern Chile, and northwestern Argentina. The poor vegetative cover and the puna animals are limited by short seasonal precipitation as well as by the low temperatures of high altitudes.

Like the paramos of the Northern Andes, punas occur above timberline, and extend upward, in modified form, to perpetual snow. Due to greater heights of the Central Andean peaks, aeolian regions, that is, regions supplied with airborne nutrients above the upper limit of vascular plants, generally the snowline, are more extensive here than above the paramos. *See* PARAMO. [H.G.B.]

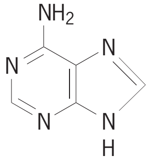
Purine A heterocyclic organic compound (**1**) containing fused pyrimidine and imidazole rings. A number of substituted purine derivatives occur in nature; some, as components of nucleic acids and coenzymes, play vital roles in the genetic and metabolic processes of all living organisms. *See* COENZYME; NUCLEIC ACID.



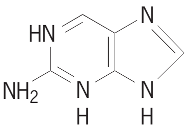
(1)

Purines are generally white solids of amphoteric character. They can form salts with both acids and bases. Conjugated double bonds in purines results in aromatic chemical properties, that confers considerable stability, and accounts for their strong ultraviolet absorption spectra. With the exception of the parent compound, most substituted purines have low solubilities in water and organic solvents.

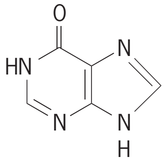
The purine bases, adenine (**2**) and guanine (**3**), together with pyrimidines, are fundamental components of all nucleic acids. Certain methylated derivatives of adenine and guanine are also present in some nucleic acids in low amounts. In biological systems, hypoxanthine (**4**), adenine, and guanine occur mainly as their 9-glycosides, the sugar being either ribose or 2-deoxyribose. Such compounds are termed nucleosides generically, and inosine (hypoxanthine nucleoside), adenosine, or guanosine specifically. The principal nucleotides contain 5′-phosphate groups, as in guanosine 5′-phosphate (GTP) and adenosine 5′-triphosphate (ATP).



(2)



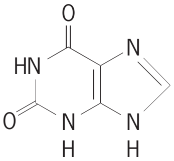
(3)



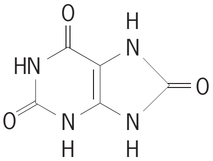
(4)

Most living organisms are capable of synthesizing purine compounds. The sequence of enzymatic reactions by which the initial purine product, inosine 5′-phosphate, is formed utilizes glycine, carbon dioxide, formic acid, and amino groups derived from glutamine and aspartic acid. Adenosine 5′-phosphate and guanosine 5′-phosphate are formed from inosine 5′-phosphate.

Metabolic degradation of purine derivatives may also occur by hydrolysis of nucleotides and nucleosides to the related free bases. Deamination of adenine and guanine produces hypoxanthine and xanthine (**5**), both of which may be oxidized to uric acid (**6**).



(5)



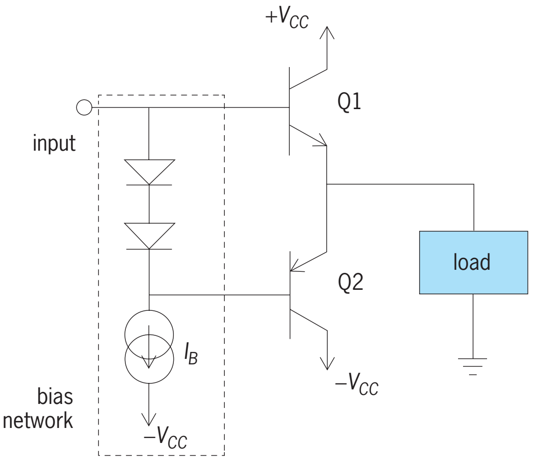
(6)

See URIC ACID.

Purine-related compounds have been investigated as potential chemotherapeutic agents. In particular, 6-mercaptopurine, in the form of its nucleoside phosphate, inhibits several enzymes required for synthesis of adenosine and guanosine nucleotides, and thus proves useful in selectively arresting the growth of tumors. The pyrazolopyrimidine has been used in gout therapy. As a purine analog, this agent serves to block the biosynthesis of inosine phosphate, as well as the oxidation of hypoxanthine and xanthine to uric acid. As a result of its use, overproduction of uric acid is prevented and the primary cause of gout is removed. *See* CHEMOTHERAPY; GOUT; PYRIMIDINE. [S.C.H.]

Push-pull amplifier An electronic circuit in which two transistors (or vacuum tubes) are used, one as a source of current and one as a sink, to amplify a signal. One device "pushes" current out into the load, while the other "pulls" current from it when necessary. A common example is the complementary-symmetry push-pull output stage widely used to drive loudspeakers (see illustration), where an *npn* transistor can source (push) current from a positive power supply into the load, or a *pnp* transistor can sink (pull) it into the negative power supply. The circuit functions as an amplifier in that the current levels at the output are larger than those at the input.

A so-called bias network in a complementary-symmetry push-pull output stage (see illustration) functions to maintain a constant voltage difference between the bases of the two transistors. It can be designed either by setting a bias current, and diode sizes or by replacing it with a different network for class B, class A, or the common compromise, class AB mode of operation.

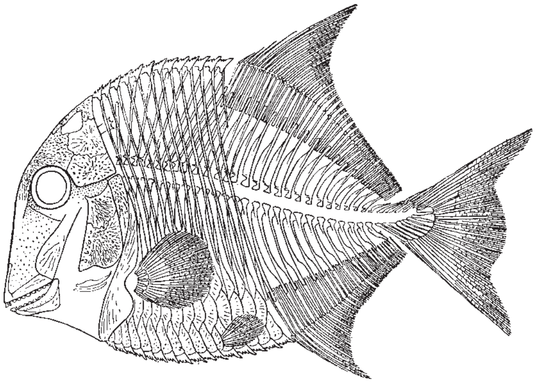


Complementary-symmetry push-pull output stage. Q1 is an *npn* transistor and Q2 is a *pnp* transistor; I_B is a bias current; positive ($+V_{CC}$) and negative ($-V_{CC}$) power supplies are shown.

In class B operation, where the bases of the transistors might simply be shorted together, only one transistor is "on" at a time and each is on average "on" for only 50% of the time; when the output current is zero, no current at all flows in the circuit. In class A operation a large voltage is maintained between the bases so that both devices stay "on" at all times, although their currents vary so that the difference flows into the load; and even when the output is zero, a large quiescent current flows from the power supplies. Class B operation is much more efficient than class A, which wastes a large amount of power when the signal is small. However, class B suffers from zero-crossing distortion as the output current passes through zero, because there is generally a delay involved as the input swings far enough to turn one transistor entirely off and then turn the other on. In class AB operation, some intermediate quiescent current is chosen to compromise between power and distortion.

Class AB amplifiers are conventionally used as loudspeaker drivers in audio systems because they are efficient enough to be able to drive the required maximum output power, often on the order of 100 W, without dissipating excessive heat, but can be biased to have acceptable distortion. Audio signals tend to be near zero most of the time, so good performance near zero output current is critical, and that is where class A amplifiers waste power and class B amplifiers suffer zero-crossing distortion. A class AB push-pull amplifier is also conventionally used as the output stage of a commercial operational amplifier. *See* AUDIO AMPLIFIER; OPERATIONAL AMPLIFIER; POWER AMPLIFIER; TRANSISTOR. [M.Sn.]

Pycnodontiformes An order of very specialized deep-bodied fishes near the holostean level of organization that are known only from the fossil record. They were a widespread group that first appeared in the Upper Triassic of Europe, flourished during the Jurassic and Cretaceous, and persisted to the Upper Eocene. Pycnodontiforms are a closely interrelated group most commonly found preserved in marine limestone and associated with coraliferous facies.



***Coelodus costue*, a pycnodont from Lower Cretaceous of Italy; length to 4 in. (10 cm). (*After A. S. Woodward*)**

They are characterized (see illustration) by a laterally compressed, disk-shaped body; long dorsal and anal fins, with each fin ray supported by its own endoskeletal element; an externally symmetrical tail; and an axial skeleton having greatly extended neural and hemal spines that are expanded in some forms, and neural and hemal arches which are well ossified—sometimes interdigitating around the notochord—but with no vertebral centra. [T.M.C.]

Pycnogonida A subphylum of marine arthropods, consisting of about 600 Recent and 3 Devonian species. The Pycnogonida, or Pantopoda, are commonly called sea spiders.

The pycnogonids are characterized by reduction of the body to a series of cylindrical trunk somites supporting the appendages, a large specialized feeding apparatus called the proboscis, gonopores opening on the second joints of the legs, and a reduced abdomen. In many genera, there are seven pairs of appendages, of which the first four, namely the chelifores, palpi, ovigers, and first walking legs, are on the first or cephalic segment. This segment also bears a dorsal tubercle containing four simple eyes. Each of the remaining three trunk segments bears a single pair of legs.

Pycnogonids are found in all seas except the inner Baltic and Caspian, from intertidal regions to depths of 21,000 ft (6500 m), and one species is bathypelagic at about 3300 ft (1000 m). They are especially common in polar seas. Most of the intertidal species spend their lives in association with coelenterates as encysted, parasitic larval and juvenile stages, or are ectoparasitic as adults, being attached to anemones and hydroids by their claws and proboscides. Most of the deep-sea species are known only as adults, and their mode of life is a mystery.

The Pycnogonida are classified primarily on the presence or absence of various anterior appendages; about 60 genera are recognized, grouped in 8 families: Nymphonidae, Callipallenidae, Phoxichilidiidae, Endeidae, Ammotheidae, Austrodecidae, Colossendeidae, and Pycnogonidae. *See* ARTHROPODA; PALAEOISOPUS. [J.W.He.]

Pygasteroida An order of Eognasthostomata which exhibits various stages in the backward migration of the anus out of the apical system. They have four genital pores, noncrenulate tubercles, and simple ambulacral plates. All members are referred to a single family, the Pygasteridae. They apparently arose from Triassic Pedinidae and occur in the Jurassic and Cretaceous of the Northern Hemisphere. They were formerly classified with other bilaterally symmetrical echinoids in the artificial assemblage Irregularia. *See* ECHINODERMATA; IRREGULARIA. [H.B.F.]

Pyrargyrite A mineral having composition Ag_3SbS_3. The mineral occurs as prismatic crystals and in massive form and in disseminated grains. The hardness is 2.5 on Mohs scale and specific gravity is 5.85. The luster is adamantine and the color a deep ruby red to black, giving it the name dark ruby silver. Pyrargyrite is an important silver ore when it is found in veins associated with proustite and other silver minerals. It has been mined as silver ore at Chanarcillo, Chile; Freiberg, Germany; Guanajuato, Mexico; and Cobalt, Ontario, Canada. *See* PROUSTITE. [C.S.Hu.]

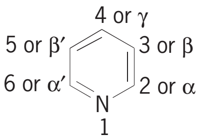
Pyrenomycetes The largest class in the phylum Ascomycota. The distinguishing feature of these fungi is the ascoma, or perithecium, that gives rise to the common name for the class, perithecial ascomycetes. Most ascomata are brown or black, but some are blue, yellow, or red. Ascomal ontogeny is ascohymenial; coiled branches form on the hyphae to initiate ascoma formation, and they are quickly enveloped by layers of hyphae to form a wall around the coil, which subsequently differentiates into ascogenous hyphae that will form the asci. The internal tissues of the ascoma vary between species. In most species, a neck with a canal forms through which the ascospores will be discharged. The asci are formed in a cluster or layer in the base of the ascoma. Most have a single rigid wall (unitunicate), and the eight ascospores are forcibly discharged through a pore in the apex of the ascus, but in some the ascus wall dissolves. The ascospores are variable in color, size, shape, and number of cells. Most pyrenomycetes also form abundant asexual conidia.

Pyrenomycetes are widespread and occur primarily on living and dead plant materials. They may cause serious disease or act as agents of decomposition, producing a well-developed mycelium that may be superficial or immersed in the host or substrate. *See* ASCOMYCOTA; EUMYCOTA; FUNGI. [R.T.Ha.]

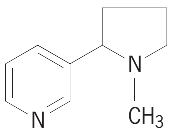
Pyrenulales An order of the class Ascolichenes, also known as the Pyrenolichenes. The flask-shaped perithecia are uniformly immersed in the medulla of the thalli with a small ostiole opening at the surface. The asci and paraphyses arise from a blackened hypothecium and line the walls of the perithecium. The spores eventually burst the ascal walls and ooze out through the ostiole in a jelly matrix.

There are about 10 families, 50 genera, and more than 1500 species in the Pyrenulales. The major taxonomic criteria for separating genera and species are the septation and color of spores, since vegetative characters are so poorly developed. [M.E.H.]

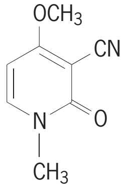
Pyridine An organic heterocyclic compound containing a triunsaturated six-membered ring of five carbon atoms and one nitrogen atom. Pyridine (**1**) and pyridine homologs are obtained by extraction of coal tar or by synthesis. The pyridine system is found in natural products, for example, in nicotine (**2**) from tobacco, in ricinine (**3**) from castor bean, in pyridoxine or vitamin B_6 (**4**), in nicotinamide or niacinamide or vitamin P (**5**), and in several groups of alkaloids. *See* Heterocyclic compounds..



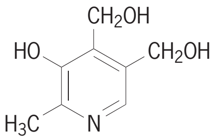
(**1**)



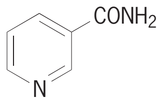
(**2**)



(**3**)



(**4**)

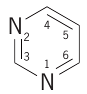


(**5**)

Pyridine (**1**) is a colorless, hygroscopic liquid with a pungent, unpleasant odor. When anhydrous it boils at 115.2–115.3°C (239.4–239.5°F). Pyridine is miscible with organic solvents as well as with water. The pyridine system is aromatic. It is stable to heat, to acid, and to alkali. Pyridine is used as a solvent for organic and inorganic compounds, as an acid binder, as a basic catalyst, and as a reaction intermediate.

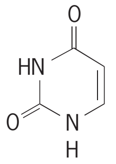
Pyridine is an irritant to skin (eczema) and other tissues (conjunctivitis), and chronic exposure has been known to cause liver and kidney damage. Repeated exposure to atmospheric levels greater than 5 parts per million is considered hazardous. [W.J.Ge.]

Pyrimidine A heterocyclic organic compound (**1**) containing nitrogen atoms at positions 1 and 3. Naturally occurring derivatives of the parent compound are of considerable biological importance as components of nucleic acids and coenzymes and, in addition, synthetic members of this group have found use as pharmaceuticals. *See* Coenzyme; Nucleic acid.

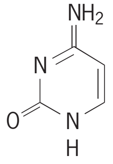


(**1**)

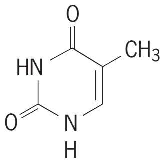
Pyrimidine compounds which are found universally in living organisms include uracil (**2**), cytosine (**3**), and thymine (**4**).



(**2**)



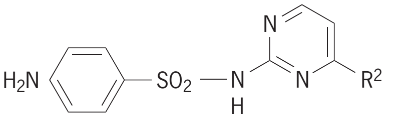
(**3**)



(**4**)

Together with purines these substances make up the “bases” of nucleic acids, uracil and cytosine being found characteristically in ribonucleic acids, with thymine replacing uracil in deoxyribonucleic acids. A number of related pyrimidines also occur in lesser amounts in certain nucleic acids. Other pyrimidines of general natural occurrence are orotic acid and thiamine (vitamin B_1). *See* Deoxyribonucleic acid (DNA); Purine; Ribonucleic acid (RNA).

Among the sulfa drugs, the pyrimidine derivatives, sulfadiazine, sulfamerazine, and sulfamethazine, have general formula (**5**). These agents are inhibitors of folic acid biosynthesis in microorganisms. The barbiturates are pyrimidine derivatives which possess potent depressant action on the central nervous system. *See* Barbiturates; Sulfonamide. [S.C.H.]



(**5**)

Pyrite A mineral having composition FeS_2. Pyrite has a Mohs hardness of 6–6.5 and a density of 5.02. The luster is metallic, the color brass yellow, and the streak greenish black or brownish black.

Pyrite, or iron pyrites, is the most common “fool’s gold,” but it is hard and brittle whereas gold is soft and sectile. Its hardness also distinguishes it from softer chalcopyrite. Marcasite was once thought to be polymorphous with pyrite, but precise analyses show that marcasite contains excess iron, whereas pyrite is stoichiometric FeS_2. *See* Marcasite.

Pyrite is the most common and most widespread sulfide mineral. It forms under almost all known conditions of mineral deposition. Under oxidizing conditions, pyrite readily alters to iron sulfates and eventually to limonite, forming gossan, the surface expression of pyrite-rich mineral deposits. *See* Limonite.

Because of its high sulfur content (53.4%), pyrite has become a source of sulfur for the production of sulfuric acid. In some places, it is mined for sulfur alone. *See* Sulfur. [L.Gr.]

Pyroclastic rocks Rocks of extrusive (volcanic) origin, composed of rock fragments produced directly by explosive eruptions. Pyroclastic fragments may represent shattered and comminuted older rocks (volcanic, plutonic, sedimentary, or metamorphic) or solidified lava droplets formed by violent explosion. *See* Tuff; Volcano. [C.A.C.]

Pyroelectricity The property of certain crystals to produce a state of electric polarity by a change of temperature. Certain dielectric (electrically nonconducting) crystals develop an electric polarization (dipole moment per unit volume) when they are subjected to a uniform temperature change. This pyroelectric effect occurs only in crystals which lack a center of symmetry and also have polar directions (that is, a polar axis). These conditions are fulfilled for 10 of the 32 crystal classes. Typical examples of pyroelectric crystals are tourmaline, lithium sulfate monohydrate, cane sugar, and ferroelectric barium titanate.

Pyroelectric crystals can be regarded as having a built-in or permanent electric polarization. When the crystal is held at constant temperature, this polarization does not manifest itself because it is compensated by free charge carriers that have reached the surface of the crystal by conduction through the crystal and from the surroundings. However, when the temperature of the crystal is raised or lowered, the permanent polarization changes, and this change manifests itself as pyroelectricity.

The magnitude of the pyroelectric effect depends upon whether the thermal expansion of the crystal is prevented by clamping or whether the crystal is mechanically unconstrained. In the clamped crystal, the primary pyroelectric effect is observed, whereas in the free crystal, a secondary pyroelectric effect is superposed upon the primary effect. The secondary effect may be regarded as the piezoelectric polarization arising from thermal expansion, and is generally much larger than the primary effect. *See* Piezoelectricity. [H.Gr.]

Pyroelectrics have a broad spectrum of potential scientific and technical applications. The most developed is the detection of infrared radiation. In addition, pyroelectric detectors can be used to measure the power generated by a radiation source (in radiometry), or the temperature of a remote hot body (in pyrometry, with corrections due to deviations from the blackbody emission). *See* Pyrometer; Radiometry.

An infrared image can be projected on a pyroelectric plate and transformed into a relief of polarization on the surface. Other potential applications of pyroelectricity include solar energy conversion, refrigeration, information storage, and solid-state science. [A.Had.]

Pyroelectricity (biology) Electrical polarity in a biological material produced by a change in temperature. Pyroelectricity is probably a basic physical property of all living organisms. First discovered in 1966 in tendon and bone, it has since been shown to exist in most animal and plant tissues and in individual cells. Pyroelectricity appears to play a fundamental part in the growth processes (morphogenesis) and in physiological functions (such as sensory perception) of organisms. *See* Pyroelectricity.

The elementary components (for example, molecules) of biological (as well as of nonbiological) pyroelectric structures have a permanent electric dipole moment, and are arranged so that all positive dipole ends point in one direction and all negative dipole ends in the opposite direction. This parallel alignment of elementary dipoles is termed spontaneous polarization because it occurs spontaneously without the action of external fields or forces. In this state of molecular order, the structure concerned has a permanent electric dipole moment on a microscopic and macroscopic level. *See* Dipole moment.

Spontaneous polarization is temperature-dependent; thus any change in temperature causes a change of the dipole moments, measurable as a change of electric charges at both ends of the polar axis. This is the pyroelectric effect. All pyroelectric structures are also piezoelectric, but the reverse is not true. *See* Ferroelectrics; Piezoelectricity.

Prerequisites for the development of spontaneous polarization and pyroelectric activity in biological structures are (1) the presence of a permanent dipole moment in the molecules or molecular aggregates and (2) a molecular shape that favors a parallel alignment as much as possible (or at least does not impede it). Both these conditions are ideally fulfilled in bar- or board-shaped molecules with a permanent dipole moment along the longitudinal molecular axis. Several important organic substances have these molecular properties, and therefore behave pyroelectrically in biological structures. Examples include the epidermis of animals and plants, sensory receptors in animals, and tissues of the nervous and skeletal systems.

Living organisms are able to detect and discriminate between different stimuli in the environment, such as rapid changes of temperature, of illumination, and of hydrostatic and uniaxial pressure. These stimuli represent different forms of energy and are transduced, or converted, into the nearly uniform type of electrical signals whose voltage-time course frequently depends on dX/dt (X = external stimulus, t = time). Such electrical signals have been recorded on cutaneous sensory receptors, on external nerve endings, on epidermal structures, and even on the cell wall of single-cell organisms. The mechanisms of detection and transduction in these biological systems, still little understood, may lie in the pyroelectric behavior of the structures. Pyroelectric (and thus piezoelectric) behavior has been proved to exist in most biological systems, which means that these systems should in principle be able to function as pyroelectric detectors and transducers. [H.A.]

Pyrolusite A mineral having composition MnO_2. Well-developed crystals (polianite) are rare; it is usually in radiating fibers or reniform coatings. The hardness is 1–2 on the Mohs scale (often soiling the fingers) and the specific gravity is 4.75. The luster is metallic and the color iron-black. It frequently forms pseudomorphs after other manganese minerals, notably manganite.

Pyrolusite is extensively mined as a manganese ore in many countries, chiefly in Russia, Ghana, India, the Republic of South Africa, Morocco, Brazil, and Cuba. *See* Manganese; Manganite. [C.S.Hu.]

Pyrolysis A chemical process in which a compound is converted to one or more products by heat. By this definition, reactions that occur by heating in the presence of a catalyst, or in the presence of air when oxidation is usually a simultaneous reaction, are excluded. The terms thermolysis or thermal reaction have been used in essentially the same sense as pyrolysis. A simple example of pyrolysis is the classic experiment in which oxygen was first prepared by heating mercuric oxide [reaction (1)].

$$HgO \xrightarrow[(570^\circ F)]{300^\circ C} Hg + {}^1\!/_2 O_2 \qquad (1)$$

Similar reactions occur with numerous other metallic oxides and salts. Thermal decomposition or calcining of limestone (calcium carbonate) is the basic step in the manufacture of lime [reaction (2)].

$$CaCo_3 \xrightarrow[(2200^\circ F)]{1200^\circ C} CaO + CO_2 \qquad (2)$$

See Lime (industry).

The term pyrolysis is most commonly associated with thermal reactions of organic compounds. Pyrolysis of material from plant and animal sources provided some of the first clues about constitution, as in the formation of isoprene from the thermal breakdown of rubber. A range of substances, including benzene, naphthalene, pyridine, and many other aromatic compounds, was obtained from coal tar, a pyrolysis product of coal. All of these pyrolysis processes lead to formation of volatile products characteristic of the source and also residues of char with high carbon content.

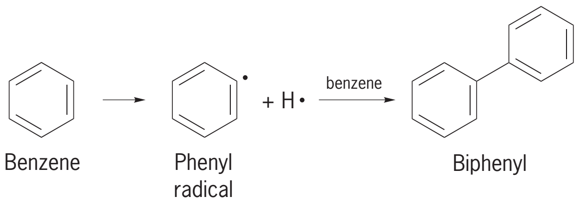
Pyrolysis reactions have been used as preparative methods and as means of generating transient intermediates that can be trapped or observed spectroscopically, or quenched by a further reaction. For preparative purposes, pyrolysis can generally be carried out by a flow process in which the reactant is vaporized with a stream of inert gas through a heated tube, sometimes at reduced pressure. In flash vacuum pyrolysis, the apparatus is placed under very low pressure, and the material to be pyrolyzed is vaporized by molecular distillation. *See* Chemical dynamics.

Types of reactions. At temperatures of 600–800°C (1100–1500°F), most organic compounds acquire sufficient vibrational energy to cause breaking of bonds with formation of free radicals. Alkanes undergo rupture of carbon-hydrogen (C-H) and carbon-carbon (C-C) bonds to two radicals that then react to give lower alkanes, alkenes, hydrogen, and also higher-molecular-weight compounds resulting from their recombination [reactions (3)].

$$CH_3CH_2CH_2CH_3 \xrightarrow[(1300^\circ F)]{700^\circ C} 2CH_3CH_2\cdot \rightarrow CH_3CH_3 + H_2C{=}CH_2 \qquad (3a)$$

$$CH_3CH_2CH_2CH_3 \xrightarrow[(1300^\circ F)]{700^\circ C} CH_3CH_2\cdot CHCH_3 + H\cdot \rightarrow CH_3CH_2HC{=}CH_2 + H_2 \qquad (3b)$$

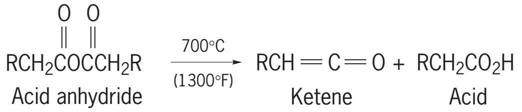
These reactions are the basis of the thermal cracking processes used in petroleum refining. Pyrolysis of simple aromatic hydrocarbons such as benzene or naphthalene produces aryl radicals, which can attack other hydrocarbon molecules to give bi- and polyaryls, as shown in reaction (4) for the formation of biphenyl.



(4)

See Cracking; Free radical.

Pyrolytic eliminations can result in formation of a multiple bond by loss of HX from a compound H—C—C—X, where X = any leaving group. A typical example is the pyrolysis of an ester, which is one of the general methods for preparing alkenes. Pyrolytic elimination is particularly useful when acid-catalyzed dehydration of the parent alcohol leads to cationic rearrangement. Another useful application of this process is the production of ketenes from acid anhydrides [reaction (5)].

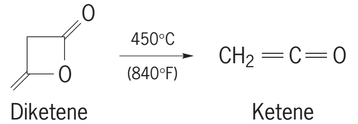


$$RCH_2\overset{O}{\overset{\|}{C}}O\overset{O}{\overset{\|}{C}}CH_2R \xrightarrow[(1300^\circ F)]{700^\circ C} RCH{=}C{=}O + RCH_2CO_2H \qquad (5)$$

See Acid anhydride; Alkene; Ester.

Another type of thermal elimination occurs by loss of a small molecule such as nitrogen (N_2), carbon monoxide (CO), carbon dioxide (CO_2), or sulfur dioxide (SO_2), leading to reactive intermediates such as arynes, diradicals, carbenes, or nitrenes. The nitrene generated from aminobenzotriazole breaks down to benzyne at 0°C (32°F). Benzyne can be trapped by addition reaction or can dimerize to biphenylene. *See* Reactive intermediates.

A number of pyrolytic reactions involve cleavage of specific C-C bonds in a carbon chain or ring. Fragmentation accompanied by transfer of hydrogen is a general reaction that occurs by a cyclic process. An example is decarboxylation of acids that contain a carbonyl group, which lose CO_2 on relatively mild heating. Acids with a double or triple carbon-to-carbon bond undergo decarboxylation at 300–400°C (570°–750°F). This type of reaction also occurs at higher temperatures with unsaturated alcohols and, by transfer of hydrogen from a C-H bond, with unsaturated ethers. Cleavage of a ring frequently occurs on pyrolysis. With alicyclic or heterocyclic four-membered rings, cleavage into two fragments is the reverse of 2 + 2 cycloaddition, as illustrated by the cracking of diketene [reaction (6)]. Pyrolysis is an important reaction in the chemistry of the pine terpenes, as in the conversion of β-pinene to myrcene. Benzocyclobutenes undergo ring opening to *o*-quinone dimethides. By combining this reaction in tandem with formation of the benzocyclobutene and a final Diels-Alder reaction, a versatile one-step synthetic method for the steroid ring system has been developed. *See* Diels-Alder reaction; Pine terpene.



(6)

Many thermal reactions involve isomerization without elimination or fragmentation. These processes can occur by way of intermediates such as diradicals, as in the pyrolysis of pinene, or they may be concerted pericyclic reactions. An example of the latter is the Claisen-Cope rearrangement of phenyl or vinyl ethers and other 1,5-diene systems. These reactions can be carried out by relatively mild heating, and they are very useful in synthesis. *See* Organic synthesis; Pericyclic reaction.

Analytical applications. Thermal breakdown of complex structures leads to very complex mixtures of products arising from concurrent dissociation, elimination, and bond fission. Separation of these mixtures provides a characteristic pyrogram that is valuable as an analytical method, particularly for polymeric materials of both biological and synthetic origin. In this application, a small sample is heated on a hot filament or by laser. The pyrolysis products are then analyzed by gas chromatography, mass spectrometry, or a combination of both techniques. *See* Gas chromatography; Mass spectrometry.

Instrumentation with appropriate interfaces and data-handling systems has been developed to permit rapid and sensitive detection of pyrolysis products for a number of applications. One example is the optimization of conditions in petroleum cracking to produce a desired product from varied crude oils. The profile of pyrolysis fragments from a polymer can also be used to detect impurities. [J.A.Mo.]

Pyrometallurgy

The branch of extractive metallurgy in which processes employing chemical reactions at elevated temperatures are used to extract metals from raw materials, such as ores and concentrates, and to treat recycled scrap metal.

For metal production, the pyrometallurgical operation commences with either a raw material obtained by mining and subsequent mineral and ore processing steps to produce a concentrate, or a recycled material such as separated materials from scrapped automobiles, machinery, or computers.

Pyrometallurgical preparation processes convert raw materials to forms suitable for future processing. Reduction processes reduce metallic oxides and compounds to metal. Oxidizing processes oxidize the feed material to an intermediate or a semifinished metal product. Refining processes remove the last of the impurities from a crude metal. *See* Electrometallurgy; Iron metallurgy; Metallurgy; Pyrometallurgy, nonferrous. [P.J.Ma.]

Pyrometallurgy, nonferrous

The branch of extractive metallurgy in which processes employing chemical reactions at elevated temperatures are used to extract and refine nonferrous metals from ores, concentrates, and recycled materials. The entire process from feed to finished metal may be pyrometallurgical, or a pyrometallurgical step may be used in conjunction with other technologies. Increasingly, a mix of processes maximizes the efficiency and advantages of an overall operation.

The processes in pyrometallurgy in general can be classified as preparatory, reduction, oxidation, and metal refining. Treatment of a given raw material or metal may involve all these steps, or some of the steps may form a part of the total processing system, which may include nonpyrometallurgical operations.

In preparatory processes, the concentrate or upgraded ore or other feed is converted by chemical reaction to a form suitable for further processing. The most common subprocesses are drying and calcination, pyrolysis and hydrolysis, roasting, sintering, and chlorination. Even though a chemical reaction does not actually take place during drying, this subprocess is included since it is often part of a subsequent high-temperature operation such as smelting. In some cases, the preparatory process is carried out to provide a material that is amenable to treatment by hydrometallurgical processing, such as the roasting of zinc concentrates to produce a zinc calcine (essentially a zinc oxide intermediate product) which is leached with sulfuric acid solution for zinc production, or it is a step such as calcination in the preparation of alumina for aluminum smelting.

Reduction processes effect the high-temperature reaction of a metal compound to the metal and its separation from the residue, as represented by the reaction below, where MX is the metal

$$MX + R \longrightarrow M + RX$$

compound, R the reacting or reducing agent, and M the metal. The reducing agent and reaction conditions (for example, temperature and pressure) and the concentration of reactants and products are selected to achieve a rapid or spontaneous reaction. These reactions usually require energy input.

The amount of reducing agent used should be low and inexpensive, relative to the value of the metal produced, while the product RX should be readily separable from the metal. Reducing agents commonly used in nonferrous pyrometallurgy include carbon (usually as coke), carbon monoxide gas (from coke), natural gas, iron and ferrosilicon (for Mg production), aluminum (for Ca production), and magnesium (for Ti, Zr, and Hf production).

For thousands of years, pyrometallurgical smelting of sulfide materials has been the key production method for nonferrous metals, in particular for copper, nickel, tin, lead, and zinc. This still remains the case on account of lower costs associated with new intensive technology and lower overall energy consumption. Formerly, it was common to roast such feed materials prior to the actual smelting operation. Roasting is still a major processing step in zinc and tin production. However, the roasting step for copper and nickel production was gradually eliminated, and during the latter part of the twentieth century continuous smelting processes were developed to directly treat sulfide concentrates, producing (by oxidation of the sulfide material) a high-grade copper matte product (~70% Cu) in a single step. In the case of lead, the metal itself can be readily produced directly. Oxidation processes are normally exothermic, a characteristic that has generally led to the development of autogenous processes, requiring virtually no fossil fuel.

Two basic types of smelting processes are used for copper or nickel production: flash smelting and bath smelting. In flash smelting, a fine concentrate feed is introduced into the furnace chamber, along with oxygen-enriched air, and the reaction principally occurs in a gas-phase system between the oxygen-bearing gas and solid particles. In bath smelting, a concentrate feed is introduced into the furnace melt, which is blown and kept highly agitated by submerged tuyeres (injecting the oxygen-enriched air), such that the feed is enveloped and reacts within the turbulent bath.

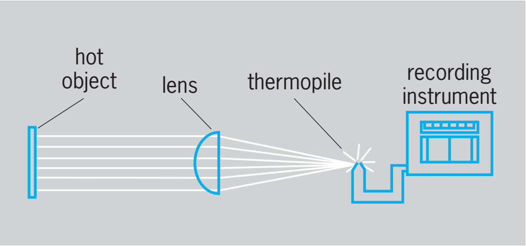
The new continuous lead smelting process can produce lead directly, while on account of the thermodynamics of the copper smelting system with the immiscible $Cu\text{-}Cu_2S$ phases being present, copper production is normally carried out in two stages: (1) copper concentrate smelting to produce a high-grade matte (typically 60–75% Cu, 4–12% Fe, ~21% S), a slag (approximately 27–30% FeO, 15–20% Fe_3O_4, 25–30% SiO_2, 1–5% Cu), and a sulfur dioxide-rich gas (9–15% SO_2 at acid plant); and (2) copper matte converting, wherein the matte is oxidized or converted to metallic copper, producing a small amount of slag and sulfur dioxide gas.

A significant amount of copper is produced from recycled materials (such as from used automobiles, motors, old electrical appliances), and the pyrometallurgical processes are well able to handle this feed load on account of the flexibility as to feed type.

In metal refining processes, the starting material is generally an impure metal, usually produced in a primary production process. Impurities are removed to yield a final metal product, meeting a product specification. The processes are classified as (1) volatilization (separation of metal or metal compound as a gas from a liquid or solid); (2) drossing and precipitation (separation of the metal or impurities as a solid from the liquid melt); and (3) slag refining (separation of metal or impurities by their extraction from one liquid into a second immiscible liquid phase). [P.J.Ma.]

Pyrometer A temperature-measuring device, originally an instrument that measures temperatures beyond the range of thermometers, but now in addition a device that measures thermal radiation in any temperature range. This article discusses radiation pyrometers; for other temperature-measuring devices *See* BOLOMETER; THERMISTOR; THERMOCOUPLE.

The illustration shows a very simple type of radiation pyrometer. Part of the thermal radiation emitted by a hot object is intercepted by a lens and focused onto a thermopile. The resultant heating of the thermopile causes it to generate an electrical signal (proportional to the thermal radiation) which can be displayed on a recorder.



Elementary radiation pyrometer. (***After D. M. Considine and S. D. Ross, Process Instruments and Controls Handbook, 2d ed., McGraw-Hill, 1974***)

Unfortunately, the thermal radiation emitted by the object depends not only on its temperature but also on its surface characteristics. The radiation existing inside hot, opaque objects is so-called blackbody radiation, which is a unique function of temperature and wavelength and is the same for all opaque materials. However, such radiation, when it attempts to escape from the object, is partly reflected at the surface. In order to use the output of the pyrometer as a measure of target temperature, the effect of the surface characteristics must be eliminated. A cavity can be formed in an opaque material and the pyrometer sighted on a small opening extending from the cavity to the surface. The opening has no surface reflection, since the surface has been eliminated. Such a source is called a blackbody source, and is said to have an emittance of 1.00. By attaching thermocouples to the black-body source, a curve of pyrometer output voltage versus blackbody temperature can be constructed. *See* BLACKBODY; HEAT RADIATION.

Pyrometers can be classified generally into types requiring that the field of view be filled, such as narrow-band and total-radiation pyrometers; and types not requiring that the field of view be filled, such as optical and ratio pyrometers. The latter depend upon making some sort of comparison between two or more signals.

The optical pyrometer should more strictly be called the disappearing-filament pyrometer. In operation, an image of the target is focused in the plane of a wire that can be heated electrically. A rheostat is used to adjust the current through the wire until the wire blends into the image of the target (equal brightness condition), and the temperature is then read from a calibrated dial on the rheostat.

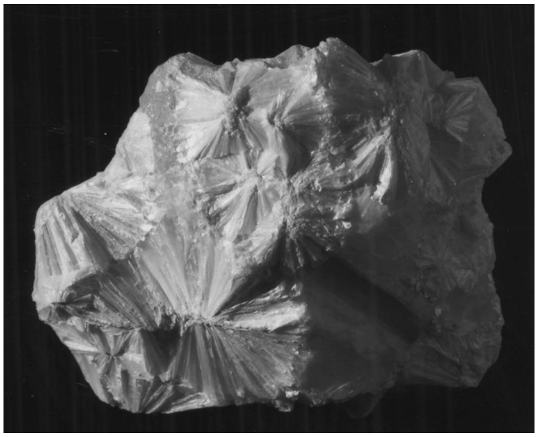
The ratio, or "two-color," pyrometer makes measurements in two wavelength regions and electronically takes the ratio of these measurements. If the emittance is the same for both wavelengths, the emittance cancels out of the result, and the true temperature of the target is obtained. This so-called gray-body assumption is sufficiently valid in some cases so that the "color temperature" measured by a ratio pyrometer is close to the true temperature. *See* TEMPERATURE MEASUREMENT; THERMOMETER. [T.P.M.]

Pyromorphite A mineral series in the apatite group, or in the larger grouping of phosphate, arsenate, and vanadate-type minerals. In this series lead (Pb) substitutes for calcium (Ca) of the apatite formula $Ca_5(PO_4)_3(F,OH,Cl)$, and little fluorine (F) or hydroxide (OH) is present. *See* APATITE.

The pyromorphite series crystallizes in the hexagonal system. Crystals are prismatic. Other forms are granular, globular, and botryoidal. Pyromorphite colors range through green, yellow, and brown; vanadinite occurs in shades of yellow, brown, and red.

Pyromorphites are widely distributed as secondary minerals in oxidized lead deposits. Pyromorphite is a minor ore of lead; vanadinite is a source of vanadium and minor ore of lead. *See* LEAD; VANADIUM. [W.R.Lo.]

Pyrophyllite A hydrated aluminum silicate with composition $Al_2Si_4O_{10}(OH)_2$. The mineral is commonly white, grayish, greenish, or brownish, with a pearly to waxy appearance and greasy feel. It occurs as compact masses, as radiating aggregates (see illustration), and as foliated masses. Pyrophyllite belongs to the layer silicate (phyllosilicate) group of minerals. The mineral is soft (hardness $1–1^1/_2$ on the Mohs scale) and has easy cleavage parallel to the structural layers. The mineral is highly stable to acids.



Specimen of pyrophyllite. (*Pennsylvania State University*)

Pyrophyllite is used principally for refractory materials and in other ceramic applications. The main sources for pyrophyllite in the United States are in North Carolina. An unusual form from the Transvaal is called African wonderstone. *See* SILICATE MINERALS. [G.W.Br.]

Pyrotechnics Mixtures of substances that produce noise, light, heat, smoke, or motion when ignited. They are used in matches, incendiaries, and other igniters; in fireworks and flares; in fuses and other initiators for primary explosives; in delay trains; for powering mechanical devices; and for dispersing materials such as insecticides.

Black powder, an intimate mixture of potassium nitrate, charcoal, and sulfur, was perhaps the earliest pyrotechnic and remains the most important one. It was discovered prior to A.D. 1000 in China during the Sung dynasty, where it was used in rockets and fireworks. Its introduction to Europe prior to 1242 eventually revolutionized warfare. Its use in blasting rock was also revolutionary, enabling rapid fragmentation of ore and other rock with a great reduction in manual labor.

A pyrotechnic mixture contains a fuel and an oxidizer, usually another ingredient to give a special effect, and often a binder. The oxidizer is usually a nitrate, perchlorate, chlorate, or peroxide of potassium, barium, or strontium. Fuels may be sulfur, charcoal, boron, magnesium, aluminum, titanium, or antimony sulfide. Examples of binders that are also fuels are dextrin and natural polysaccharides such as red gum. Salts of strontium, calcium, barium, copper, and sodium and powdered magnesium metal when combined with a fuel and oxidizer can give the special effects of scarlet, brick red, green, blue-green, yellow, and white flames, respectively.

Many pyrotechnic mixtures are easily ignited by impact, friction, flame, sparks, or static electricity. Even those that burn quietly in small quantities can explode violently when ignited under confinement or in larger quantities. [D.L.C.]

Pyrotheria An extinct order of primitive, mastodonlike, herbivorous, hoofed mammals restricted to the Eocene and Oligocene deposits of South America. There is only one family (Pyrotheriidae) in the order and four genera in the family.

The characters of this group superficially resembling those in early proboscideans are nasal openings over orbits indicating the presence of a trunk, strong neck musculature, and six upper and four lower bilophodont cheek teeth. Pyrotheres are distantly related to the members of the superorder Paenungulata, including Proboscidea, Xenungulata, and others. *See* PROBOSCIDEA; XENUNGULATA. [G.T.J.]

Pyroxene A large, geologically significant group of dark, rock-forming silicate minerals. Pyroxene is found in abundance in a wide variety of igneous and metamorphic rocks. Because of their structural complexity and their diversity of chemical composition and geologic occurrence, these minerals have been intensively studied by using a wide variety of modern analytical techniques. Knowledge of pyroxene compositions, crystal structures, phase relations, and detailed microstructures provides important information about the origin and thermal history of rocks in which they occur.

The general chemical formula for pyroxenes is $M2M1T_2O_6$, where T represents the tetrahedrally coordinated sites, occupied primarily by silicon cations (Si^{4+}). Names of specific end-member pyroxenes are assigned based on composition and structure type. Those pyroxenes containing primarily calcium (Ca^{2+}) or sodium (Na^+) cations in the M2 site are monoclinic. Pyroxenes containing primarily Mg^{2+} or iron(II) (Fe^{2+}) cations in the M2 site are orthorhombic at low temperatures, but they may transform to monoclinic at higher temperature. *See* CRYSTAL STRUCTURE; CRYSTALLOGRAPHY.

Common pyroxenes have specific gravity ranging from about 3.2 (enstatite, diopside) to 4.0 (ferrosilite). Hardnesses on the Mohs scale range from 5 to 6. Iron-free pyroxenes may be colorless (enstatite, diopside, jadeite); as iron content increases, colors range from light green or yellow through dark green or greenish brown, to brown, greenish black, or black (orthopyroxene, pigeonite, augite, hedenbergite, aegirine). Spodumene may be colorless, yellowish emerald green (hiddenite), or lilac pink (kunzite). *See* HARDNESS SCALES; SPODUMENE.

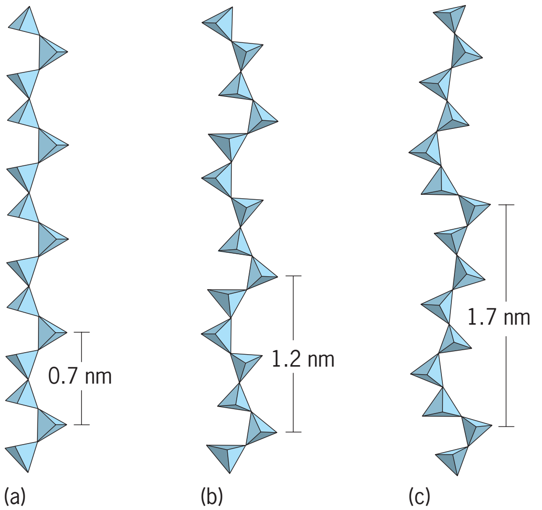
Pyroxenes in the rock-forming quadrilateral are essential constituents of ferromagnesian igneous rocks such as gabbros and their extrusive equivalents, basalts, as well as most peridotites. Pyroxenes may also be present as the dark constituents of more silicic diorites and andesites. *See* ANDESITE; BASALT; DIORITE; GABBRO; IGNEOUS ROCKS; PERIDOTITE.

Pyroxenes, especially those of the diopside-hedenbergite series, are found in medium- to high-grade metamorphic rocks of the amphibolite and granulite facies. *See* METAMORPHISM.

The peridotites found in the Earth's upper mantle contain Mg-rich, Ca-poor pyroxenes, in addition to olivine and other minor minerals. At successively greater depths in the mantle, these Mg-rich pyroxenes will transform sequentially to spinel (Mg_2SiO_4) plus stishovite (SiO_2), an ilmenite structure, or a garnet structure, depending on temperature; and finally at depths of around 360–420 mi (600–700 km) to an $MgSiO_3$ perovskite structure. *See* ASTHENOSPHERE; EARTH INTERIOR; GARNET; ILMENITE; OLIVINE; PEROVSKITE; SILICATE MINERALS; SPINEL; STISHOVITE. [C.W.Bu.]

Pyroxenite A heavy, dark-colored, phaneritic (visibly crystalline) igneous rock composed largely of pyroxene with smaller amounts of olivine or hornblende. Pyroxenite composed largely of orthopyroxene occurs with anorthosite and peridotite in large, banded gabbro bodies. Some of these pyroxenite masses are rich sources of chromium. Certain pyroxenites composed largely of clinopyroxene are also of magmatic origin, but many probably represent products of reaction between magma and limestone. Other pyroxene-rich rocks have formed through the processes of metamorphism and metasomatism. *See* Gabbro; Igneous rocks; Peridotite; Pyroxene. [C.A.C.]

Pyroxenoid A group of silicate minerals whose physical properties resemble those of pyroxenes. In contrast with the two-tetrahedra periodicity of pyroxene single silicate chains, the pyroxenoid crystal structures contain single chains of $(SiO_4)^{4-}$ silicate tetrahedra having repeat periodicities ranging from three to nine (see illustration). The tetrahedron is a widely used geometric representation for the basic building block of most silicate minerals, in which all silicon cations (Si^{4+}) are bonded to four oxygen anions arranged as if they were at the corners of a tetrahedron. In pyroxenoids, as in other single-chain silicates, two of the four oxygen anions in each tetrahedron are shared between two Si^{4+} cations to form the single chains, and the other two oxygen anions of each tetrahedron are bonded to divalent cations, such as calcium (Ca^{2+}), iron (Fe^{2+}), or manganese (Mn^{2+}). These divalent cations bond to six (or sometimes seven or eight) oxygen anions, forming octahedral (or irregular seven- or eight-cornered) coordination polyhedra. *See* Pyroxene; Silicate minerals.



Tetrahedral silicate chains in three pyroxenoid structures: (*a*) wollastonite with three-tetrahedra periodicity, (*b*) rhodonite with five-tetrahedra periodicity, and (*c*) pyroxmangite-pyrox ferroite with seven-tetrahedra periodicity.

The pyroxenoid structures have composite structural units consisting of strips of octahedra (or larger polyhedra) two or more units wide formed by sharing of polyhedral edges, to which the silicate tetrahedral chains are attached on both top and bottom. The repeat periodicity of the octahedral strips is the same as that of the silicate chains to which they are attached. These composite units are cross-linked to form the three-dimensional crystal structures. The pyroxenoid minerals are triclinic, with either $C\bar{1}$ or $I\bar{1}$ space-group symmetry depending on the stacking of the composite units, and *c*-axis lengths ranging from about 0.71 nanometer for three-repeat silicate tetrahedral chains to about 2.3 nm for nine-repeat chains. *See* Crystal structure.

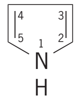
There are two series of pyroxenoid minerals, one anhydrous and one hydrous. The anhydrous pyroxenoids are significantly more abundant. A general formula for anhydrous pyroxenoids is $(Ca, Mn, Fe^{2+})SiO_3$. Silicate-chain repeat length is inversely proportional to mean divalent cation size. The hydrogen in hydrous pyroxenoids is hydrogen-bonded between two oxygen atoms; additional hydrogen in santaclaraite is bound as hydroxyl (OH) and as a water molecule (H_2O). [C.W.Bu.]

Pyrrhotite A mineral with composition $Fe_{1-x}S$ ($x = 0$ to 0.2). Eskebornite, $Fe_{1-x}Se$, is the selenium analog. The iron-deficient pyrrhotites are ferrimagnetic at room temperature, but at some higher temperature they become paramagnetic, presumably because of vacancy disorder.

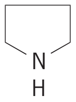
The mineral occurs as rounded grains to large masses, more rarely as tabular pseudohexagonal crystals and rosettes. Color is brownish bronze-yellow with dark grayish-black streaks. Hardness is 4 on Mohs scale and specific gravity 4.6 (for the composition Fe_7S_8).

Pyrrhotite occurs in basic igneous rocks as a late-stage fractional differentiate, particularly in norites and gabbros, and sufficient quantities may constitute an ore of iron. Pyrrhotite also occurs with magnetite and chondrodite in contact metamorphic marbles, and in low-temperature veins with calcite and other sulfides and sulfosalts. [P.B.M.]

Pyrrole One of a group of organic compounds containing a doubly unsaturated five-membered ring in which nitrogen occupies one of the ring positions. Pyrrole (**1**) is a representative compound. The pyrrole system is found in the green leaf pigment, chlorophyll, in the red blood pigment, hemoglobin, and in the blue dye, indigo. Interest in these colored bodies has been largely responsible for the intensive study of pyrroles. Tetrahydropyrrole, or pyrrolidine (**2**), is part of the structures of two protein amino acids, proline and hydroxyproline. *See* Heterocyclic compounds; Indole; Porphyrin.



(1)



(2)

Pyrrole is a liquid that darkens and resinifies on standing in air, and that polymerizes quickly when treated with mineral acid. Familiar substitution processes, such as halogenation, nitration, sulfonation, and acylation, can be realized. Pyrrole, by virtue of its heterocyclic nitrogen, is very weakly basic. The hydrogen at the 1 position is removable as a proton, and accordingly, pyrrole is also an acid, although a weak one.

Pyrrolidine can be prepared by catalytic hydrogenation of pyrrole or by ring-closure reactions. Another derivative of pyrrole, 2-ketopyrrolidine, or pyrrolidone, is of considerable interest in connection with the preparation of polyvinylpyrrolidone. Pyrrolidone is combined with acetylene to form vinylpyrrolidone; polymerization of this material furnishes polyvinylpyrrolidone, which is suitable for maintaining osmotic pressure in blood and so acting as an extender for plasma or whole blood. *See* Pyridine. [W.J.Ge.]

Pythagorean theorem This theorem states that in any right triangle the square on the hypotenuse is equal to the sum of the squares on the other two sides: $r^2 = x^2 + y^2$. More than 100 different proofs have been given for this extremely important theorem of euclidean plane geometry.

The three-dimensional Pythagorean theorem may be phrased "the square of the diagonal of a rectangular box is equal to the sum of the squares of three adjacent edges that meet at a vertex: $r^2 = x^2 + y^2 + z^2$." [J.S.F.]

Q

Q (electricity) Often called the quality factor of a circuit, Q is defined in various ways, depending upon the particular application. In the simple RL and RC series circuits, Q is the ratio of reactance to resistance, as in Eqs. (1), where X_L is the inductive

$$Q = \frac{X_L}{R} \quad Q = \frac{X_C}{R} \quad \text{(a numerical value)} \tag{1}$$

reactance, X_C is the capacitive reactance, and R is the resistance. An important application lies in the dissipation factor or loss angle when the constants of a coil or capacitor are measured by means of the alternating-current bridge.

Q has greater practical significance with respect to the resonant circuit, and a basic definition is given by Eq. (2), where

$$Q_0 = 2\pi \frac{\text{max stored energy per cycle}}{\text{energy lost per cycle}} \tag{2}$$

Q_0 means evaluation at resonance. For certain circuits, such as cavity resonators, this is the only meaning Q can have.

For the RLC series resonant circuit with resonant frequency f_0, Eq. (3) holds, where R is the total circuit resistance, L is the

$$Q_0 = \frac{2\pi f_0 L}{R} = \frac{1}{2\pi f_0 C R} \tag{3}$$

inductance, and C is the capacitance. Q_0 is the Q of the coil if it contains practically the total resistance R. The greater the value of Q_0, the sharper will be the resonance peak.

The practical case of a coil of high Q_0 in parallel with a capacitor also leads to $Q_0 = 2\pi f_0 L/R$. R is the total series resistance of the loop, although the capacitor branch usually has negligible resistance.

In terms of the resonance curve, Eq. (4) holds, where f_0 is

$$Q_0 = \frac{f_0}{f_2 - f_1} \tag{4}$$

the frequency at resonance, and f_1 and f_2 are the frequencies at the half-power points. *See* Resonance (alternating-current circuits). [B.L.R.]

Q meter A direct-reading instrument widely used for measuring the Q of an electric circuit at radio frequencies. Originally designed to measure the Q of coils, the Q meter has been developed into a flexible, general-purpose instrument for determining many other quantities such as (1) the distributed capacity, effective inductance, and self-resonant frequency of coils; (2) the capacitance, Q or power factor, and self-resonant frequency of capacitors; (3) the effective resistance, inductance or capacitance, and the Q of resistors; (4) characteristics of intermediate- and radio-frequency transformers; and (5) the dielectric constant, dissipation factor, and power factor of insulating materials. *See* Electrical measurements; Q (electricity). [I.F.K./E.C.St.]

Quadrature The condition in which the phase angle between two alternating quantities is 90°, corresponding to one-quarter of an electrical cycle. The electric and magnetic fields of electromagnetic radiation are in space quadrature, which means that they are at right angles in space. *See* Electromagnetic radiation.

The current and voltage of a perfect coil are in quadrature because the coil current lags behind the coil voltage by exactly 90°. The current and voltage of a perfect capacitor are also in quadrature, but here the current leads the voltage by 90°. In these last two cases the current and voltage are in time quadrature. [J. Mar.]

Quadric surface A surface defined analytically by an equation of the second degree in three variables. If these variables are x, y, z, such an equation has the form:

$$\begin{aligned} &ax^2 + by^2 + cz^2 + 2exy + 2fxz \\ &\qquad + 2gyz + 2px + 2qy + 2rz + d = 0 \end{aligned}$$

Every plane section of such a surface is a conic. *See* Cylinder; Ellipsoid and spheroid; Hyperboloid; Paraboloid; Surface and solid of revolution. [J.S.F.]

Qualitative chemical analysis The branch of chemistry concerned with identifying the elements and compounds present in a sample of matter. Inorganic qualitative analysis traditionally used classical "wet" methods to detect elements or groups of chemically similar elements, but instrumental methods have largely superseded the test-tube methods. Methods for the detection of organic compounds or classes of compounds have become increasingly available and important in organic, forensic, and clinical chemistry. Once it is known which elements and compounds are present, the role of quantitative analysis is to determine the composition of the sample. *See* Analytical chemistry; Quantitative chemical analysis.

Inorganic analysis. The operating principles of all systematic inorganic qualitative analysis schemes for the elements are similar: separation into groups by reagents producing a phase change; isolation of individual elements within a group by selective reactions; and confirmation of the presence of individual elements by specific tests.

Through usage and tradition, descriptive terms for sample sizes have been:

macro	0.1 gram or more
semimicro	0.01 to 0.1 gram
micro	1milligram (1 mg or 10^{-3} g)
ultramicro	1 microgram (1 μg or 10^{-6} g)
submicrogram	less than 1 microgram

For defining the smallest amount of a substance that can be detected by a given method, the term "limit of identification" is used. Under favorable conditions, an extremely sensitive method can detect as little as 10^{-15} g.

Spot tests are selective or specific single qualitative chemical tests carried out on a spot plate (a glass or porcelain plate with small depressions in which drop-size reactions can be carried out), on paper, or on a microscope slide. On paper or specially prepared adsorbent surfaces, spot tests become one- or two-dimensional through the use of solvent migration and differential adsorption (thin-layer chromatography). Containing selected indicator dyes, pH indicator paper strips are widely used for pH estimation. Solid reagent monitoring devices and indicator tubes are used for the detection and estimation of pollutant gases in air. *See* CHROMATOGRAPHY; PH.

By use of the microscope, crystal size and habit can be used for qualitative identification. With the addition of polarized light, chemical microscopy becomes a versatile method. *See* CHEMICAL MICROSCOPY.

Any instrumental method of quantitative analysis can be adapted to qualitative analysis. Some, such as electrochemical methods, are not often used in qualitative analysis (an exception would be the ubiquitous pH meter). Others, such as column chromatography (gas and liquid) and mass spectrometry, are costly and uncomplicated but capable of providing unique results. Emission spectroscopy is important in establishing the presence or absence of a suspected element in forensic analysis. The simple qualitative flame test developed into flame photometry and subsequently into atomic absorption spectrometry, *See* ATOMIC SPECTROMETRY; FLAME PHOTOMETRY; SPECTROCHEMICAL ANALYSIS.

Bombardment of surfaces by x-rays, electrons, and positive ions has given rise to a number of methods useful in analytical chemistry. X-ray diffraction is used to determine crystal structure and to identify crystalline substances by means of their diffraction patterns. X-ray fluorescence analysis employs x-rays to excite emission of characteristic x-rays by elements. The electron microprobe uses electron bombardment in a similar manner to excite x-ray emission. *See* SECONDARY ION MASS SPECTROMETRY (SIMS); X-RAY DIFFRACTION; X-RAY FLUORESCENCE ANALYSIS.

Neutron activation analysis, wherein neutron bombardment induces radioactivity in isotopes of elements not naturally radioactive, involves measurement of the characteristic gamma radiation and modes of decay produced in the target atoms. *See* ACTIVATION ANALYSIS. [J.L.L.]

Organic analysis. Qualitative analysis of an organic compound is the process by which the characterization of its class and structure is determined. Due to the numerous classes of organic compounds and the complexity of their molecular structures, a systematic analytical procedure is often required.

A typical procedure entails an initial assignment of compound classification, followed by a complete identification of the molecular structure.

The initial step is an examination of the physical characteristics. Color, odor, and physical state can be valuable clues. The physical constants of an unknown compound provide pertinent data for the analyst. Constants such as melting point, boiling point, specific gravity, and refractive index are commonly measured.

The preliminary chemical tests which are applied are elemental analysis procedures. The elements generally associated with carbon, hydrogen, and oxygen are sulfur, nitrogen, and the halogens. The analyst is usually interested in the latter group. These elements are converted to water-soluble ionic compounds via sodium fusion. The resulting products are then detected with wet chemical tests. The solubility of a compound in various liquids provides information concerning the molecular weight and functional groups present in the compound. In order to indicate the presence or absence of a functional group, specific classification reactions are tested. The reactions are simple, are rapid, and require a small quantity of sample. No single test is conclusive evidence. A judicious choice of reactions can confirm or negate the presence of a functional group.

Instrumental methods are commonly applied for functional group determination and structure identification. Absorption spectroscopy and infrared absorption spectroscopy are among the most important techniques. Whenever a molecule is exposed to electromagnetic radiation, certain wavelengths cause vibrational, rotational, or electronic effects within the molecule. The radiation required to cause these effects is absorbed. The nature and configuration of the atoms determine which specific wavelengths are absorbed. Raman spectroscopy is slightly different from the other spectroscopic techniques. A sample is irradiated by a monochromatic source. Depending upon the vibrational and rotational energies of the functional groups in the sample, light is scattered from the sample in a way which is characteristic of the functional groups. Instrumental techniques are also valuable for structure identification. In addition to infrared spectroscopy, nuclear magnetic resonance and mass spectrometry are widely used. Other, less common techniques are electron spin resonance, x-ray diffraction, and nuclear quadrupole spectroscopy. *See* INFRARED SPECTROSCOPY; MASS SPECTROMETRY; NUCLEAR MAGNETIC RESONANCE (NMR); RAMAN EFFECT.

In addition to chemical structure, the physical structure of a sample can be important. Thermal analysis is a useful procedure for examining structural characteristics. Among the most popular methods are thermogravimetry, differential thermal analysis, differential scanning calorimetry, and thermal mechanical analysis. *See* CALORIMETRY.

Although the implementation of instrumental methods has greatly simplified qualitative analytical procedures, no individual instrument is capable of complete identification for all samples. A complement of instrumental and wet chemical techniques is generally required for adequate proof of identification. *See* SPECTROSCOPY. [S.S.; K.Lo.]

Quality control The operational techniques and the activities that sustain the quality of a product or service in order to satisfy given requirements. Quality control is a major component of total quality management and is applicable to all phases of the product life cycle: design, development, manufacturing, delivery and installation, and operation and maintenance.

The quality-control cycle consists of four steps: quality planning, data collection, data analysis, and implementation. Quality planning consists of defining measurable quality objectives. Quality objectives are specific to the product or service and to the phase in their life cycle, and they should reflect the customer's requirements.

The collection of data about product characteristics that are relevant to the quality objectives is a key element of quality control. These data include quantitative measurements (measurement by variables), as well as determination of compliance with given standards, specifications, and required product features (measurement by attributes). Measurements may be objective, that is, of physical characteristics, which are often used in the control of the quality of services. Since quality control was originally developed for mass manufacturing, which relied on division of labor, measurements were often done by a separate department. However, in the culture of Total Quality Management, inspection is often done by the same individual or team producing the item.

The data are analyzed in order to identify situations that may have an adverse effect on quality and may require corrective or preventive action. The implementation of those actions as indicated by the analysis of the data is undertaken, including modifications of the product design or the production process, to achieve continuous and sustainable improvement in the product and in customer satisfaction.

The methods and techniques for data analysis in quality control are generic and can be applied to a variety of situations. The techniques are divided into three main categories: diagnostic techniques; process control, which includes process capability assessment and control charts; and acceptance sampling.

Diagnostic techniques serve to identify and pinpoint problems or potential problems that affect the quality of processes and products, and include the use of flowcharts, cause-and-effect diagrams, histograms, Pareto diagrams, location diagrams, scatter plots, and boxplots.

Process-control methods are applicable to systems that produce a stream of product units, either goods or services. They serve to control the processes that affect those product characteristics that are relevant to quality as defined in the quality objectives. For example, in a system that produces metal parts, some of the processes that might need to be controlled are cutting, machining, deburring, bending, and coating. The relevant product characteristics are typically spelled out in the specifications in terms of physical dimensions, position of features, surface smoothness, material hardness, paint thickness, and so on. In a system that produces a service, such as a telephone help line, the relevant processes could be answering the call, identifying the problem, and solving the problem. The characteristics that are relevant to quality as perceived by the customer might include response time, number of referrals, frequency of repeat calls for the same problem, and elapsed time to closure.

Process control focuses on keeping the process operating at a level that can meet quality objectives, while accounting for random variations over which there is no control. There are two main aspects to process control: control charts and capability analysis. Control charts are designed to ascertain the statistical stability of the process and to detect changes in its level or variability that are due to assignable causes and can be corrected. Capability analysis considers the ability of the process to meet quality objectives as implied by the product specifications.

Process-control techniques were originally developed for manufactured goods, but they can be applied to a variety of situations as long as the statistical distribution of the characteristics of interest can be approximated by the normal distribution. In other cases, the principles still apply, but the formula may need to be modified to reflect the specific mathematical expression of the probability distribution functions. *See* PROCESS CONTROL.

Acceptance sampling refers to the procedures used to decide whether or not to accept product lots or batches based on the results of the inspection of samples drawn from the lots. Acceptance sampling techniques were originally developed for use by customers of manufactured products while inspecting lots delivered by their suppliers. These techniques are particularly well suited to situations where a decision on the quality level of product lots and their subsequent disposition needs to be made but it is not economic or feasible to inspect the entire production output. [T.Ra.]

Quantitative chemical analysis

The determination of the amount of an element on compound in a sample. Selection of a technique is based in part on the size of sample available, the quantity of analyte expected to be in the sample, the precision and accuracy of the technique, and the speed of analysis required. All techniques require calibration with respect to some standard of known composition. Caution is necessary to prevent other substances from giving signals falsely attributable to the sought-for substance, called the analyte. *See* CALIBRATION.

Direct measurement of a signal related to concentration or activity of the chemical species of interest is the most intuitive approach. Generally, a linear relationship between signal (or its logarithm) and concentration (or its logarithm) is sought. The relationship between signal and concentration is called a working curve. The slope of the line describing the relationship is known as sensitivity. The smallest quantity which is measurably different from the absence of analyte is the detection limit. Although a linear working curve is the simplest form to use, nonlinear curves may still be employed (either graphically or with the use of computers).

Titration is the process by which an unknown quantity of analyte (generally in solution) is determined by adding to it a standard reagent with which it reacts in a definite and known proportion. A chemical or instrumental means is provided to indicate when the standard reagent has consumed exactly the amount of analyte initially present. Each determination is performed with a reagent whose concentration is directly traceable to a primary standard, so that accuracy is frequently superior to that of other methods. *See* STOICHIOMETRY; TITRATION.

The sensitivity of a method is related to the method and analyte of interest, as well as to the presence of other species in the sample. The materials other than the analyte constitute a sample matrix. For example, seawater is a matrix quite different from distilled water because of the large amount of dissolved electrolyte present. If a signal can be derived from the analyte which is proportional to the amount of the analyte, but the sensitivity of the signal to concentration varies as a function of the sample matrix, the method of standard additions may be useful. The signal from the analyte is measured, after which small, known quantities of analyte are successively added to the sample, and the signal remeasured. The sensitivity of the method can thus be obtained, and the initial, preaddition signal interpreted to give the amount of analyte (C_1) initially present by using the relationship shown in the equation below, where S_1 is the initial

$$C_1 = \frac{\Delta C}{\Delta S} \cdot S_1$$

signal, C_1 the initial quantity of analyte, ΔC the standard addition of analyte, and ΔS the change in the signal caused by the addition. The sensitivity is $\Delta C/\Delta S$.

This approach is applicable only in the absence of reagent blanks, that is, signals caused by the presence of analyte in the reagent used for the determination.

In many methods, aliquots of samples are introduced into the measurement instrument. The signal from the analyte may vary with sample uptake rate or volume. To compensate for such effects, an internal standard, or species other than the analyte, may be added to the analyte in a known concentration prior to determination. The signal due to the internal standard is measured simultaneously with the analyte signal. Variation of the signal of the internal standard is interpreted to indicate the variation in sample uptake, which should be the same for both analyte and internal standard. The ratio of analyte signal to internal standard signal is independent of sample uptake. Thus the ratio of analyte to internal standard signal is used to establish the working curve, rather than using analyte signal alone.

If the relationship between signal and analyte concentration is nonlinear, quantitation may require the use of null comparison. A signal is observed from the analyte and from a standard whose concentration can be adjusted in a known way. When the signal from the adjustable standard equals the signal from the analyte, the two have identical concentrations. This condition is called a null, as there is no detectable difference between the sample and reference signals.

It is good laboratory practice to check every quantitative measurement for the influence of species other than the one being sought. For example, a glass electrode designed to sense hydrogen ion will also respond to high concentrations of sodium ion. The degree to which a given sensor responds to one species in preference to another is called the selectivity coefficient. If a general detector is desired, this coefficient ideally should be 1.0. If a species-specific detector is desired, the coefficient should be infinite. A signal of unknown or general origin which appears to underlie the analyte signal is known as background. This quantity, together with that for the reagent blank, may be subtracted from the raw signal and thus be compensated. However, variations in their level may prevent reliable compensation, particularly when small quantities of analyte are to be determined.

For further information on common quantitative techniques *see* ACTIVATION ANALYSIS; CALORIMETRY; CHEMICAL MICROSCOPY; CHROMATOGRAPHY; COMBUSTION; ELECTRON SPECTROSCOPY; ELECTROPHORESIS; GAS CHROMATOGRAPHY; GEL PERMEATION CHROMATOGRAPHY; IMMUNOASSAY; IMMUNOELECTROPHORESIS; ION EXCHANGE; ISOTOPE DILUTION TECHNIQUES; KINETIC METHODS OF ANALYSIS; MASS SPECTROMETRY; NUCLEAR MAGNETIC RESONANCE (NMR); POLARIMETRIC ANALYSIS; SPECTROSCOPY; X-RAY SPECTROMETRY. [A.Sche.]

Quantized electronic structure (QUEST)

A material that confines electrons in such a small space that their wavelike behavior becomes important and their properties are strongly modified by quantum-mechanical effects. Such structures occur in nature, as in the case of atoms, but can be synthesized artificially with great flexibility of design and applications. They have been fabricated most frequently with layered semiconductor materials. Generally, the confinement regions for electrons in these structures are 1–100 nanometers in size. The allowable energy levels, motion, and optical properties of the electrons are strongly affected by the quantum-mechanical effects. The structures are referred to as quantum wells, wires, and dots, depending on whether electrons are confined with respect to motion in one, two, or three dimensions. Multiple closely spaced wells between which electrons can move by quantum-mechanical tunneling through intervening thin barrier-material layers are referred to as superlattices. *See* QUANTUM MECHANICS.

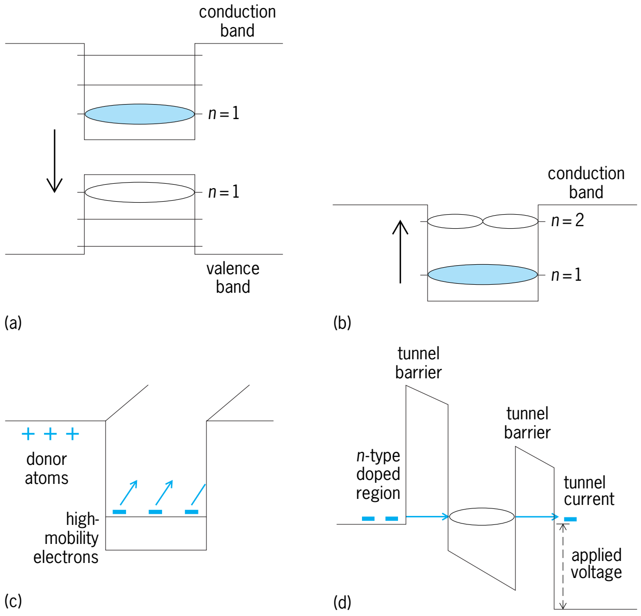
The most frequently used fabrication technique for quantized electronic structures is epitaxial growth of thin single-crystal semiconductor layers by molecular-beam epitaxy or by chemical vapor growth techniques. These artificially synthesized quantum structures find major application in high-performance transistors such as the microwave high-electron-mobility transistor (HEMT), and in high-performance solid-state lasers such as the semiconductor quantum-well laser. They also have important scientific applications for the study of fundamental two-dimensional, one-dimensional, and zero-dimensional physics problems in which particles are confined so that they have free motion in only two, one, or zero directions. Chemically formed nanocrystals, carbon nanotubes, zeolite cage compounds, and carbon buckyball C_{60} molecules are also important quantized electronic structures.

The optical applications are based on the interactions between light and electrons in the quantum structures. The absorption of a photon by an electron in a quantum well raises the electron from occupied quantum states to unoccupied quantum states. Electrons and holes in quantum wells may also recombine, with the resultant emission of photons from the quantized electronic structure as the electron drops from a higher state to a lower state. *See* ELECTRON-HOLE RECOMBINATION.

The photon emission is the basis for quantum-well semiconductor lasers, which have widespread applications in optical fiber communications and compact disk and laser disk optical recording. Quantum-well lasers operate by electrically injecting or pumping electrons into the lowest-conduction-band ($n = 1$) quantum-well state, where they recombine with holes in the highest-valence-band ($n = 1$) quantum-well state (that is, the electrons drop to an empty $n = 1$ valence-band state; illus. *a*), producing the emission of photons. These photons stimulate further photon emission and produce high-efficiency lasing. *See* COMPACT DISK; LASER; OPTICAL COMMUNICATIONS; OPTICAL RECORDING.

The photon absorption is the basis for quantum-well photodetectors and light modulators. In the quantum-well infrared photodetector an electron is promoted from lower (say, $n = 1$) to higher (say, $n = 2$) conduction band quantum-well states (illus. *b*) by absorption of an infrared photon. An electron in the higher state can travel more freely across the barriers, enabling it to escape from the well and be collected in a detector circuit. Changes in quantum-well shapes produced by externally applied electric fields can change the absorption wavelengths for light in a quantized electronic structure. The shift in optical absorption wavelength with electric field is known as the quantum-confined Stark effect. It forms the basis for semiconductor light modulators and semiconductor optical logic devices. *See* OPTICAL DETECTORS; OPTICAL MODULATORS; STARK EFFECT.

Modulation doping is a special way of introducing electrons into quantum wells for electrical applications. The electrons come from donor atoms lying in adjacent barrier layers (illus. *c*). Modulation doping is distinguished from conventional uniform doping in that it produces carriers in the quantum well without introducing impurity dopant atoms into the well. Since there are no impurity atoms to collide with in the well, electrons there are free to move with high mobility along the quantum-well layer. Resistance to electric current flow is thus much reduced relative to electrical resistance in conventional semiconductors. This enhances the low-noise and high-speed applications of quantum wells and is the basis of the high-electron-mobility transistor (HEMT), which is also known as the modulation-doped field-effect transistor (MODFET). HEMTs are widely used in microwave receivers for direct reception of satellite television broadcasts. *See* TRANSISTOR.



Principles of operation of quantum-well devices. (*a*) Quantum-well laser. (*b*) Quantum-well infrared detector. (*c*) High-electron-mobility transistor (HEMT or MODFET). Electrons in the quantum well that came from donor atoms in the barrier are free to move with high mobility in the direction perpendicular to the page. (*d*) Resonant tunneling device.

Electrical conductivity in carbon nanotubes occurs without doping and results from the absence of any energy gap in the electronic energy band structure of the nanotubes and the presence of allowed states at the Fermi energy. Individual nanotubes can be electrically contacted. Simple quantum wire transistors displaying quantized electron motion have been formed from single nanotubes.

Quantum-mechanical tunneling is another important property of quantized electronic structures. Tunneling of electrons through thin barrier layers between quantum wells is a purely quantum-mechanical effect without any real analog in classical physics or classical mechanics. It results from the fact that electrons have wavelike properties and that the particle waves can penetrate into the barrier layers. This produces a substantial probability that the particle wave can penetrate entirely through a barrier layer and emerge as a propagating particle on the opposite side of the barrier. The penetration probability has an exponential drop-off with barrier thickness. The tunneling is greatest for low barriers and thin barriers.

This effect finds application in resonant tunnel devices, which can show strong negative resistance in their electrical properties. In such a device (illus. *d*), electrons from an *n*-type doped region penetrate the barrier layers of a quantum well by tunneling. The tunneling current is greatest when the tunneling electrons are at the same energy as the quantum-well energy. The tunneling current actually drops at higher applied voltages, where the incident electrons are no longer at the same energy as the quantum-state energy, thus producing the negative resistance characteristic of the resonant tunneling diode. *See* ARTIFICIALLY LAYERED STRUCTURES; NANOSTRUCTURE; NEGATIVE-RESISTANCE CIRCUITS; RESONANCE (QUANTUM MECHANICS); TUNNELING IN SOLIDS.

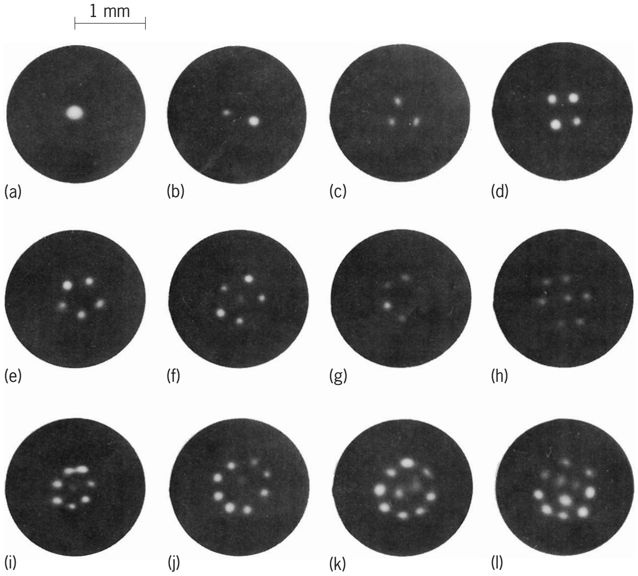
[A.C.Go.]

Quantized vortices

A type of flow pattern exhibited by superfluids, such as liquid ^{4}He below 2.17 K (−455.76°F). The term vortex designates the familiar whirlpool pattern where the fluid moves circularly around a central line and the velocity diminishes inversely proportionally to the distance from the center. The strength of a vortex is determined by the circulation, which is the line integral of the velocity around any path enclosing the central line. *See* VORTEX.

A superfluid is believed to be characterized by a macroscopic (that is, large-scale) quantum-mechanical wave function ψ. This wave function locks the superfluid into a coherent state. Since the velocity around the vortex increases without limit as the center is approached, the superfluid density and thus ψ must vanish at the center in order to avoid an infinite energy. Thus the central core of the vortex marks the zeros, or nodal lines, in the macroscopic wave function. *See* QUANTUM MECHANICS.

Quantized vortex lines are usually produced by rotating a vessel containing superfluid helium. At very low rotation speeds, no vortices exist: the superfluid remains at rest while the vessel rotates. At a certain speed the first vortex appears and corresponds to the first excited rotational state of the system. If the container continues to accelerate, additional quantized vortices will appear. At any given speed the vortices form a regular array which rotates with the vessel.



Stationary configurations of vortices which appear when a cylindrical container of superfluid ^{4}He is rotated about its axis. As the rotation speed increases from a to *f*, more vortices appear and the patterns become more complex. (*From E. J. Yarmchuk, M. J. V. Gordon, and R. E. Packard, Observation of stationary vortex arrays in rotating superfluid helium, Phys. Rev. Lett., 43:214–217, 1979*)

Quantized vortex lines were first detected in the mid-1950s by their influences on superfluid thermal waves traveling across the lines. In the late 1950s it was discovered that electrons in liquid helium form tiny charged bubbles which can become trapped on the vortex core but can move quite freely along the line. These electron bubbles (often referred to as ions) have been one of the most useful probes of quantized vortices. Researchers have been able to use ions to detect single quantized vortex lines. In one experiment the trapped ions are pulled out at the top of the vortex lines, accelerated, and focused onto a phosphor screen. The pattern of light thus produced on the phosphor is a map of the position of the vortices where they contact the liquid meniscus (see illustration). *See* LIQUID HELIUM; SUPERFLUIDITY. [R.E.P.]

Quantum (physics)

A term characterizing an excitation in a wave or field, connoting fundamental particlelike properties such as energy or mass, momentum, and angular momentum for this excitation. In general, any field or wave equation that is quantized, including systems already treated in quantum mechanics that are second-quantized, leads to a particle interpretation for the excitations which are called quanta of the field. This term historically was first applied to indivisible amounts of electromagnetic, or light, energy usually referred to as photons. The photon, or quantum of the electromagnetic field, is a massless particle, best interpreted as such by quantizing Maxwell's equations. Analogously, the electron can be said to be the quantum of the Dirac field through second quantization of the Dirac equation, which also leads to the prediction of the existence of the positron as another quantum of this field with the same mass but with a charge opposite to that of the electron. In similar fashion, quantization of the gravitational field equations suggests the existence of the graviton. The pi meson or pion was theoretically predicted as the quantum of the nuclear force field. Another quantum is the quantized lattice vibration, or phonon, which can be interpreted as a quantized sound wave since it travels through a quantum solid or fluid, or through nuclear matter, in the same manner as sound goes through air.

The use of quantum as an adjective (quantum mechanics, quantum electrodynamics) implies that the particular subject is to be treated according to the modern rules that have evolved for quantized systems. *See* ELEMENTARY PARTICLE; GRAVITATION; GRAVITON; MAXWELL'S EQUATIONS; MESON; PHONON; PHOTON; QUANTUM ELECTRODYNAMICS; QUANTUM FIELD THEORY; QUANTUM MECHANICS. [K.E.L.]

Quantum acoustics

The investigation of the effects of the laws of quantum mechanics on the propagation and absorption of sound. At the present stage of development of physical science, quantum mechanics is the most fundamental theory of physical phenomena. However, for many applications in the everyday world, a sufficiently accurate description of nature is provided by classical mechanics. Quantum acoustics refers to acoustic experiments that are carried out under conditions such that the results can be understood only in terms of quantum theory. As a general tendency, quantum effects become more important in acoustic experiments that are performed with higher-frequency sound waves or that are carried out at lower temperatures. *See* NONRELATIVISTIC QUANTUM THEORY; QUANTUM MECHANICS.

Sound and phonons. To understand the quantum nature of sound, it is valuable to consider the origins of the quantum theory of light. Experiments in the latter part of the nineteenth century showed that the classical theory of electromagnetism combined with the laws of statistical mechanics could not explain the spectrum of light emitted by a heated surface. To reconcile theory and experiment, Max Planck in 1900 proposed that the energy of a light wave is quantized. This means that only certain values of the energy of the wave are allowed. These allowed values are given by the equation

$$E = n\hbar\omega$$

where $\hbar$ is Planck's constant divided by 2π, ω is the angular frequency of the light wave, and n is an integer. The modern interpretation of this formula describes this energy in terms of elementary quanta called photons. Each photon has an energy $\hbar\omega$, and the wave is made up of n photons. It was later realized that this same quantization of energy should apply to sound waves. These fundamental units of sound energy were given the name phonons. *See* HEAT RADIATION; LIGHT; PHONON; PHOTON.

Phonoatomic effect. One of the earliest experiments that confirmed the idea that light consists of photons was the photoelectric effect. In this effect the energy of light quanta is used to eject electrons from the surface of a metal. Only if the frequency of the light is sufficiently high do the photons have enough energy to knock the electrons out of the metal. The detection of this threshold frequency is thus strong evidence for quantization of energy. An analogous experiment has been performed with sound. In the experiment, sound is generated by a source in a vessel of liquid helium maintained at very low temperature, less than 0.1 K above absolute zero. In liquid helium, each atom is bound to the other atoms in the liquid by an energy that is unusually small compared to that of other liquids. For sound of sufficiently high frequency, the sound quanta when they arrive at the surface of the liquid have sufficient energy to knock helium atoms out of the liquid. These atoms can be detected by a suitable receiver placed above the surface of the liquid. The energy of an ejected atom, which determines its velocity, is equal to the energy of a phonon minus the binding energy. The time of arrival of the ejected atoms at the receiver is, in turn, determined by this velocity and hence is dependent on the frequency of the sound wave. Experiments have confirmed that the helium atoms arrive at the time expected based on this theory. *See* Photoemission.

Phonon-phonon interactions. Sound waves in solids are attenuated during their propagation by a wide variety of physical processes. In many materials the most important mechanisms are related to impurities or defects in the solid, such as cracks, grain boundaries, or dislocations. Even when sound travels through a perfect crystal containing no defects, it is found that a measurable attenuation still occurs. In insulating crystals, where there are no free electrons, this attenuation is due to an interaction between the sound wave and the random thermal vibrations of the atoms in the solid. These random vibrations, which constitute the heat energy of the solid, are also quantized and are called thermal phonons. The attenuation of the sound wave can be attributed to collisions with the thermal phonons in which some of the sound quanta are scattered out of the sound beam. This mechanism is referred to as phonon-phonon scattering. *See* Crystal defects; Lattice vibrations; Sound absorption.

In a linear elastic solid the elastic stress is exactly proportional to the strain, a phenomenon that is called Hooke's law. If Hooke's law holds, the presence of one wave does not affect the propagation of another, and so there are no interactions between phonons. Phonon-phonon scattering occurs because real solids always exhibit some deviations from linear elastic behavior. This nonlinearity is called anharmonicity. *See* Hooke's law; Nonlinear acoustics.

Even when the temperature is very low and there are very few thermal phonons, anharmonicity can still give rise to an attenuation of a sound wave. This is because the sound phonons can spontaneously decay into phonons of lower frequencies. The rate at which this decay occurs is proportional to the frequency of the sound wave to the fifth power, and so the attenuation is important only for sound waves of very high frequency. If the number of phonons is sufficiently large, it is possible under some circumstances for there to be a large buildup in the population of some of the decay phonons. This process is called parametric amplification. *See* Parametric amplifier. [H.J.Ma.]

Quantum anomalies

Phenomena that arise when a quantity that vanishes according to the dynamical rules of classical physics acquires a finite value when quantum rules are used. For example, the classical Poisson bracket for some entities may vanish; yet the corresponding quantum commutator may be nonzero—this is a commutator anomaly. Alternatively, the flow of some material current may satisfy a continuity equation by virtue of the classical equations of motion, indicating conservative flow; but upon quantization the continuity equation may fail and the flow may no longer be conservative in the quantum theory—this is an anomalous divergence (of the current in question). Since the forms of Poisson brackets and quantum commutators as well as the occurrence of continuity equations for currents are related to symmetries and conservation laws of the theory, quantum anomalies serve to break some symmetries and destroy some conservation laws of classical models. This violation of symmetry is not driven by explicit symmetry-breaking terms in the dynamical equations—rather the quantization procedure itself violates the classical symmetry. The mathematical reason for this phenomenon is that classical dynamics, involving a finite number of degrees of freedom, usually leads to a quantum theory on an infinite-dimensional vector space (Hilbert space), and this "infinity" gives rise to novel effects. *See* Canonical transformations; Conservation laws (physics); Equation of continuity; Hilbert space; Nonrelativistic quantum theory; Symmetry laws (physics).

The physically interesting setting for these phenomena is in quantum field theory, especially as applied to elementary particle physics, where the mechanism serves as an important source for symmetry breaking. Quantum anomalies also play a role in various other branches of physics, in which quantum field theory finds application, including condensed matter, supersymmetry, string theory, and motion in curved space-time. *See* Elementary particle; Quantum field theory; Space-time; Superstring theory; Supersymmetry; Symmetry breaking. [R.J.]

Quantum chemistry

A branch of chemistry concerned with the application of quantum mechanics to chemical problems. More specifically, it is concerned with the electronic structure of molecules. Methods developed since 1960 permit the quantum chemist to obtain reliable approximate solutions to the nonrelativistic Schrödinger equation. The method which dominates the field of quantum chemistry is the Hartree-Fock or self-consistent-field approximation. *See* Hamilton's equations of motion; Quantum mechanics.

For closed-shell molecules, the form of the Hartree-Fock wave function is given by Eq. (1), in which $A(n)$, the antisymmetrizer

$$\Psi_{HF} = A(n)\phi_1(1)\phi_2(2)\ldots\phi_n(n) \qquad (1)$$

for n electrons, has the effect of making a Slater determinant out of the orbital product on which it operates. The ϕ's are spin orbitals, products of a spatial orbital χ and a one-electron spin function α or β. For any given molecular system, there are an infinite number of wave functions of form (1), but the Hartree-Fock wave function is the one for which the orbitals ϕ have been varied to yield the lowest possible energy [Eq. (2)].

$$E = \int \Psi \times {}_{HF} H \Psi_{HF} d\tau \qquad (2)$$

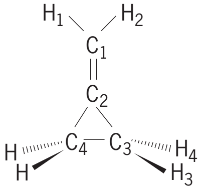
The resulting Hartree-Fock equations are relatively tractable due to the simple form of the energy E for single determinant wave functions [Eq. (3)].

$$E_{HF} = \sum_i I(i \mid i) + \sum_i \sum_{j>i} [(ij \mid ij) - (ij \mid ji)] \qquad (3)$$

To solve the Hartree-Fock equations exactly, either the orbitals ϕ must be expanded in a complete set of analytic basis functions or strictly numerical (that is, tabulated) orbitals must be obtained. The former approach is impossible from a practical point of view for systems with more than two electrons, and the latter has been accomplished only for atoms and for a few diatomic molecules. Therefore, the exact solution of the Hartree-Fock equations is abandoned for polyatomic molecules. Instead an incomplete (but reasonable) set of analytic basis functions is adopted and solved for the best variational [that is, lowest energy given by Eq. (2)] wave function of form (1). Such a wave function is referred to as being of self-consistent-field (SCF) quality. For very-large-basis sets, then, it is reasonable to refer to the resulting SCF wave function as near-Hartree-Fock.

For large chemical systems, only minimum basis sets (MBS) can be used in ab initio theoretical studies. The term "large" includes molecular systems, with 100 or more electrons.

Ab initio theoretical methods have had the greatest impact on chemistry in the area of structural predictions. The most encouraging aspect of ab initio geometry predictions is their reliability. Essentially all molecular structures appear to be reliably predicted at the Hartree-Fock level of theory. Even more encouraging, many structures are accurately reproduced by using only minimum-basis-set self-consistent-field methods. A fairly typical example is methylenecyclopropane (see structure), with its



minimum-basis-set self-consistent-field structure compared with experiment in the table. Carbon-carbon bond distances differ typically by 0.002 nm from experiment, and angles are rarely in error by more than a few degrees. Thus, for many purposes, theory may be considered complementary to experiment in the area of structure prediction.

Minimum-basis-set self-consistent-field geometry prediction compared with experiment for methylenecyclopropane

Parameter*	Theory	Experiment
$r\ (C_1{=}C_2)$	0.1298 nm	0.1332 nm
$r\ (C_2{-}C_3)$	0.1474 nm	0.1457 nm
$r\ (C_3{-}C_4)$	0.1522 nm	0.1542 nm
$r\ (C_1{-}H_1)$	0.1083 nm	0.1088 nm
$r\ (C_3H_3)$	0.1083 nm	0.109
$\theta(H_1C_1H_2)$	116.0°	114.3°
$\theta(H_3C_3H_4)$	113.6°	113.5°
$\theta(H_{34}C_3C_4)$	149.4°	150.8°

*Here *r* represents the carbon-carbon bond distance; θ represents the bond angle in degrees of H-C-H bonds; the numbers on C and H correspond to the numbered atoms in the displayed structure.

The most important post-Hartree-Fock methods for quantum chemistry are perturbation theory and the configuration interaction (CI) and coupled cluster (CC) methods. These three rigorous approaches may be labeled "convergent" quantum-mechanical methods, as each is ultimately capable of yielding exact solutions to Schrödinger's equation. The coupled cluster method treats excitations based on the number of electrons by which they differ from the Hartree-Fock reference function. Thus the CCSD method incorporates amplitudes differing by single (S) and double (D) excitations from Hartree-Fock. The CCSDT method adds all triple excitations to the CCSD treatment. As one goes to higher and higher excitations (for example, CCSDTQ includes all configurations differing by one, two, three, or four electrons from the Hartree-Fock reference configuration), one approaches the exact quantum-mechanical result.

In fact, coupled cluster theory beyond CCSD becomes impractical for large molecular systems. Thus, although the coupled cluster path to exact results is clear, it becomes a difficult road to follow. Triple excitations are sufficiently important that effective coupled cluster methods have been developed in which the effects of triples are approximated. The best of these methods, CCSD(T), is the closest thing to a panacea that exists today in quantum chemistry for very difficult problems involving smaller molecules. However, the range of applicability of the theoretically superior CCSD(T) method is much narrower than that of the popular hybrid Hartree-Fock/density functional methods. Thus, for most chemists the Hartree-Fock and density functional methods are likely to play central roles in molecular electronic structure theory for many years to come. *See* CHEMICAL BONDING; MOLECULAR ORBITAL THEORY; MOLECULAR STRUCTURE AND SPECTRA; RESONANCE (MOLECULAR STRUCTURE). [H.F.S.]

Quantum chromodynamics

A theory of the strong ("nuclear") interactions among quarks, which are regarded as fundamental constituents of matter. Quantum chromodynamics (QCD) seeks to explain why quarks combine in certain configurations to form the observed patterns of subnuclear particles, such as the proton and pi meson. According to this picture, the strong interactions among quarks are mediated by a set of force particles known as gluons. Strong interactions among gluons may lead to new structures that correspond to as-yet-undiscovered particles. The long-studied nuclear force that binds protons and neutrons together in atomic nuclei is regarded as a collective effect of the elementary interactions among constituents of the composite protons and neutrons. *See* NUCLEAR STRUCTURE.

Quantum chromodynamics has not yet been subjected to precise experimental tests. Several qualitative predictions of quantum chromodynamics do seem to have been borne out. Part of the esthetic appeal of the theory is due to the fact that quantum chromodynamics is nearly identical in mathematical structure to quantum electrodynamics (QED) and to the unified theory of weak and electromagnetic interactions. This resemblance encourages the hope that a unified description of the strong, weak, and electromagnetic interactions may be at hand. *See* ELECTROWEAK INTERACTION; QUANTUM ELECTRODYNAMICS; WEAK NUCLEAR INTERACTIONS.

Gauge theories. At the heart of current theories of the fundamental interactions is the idea of gauge invariance. It is widely believed that gauge theories constructed to embody various symmetry principles represent the correct quantum-mechanical descriptions of the strong, weak, and electromagnetic interactions. *See* GAUGE THEORY; SYMMETRY LAWS (PHYSICS).

Color. Although the idea that the strongly interacting particles are built up of quarks brought new order to hadron spectroscopy and suggested new relations among mesons and baryons, the constituent description brought with it a number of puzzles. According to the Pauli exclusion principle, identical spin-$^1/_2$ particles cannot occupy the same quantum state. As a consequence, the observed baryons such as Δ^{++} (*uuu*) and Ω^- (*sss*), which would be composed of three identical quarks in the same state, would seem to be forbidden configurations. To comply with the Pauli principle, it is necessary to make the three otherwise identical quarks distinguishable by supposing that every flavor of quark exists in three varieties, fancifully labeled by the colors red, green, and blue. Color may be regarded as the strong-interaction analog of electric charge. Color cannot be created or destroyed by any of the known interactions. Like electric charge, it is said to be conserved. *See* COLOR (QUANTUM MECHANICS); EXCLUSION PRINCIPLE.

In the face of evidence that color could be regarded as the conserved charge of the strong interactions, it was natural to seek a gauge symmetry that would have color conservation as its consequence. An obvious candidate for the gauge symmetry group is the unitary group SU(3), now to be applied to color rather than flavor. The theory of strong interactions among quarks that is prescribed by local color gauge symmetry is known as quantum chromodynamics. The mediators of the strong interactions are eight massless spin-1 bosons, one for each generator of the symmetry group. These strong-force particles are named gluons because they make up the "glue" that binds quarks together into hadrons. Gluons also carry color and hence have strong interactions among themselves.

Asymptotic freedom. The theoretical description of the strong interactions has historically been inhibited by the very strength of the interaction, which renders low-order perturbative calculations untrustworthy. However, in 1973 it was found that in many circumstances the effective strength of the interaction in Yang-Mills theories becomes increasingly feeble at short distances, a property known as asymptotic freedom. For quantum chromodynamics, this remarkable observation implies that the interaction between quarks becomes weak at small separations. This discovery raises the hope that some aspects of the strong interactions might be treated by using familiar computational techniques that are predicated upon the smallness of the interaction strength.

Quarkonium. It was suggested in 1974 that the bound system of an extremely massive quark with its antiquark would be so small that the strong force would be extremely feeble. In this case, the binding between quark and antiquark is mediated by the exchange of a single massless gluon, and the spectrum of bound states resembles that of an exotic atom composed of an electron and an antielectron (positron) bound electromagnetically in a Coulomb potential generated by the exchange of a massless photon. Since the electron-positron atom is known as positronium, the heavy quark-antiquark atom has been called quarkonium. Two families of heavy quark-antiquark bound states, the ψ/J system composed of charmed quarks and the Υ system made up of b quarks, have been discovered. Both have level schemes characteristic of atomic spectra, which have been analyzed by using tools of nonrelativistic quantum mechanics developed for ordinary atoms. The atomic analogy has proved extremely fruitful for studying the strong interaction. *See* Charm; J/psi particle; Positronium.

Lattice models. To deal with the existence and properties of the hadrons themselves, it is necessary to devise a new computational approach that does not break down when the interaction becomes strong. The most promising method has been the crystal lattice formulation of the theory. By considering the values of the color field only on individual lattice sites, it is possible to use many of the techniques developed in statistical physics for the study of spin systems such as magnetic substances. *See* Elementary particle; Fundamental interactions; Gluons; Ising model; Quantum field theory; Quarks; Standard model; Statistical mechanics; Strong nuclear interactions. [C.Q.]

Quantum electrodynamics

The field of physics that studies the interaction of electromagnetic radiation with electrically charged matter within the framework of relativity and quantum mechanics. It is the fundamental theory underlying all disciplines of science concerned with electromagnetism, such as atomic physics, chemistry, biology, the theory of bulk matter, and electromagnetic radiation.

Efforts to formulate quantum electrodynamics (QED) were initiated by P. A. M. Dirac, W. Heisenberg, and W. Pauli soon after quantum mechanics was established. The first step was to remedy the obvious shortcoming of quantum mechanics: that it applies only to the case where particle speeds are small compared with that of light, c. This led to Dirac's discovery of a relativistic wave equation, in which the wave function has four components and is multiplied by certain 4×4 matrices. His equation incorporates in a natural manner the observed electron-spin angular momentum, which implies that the electron is a tiny magnet. The strength of this magnet (magnetic moment) was predicted by Dirac and agreed with observation. A detailed prediction of the hydrogen spectrum was also in good agreement with experiment. *See* Atomic structure and spectra; Electron spin; Matrix theory.

In order to go beyond this initial success and calculate higher-order effects, however, the interaction of charge and electromagnetic field had to be treated dynamically. To begin with, a good theoretical framework had to be found for describing the wave-particle duality of light, that is, the experimentally well-established fact that light behaves like a particle (photon) in some cases but like a wave in others. Similarly, the electron manifests wave-particle duality, another observed fact. Once this problem was settled, the next question was how to deal with the interaction of charge and electromagnetic field. It is here that the theory ran into severe difficulties. Its predictions often diverged when attempts were made to calculate beyond lowest-order approximations. This inhibited the further development of the theory for nearly 20 years. Stimulated by spectroscopic experiments vastly refined by microwave technology developed during World War II, however, S. Tomonaga, R. P. Feynman, and J. Schwinger discovered that the difficulties disappear if all observable quantities are expressed in terms of the experimentally measured charge and mass of the electron. With the discovery of this procedure, called renormalization, quantum electrodynamics became a theory in which all higher-order corrections are finite and well defined. *See* Nonrelativistic quantum theory; Photon; Quantum mechanics; Relativistic quantum theory; Relativity; Wave mechanics.

Quantum electrodynamics is the first physical theory ever developed that has no obvious intrinsic limitation and describes physical quantities from first principles. Nature accommodates forces other than the electromagnetic force, such as those responsible for radioactive disintegration of heavy nuclei (called the weak force) and the force that binds the nucleus together (called the strong force). A theory called the standard model, has been developed which unifies the three forces and accounts for all experimental data from very low to extremely high energies. This does not mean, however, that quantum electrodynamics fails at high energies. It simply means that the real world has forces other than electromagnetism.

High-precision tests have provided excellent confirmation for the validity of the renormalization theory of quantum electrodynamics. In the high-energy regime, tests using electron-positron colliding-beam facilities at various high-energy physics laboratories have confirmed the predictions of quantum electrodynamics at center-of-mass energies up to 1.8×10^{11} electronvolts (180 GeV). The uncertainty principle implies that this is equivalent to saying that quantum electrodynamics is valid down to about 10^{-17} meter, a distance 100 times shorter than the radius of the proton.

High-precision tests of quantum electrodynamics have also been carried out at low energies by using various simple atomic systems. The most accurate is that of the measurement of the magnetic moment of the electron, or the gyromagnetic ratio g, the ratio of spin and rotation frequencies, which is correctly predicted by quantum electrodynamics to 12 significant figures. This is the most precise confirmation of any theory ever carried out. *See* Quantum field theory. [T.K.]

Quantum electronics

A loosely defined field concerned with the interaction of radiation and matter, particularly those interactions involving quantum energy levels and resonance phenomena, and especially those involving lasers and masers. Quantum electronics encompasses useful devices such as lasers and masers and their practical applications; related phenomena and techniques, such as nonlinear optics and light modulation and detection; and related scientific problems and applications, such as quantum noise processes, laser spectroscopy, picosecond spectroscopy, and laser-induced optical breakdown.

In one sense any electronic device, even one as thoroughly classical in nature as a vacuum tube, may be considered a quantum electronic device, since quantum theory is accepted to be the basic theory underlying all physical devices. In practice, however, quantum electronics is usually understood to refer to only those devices such as lasers and atomic clocks in which stimulated transitions between discrete quantum energy levels are important, together with related devices and physical phenomena which are excited or explored using lasers. Other devices such as transistors or superconducting devices which may be equally quantum-mechanical in nature are not usually included in the domain of quantum electronics. *See* Atomic clock; Laser; Laser spectroscopy; Maser; Nonlinear optics; Optical detectors; Optical modulators; Optical pulses; Quantum mechanics. [A.E.S.]

Quantum field theory

The quantum-mechanical theory of physical systems whose dynamical variables are local functions of space and time. As distinguished from the quantum mechanics of atoms, quantum field theories describe systems with an infinite number of degrees of freedom. Such theories provide the natural language for describing the interactions and properties of elementary particles, and have proved to be successful in providing the basis for the fundamental theories of the interactions of matter. The present understanding of the basic forces of nature is based on quantum field theories of the strong, weak, electromagnetic, and gravitational interactions. Quantum field theory is also useful in the study of many-body systems, especially in situations where the characteristic length of a system is large compared to its microscopic scale. *See* NONRELATIVISTIC QUANTUM THEORY; QUANTUM MECHANICS.

Quantum field theory originated in the attempt, in the late 1920s, to unify P. A. M. Dirac's relativistic electron theory and J. C. Maxwell's classical electrodynamics in a quantum theory of interacting photon and electron fields. This effort was completed in the 1950s and was extremely successful. At present the quantitative predictions of the theory are largely limited to perturbative expansions (believed to be asymptotic) in powers of the fine-structure constant. However, because of the extremely small value of this parameter, $\alpha = e^2/\hbar c \approx 1/137$ (where e is the electron charge, $\hbar$ is Planck's constant divided by 2π, and c is the speed of light), such an expansion is quite adequate for most purposes. The remarkable agreement of the predictions of quantum electrodynamics with high-precision experiments (sometimes to an accuracy of 1 part in 10^{12}) provides strong evidence for the validity of the basic tenets of relativistic quantum field theory. *See* CLASSICAL FIELD THEORY; ELECTROMAGNETIC RADIATION; MAXWELL'S EQUATIONS; PERTURBATION (QUANTUM MECHANICS); PHOTON; QUANTUM ELECTRODYNAMICS; RELATIVISTIC ELECTRODYNAMICS; RELATIVISTIC QUANTUM THEORY.

Quantum field theory also provides the natural framework for the treatment of the weak, strong, and gravitational interactions.

The first of such applications was Fermi's theory of the weak interactions, responsible for radioactivity, in which a hamiltonian was constructed to describe beta decay as a product of four fermion fields, one for each lepton or nucleon. This theory has been superseded by the modern electroweak theory that unifies the weak and the electromagnetic interactions into a common framework. This theory is a generalization of Maxwell's electrodynamics which was the first example of a gauge theory, based on a continuous local symmetry. In the case of electromagnetism the local gauge symmetry is the space-time-dependent change of the phase of a charged field. The existence of massless spin-1 particles, photons, is one of the consequences of the gauge symmetry. The electroweak theory is based on generalizing this symmetry to space-time-dependent transformations of the labels of the fields, based on the group SU(2) × U(1). However, unlike electromagnetism, part of this extended symmetry is not shared by the ground state of the system. This phenomenon of spontaneous symmetry breaking produces masses for all the elementary fermions and for the gauge bosons that are the carriers of the weak interactions, the $W^{\pm}$ and Z bosons. (This is known as the Higgs mechanism.) The electroweak theory has been confirmed by many precision tests, and almost all of its essential ingredients have been verified. *See* ELECTROWEAK INTERACTION; GAUGE THEORY; INTERMEDIATE VECTOR BOSON; SYMMETRY BREAKING; SYMMETRY LAWS (PHYSICS); WEAK NUCLEAR INTERACTIONS.

The application of quantum field theory to the strong or nuclear interactions dates from H. Yukawa's hypothesis that the short-range nuclear forces arise from the exchange of massive particles that are the quanta of local fields coupled to the nucleons, much as the electromagnetic interactions arise from the exchange of massless photons that are the quanta of the electromagnetic field. The modern theory of the strong interactions, quantum chromodynamics, completed in the early 1970s, is also based on a local gauge theory. This is a theory of spin-$^1/_2$ quarks invariant under an internal local SU(3) (color) gauge group. The observed hadrons (such as the proton and neutron) are SU(3) color-neutral bound states of the quarks whose interactions are dictated by the gauge fields (gluons). This theory exhibits almost-free-field behavior of quarks and gluons over distances and times short compared to the size of a hadron (asymptotic freedom), and a strong binding of quarks at large separations that results in the absence of colored states (confinement). *See* ELEMENTARY PARTICLE; GLUONS; MESON; QUANTUM CHROMODYNAMICS; QUARKS.

Quantum field theory has been tested down to distances of 10^{-20} m. There appears to be no reason why it should not continue to work down to Planck's length, $(G\hbar/c^3)^{1/2} \approx 10^{-35}$ m (where G is the gravitational constant), where the quantum effects of gravity become important. In the case of gravity, A. Einstein's theory of general relativity already provides a very successful classical field theory. However, the union of quantum mechanics and general relativity raises conceptual problems that seem to call for a radical reexamination of the foundations of quantum field theory. *See* FUNDAMENTAL INTERACTIONS; GRAVITATION; QUANTUM GRAVITATION; RELATIVITY. [D.Gr.]

Quantum gravitation The quantum theory of the gravitational field; also, the study of quantum fields in a curved space-time. In classical general relativity, the gravitational field is represented by the metric tensor $g_{\mu\nu}$ of space-time. This tensor satisfies Einstein's field equation, with the energy-momentum tensor of matter and radiation as a source. However, the equations of motion for the matter and radiation fields also depend on the metric.

Classical field theories such as Maxwell's electromagnetism or the classical description of particle dynamics are approximations valid only at the level of large-scale macroscopic observations. At a fundamental level, elementary interactions of particles and fields must be described by relativistic quantum mechanics, in terms of quantum fields. Because the geometry of space-time in general relativity is inextricably connected to the dynamics of matter and radiation, a consistent theory of the metric in interaction with quantum fields is possible only if the metric itself is quantized. *See* MAXWELL'S EQUATIONS; QUANTUM FIELD THEORY; RELATIVISTIC QUANTUM THEORY; RELATIVITY.

Under ordinary laboratory conditions the curvature of space-time is so extremely small that in most quantum experiments gravitational effects are completely negligible. Quantization in Minkowski space is then justified. Gravity is expected to play a significant role in quantum physics only at rather extreme conditions of strongly time-dependent fields, near or inside very dense matter. The scale of energies at which quantization of the metric itself becomes essential is given by $(\hbar c^5/G)^{1/2} \approx 10^{19}$ GeV, where G is the gravitational constant, $\hbar$ is Planck's constant divided by 2π, and c is the velocity of light. Energies that can be reached in the laboratory or found in cosmic radiation are far below this order of magnitude. Only in the very early stages of the universe, within a proper time of the order of $(G\hbar/c^5)^{1/2} \approx 10^{-43}$ s after the big bang, would such energies have been produced. *See* BIG BANG THEORY.

In most physical systems the metric is quasistationary over macroscopic distances so that its fluctuations can be ignored. A quantum description of fields in a curved space-time can then be given by treating the metric as a classical external field in interaction with the quantum fields.

Quantum effects of black holes. The most striking quantum effect in curved space-time is the emission of radiation by black holes. A black hole is an object that has undergone gravitational collapse. Classically this means that it becomes confined to a space-time region in which the metric has a singularity (the curvature becomes infinite). This region is bounded by a surface, called the horizon, such that any matter or radiation falling inside becomes trapped. Therefore, classically the mass of a black hole can only increase. However, this is no longer the case if quantum effects are taken into account. When, because of fluctuations of the quantum field, particle-antiparticle or photon pairs are created near the horizon of a black hole, one of the particles carrying negative energy may move toward the hole, being absorbed by it, while the other moves out with positive energy. *See* BLACK HOLE; GRAVITATIONAL COLLAPSE.

It is found that the total rate of emission is inversely proportional to the square of the mass. For stellar black holes whose masses are of the order of a solar mass, the emission rate is negligibly small and unobservable. Only primordial black holes, of mass less than 10^{13} kg, formed very early in the quantum era of the universe, would have been small enough to produce quantum effects that could play any significant role in astrophysics or in cosmology. *See* Astrophysics.

Quantization of the metric. There are basically two approaches to the quantization of the metric, the canonical and the covariant quantization. A third method, which can be derived from the first and is now most widely used, is based on the Feynman path integral representation for the vacuum-to-vacuum amplitude, which is the generator of Green's functions for the quantum theory. One important feature of this method is that since the topology of the manifold is not specified at the outset it is possible to include a sum over paths in different topologies. The outcome of this idea is that the vacuum would, at the level of the Planck length, $(G\hbar/c^3)^{1/2} \approx 10^{-35}$ m, acquire a foamlike structure. *See* Feynman integral; Green's function.

At present a complete, consistent theory of quantum gravity is still lacking. The formal theory fails to satisfy the power-counting criterion for renormalizability. In every order of the perturbation expansion, new divergences appear which could only be canceled by counterterms that do not exist in the original lagrangian. This may not be just a technical problem but the reflection of a conceptual difficulty stemming from the dual role, geometric and dynamic, played by the metric. *See* Renormalization.

Supergravity and superstrings. Supergravity is a geometric extension of general relativity which incorporates the principle of supersymmetry. Supersymmetry is a kind of symmetry, discovered in the 1970s, that allows for the transformation of fermions and bosons into each other. (Fermions carry half-integer spin while bosons carry integer spin; they also obey different statistics.) Supergravity can be formulated in space-time manifolds with a total of $D = d + 1$ dimensions, where d, the number of space dimensions, can be as large as 10. They constitute truly unified theories of all interactions including gravity.

In the early 1980s, some encouraging results were found with a theory based on the idea that the basic objects of nature are not pointlike but actually one-dimensional objects like strings, which can be open or closed. Incorporating supersymmetry into the theory leads to a critical dimension $D = 10$.

In the approximation of neglecting string excitations, certain superstring models may be described in terms of local fields as a $D = 10$ supergravity theory. At present, these are the only theories that both include gravity and can be consistently quantized. Although a superstring theory may eventually become the ultimate theory of all the interactions, there is still a very long way to go in making the connection between its fundamental fields and the fields representing the particles and their interactions as observed at low energies. *See* Fundamental interactions; Gravitation; Supergravity; Superstring theory; Supersymmetry. [S.W.MacD.]

Quantum mechanics

Quantum mechanics The modern theory of matter, of electromagnetic radiation, and of the interaction between matter and radiation; also, the mechanics of phenomena to which this theory may be applied. Quantum mechanics, also termed wave mechanics, generalizes and supersedes the older classical mechanics and Maxwell's electromagnetic theory. Atomic and subatomic phenomena provide the most striking evidence for the correctness of quantum mechanics and best illustrate the differences between quantum mechanics and the older classical physical theories. Quantum mechanics is needed to explain many properties of bulk matter, for instance, the temperature dependence of the specific heats of solids.

The formalism of quantum mechanics is not the same in all domains of applicability. In approximate order of increasing conceptual difficulty, mathematical complexity, and likelihood of future fundamental revision, these domains are the following: (i) Nonrelativistic quantum mechanics, applicable to systems in which particles are neither created nor destroyed, and in which the particles are moving slowly compared to the velocity of light. Here a particle is defined as a material entity having mass, whose internal structure either does not change or is irrelevant to the description of the system, (ii) Relativistic quantum mechanics, applicable in practice to a single relativistic particle (one whose speed equals or nearly equals c); here the particle may have zero rest mass, in which event, its speed must equal c. (iii) Quantum field theory, applicable to systems in which particle creation and destruction can occur; the particles may have zero or nonzero rest mass. This article is concerned mainly with nonrelativistic quantum mechanics, which apparently applies to all atomic and molecular phenomena, with the exception of the finer details of atomic spectra. Nonrelativistic quantum mechanics also is well established in the realm of low-energy nuclear physics. *See* Atomic structure and spectra; Nuclear physics; Quantum field theory; Relativistic quantum theory.

Planck's constant. The quantity 6.626×10^{-34} joule-second, first introduced into physical theory by Max Planck in 1901, is a basic ingredient of the formalism of quantum mechanics. Planck's constant commonly is denoted by the letter h; the notation $\hbar = h/2\pi$ also is standard.

Uncertainty principle. In classical physics the observables characterizing a given system are assumed to be simultaneously measurable (in principle) with arbitrarily small error. For instance, it is thought possible to observe the initial position and velocity of a particle and therewith, using Newton's laws, to predict exactly its future path in any assigned force field. According to the uncertainty principle, accurate measurement of an observable quantity necessarily produces uncertainties in one's knowledge of the values of other observables. In particular, for a single particle relation (1*a*) holds, where Δx represents the uncertainty (error) in the location of the x coordinate of the particle at any instant, and Δp_x is the simultaneous uncertainty in the x component of the particle momentum. Relation (1*a*) asserts that under the best circumstances, the product $\Delta x \Delta p_x$ of the uncertainties cannot be less than about 10^{-34} joule second.

$$\Delta x \Delta p_x > \hbar \tag{1a}$$

$$\Delta t \ \Delta E \gtrsim \hbar \tag{1b}$$

The uncertainty relation (1*b*) is derived and interpreted somewhat differently than relation (1*a*); it asserts that for any system, an energy measurement with error ΔE must be performed in a time not less than $\Delta t \sim \hbar/\Delta E$. If a system endures for only Δt seconds, any measurement of its energy must be uncertain by at least $\Delta E \sim \hbar \Delta t$. *See* Uncertainty principle.

Wave-particle duality. It is natural to identify such fundamental constituents of matter as protons and electrons with the mass points or particles of classical mechanics. According to quantum mechanics, however, these particles, in fact all material systems, necessarily have wavelike properties. Conversely, the propagation of light, which, by Maxwell's electromagnetic theory, is understood to be a wave phenomenon, is associated in quantum mechanics with massless energetic and momentum-transporting particles called photons. The quantum-mechanical synthesis of wave and particle concepts is embodied in the de Broglie relations, given by Eqs. (2*a*) and (2*b*). These give the wavelength λ and wave frequency f associated with a free particle (a particle moving freely under no forces) whose momentum is p and energy is E; the same relations give the photon momentum p and energy E associated with an electromagnetic wave in free space (that is, in a vacuum) whose wavelength is λ and frequency is f. *See* Photon.

$$\lambda = h/p \tag{2a}$$

$$f = E/h \tag{2b}$$

The wave properties of matter have been demonstrated conclusively for beams of electrons, neutrons, atoms (hydrogen, H, and helium, He), and molecules (H_2). When incident upon crystals, these beams are reflected into certain directions, forming diffraction patterns. Diffraction patterns are difficult to explain on a particle picture; they are readily understood on a wave picture, in which wavelets scattered from regularly spaced atoms in the crystal lattice interfere constructively along certain directions only. *See* ELECTRON DIFFRACTION; NEUTRON DIFFRACTION.

The particle properties of light waves are observed in the photoelectric effect and the compton effect. *See* COMPTON EFFECT; PHOTOEMISSION.

Complementarity. Wave-particle duality and the uncertainty principle are thought to be examples of the more profound principle of complementarity, first enunciated by Niels Bohr (1928). According to the principle of complementarity, nature has "complementary" aspects; an experiment which illuminates one of these aspects necessarily simultaneously obscures the complementary aspect. To put it differently, each experiment or sequence of experiments yields only a limited amount of information about the system under investigation; as this information is gained, other equally interesting information (which could have been obtained from another sequence of experiments) is lost. Of course, the experimenter does not forget the results of previous experiments, but at any instant, only a limited amount of information is usable for predicting the future course of the system.

Quantization. In classical physics the possible numerical values of each observable, meaning the possible results of exact measurement of the observable, generally form a continuous set. For example, the x coordinate of the position of a particle may have any value between $-\infty$ and $+\infty$. In quantum mechanics the possible numerical values of an observable need not form a continuous set, however. For some observables, the possible results of exact measurement form a discrete set; for other observables, the possible numerical values are partly discrete, partly continuous; for example, the total energy of an electron in the field of a proton may have any positive value between 0 and $+\infty$, but may have only a discrete set of negative values, namely, -13.6, $-13.6/4$, $-13.6/9$, $-13.6/16$ eV,... Such observables are said to be quantized; often there are simple quantization rules determining the quantum numbers which specify the allowable discrete values. Spectroscopy, especially the study of atomic spectra, probably provides the most detailed quantitative confirmation of quantization.

Probability considerations. The uncertainty and complementarity principles, which limit the experimenter's ability to describe a physical system, must limit equally the experimenter's ability to predict the results of measurement on that system. Suppose, for instance, that a very careful measurement determines that the x coordinate of a particle is precisely $x = x_0$. This is permissible in nonrelativistic quantum mechanics. Then formally, the particle is known to be in the eigenstate corresponding to the eigenvalue $x = x_0$ of the x operator. Under these circumstances, an immediate repetition of the position measurement again will indicate that the particle lies at $x = x_0$. Knowing that the particle lies at $x = x_0$ makes the momentum p_x of the particle completely uncertain, however, according to relation (1*a*). A measurement of p_x immediately after the particle is located at $x = x_0$ could yield any value of p_x from $-\infty$ to $+\infty$.

More generally, suppose the system is known to be in the eigenstate corresponding to the eigenvalue α of the observable A. Then for any observable B, which is to some extent complementary to A, that is, for which an uncertainty relation of the form of relations (1) limits the accuracy with which A and B can simultaneously be measured, it is not possible to predict which of the many possible values $B = \beta$ will be observed. However, it is possible to predict the relative probabilities $P_\alpha(\beta)$ of immediately thereafter finding the observable B equal to β, that is, of finding the system in the eigenstate corresponding to the eigenvalue $B = \beta$.

To the eigenvalues correspond eigenfunctions, in terms of which $P_\alpha \lesssim \beta$ can be computed. In particular, when α is a discrete eigenvalue of A, and the operators depend only on x and p_x, the probability $P_\alpha(\beta)$ is postulated as in Eq. (3), where $u(x,\alpha)$

$$P\alpha(\beta) = \left| \int_{-\infty}^{\infty} dx\, v^*(x, \beta) u(x, \alpha) \right|^2 \tag{3}$$

is the eigenfunction corresponding to $A = \alpha$; $v(x,\beta)$ is the eigenfunction corresponding to $B = \beta$; and the * denotes the complex conjugate. The integral in Eq. (3) is called the projection of $u(x,\alpha)$ on $u(x,\beta)$. The quantity $|u(x,\alpha)|^2\, dx$ is the probability that the system, known to be in the eigenstate $A = \alpha$, will be found in the interval x to $x + dx$. *See* EIGENVALUE (QUANTUM MECHANICS).

Wave function. When the system is known to be in the eigenstate corresponding to $A = \alpha$, the eigenfunction $u(x,\alpha)$ is the wave function; that is, it is the function whose projection on an eigenfunction $v(x,\beta)$ of any observable B gives the probability of measuring $B = \beta$. The wave function $\psi(x)$ may be known exactly; in other words, the state of the system may be known as exactly as possible (within the limitations of uncertainty and complementarity), even though $\psi(x)$ is not the eigenfunction of a known operator. This circumstance arises because the wave function obeys Schrödinger's wave equation. Knowing the value of $\psi(x)$ at time $t = 0$, the wave equation completely determines $\psi(x)$ at all future times. In general, however, if $\psi(x,0) = u(x,\alpha)$, that is, if $\psi(x,t)$ is an eigenfunction of A at $t = 0$, then $\psi(x,t)$ will not be an eigenfunction of A at later times $t > 0$.

A system described by a wave function is said to be in a pure state. Not all systems are described by wave functions, however. For example, a beam of hydrogen atoms streaming out of a small hole in a hydrogen discharge tube can be regarded as a statistical ensemble or mixture of pure states oriented with equal probability in all directions.

Schrödinger equation. Equation (4) describes a plane wave of frequency f, wavelength λ, and amplitude $A(\lambda)$, propagating

$$\psi(x, t) = A(\lambda)\exp\left[2\pi i \left(\frac{x}{\lambda} - ft\right)\right] \tag{4}$$

in the positive x direction. The previous discussion concerning wave-particle duality suggests that this is the form of the wave function for a beam of free particles moving in the x direction with momentum $p = p_x$, with Eq. (2) specifying the connections between f, λ, and E, p. Differentiating Eq. (4), it is seen that Eqs. (5) hold. Since for a free particle $E = p^2/2m$, it follows also that Eq. (6) is valid.

$$p_x\psi = \frac{h}{\lambda}\psi = \frac{\hbar}{i}\frac{\partial\psi}{\partial x} \tag{5a}$$

$$E\psi = hf\psi = -\frac{\hbar}{i}\frac{\partial\psi}{\partial t} \tag{5b}$$

$$\frac{-\hbar^2}{2m}\frac{\partial^2\psi}{\partial x^2} = -\frac{\hbar}{i}\frac{\partial\psi}{\partial t} \tag{6}$$

See WAVE MOTION.

Equation (6) holds for a plane wave of arbitrary λ, and therefore for any superposition of waves of arbitrary λ, that is, arbitrary p_x. Consequently, Eq. (6) should be the wave equation obeyed by the wave function of any particle moving under no forces, whatever the projections of the wave function on the eigenfunctions of p_x. Equations (5) and (6) further suggest that for a particle whose potential energy $V(x)$ changes, in other words, for a particle in a conservative force field, $\psi(x,t)$ obeys Eq. (7).

$$\frac{-\hbar^2}{2m}\frac{\partial^2\psi}{\partial x^2} + V(x)\psi = -\frac{\hbar}{i}\frac{\partial\psi}{\partial t} \tag{7}$$

Equation 7 is the time-dependent Schrödinger equation for a one-dimensional (along x), spinless particle. Noting Eq. (5*b*), and observing that Eq. (7) has a solution for the form of Eq. (8), it is inferred that $\psi(x)$ of Eq. (8) obeys the time-dependent Schrödinger equation, Eq. (9).

$$\psi(x, t) = \psi(x)\, exp\, (-iEt/\hbar) \tag{8}$$

$$\frac{-\hbar^2}{2m}\frac{\partial^2\psi}{\partial x^2} + V(x)\psi = E\psi \tag{9}$$

See FORCE.

Equation (9) is solved subject to reasonable boundary conditions, for example, that ψ must be continuous and must not become infinite as x approaches $\pm\infty$. These boundary conditions restrict the values of E for which there exist acceptable solutions $\psi(x)$ to Eq. (9), the allowed values of E depending on $V(x)$. In this manner, the allowed energies of atomic hydrogen listed in the earlier discussion of quantization are obtained.

The forms of Eqs. (5*a*), (7), and (9) suggest that the classical observable p_x, must be replaced by the operator $(\hbar/i)\ (\partial/\partial x)$. With this replacement, Eq. (10) holds. In other words, whereas

$$(xp_x - p_x x)\psi = i\hbar\psi \tag{10}$$

the classical canonically conjugate variables x and p_x are numbers, obeying the commutative law in Eq. (11*a*), the quantum-mechanical quantities x and p_x are noncommuting operators, obeying Eq. (11*b*).

$$xp_x - p_x x = 0 \tag{11a}$$

$$xp_x - p_x x = i\hbar \tag{11b}$$

Correspondence principle. Since classical mechanics and Maxwell's electromagnetic theory accurately describe macroscopic phenomena, quantum mechanics must have a classical limit in which it is equivalent to the older classical theories. Although there is no rigorous proof of this principle for arbitrarily complicated quantum-mechanical systems, its validity is well established by numerous illustrations. [E.G.]

Quantum mineralogy Quantum mechanics applied to mineralogical systems. A theoretical understanding of chemical bonding and the electronic structure of minerals is fundamental to understanding the behavior of minerals. The principal goal of quantum mineralogy is to calculate from first principles the properties and transformations of solid earth materials. One of the advantages of this theoretical tool is the ability to predict the behavior of materials at conditions which are not readily accessible to experiment. More importantly, though, experimental observations may be interpreted in terms of quantum-mechanical theory. *See* CHEMICAL BONDING; QUANTUM CHEMISTRY; QUANTUM MECHANICS.

The methods used in quantum mineralogy are no different from those used for other chemical systems. They range from simple conceptions of the chemical bond in terms of quantum-mechanical expressions to rigorous calculation of wave functions for model systems. Too often, the more exact the quantum-mechanical calculation, the less understandable are the results for the nonspecialist. Despite such limitations, quantum mineralogy is a powerful theoretical probe into the nature, of structure, bonding, and properties of mineral systems. The size and complexity of model systems that can be considered in rigorous calculations continue to grow rapidly with increasing efficiency of computer hardware and program algorithms. *See* CHEMICAL STRUCTURES; MINERALOGY; SOLID-STATE CHEMISTRY; SOLID-STATE PHYSICS. [B.C.C.]

Quantum numbers The quantities, usually discrete with integer or half-integer values, which are needed to characterize a physical system of one or more atomic or subatomic particles. Specification of the set of quantum numbers serves to define such a system or, in other words, to label the possible states the system may have. In general, quantum numbers are obtained from conserved quantities determinable by performing symmetry transformations consisting of arbitrary variations of the system which leave the system unchanged. For example, since the behavior of a set of particles should be independent of the location of the origin in space and time (that is, the symmetry operation is translation in space-time), it follows that momentum and energy are rigorously conserved. *See* SYMMETRY LAWS (PHYSICS).

In general, each physical system must be studied individually to find the symmetry transformations, and thus the conserved quantities and possible quantum numbers. The quantum numbers themselves, that is, the actual state labels, are usually the eigenvalues of the physical operators corresponding to the conserved quantities for the system in question. *See* EIGENVALUE (QUANTUM MECHANICS); ELEMENTARY PARTICLE; PARITY (QUANTUM MECHANICS).

It is not necessary that the conserved quantity be "quantized" in order to be regarded as a quantum number; for example, a free particle possesses energy and momentum, both of which can have values from a continuum but which are used to specify the state of the particle. [K.E.L.]

Quantum solids A class of solids whose atoms or molecules undergo large zero-point motion even in the quantum ground state (at temperature $T = 0\ \mathrm{K} = -459.67^\circ\mathrm{F}$) as a result of their small mass and the weak attractive part of their interaction potential. The most striking examples are the isotopes of helium, ^{3}He and ^{4}He, which have a root-mean-square displacement from their lattice sites of approximately 25%. Further examples are the molecular hydrogens, H_2, D_2, and HD, as well as some heavier molecular solids. *See* INTERMOLECULAR FORCES; QUANTUM MECHANICS.

These materials display quantum effects in their bulk properties when cooled to temperatures near absolute zero so that the chaotic thermal motion is reduced. Both of the helium isotopes remain liquid all the way to absolute zero, unless external pressure ($\sim$3 megapascals $\approx$ 30 atm) is applied. This is because the atoms are not at rest at 0 K; the zero-point motion acts as an internal pressure which must be overcome in order to bring the atoms close enough together for solidification. All other substances, including the hydrogens, freeze under their own vapor pressure above 10 K.

The two melting curves are quite different in detail because of the different types of quantum statistics which the particles obey. There is a pronounced minimum in the ^{3}He melting pressure which is unique, and can be understood by considering the entropies of the liquid and the solid. The pressure minimum leads to the bizarre situation of the addition of heat causing freezing. The inverse of this process, the adiabatic formation of the solid by compression, is an important process which has been used extensively to cool liquid and solid ^{3}He to temperatures of approximately 1 mK. *See* CRYOGENICS; LIQUID HELIUM. [E.D.A.]

Quantum statistics The statistical description of particles or systems of particles whose behavior must be described by quantum mechanics rather than by classical mechanics. As in classical, that is, Boltzmann statistics, the interest centers on the construction of appropriate distribution functions. However, whereas these distribution functions in classical statistical mechanics describe the number of particles in given (in fact, finite) momentum and positional ranges, in quantum statistics the distribution functions give the number of particles in a group of discrete energy levels. In an individual energy level there may be, according to quantum mechanics, either a single particle or any number of particles. This is determined by the symmetry character of the wave functions. For antisymmetric wave functions only one particle (without spin) may occupy a state; for symmetric wave functions, any number is possible. Based on this distinction, there are two separate distributions, the Fermi-Dirac distribution for systems described by antisymmetric wave functions and the Bose-Einstein distribution for systems described by symmetric wave functions. *See* BOLTZMANN STATISTICS; BOSE-EINSTEIN STATISTICS; EXCLUSION PRINCIPLE; FERMI-DIRAC STATISTICS; KINETIC THEORY OF MATTER; QUANTUM MECHANICS; STATISTICAL MECHANICS. [M.Dr.]

Quantum theory of matter The microscopic explanation of the properties of condensed matter, that is, solids and liquids, based on the fundamental laws of quantum mechanics. Without the quantum theory, some properties of matter such as magnetism and superconductivity have no explanation at all, while for others only a phenomenological description can be obtained. With the theory, it is at least possible to comprehend what is needed to approach a complete understanding.

The theoretical problem of condensed matter—large aggregates of elementary particles with mutual interactions—is the quantum-mechanical many-body problem: an enormous number, of order 10^{23}, of constituent particles in the presence of a heat bath and interacting with each other according to quantum-mechanical laws. What makes the quantum physics of matter different from the traditional quantum theory of elementary particles is that the fundamental constituents (electrons and ions) and their interactions (Coulomb interactions) are known but the solutions of the appropriate quantum-mechanical equations are not. This situation is not due to the lack of a sufficiently large computer, but is caused by the fact that totally new structures, such as crystals, magnets, ferroelectrics, superconductors, liquid crystals, and glasses, appear out of the complexity of the interactions among the many constituents. The consequence is that entirely new conceptual approaches are required to construct predictive theories of matter. The usual technique for approaching the quantum many-body problem for a condensed-matter system is to try to reduce the huge number of variables (degrees of freedom) to a number which is more manageable but still can describe the essential physics of the phenomena being studied. *See* CRYSTAL; FERROELECTRICS; GLASS; LIQUID CRYSTALS; MAGNETIC MATERIALS; QUANTUM MECHANICS; SOLID-STATE PHYSICS; SUPERCONDUCTIVITY. [E.A.]

Quantum theory of measurement The attempt to reconcile the counterintuitive features of quantum mechanics with the hypothesis that quantum mechanics is in principle a complete description of the physical world, even at the level of everyday objects. A paradox arises because, at the atomic level where the quantum formalism has been directly tested, the most natural interpretation implies that where two or more different outcomes are possible it is not necessarily true that one or the other is actually realized, whereas at the everyday level such a state of affairs seems to conflict with direct experience.

The resolution of this paradox that is probably most favored by practicing physicists proceeds in two stages. At stage 1, it is pointed out that, quite generically, whenever the quantum formalism appears to generate a superposition of macroscopically distinct states it is impossible to demonstrate the effects of interference between them. The reasons for this claim include the facts that the initial state of a macroscopic system is likely to be unknown in detail; the initial state has extreme sensitivity to random external noise; and most important, merely by virtue of its macroscopic nature any such system will rapidly have its quantum-mechanical state correlated (entangled) with that of its environment in such a way that no measurement on the system alone (without a simultaneous measurement of the complete state of the environment) can demonstrate any interference between the two states in question—a result often known as decoherence. Thus, it is argued, the outcome of any possible experiment on the ensemble of macroscopic systems prepared in this way will be indistinguishable from that expected if each system had actually realized one or the other of the two macroscopically distinct states in question. Stage 2 of the argument (often not stated explicitly) is to conclude that if this is indeed true, then it may be legitimately asserted that such realization of a definite macroscopic outcome has indeed taken place by this stage.

Most physicists agree with stage 1 of the argument. However, not all agree that the radical reinterpretation of the meaning of the quantum formalism which is implicit at stage 2 is legitimate; that is, an interpretation in terms of realization, by each individual system, of one alternative or the other, forbidden at the atomic level by the observed phenomenon of interference, is allowed once, on going to the macroscopic level, the phenomenon disappears. Consequently, various alternative interpretations have been developed. *See* QUANTUM MECHANICS. [A.J.L.]

Quark-gluon plasma A predicted state of matter containing deconfined quarks and gluons. According to the theory of strong interactions, called quantum chromodynamics, hadrons such as mesons and nucleons (the generic name for protons and neutrons) are bound states of more fundamental objects called quarks. The quarks are confined within the individual hadrons by the exchange of particles called gluons. However, calculations indicate that at sufficiently high temperatures or densities, hadronic matter should evolve into a new phase of matter containing deconfined quarks and gluons, called a quark-gluon plasma or quark matter. Such a state of matter is thought to have existed briefly in the period about 1–10 microseconds after the big bang, and might also exist inside the cores of dense neutron stars. *See* BIG BANG THEORY; HADRON; NEUTRON STAR; QUANTUM CHROMODYNAMICS.

The study of such a new state of matter requires a means for producing it under controlled laboratory conditions. Experimentally the transition from the hadronic to the quark-gluon phase requires collisions of beams of heavy ions such as nuclei of gold or uranium (although lighter nuclei can be used) with other heavy nuclei at high enough energies to produce the necessary extreme conditions of heat and compression. Quantum chromodynamics calculations using the lattice gauge model indicate that energy densities of at least 1–2 GeV/fm^3 (1 femtometer = 10^{-15} m), about 10 times that found in ordinary nuclear matter, must be produced in the collision for plasma formation to occur. *See* NUCLEAR REACTION; RELATIVISTIC HEAVY-ION COLLISIONS.

Accelerator experiments using beams of nuclei with energies of 10–200 GeV/nucleon bombarding stationary nuclear targets have found interesting phenomena such as nuclear stopping. In such cases, the colliding nucleons of the target and projectile are observed to pile up on each other, achieving large nuclear matter densities (two to four times normal nuclear density, or higher) corresponding to energy densities near the threshold for quark matter production. Other results of these experiments suggest that conditions favorable to thermal and chemical equilibrium may be present in some of these collisions. Such experiments can provide critical tests of the theory of the strong interaction and illuminate the earliest moments of the universe. *See* ELEMENTARY PARTICLE; GLUONS; QUARKS. [L.S.S.]

Quarks The basic constituent particles of which elementary particles are understood to be composed. Theoretical models built on the quark concept have been very successful in understanding and predicting many phenomena in the physics of elementary particles.

The study of the elastic scattering of electrons on protons demonstrated that the proton has a finite form factor, that is, a finite radial extent of its electric charge and magnetic moment distributions. It was plausible that the charge cloud which constitutes the proton is a probability distribution of some smaller, perhaps pointlike constituents, just as the charge cloud of an atom was learned to be the probability distribution of electrons. Subsequent high-energy, deep inelastic scattering experiments of electrons on protons, leading to meson production, revealed form factors corresponding to pointlike constituents of the proton. These proton constituents, first referred to as partons, are now understood to include the constituent quarks of the proton.

These high-energy collisions also produced an abundance of resonance states, equivalent to short-lived particles. The spectroscopy of these hadronic states revealed an order and symmetry among the observed hadrons that could be interpreted in terms of representations of the SU(3) symmetry group. This in turn is interpreted as a consequence of the grouping of elementary constituents of fractional electric charge in pairs and triplets to form the observed particles. The general features of the quark model of hadrons have withstood the tests of time,

Properties of quarks

Flavor	Mass[†], GeV/c^2	Electric charge[‡]	Baryon number	Spin[§]	Isotopic spin	Strangeness	Charm
u	0.0015–0.004	+2/3	+1/3	1/2	1/2	0	0
d	0.004–0.008	−1/3	+1/3	1/2	1/2	0	0
c	1.15–1.35	+2/3	+1/3	1/2	0	0	+1
s	0.080–0.130	−1/3	+1/3	1/2	0	−1	0
t	174.3±5.1[¶]	+2/3	+1/3	1/2	0	0	0
b	4.1–4.4	−1/3	+1/3	1/2	0	0	0

[†] As the mass of baryons composed of quarks is strongly influenced by the gluons binding the quarks, and as free quarks are not observed, the masses are theoretical estimates.

[‡] Charge is in units of the magnitude of the charge of an electron, 1.6×10^{-19} coulomb.

[§] Spin is in units of Planck's constant divided by 2π, written as $\hbar$.

[¶] The top quark mass is deduced from experimental measurements of its decay dynamics.

and the static properties of hadrons are consistent with predictions of this model. *See* Symmetry laws (physics); Unitary symmetry.

Thus, the proton and neutron are not fundamental constituents of matter, but each is composed of three quarks, very much as the nuclei of ^{3}H and ^{3}He are made of protons and neutrons, and the molecules of NO_2 and N_2O are made of oxygen and nitrogen atoms.

There are two kinds (or "flavors") of quarks of very low mass of which the proton, neutron, and pions are composed, and a third, more massive quark which is a constituent of "strange" particles, including the K mesons and hyperons such as the Λ^0. These are known as the up quark (u), the down quark (d), and the strange quark (s). Baryons are composed of three quarks, for example the proton (uud), neutron (udd), Λ^0 (uds), and Ξ^- (dss). Antiparticles such as antiprotons are formed by the antiquarks of those forming the particle, for example, the antiproton $\bar{p}(\bar{u}\bar{u}\bar{d})$. Mesons are composed of a quark-antiquark pair, such as the $\pi^+(u\bar{d})$, $\pi^-(\bar{u}d)$, $K^+(u\bar{s})$, and $K^-(\bar{u}s)$. *See* Baryon; Hyperon; Meson; Strange particles.

The quantum numbers of quarks are added to give the quantum numbers of the elementary particle which they form on combination. The unit of electrical charge of a quark is +2/3 or −1/3 of the charge on a proton (1.6×10^{-19} coulomb), and the baryon number of each quark is +1/3 (see table). The charge, baryon number, and so forth, of each antiquark are just the negative of that for each quark.

During the 1970s, experiments at electron-positron colliders and proton accelerators detected a relatively long-lived (that is, very narrow, in energy) resonant state of about 3.1 GeV total energy. This was interpreted as evidence for a new quark, the charm (c) quark, produced as a quark-antiquark resonance analogous to the ϕ. The discovery of this J/ψ resonance was followed by the observation and study of meson systems, now labeled D mesons, containing a single c or quark (paired with an antiquark of another flavor), as well as baryon states containing these quarks. *See* Charm; J/psi particle; Particle accelerator.

A few years later, experiments with higher-energy proton beams, studying the spectra of muon-antimuon pairs at the Fermi National Accelerator Laboratory, discovered a more massive, narrow resonant state at about 9.4 GeV, which was labeled the Υ (upsilon). This was interpreted as evidence for a more massive quark, the b (bottom) quark. Subsequent experiments at proton and electron accelerators confirmed the existence of the b quark and also observed a corresponding family of meson resonant states, now referred to as B mesons.

During the 1990s, experiments observing collisions of protons and antiprotons at an energy of 1.8 TeV in the center of mass established the existence of the t (top) quark, primarily through analysis of its decay to a B meson and a W intermediate vector boson. The t mass of 174.3 ± 5.1 GeV/c^2 (about the mass of a tungsten atom) is so great that its weak decay through this channel is very fast, and mesonic states of the t and $\bar{t}$ quark (analogous to the Υ, the J/ψ, and the ϕ) are not observed, although the observed t's are from the production of pairs. *See* Intermediate vector boson.

Quarks are understood to have a spin of 1/2; that is, their intrinsic angular momentum is $\hbar/2$ (where $\hbar$ is Planck's constant h divided by 2π), just as for the electron and muon. A problem arose when the structure of observed baryons required two or, in some cases, three quarks of the same flavor in the same quantum state, a situation forbidden for spin-1/2 particles by the Pauli exclusion principle. In order to accommodate this contradiction, a new quantum variable, arbitrarily labeled color, was introduced; the idea is that each quark is red, green, or blue (and the antiquarks, antired, and so forth). The color quantum number then breaks the degeneracy and allows up to three quarks of the same flavor to occupy a single quantum state. Confirmation of the color concept has been obtained from experiments with electron-positron storage rings, and the theory of quantum chromodynamics (QCD), based on this concept, has been developed. According to quantum chromodynamics, hadrons must be colorless; for example, baryons must consist of a red, a green, and a blue quark, and mesons of a quark-antiquark pair of the same color (for example, a red quark and an anti-red antiquark). *See* Color (quantum mechanics); Exclusion principle; Spin (quantum mechanics).

The field quanta of quantum chromodynamics are gluons, massless, spin-1 quanta which interact with quarks. This is very analogous to the manner in which photons, the quanta of electromagnetic interaction, interact with particles containing electric charge and are responsible for electromagnetic forces. The QCD theory is part of the now widely accepted standard model of elementary particle interactions, together with the electroweak theory. Experiments have increasingly confirmed details of the standard model to the extent that most physicists are confident that it is fundamentally correct. *See* Electroweak interaction; Gluons; Quantum chromodynamics; Standard model.

There are three sets, or "generations," of quarks and leptons. Each generation contains a charged lepton (electron, muon, or tau lepton); a correspoding neutrino; a charge −1/3 quark color triad; and a charge +2/3 quark triad. *See* Lepton; Neutrino.

Quarks and the theory of quantum chromodynamics are now firmly established as cornerstones of the standard model of elementary particles (together with the electroweak theory, charged leptons, neutrinos, and so forth). However, unanswered questions remain.

The advanced string and M theories have the property of supersymmetry, which demands that every spin-1/2 quark and lepton must have a partner with integral spin. As of 2004, no experimental evidence for any of these supersymmetric (SUSY) particles had been found. *See* Superstring theory; Supersymmetry.

Contemporary theories also predict that there exists one or more massive particles of integral spin, the Higgs paticles, responsible for the rest masses of the quarks and charged leptons. Again, the lack of evidence suggests that the Higgs particles must also have a rest mass of over 100 GeV/c^2, if they exist. *See* HIGGS BOSON.

Quarks may be permanently stable against decay via the weak interaction; however, it is also possible that quarks spontaneously decay to leptons. Intensive searches for the decay of the proton (into a neutral pion and a positron, for example) have been negative, setting a lower limit of over 10^{32} years for the proton lifetime. However, the apparent asymmetry of the universe between matter and antimatter (there is, at present, no evidence for primordial antimatter) suggests that antiprotons, for example, may spontaneously decay (or transform) more readily. *See* ANTIMATTER; PROTON.

Some theories have postulated that quarks are composed of smaller constituents, just as other objects that were originally believed to be fundamental subsequently were found to have internal structure. So far, all observations are compatible with the quarks as point objects, like the electron. [L.W.J.]

Quarrying The process of extracting stone for commercial use from natural rock deposits. The industry has two major branches: a dimension-stone branch, involving preparation of blocks of various sizes and shapes for use as building stone, monumental stone, paving stone, curbing, and flagging; and a crushed-stone branch, involving preparation of crushed and broken stone for use as a basic construction, chemical, and metallurgical raw material. [S.H.Bo.]

Quartz The most common oxide on the Earth'ssurface, constituting 12% of the crust by volume. Quartz is a crystalline form of silicon dioxide (SiO_2). Among the igneous rocks, quartz is especially common within granites, granodiorites, pegmatites, and rhyolites. In addition, quartz can be observed in low- to high-grade metamorphic rocks, including phyllites, quartzites, schists, granulites, and eclogites. Because hydrothermal fluids are enriched in dissolved silica, the passage of fluids through rock fractures results in the emplacement of quartz veins. *See* GRANITE; GRANODIORITE; IGNEOUS ROCKS; METAMORPHIC ROCKS; PEGMATITE; RHYOLITE.

Once quartz has formed, it persists through erosional reworking because of its low solubility in water (parts per million) and its high mechanical hardness (7 on Mohs scale). Consequently, quartz becomes increasingly concentrated in beach sands as they mature, and it is a major component of sandstone. In sedimentary environments, quartz also forms as the final crystallization product during silica diagenesis; amorphous silica on the sea floor that derives from the skeletons of diatoms, radiolarians, and sponges will transform to quartz upon prolonged exposure to increased temperatures ($\leq$300°C or 572°F) and pressures ($\leq$2 kilobars or 200 pascals) after burial. *See* DIAGENESIS; HARDNESS SCALES; SANDSTONE.

As with virtually all silicates, the atomic framework of the quartz structure consists of Si^{4+} cations that are tetrahedrally coordinated by oxygen anions (O^{2-}). Every oxygen anion is bonded to two silicon cations, so that the tetrahedral units are corner-linked to form continuous chains. In low-temperature quartz (or α-quartz), two distinct tetrahedral chains spiral about the crystallographic c axis.

Although the silica tetrahedra can be depicted as spirals about the c axis in a left-handed sense, right-handed quartz crystals are found in nature as abundantly as are left-handed crystals. These enantiomorphic varieties are known as the Brazil twins of quartz, and they may be distinguished by crystal shape (corresponding crystal faces occur in different orientations) and by opposite optical activities. *See* CRYSTAL OPTICS.

Impurity concentrations in natural α-quartz crystals usually fall below 1000 parts per million. The violet and yellow hues observed in amethyst and citrine are associated with Fe, and black smoky quartz contains Al. The white coloration of milky quartz reflects light scattering off minute fluid inclusions, and the pink tint in rose quartz is believed to arise from fine-scale intergrowths of a pegmatitic mineral called dumortierite [$Al_{27}B_4Si_{12}O_{69}(OH)_3$]. *See* AMETHYST; DUMORTIERITE.

Quartz is used predominantly by the construction industry as gravel and as aggregate in concrete. In addition, quartz is important in advanced technologies. Quartz is piezoelectric and has an extremely high quality factor. The high quality factor means that a bell made of quartz would resonate (ring) for a very long time. This property, combined with its piezoelectric behavior, makes quartz the perfect crystal for oscillators in watches.

Compression of α-quartz perpendicular to the c axis creates an electrostatic charge, and this property is exploited in oscillator plates in electronic components. Large flawless crystals of quartz are routinely synthesized for oscillators and for prisms in laser optic systems. Quartz also is employed in abrasives, fluxes, porcelains, and paints. *See* CONCRETE; OSCILLATOR; PIEZOELECTRICITY. [P.J.H.]

Quartz clock A clock that makes use of the piezoelectric property of a quartz crystal. When a quartz crystal vibrates, a difference of electric potential is produced between two of its faces. The crystal has a natural frequency of vibration that depends on its size and shape. If it is placed in an oscillating electric circuit having nearly the same frequency as the crystal, it is caused to vibrate at its natural frequency, and the frequency of the entire circuit becomes the same as the natural frequency of the crystal. *See* OSCILLATOR; PIEZOELECTRICITY.

In the quartz oscillator, this natural frequency may be used to produce such other frequencies as 1 or 5 MHz. A clock displaying the time of day can also be driven by using one of these frequencies.

The natural frequency of a quartz crystal is nearly constant if precautions are taken when it is cut and polished and it is maintained at nearly constant temperature and pressure. After a crystal has been placed in operation, its frequency usually varies slowly as a result of physical changes. If allowance is made for changes, laboratory quartz-crystal clocks may run for a year with accumulated errors of less than a few thousandths of a second. However, quartz crystals typically used in watches may accumulate errors of several tens of seconds in one year. *See* WATCH.

The advantage of quartz clocks is that they are relatively inexpensive and easy to use in various applications such as computers and microprocessors. Thus, despite their inaccuracy relative to some other types of clocks, they enjoy wide popularity, particularly in applications requiring accurate timekeeping over a relatively short time span. In these applications, the rates and epochs of the quartz clocks may be readjusted periodically to account for possible accumulated errors. *See* CLOCK; COMPUTER; HOROLOGY; MICROPROCESSOR; TIME. [D.D.McC.]

Quartzite A metamorphic rock consisting largely or entirely of quartz. Most quartzites are formed by metamorphism of sandstone; but some have developed by metasomatic introduction of quartz, SiO_2, often accompanied by other chemical elements, for example, metals and sulfur (ore quartzites). *See* METAMORPHIC ROCKS; METASOMATISM; SANDSTONE.

Pure sandstones yield pure quartzites. Impure sandstones yield a variety of quartzite types. The cement of the original sandstone is in quartzite recrystallized into characteristic silicate minerals, whose composition often reflects the mode of development. Even the Precambrian quartzites correspond to types that are parallel to present-day deposits. *See* QUARTZ. [T.F.W.B.]

Quasar An astronomical object that appears starlike on a photographic plate but possesses many other characteristics, such as a large redshift, that prove that it is not a star. The name quasar is a contraction of the term quasistellar object (QSO), which was originally applied to these objects for their photographic appearance. The objects appear starlike because their angular diameters are less than about 1 second of arc, which is the resolution limit of ground-based optical telescopes imposed by atmospheric effects.

Quasars were discovered in 1961 when it was noticed that very strong radio emission was coming from a localized direction in the sky that coincided with the position of a starlike object. When the positions of small-angular-diameter radio sources were accurately determined, the coincidence with starlike objects on optical photographs led to the discovery of a new, hitherto-unsuspected class of objects, the quasars. The full significance of the discovery was not appreciated until 1963, when it was noted that the hydrogen emission lines seen in the optical spectrum of the quasar 3C 273 were shifted by about 16% to the red from their normal laboratory wavelength. This redshift of the spectral lines is characteristic of galaxies whose spectra are redshifted because of the expansion of the universe and is not characteristic of stars in the Milky Way Galaxy.

The color of quasars is generally much bluer than that of most stars with the exception of white dwarf stars. The blueness of quasars as an identifying characteristic led to the discovery that many blue starlike objects have a large redshift and are therefore quasars. The quasistellar objects discovered this way turned out to emit little or no radio radiation and to be about 20 times more numerous than the radio-emitting quasistellar radio sources (QSSs). Why some should be strong radio emitters and most others not is unknown. Several orbiting x-ray satellites have found that most quasars also emit strongly at x-ray frequencies. Gamma rays have also been observed in many quasars. *See* GAMMA-RAY ASTRONOMY; X-RAY ASTRONOMY.

The emission from quasars varies with time. The shortest time scale of variability ranges from years to months at short radio wavelengths, to days at optical wavelengths, to hours at x-ray wavelengths. These different time scales suggest that the emissions from the different bands originate from different regions in the quasar. The rapid fluctuations indicate that there are some components in quasars that have diameters less than a light-hour or of the order of 10^9 km (10^9 mi), the size of the solar system. Very highly active quasars are sometimes referred to as optically violent variables (OVVs), blazars, or BL Lac's, after the prototype BL Lacertae, a well-known variable "star" that turned out to be a quasar. The optically violent variables have no or very weak emission lines in their optical spectrum.

The many similarities of the observed characteristics of quasars with radio galaxies, Seyfert galaxies, and BL Lacertae objects strongly suggest that quasars are active nuclei of galaxies. Quasars with large redshifts are spatially much more numerous than those with small redshifts. Because high-redshift objects are very distant and emitted their radiation at an earlier epoch, quasars must have been much more common in the universe about 10^{10} years ago. Observations with the Hubble Space Telescope have shown that this is the same epoch when galaxies are observed to be forming. Thus it is likely that quasars are associated with the birth of some galaxies.

More than 10^{53} J of energy are released in quasars over their approximately 10^6-year lifetime. Of the known energy sources, only gravitational potential energy associated with a mass about 10^9 times the mass of the Sun can provide this energy, but it is unknown how this gravitational energy produces jets of particles that are accelerated to very near the speed of light.

Several theories have been proposed for quasars. However, the most favored interpretation is that quasars are massive black holes surrounded by rapidly spinning disks of gas in the nuclei of some galaxies. The hot gas in the disk emits the x-ray and optical continuum, a heated halo around the disk produces the emission lines, and the relativistic radio jets are ejected along the rotation axis of the spinning disk. *See* ASTRONOMICAL SPECTROSCOPY; ASTROPHYSICS, HIGH-ENERGY; BLACK HOLE; INFRARED ASTRONOMY; NEUTRON STAR; RADIO ASTRONOMY. [W.D.]

Quasiatom

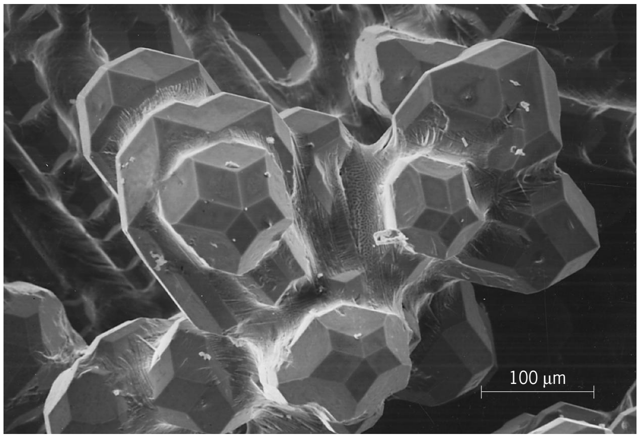
Quasiatom A structure in which the nuclei of two atoms approach each other closely and their electrons are arranged in atomic orbitals characteristic of a single atom of atomic number equal to the sum of the nuclear charges. Quasiatoms can be formed for short times in atom-atom and ion-atom collisions when the nuclei are much closer than the mean orbital radius of the innermost K-shell electrons. The electrons are then bound in the electric field of both nuclear charges Z_1 and Z_2, which resembles the spherically symmetric $1/r^2$ Coulomb field of a single united atom having charge $Z_{ua} = Z_1 + Z_2$. *See* ATOMIC STRUCTURE AND SPECTRA.

An interesting effect is associated with quasiatoms with $Z > 173$, in which the 1*s* binding energy is more than twice the electron rest mass, $E_{1s} > 2mc^2$. If a vacancy exists in this orbital, it is energetically favorable to create an electron-positron pair with the electron bound in this state. The positron would be repelled from the nucleus with kinetic energy equal to $E_{e^+} = |E_{1s}| - 2mc^2$. In the Dirac hole picture, in which the vacuum consists of a negative energy continuum ($E < -mc^2$) filled with electrons, the 1*s* level is said to fall into the negative-energy Dirac sea as Z increases above the critical value, $Z_{cr} = 173$. A 1*s* hole (vacancy) becomes embedded in the negative continuum as an unstable resonance state that decays in a time of $\sim 10^{-19}$ s to a bound electron and a spontaneously emitted monoenergetic positron.

The quantum electrodynamic vacuum in the presence of a bare supercritical nuclear charge is therefore unstable and decays to a fundamentally new charged vacuum, which consists of the nucleus with two 1*s* electrons (from the two spin orientations). At higher values of Z_{ua}, as additional quasiatomic levels enter the negative continuum, the charge of the quantum electrodynamic vacuum increases accordingly. If detected, spontaneous positron emission would represent the first observation of a phase transition in a gauge field theory. *See* ANTIMATTER; ELECTRON-POSITRON PAIR PRODUCTION; GAUGE THEORY; PHASE TRANSITIONS; POSITRON; QUANTUM ELECTRODYNAMICS; SUPERCRITICAL FIELDS. [T.E.C.]

Quasicrystal

Quasicrystal A solid with conventional crystalline properties but exhibiting a point-group symmetry inconsistent with translational periodicity. Like crystals, quasicrystals display discrete diffraction patterns, crystallize into polyhedral forms, and have long-range orientational order, all of which indicate that their structure is not random. But the unusual symmetry and the finding that the discrete diffraction pattern does not fall on a reciprocal periodic lattice suggest a solid that is quasiperiodic. Their discovery in 1982 contradicted a long-held belief that all crystals would be periodic arrangements of atoms or molecules.



Quasicrystals of an alloy of aluminum, copper, and iron, displaying an external form consistent with their icosahedral symmetry.

It is easily shown that in two and three dimensions the possible rotations that superimpose an infinitely repeating periodic structure on itself are limited to angles that are 360°/*n*, where *n* can be only 1, 2, 3, 4, or 6. Various combinations of these rotations lead to only 32 point groups in three dimensions, and 230 space groups which are combinations of the 14 Bravais lattices that describe the periodic translations with the allowed rotations. Until the 1980s, all known crystals could be classified according to this limited set of symmetries allowed by periodicity. Periodic structures diffract only at discrete angles (Bragg's law) that can be described by a reciprocal lattice, in which the diffraction intensities fall on lattice points that, like all lattices, are by definition periodic, and which has a symmetry closely related to that of the structure. *See* CRYSTAL; CRYSTALLOGRAPHY; X-RAY CRYSTALLOGRAPHY; X-RAY DIFFRACTION.

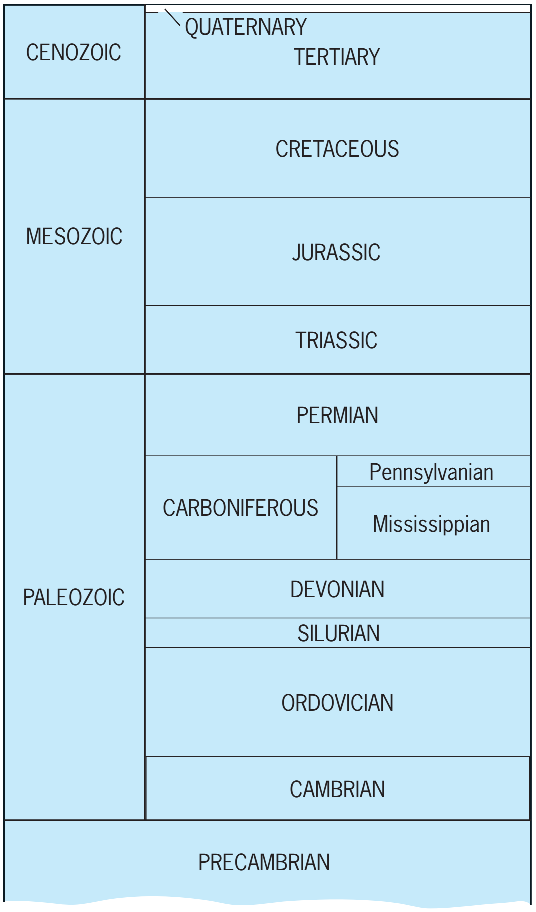
Icosahedral quasicrystals were discovered in 1982 during a study of rapid solidification of molten alloys of aluminum with one or more transition elements, such as manganese, iron, and chromium. Since then, many different alloys of two or more metallic elements have led to quasicrystals with a variety of symmetries and structures. The illustration shows the external polyhedral form of an icosahedral aluminum-copper-iron alloy.

The diffraction patterns of quasicrystals violate several predictions resulting from periodicity. Quasicrystals have been found in which the quantity *n* is 5, 8, 10, and 12. In addition, most quasicrystals exhibit icosahedral symmetry in which there are six intersecting fivefold rotation axes. Furthermore, in the electron diffraction pattern the diffraction spots do not fall on a (periodic) lattice but on what has been called a quasilattice. *See* ELECTRON DIFFRACTION. [J.W.C.; D.S.]

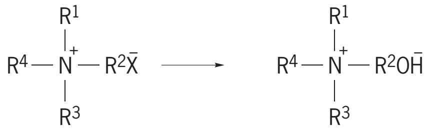
Quasielastic light scattering Small frequency shifts or broadening from the frequency of the incident radiation in the light scattered from a liquid, gas, or solid. The term quasielastic arises from the fact that the frequency changes are usually so small that, without instrumentation specifically designed for their detection, they would not be observed and the scattering process would appear to occur with no frequency changes at all, that is, elastically. The technique is used by chemists, biologists, and physicists to study the dynamics of molecules in fluids, mainly liquids and liquid solutions. It is often identified by a variety of other names, the most common of which is dynamic light scattering (DLS).

Several distinct experimental techniques are grouped under the heading of quasielastic light scattering (QELS). Photon correlation spectroscopy (PCS) is the technique most often used to study such systems as macromolecules in solution, colloids, and critical phenomena where the molecular motions to be studied are rather slow. This technique, also known as intensity fluctuation spectroscopy and, less frequently, optical mixing spectroscopy, is used to measure the dynamical constants of processes with relaxation time scales slower than about 10^{-6} s. For faster processes, dynamical constants are obtained by utilizing techniques known as filter methods, which obtain direct measurements of the frequency changes of the scattered light by utilizing a monochromator or filter much as in Raman spectroscopy. *See* RAMAN EFFECT; SCATTERING OF ELECTROMAGNETIC RADIATION. [R.P.]

Quaternary A period that encompasses at least the last 3,000,000 years of the Cenozoic Era, and is concerned with major worldwide glaciations and their effect on land and sea, on worldwide climate, and on the plants and animals that lived then. The Quaternary is divided into the Pleistocene Epoch and Holocene. The universal term Pleistocene is gradually re-placing Quaternary; Holocene involves the last 7000 years since the Pleistocene. *See* CENOZOIC; GLACIAL EPOCH; HOLOCENE; PLEISTOCENE. [S.E.Wh.]



Quaternary ammonium salts Analogs of ammonium salts in which organic radicals have been substituted for all four hydrogens of the original ammonium cation. Substituents may be alkyl, aryl, or aralkyl, or the nitrogen may be part of a ring system. Such compounds are usually prepared by treatment of an amine with an alkylating reagent under suitable conditions. They are typically crystalline solids which are soluble in water and are strong electrolytes. Treatment of the salts with silver oxide, potassium hydroxide, or an ion-exchange resin converts them to quaternary ammonium hydroxides, which are very strong bases, as shown in the reaction below.



$$\begin{array}{c} R^1 \\ | \\ R^4-\overset{+}{N}-R^2\overset{-}{X} \\ | \\ R^3 \end{array} \longrightarrow \begin{array}{c} R^1 \\ | \\ R^4-\overset{+}{N}-R^2\overset{-}{OH} \\ | \\ R^3 \end{array}$$

Quaternary ammonium salt — Quaternary ammonium hydroxide

Some quaternary ammonium salts have found use as water repellents, fungicides, emulsifiers, paper softeners, antistatic agents, and corrosion inhibitors. *See* AMINE; AMMONIUM SALT; SURFACTANT. [P.E.F.]

Quaternions An associative, noncommutative algebra based on four linearly independent units or basal elements. Quaternions were originated in 1843, by W. R. Hamilton.

The four linearly independent units in quaternion algebra are commonly denoted by 1, *i, j, k*, where 1 commutes with *i, j, k* and is called the principal unit or modulus. These four units are assumed to have the following multiplication table:

$$1^2 = 1i^2 = j^2 = k^2 = ijk = -1$$

$$i(jk) = (ij)k = ijk$$

$$1i = i1 \qquad 1j = j1 \qquad 1k = k1$$

The *i, j, k* do not commute with each other in multiplication, that is, $ij \neq ji$, $jk \neq kj$, $ik \neq ki$, etc. But all real and complex numbers do commute with *i, j, k*, thus if *c* is a real number, then $ic = ci$, $jc = ci$, and $kc = ck$. On multiplying $ijk = -1$ on the left by *i*, so that $iijk = i(-1) = -i$, it is found, since $i^2 = -1$, that $jk = i$. Similarly $jjk = ji = -k$; when exhausted, this process leads to all the simple noncommutative relations for *i, j, k*, namely,

$$ij = -ji = k \qquad jk = -kj = i \qquad ki = -ik = j$$

More complicated products, for example, $jikjk = -kki = i$, are evaluated by substituting for any adjoined pair the value given in the preceding series of relations and then proceeding similarly to any other adjoined pair in the new product, and so on until the product is reduced to ± 1, $\pm i$, $\pm j$, or $\pm k$. Multiplication on the right is also permissible; thus from $ij = k$, one has $ijj = kj$, or $-i = kj$. Products such as *jj* and *jjj* may be written j^2 and j^3.

All the laws and operations of ordinary algebra are assumed to be valid in the definition of quaternion algebra, except the commutative law of multiplication for the units *i, j, k*. Thus the associative and distributive laws of addition and multiplication apply Without restriction throughout. Addition is also commutative, for example, $i + j = j + i$. [D.M.Y.]

Quebracho Any of a number of trees belonging to different genera but having similar qualities, all indigenous to South America and valuable for both wood and bark. The heartwood of one South American tree, *Schinopsis lorentzii* (family Anacardiaceae), is called quebracho (meaning ax-breaker) in reference to the exceedingly hard wood, one of the hardest known. Quebracho is the world's most important source of tannin. *See* SAPINDALES; TANNIN. [P.D.St./E.L.C.]

Queueing theory The mathematical theory of the formation and behavior of queues or waiting lines. The name is also applied loosely to the mathematical study of a wide variety of problems connected with traffic congestion and storage systems. Uneven flow through a service point, with fluctuating arrivals and service times, constitutes a major topic of operations research. For the mathematician, queueing theory is particularly interesting because it is concerned with relatively simple stochastic processes, which are in general non-Markovian and possibly stationary. *See* OPERATIONS RESEARCH; STOCHASTIC PROCESS.

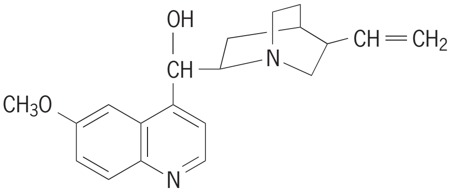
The principal pioneer of queueing theory, A. K. Erlang, began in 1908 to study problems of telephone congestion. It is of interest to study the waiting times of subscribers in a manually operated system—for example, the average waiting time and the chance that a subscriber will obtain service immediately without waiting—and to examine how much the waiting times will be affected if the number of operators is altered, or conditions are changed in any other way. If there are more operators or if service can be speeded up, subscribers will be pleased because waiting will be reduced, but the improved facility will be more expensive to maintain; therefore, a reasonable balance must be struck.

Related problems in the use of automatic telephone exchanges and of long-distance lines able to carry only a limited number of messages simultaneously have resulted in much mathematical study of telephone traffic problems. Similar problems arise in other contexts. In a factory a number of machines, such as looms, may be under the care of one or more repairer. If a machine breaks down, it must stand idle until a repairer is free from repairing other machines. Machines here correspond to telephone subscribers, breakdown corresponds to attempts to make a call, and repair corresponds to connection. Other examples of congestion situations are aircraft flying around in circles waiting to use an airport landing strip, automobiles lining up at a turnpike toll booth, and customers lining up at the counter of a retail shop, waiting for service.

What is most interesting to investigate varies with the circumstances. Sometimes it is the mean waiting time of customers, sometimes the frequency with which the queue length exceeds a given limit, sometimes the proportion of the servers' time that is idle, and sometimes the average duration of a period during which a server is continuously occupied. In the study of stocking a warehouse or retail shop, known generally as the theory of inventories, the frequency with which the stock will be exhausted is considered under various reordering policies. Similar considerations apply in the theory of dams and water storage. *See* LINEAR PROGRAMMING; SYSTEMS ENGINERRING. [F.j.An.]

Quince The deciduous tree *Cydonia oblonga*, originally from Asia, grown for its edible fruit. The fruit is a pear-shaped or apple-shaped pome, characteristically tomentose, aromatic, sour, astringent, and green, turning clear yellow at maturity. Used mostly for jam and jelly or as a stewed fruit, the fruit of the quince develops a pink color in cooking. *See* DECIDUOUS PLANTS; FRUIT; FRUIT, TREE; ROSALES. [H.B.T.]

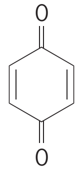
Quinine The chief alkaloid of the bark of the cinchona tree, which is indigenous to certain regions of South America. The structure of quinine is shown below.



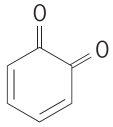
Until the 1920s quinine was the best chemotherapeutic agent for the treatment of malaria. However, clinical studies definitely established the superiority of the newer synthetic antimalarials such as primaquine, chloroquine, and chloroguanide. *See* ALKALOID; MALARIA. [S.M.K.]

Quinoa An annual herb, *Chenopodium quinoa* (family Chenopodiaceae), a native of Peru, and the staple food of many people in South America. These plants, grown at high altitudes, produce large quantities of highly nutritious seeds used whole in soups or ground into flour, which is made into bread or cakes. The seeds are also used as poultry feed, in medicine, and in making beer. In the United States the leaves are sometimes used as a substitute for spinach. *See* CARYOPHYLLALES. [P.D.St./E.L.C.]

Quinone One of a class of aromatic diketones in which the carbon atoms of the carbonyl groups are part of the ring structure. The name quinone is applied to the whole group, but it is often used specifically to refer to *p*-benzoquinone (**1**), *o*-Benzoquinone (**2**) is also known but the meta isomer does not exist.



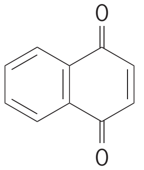
(1)



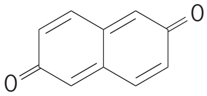
(2)

Quinones are prepared by oxidation of the corresponding aromatic ring systems containing amino ([bd]NH_2) or hydroxyl ([bd]OH) groups on one or both of the carbon atoms being converted to the carbonyl group.

Three of the several possible quinones derived from naphthalene are known: 1,4-naphthoquinone (**2**), 1,2-naphtho-quinone, and 2,6-naphthoquinone (**4**).



(3)



(4)

Important naturally occurring naphthoquinones are vitamins K_1 and K_2 which are found in blood and are responsible for proper blood clotting reaction. A number of quinone pigments have been isolated from plants and animals. Illustrative of these are juglone found in unripe walnut shells and spinulosin from the mold *Penicillium spinulosum*. 9,10-Anthraquinone derivatives form an important class of dyes of which alizarin is the parent type. *p*-Benzoquinone is manufactured for use as a photographic developer. *See* ANTHRAQUINONE PIGMENTS; AROMATIC HYDROCARBON; DYE; HYDROQUINONE; KETONE; OXDATION-REDUCTION; VITAMIN K. [D.A.S.]

R

Rabies An acute, encephalitic viral infection. Human beings are infected from the bite of a rabid animal, usually a dog. Canine rabies can infect all warm-blooded animals, and death usually results. *See* ANIMAL VIRUS.

The virus is believed to move from the saliva-infected wound through sensory nerves to the central nervous system, multiply there with destruction of brain cells, and thus produce encephalitis, with severe excitement, throat spasm upon swallowing (hence hydrophobia, or fear of water), convulsions, and death—with paralysis sometimes intervening before death.

All bites should immediately be cleaned thoroughly with soap and water, and a tetanus shot should be considered. The decision to administer rabies antibody, rabies vaccine, or both depends on four factors: the nature of the biting animal; the existence of rabies in the area; the manner of attack (provoked or unprovoked) and the severity of the bite and contamination by saliva of the animal; and recommendations by local public health officials. *See* PUBLIC HEALTH; TETANUS.

Diagnosis in the human is made by observation of Negri bodies (cytoplasmic inclusion bodies) in brains of animals inoculated with the person's saliva, or in the person's brain after death. A dog which has bitten a person is isolated and watched for 10 days for signs of rabies; if none occur, rabies was absent. If signs do appear, the animal is killed and the brain examined for Negri bodies, or for rabies antigen by testing with fluorescent antibodies. *See* FLUORESCENCE MICROSCOPE; VIRAL INCLUSION BODIES.

Individuals at high risk, such as veterinarians, must receive preventive immunization. If exposure is believed to have been dangerous, postexposure prophylaxis should be undertaken. If antibody or immunogenic vaccine is administered promptly, the virus can be prevented from invading the central nervous system. An inactivated rabies virus vaccine is available in the United States. It is made from virus grown in human or monkey cell cultures and is free from brain proteins that were present in earlier Pasteur-type vaccines. This material is sufficiently antigenic that only four to six doses of virus need be given to obtain a substantial antibody response. *See* VACCINATION. [J.L.Me.]

Raccoon Any of the carnivorous mammals which belong to the family Procyonidae, of which there are 16 species, found only in the New World. The robust body is covered with long gray-brown hair, the face is marked by a black mask across the eyes, and the bushy tail has five to seven black rings. The raccoon is plantigrade when standing but walks with its heels off the ground. The digits are long and terminate in nonretractile claws. This animal is found in woodland areas near forest edges, and is a good climber. Primarily terrestrial, it is also a good swimmer, although it cannot pursue prey underwater. A litter of five or six is born each year, and the animals live and travel in family groups. *See* CARNIVORA; MAMMALIA. [C.B.C.]

Racemization The formation of a racemate from a pure enantiomer. Alternatively stated, racemization is the conversion of one enantiomer in a 50:50 mixture of the two enantiomers (+ and −, or R and S) of a substance. Racemization is normally associated with the loss of optical activity over a period of time since 50:50 mixtures of enantiomers are optically inactive. *See* OPTICAL ACTIVITY.

Racemization is an energetically favored process since it reflects a change from a more ordered to a more random state. But the rate at which enantiomers racemize is typically quite slow unless a suitable mechanistic pathway is available, since racemization usually, but not always, requires that a chemical bond at the chiral center of an enantiomer be broken. Racemization of enantiomers possessing more than one chiral center requires that all chiral centers of half of the molecules invert their configurations. *See* ENTROPY.

The observation and study of racemization have important implications for the understanding of the mechanisms of chemical reactions and for the synthesis and analysis of chiral natural products such as peptides. Moreover, racemization is of economic importance since it provides a way of converting an unwanted enantiomer into a useful one. Synthetic medicinal agents are often produced industrially as racemates. After resolution and isolation of the desired enantiomer, half of the product would have to be discarded were it not for the possibility of racemizing the unwanted isomer and of recycling the resultant racemate. [S.H.W.]

Radar An acronym for radio detection and ranging, the original and still principal application of radar. The name is applied to both the technique and the equipment used.

Radar is a sensor; its purpose is to provide estimates of certain characteristics of its surroundings of interest to a user, most commonly the presence, position, and motion of such objects as aircraft, ships, or other vehicles in its vicinity. In other uses, radars provide information about the Earth's surface (or that of other astronomical bodies) or about meteorological conditions. To provide the user with a full range of sensor capability, radars are often used in combinations or with other elements of more complete systems.

Radar operates by transmitting electromagnetic energy into the surroundings and detecting energy reflected by objects. If a narrow beam of this energy is transmitted by the directive antenna, the direction from which reflections come and hence the bearing of the object may be estimated. The distance to the reflecting object is estimated by measuring the period between the transmission of the radar pulse and reception of the echo. In most radar applications this period will be very short since electromagnetic energy travels with the velocity of light.

Kinds of radar. The physical nature of radars varies greatly. Several radars are available for use on small boats as a safety and navigation aid, some so small as to be carried by an operator. Another radar seen in a hand-held form is that used by police to measure the speed of automobiles. *See* MARINE NAVIGATION.

Perhaps the largest radars are those covering acres of land, long arrays of antennas all operating together to monitor the flight of space vehicles or astronomical bodies. Other very large radars are designed to monitor flight activity at substantial distances. These are large mainly because they must use longer-than-usual radio wavelengths associated with ionospheric containment of the signal for over-the-horizon operations.

More common in size are those radars seen at airports, with rotating antennas 20– 40 ft (6–12 m) wide. Radars intended for mobile use, particularly airborne radars, are quite compact. *See* AIRBORNE RADAR.

Airborne and spaceborne radars have been developed to perform ground mapping with extraordinary resolution by special Doppler-sensitive processing while the radar is moved over a substantial distance. Such radars are called synthetic-aperture radars (SARS) because of the very large virtual antenna formed by the path covered while the processing is performed. Interferometry can provide topological information (3D SAR), and polarimetry and other signal analysis can provide more information on the nature of the surface (type of vegetation, for example). *See* Remote sensing; Synthetic aperture radar (SAR).

Radars intended principally to determine the presence and position of reflecting targets in a region around the radar are called search radars. Other radars examine further the targets detected: examples are height finders with antennas that scan vertically in the direction of an assigned target, and tracking radars that are aimed continuously at an assigned target to obtain great accuracy in estimating target motion. In some modern radars, these search and track functions are combined, usually with some computer control. Surveillance radar connotes operation of this sort, somewhat more than just search alone. There are also very complex and versatile radars with considerable computer control, with which many functions are performed and which are therefore called multifunction radars. Very accurate tracking radars intended for use at missile test sites or similar test ranges are called instrumentation radars. Radars designed to detect clouds and precipitation are called meteorological or weather radars. *See* Radar meteorology; Surveillance radar.

Some radars have separate transmit and receive antennas sometimes located miles apart. These are called bistatic radars, the more conventional single-antenna radar being monostatic. Some useful systems have no transmitter at all and are equipped to measure, for radarlike purposes, signals from the targets themselves. Such systems are often called passive radars, but the terms radiometers or signal intercept systems are generally more appropriate. *See* Passive radar.

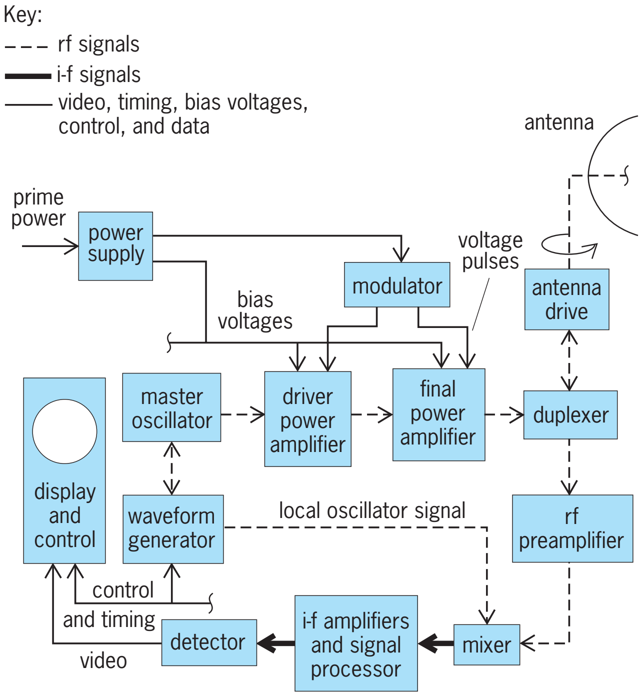
The terms primary and secondary are used to describe, respectively, radars in which the signal received is reflected by the target and radars in which the transmission causes a transponder (transmitter-responder) carried aboard the target to transmit a signal back to the radar. *See* Air-traffic control; Electronic navigation systems.

Operation. It is convenient to consider radars composed of four principal parts: the transmitter, antenna, receiver, and display (see illustration).

The transmitter provides the rf signal in sufficient strength (power) for the radar sensitivity desired and sends it to the antenna, which causes the signal to be radiated into space in a desired direction. The signal propagates (radiates) in space, and some of it is intercepted by reflecting bodies. These reflections, in part at least, are radiated back to the antenna. The antenna collects them and routes all such received signals to the receiver, where they are amplified and detected. The presence of an echo of the transmitted signal in the received signal reveals the presence of a target. The echo is indicated by a sudden rise in the output of the detector, which produces a voltage (video) proportional to the sum of the rf signals being received and the rf noise inherent in the receiver itself. The time between the transmission and the receipt of the echo discloses the range to the target. The direction or bearing of the target is disclosed by the direction the antenna is pointing when an echo is received.

A duplexer permits the same antenna to be used on both transmit and receive, and is equipped with protective devices to block the very strong transmit signal from going to the sensitive receiver and damaging it. The antenna forms a beam, usually quite directive, and, in the search example, rotates throughout the region to be searched. *See* Antenna (electromagnetism).

The radar reflections are among the signals received by the antenna in the period between transmissions. Most search radars have a pulse repetition frequency (prf), antenna beam-width, and rotation rate such that several pulses are transmitted (perhaps 20 to 40) while the antenna scans past a target. This allows a buildup of the echo being received. Most radars are equipped with low-noise rf preamplifiers to improve sensitivity. The signal is then “mixed” with (multiplied by) a local oscillator signal to produce a convenient intermediate-frequency (i-f) signal, commonly at 30 or 60 MHz; the same principle is used in all heterodyne radio receivers. The local oscillator signal, kept offset from the transmit frequency by precisely this intermediate frequency, is supplied by the transmitter oscillators during reception. After other significant signal processing in the i-f circuitry (of a digital nature in many newer radars), a detector produces a video signal, a voltage proportional to the strength of the processed i-f signal. This video can be applied to a cathode-ray-tube (CRT) display so as to form a proportionately bright spot (a blip), which could be judged to originate from a target echo. However, increasingly radars use artificial computerlike displays based on computer analysis of the video. Automatic detection and automatic tracking (based on a sequence of dwells) are typical of such data processing, reports being displayed for radar operator management and also made instantly available to the user system. *See* Cathode-ray tube; Electronic display; Heterodyne principle; Mixer; Preamplifier; Radio receiver.



Block diagram of a pulse radar.

Radar carrier frequencies are broadly identified by a nomenclature that originated in wartime secrecy and has since been found very convenient and widely accepted. The spectrum is divided into bands, the frequencies and wavelengths of which are given in the table. The charged layers of the ionosphere present a highly refractive shell at radio frequencies well below the microwave frequencies of most radars. Consequently, over-the-horizon radars have been built in the 10-MHz area to exploit this skip path. *See* Continuous-wave radar; Monopulse radar; Radio spectrum allocations. [R.T.H.]

Radar-absorbing materials Materials that are designed to reduce the reflection of electromagnetic radiation from a conducting surface in the frequency range from approximately 100 MHz to 100 GHz. The level of reduction that is achieved varies from a few decibels to greater than 50 dB, reducing the reflected energy by as much as 99.999%.

Two methods have been widely adopted in order to produce such absorbers. The first is to avoid a discrete change of impedance at the material surface by gradually varying the impedance. The removal of the discontinuity at the surface allows the microwave energy to be transmitted into the absorbing medium without reflection. This transition from the impedance of free space to that of the bulk material is commonly achieved by a geometric profile. The carbon-loaded foam pyramids used as the lining of anechoic chambers are typical of this type of absorber. To produce such absorbers, it is necessary in practice to taper the material over distances which are large compared with the wavelength of the frequencies to be absorbed. Therefore, practical absorbers of this type giving greater than 20 dB absorption vary in thickness from about 0.8 in. (2 cm) at 10 GHz and above to 6 ft (2 m) at 100 MHz and above. The absorber performance improves with increasing thickness until the point is reached where all of the energy that enters the material is absorbed and only the front-face reflection is left. While this type of absorber is capable of producing a very high degree of absorption over a broad bandwidth, it is at the same time a relatively thick material. *See* Anechoic chamber.

The second method of absorber design produces much thinner absorbing layers which are capable of producing good absorption ($\geq$25 dB) with restricted bandwidths. These materials achieve the absorption by a combination of attenuation within the material and destructive interference at the interface. The electromagnetic properties and the thickness of the layer are such that the initial reflected wave and the sum of the emergent rays resulting from the multiple reflections within the material are equal in magnitude and opposite in phase. The thickness of the layer is close to a quarter-wavelength at the frequency of operation, giving a 180° phase difference between the interface reflection and the emergent waves. *See* Interference of waves.

Microwave-absorbing materials are widely used both within the electronics industry and for defense purposes. Their uses can be classified into three major areas: (1) for test purposes so that accurate measurements can be made on microwave equipment unaffected by spurious reflected signals; (2) to improve the performance of any practical microwave system by removing unwanted reflections which can occur if there is any conducting material in the radiation path; and (3) to camouflage a military target by reducing the reflected radar signal. *See* Electronic warfare; Microwave; Microwave measurements; Reflection of electromagnetic radiation. [S.B.M.]

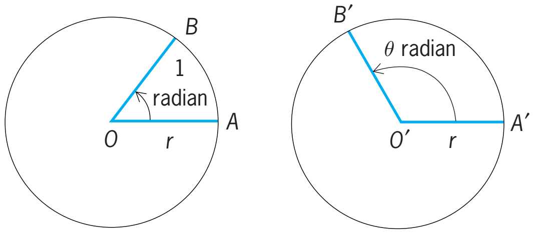
Radar astronomy A powerful astronomical technique that uses radar echoes to furnish otherwise-unavailable information about bodies in the solar system. By comparing a radar echo to the transmitted signal, information can be obtained about the target's size, shape, topography, surface bulk density, spin vector, and orbital elements. While other astronomical techniques rely on passive measurement of reflected sunlight or naturally emitted radiation, the illumination used in radar astronomy is a coherent signal whose polarization and time modulation or frequency modulation are tailored to meet specific scientific objectives. Through measurements of the distribution of echo power in time delay or Doppler frequency, radar achieves spatial resolution of a planetary target despite the fact that the radar beam is typically much larger than the angular extent of the target. This capability is particularly valuable for asteroids and planetary satellites, which appear as unresolved point sources through optical telescopes. Moreover, the centimeter-to-meter wavelengths used in radar astronomy readily penetrate cometary comas and the optically opaque clouds that conceal Venus and Titan, and also permit determination of near-surface roughness (abundance of wavelength-scale rocks), bulk density, and metal concentration in planetary regoliths. *See* Asteroid; Satellite (astronomy); Saturn; Venus.

A radar telescope is esssentially a radio telescope equipped with a high-power transmitter (a klystron vacuum-tube amplifier) and specialized instrumentation that links the transmitter, low-noise maser receiver, high-speed data-acquisition computer, and antenna together in an integrated radar system. Planetary radars, which must detect echoes from targets at distances from about 10^6 km for closely approaching asteroids and comets to more than 10^9 km for Saturn's rings and satellites, are the largest and most sensitive radars on Earth. *See* Klystron; Maser; Radar; Radio telescope. [S.J.O.]

Radar meteorology The application of radar to the study of the atmosphere and to the observation and forecasting of weather. Meteorological radars transmit electromagnetic waves at microwave and radio-wave frequencies. Water and ice particles, inhomogeneities in the radio refractive index associated with atmospheric turbulence and humidity variations, insects, and birds scatter radar waves. The backscattered energy received at the radar constitutes the returned signal. Meteorologists use the amplitude, phase, and polarization state of the backscattered energy to deduce the location and intensity of precipitation, the wind speed along the direction of the radar beam, and precipitation type (for example, rain or hail). *See* Meteorological radar; Radar; Weather forecasting and prediction.

Much of the understanding of the structure of storms derives from measurements made with networks of Doppler radars. They are used to investigate the complete three-dimensional wind fields associated with storms, fronts, and other meteorological phenomena. *See* Doppler; Precipitation (meteorology); Storm; Storm detection; Thunderstorm. [R.M.Ra.]

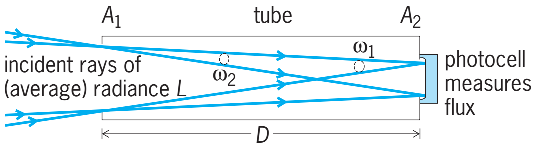
Radian measure A radian is the angle subtended at the center of a circle by an arc of the circle equal in length to its radius. It is proved in geometry that equal central angles of two circles subtend arcs proportional to their radii; and the converse is true. Hence the radian is independent of the length of the radius. The illustration represents two circles of radius r. Arc AB of length r subtends 1 radian (rad) at the center O of the circle, and arc $A'B'$ of length s subtends θ rad at its center. Since arcs on equal circles are proportional to their subtended central angles, $s/r = \theta/1$, or the formula $s = r\theta$ holds. If $\theta = 2\pi$, $s = 2\pi r$, the circumference of the circle. Therefore 2π rad is the complete angle about a point or 360°, and 2π rad $= 360°$, 1 rad $= 360°/2\pi = 57.2958\pi$.



Diagrams showing radian measurement.

The degree as a unit of angle has come down from antiquity. However, its use in various theories involves clumsy constants. The use of the radian avoids these constants. The radian is employed generally as a measure of angle in theoretical discussions; when no unit of angle is mentioned, the radian is understood. [L.M.K.]

Radiance The physical quantity that corresponds closely to the visual brightness of a surface. A simple radiometer for measuring the (average) radiance of an incident beam of optical radiation (light, including invisible infrared and ultraviolet radiation) consists of a cylindrical tube, with a hole in each end cap to define the beam cross section there, and with a photocell against one end to measure the total radiated power in the beam of all rays that reach it through both holes (see illustration).



A simple radiometer.

If A_1 and A_2 are the respective areas of the two holes, D is the length of the tube (distance between holes), and Φ is the radiant flux or power measured by the photocell, then the (average) radiance is approximately given by the equation $L = \Phi/(A_1 \cdot A_2/D^2)\ \mathrm{W \cdot m^{-2} \cdot sr^{-1}}$. [F.E.N.]

Radiant heating Any system of space heating in which the heat-producing means is a surface that emits heat to the surroundings by radiation rather than by conduction or convection. The surfaces may be radiators such as baseboard radiators or convectors, or they may be the panel surfaces of the space to be heated. *See* Panel heating and cooling.

The heat derived from the Sun is radiant energy. Radiant rays pass through gases without warming them appreciably, but they increase the sensible temperature of liquid or solid objects upon which they impinge. The same principle applies to all forms of radiant-heating systems, except that convection currents are established in enclosed spaces and a portion of the space heating is produced by convection. Any radiant-heating system using a fluid heat conveyor may be employed as a cooling system by substituting cold water or other cold fluid. However, the technique is not practical on the scale required for comfort control of an occupied space. [E.L.W./R.Ko.]

Radiation The emission and propagation of energy; also, the emitted energy itself. The etymology of the word implies that the energy propagates rectilinearly, and in a limited sense, this holds for the many different types of radiation encountered.

The major types of radiation may be described as electromagnetic, acoustic, and particle, and within these major divisions there are many subdivisions. Electromagnetic radiation is classified roughly in order of decreasing wavelength as radio, microwave, visible, ultraviolet, x-rays, and γ-rays. Acoustic or sound radiation may be classified by frequency as infrasonic, sonic, or ultrasonic in order of increasing frequency, with sonic being between about 16 and 20,000 Hz. The traditional examples of particle radiation are the α- and β-rays of radioactivity. *See* Electromagnetic radiation; Radioactivity; Sound. [McA.H.H.]

Radiation biology The study of the action of ionizing and nonionizing radiation on biological systems. Ionizing radiation includes highly energetic electromagnetic radiation (x-rays, gamma rays, or cosmic rays) and particulate radiation (alpha particles, beta particles, neutrons, or heavy charged ions). Nonionizing radiation includes ultraviolet radiation, microwaves, and extralow-frequency (ELF) electromagnetic radiation. These two types of radiation have different modes of action on biological material: ionizing radiation is sufficiently energetic to cause ionizations, whereas nonionizing radiation causes molecular excitations. In both cases, the result is that chemical bonds of molecules may be altered, causing mutations, cell death, or other biological changes. *See* Electromagnetic radiation; Radiation.

Ionizing radiation originates from external sources (medical x-ray equipment, cathode-ray tubes in television sets or computer video displays) or from internal sources (ingested or inhaled radioisotopes, such as radon-222, strontium-90, and iodine-131), and is either anthropogenic or natural.

Nonionizing radiation originates from natural sources (sunlight, Earth's magnetic field, lightning, static electricity, endogenous body currents) and technological sources (computer video displays and television sets, microwave ovens, communications equipment, electric equipment and appliances, and high-voltage transmission lines).

Ionizing radiation. The action of ionizing radiation is best described by the three stages (physical, chemical, and biological) that occur as a result of energy release in the biological target material.

Physical stage. All ionizing radiation causes ionizations of atoms in the biological target material. The Compton effect, which predominates at the energies of electromagnetic radiation that are commonly encountered (for example, x-rays or gamma rays), strips orbital electrons from the atoms. These electrons (Compton electrons) travel through the target material, colliding with atoms and thereby releasing packets of energy. For low-energy x-rays, the photoelectric effect predominates, producing photoelectrons that transfer their energy in the same manner as Compton electrons. *See* Compton effect; Electron; Gamma rays; X-rays.

The absorbed dose of ionizing radiation is measured as the gray (Gy, 1 joule of energy absorbed by 1 kilogram of material). Because of the very localized absorption of ionizing radiation, an amount of ionizing radiation energy equivalent to 1/100 the heat energy in a cup of coffee will result in a 50% chance that the person absorbing the radiation will die in 30 days.

Neutrons with energies between 10 keV and 10 MeV transfer energy mainly by elastic scattering, that is, billiard-ball-type collisions, of atomic nuclei in the target material. In this process the nucleus is torn free of some or all of the orbital electrons because its velocity is greater than that of the orbital electrons. The recoiling atomic nucleus behaves as a positively charged particle. Because the mass of the neutron is nearly the same as that of the hydrogen atom, hydrogenous materials are most effective for energy transfer. *See* Neutron.

Chemical stage. Chemical changes in biological molecules are caused by the direct transfer of radiation energy (direct radiation action) or by the production of chemically reactive products from radiolysis of water that diffuses to the biological molecule (indirect radiation action). More than half the biological action of low linear-energy-transfer (LET) ionizing radiation (for example, x-rays and gamma rays) results from indirect radiation action, about 90% of which is due to the action of the hydroxyl radical (OH·). For high linear-energy-transfer radiation, direct radiation action predominates. Chemicals that react with hydroxyl radicals, rendering them unreactive, provide protection against indirect radiation damage. *See* Linear energy transfer (biology); Radiation chemistry.

The most important biological targets for damage from ionizing radiation are probably the plasma membrane and DNA, because there is only one copy, or a few copies, in the cell; because they serve critical roles for the survival and propagation of cells; and because they are large. The last factor is important because ionizing radiation releases its energy in a random manner; thus the larger the target, the more likely that it will be damaged by radiation. Consequences of radiation damage in membranes are changes in ion permeability, with leakage of potassium ions; changes in active transport; and cell lysis. Lesions in DNA include single-strand breaks, double-strand breaks, base damage, interstrand cross-links, and DNA-protein cross-links. *See* Cell membranes; Deoxyribonucleic acid (DNA).

Biological stage. Various biological effects can result from the actions of ionizing radiation. Reproductive death is most pronounced in mammalian cells that are actively dividing and in nondifferentiated tissue. Thus, dividing tissues (bone marrow and the germinal cells of the ovary and testis) are radiosensitive, and nondividing tissues (liver, kidney, brain, muscle, cartilage, and connective tissue) are radioresistant. Developing embryos are quite radiosensitive. The radiosensitivity of organisms varies greatly, being related to their intrinsic sensitivity to radiobiological damage and to their ability to repair the damage. Radiation doses resulting in 10% survival range from 3 Gy (mouse and human cells), to greater than 1000 Gy (the bacterium *Deinococcus radiodurans*).

The three organ systems that generally contribute to the death of mammals following a single dose of whole-body irradiation are, in decreasing order of radiosensitivity, the hematopoietic system, the gastrointestinal system, and the cerebrovascular system. Late somatic effects may take years or decades to appear and include genetic mutations transmitted to subsequent generations, tumor development and carcinogenesis, and shortening of life span. *See* MUTAGENS AND CARCINOGENS; MUTATION; TUMOR.

Nonionizing radiation. Of all the nonionizing radiations, only ultraviolet radiation, microwaves, and high-voltage electromagnetic radiation are considered in the study of radiation biology.

Ultraviolet radiation. Since it can penetrate only several layers of cells, the effects of ultraviolet (UV) radiation on humans are restricted to the skin and the eyes. Ultraviolet radiation is divided into UV-C (wavelength of 200–280 nanometers), UV-B (280– 320 nm), and UV-A (320–400 nm). The most biologically damaging is UV-C, and the least damaging is UV-A. The solar spectrum at the Earth's surface contains only the UV-B and UV-A radiations.

Biological effects can arise only when absorption of ultraviolet radiation occurs. Absorption is dependent on the chemical bonds of the material, and it is highly specific. Sunburn is a form of erythema produced by overexposure to the UV-B portion of the solar spectrum. A rare but deadly form of skin cancer in humans, malignant melanoma, is induced by exposure to sunlight, with occurrences localized on those regions of the body that are most frequently exposed. Ultraviolet light can also cause photochemical damage. Cyclobutane pyrimidine dimers are the main photoproduct following exposure to UV-C and UV-B, and they can lead to cell death and precarcinogenic lesions. Other types of dimers are considered to be especially mutagenic. DNA-protein cross-links that are observed after ultraviolet radiation can be lethal. *See* PHOTOCHEMISTRY.

Survival from ultraviolet irradiation is reduced as the dose of radiation is increased. The shapes of survival curves are similar to those for lethality from ionizing radiation, they are dependent on the presence or absence of repair systems. The four repair systems that enhance biological survival include photoreactivation (splitting of cyclobutane dimers in the DNA of cells that have been irradiated by ultraviolet light); DNA excision repair; DNA recombination repair; and an inducible repair system of bacteria known as SOS repair. *See* ULTRAVIOLET RADIATION; ULTRAVIOLET RADIATION (BIOLOGY).

Microwaves. Microwaves are electromagnetic radiation in the region from 30 MHz to 300 GHz. They originate from devices such as telecommunications equipment and microwave ovens. Thermal effects of microwaves occur at exposure rates greater than 10 mW/cm^2 (70 mW/in.^{2}), while nonthermal effects are associated with exposure rates less than 10 mW/cm^2. Material with a high water content will have a higher absorption coefficient for microwaves, and thus a greater thermal response to microwave action. Microwave absorption is high in skin, muscle, and internal organs, and lower in bone and fat tissue. *See* MICROWAVE.

Cultured mammalian cells exposed to microwaves at a high power density show chromosome abnormalities after 15 min of exposure. Progression through the cell cycle is also temporarily interrupted, which interrupts DNA synthesis. Chromosome aberrations in peripheral blood lymphocytes are significantly greater for persons who are occupationally exposed to microwaves. Microwaves can be lethal when the power intensity and exposure time are sufficient to cause a rise in temperature that exceeds an organism's homeostatic capabilities.

There are also some nonthermal effects associated with microwaves. A list of clinical symptoms includes increased fatigue, periodic or constant headaches, extreme irritability, decreased hearing acuity, and drowsiness during work. Laboratory studies involving exposure of animals to microwaves have produced changes in the electroencephalogram, blood-brain barrier, central nervous system, hematology, and behavior. Cell membrane permeability is also altered.

Extremely low frequency electromagnetic fields. This type of radiation is generated by the electric and magnetic fields associated with high-voltage current in power transmission lines, and also some household and industrial electrical equipment. Biological effects from ELF radiation are the least understood, and the potential consequences are the most controversial. The issue of potential biological damage from this type of radiation has arisen only since the introduction of very high voltage electric power transmission lines (440 kV and above) and the occurrence of widespread use of various electrical and electronic equipment. *See* ELECTROMAGNETIC PULSE (EMP).

Biological studies on ELF electromagnetic fields have been performed on cells and whole animals; and epidemiological studies have been carried out on populations exposed occupationally. The results share some common features: (1) There is not always a clear dose response; that is, increasing the exposure does not necessarily give rise to an increased biological effect. (2) Some biological effects are seen only at certain frequencies and dose rates. Some of the reported effects are subjective, and may be related to normal physiological adaptation to environmental changes. In humans, qualitative biological effects of low-frequency radiation (0 to 300 Hz) include headaches, lethargy, and decreased sex drive. Humans have been noted to perceive the presence of a 60-Hz electric field when the intensity is in the range of 2 to 12 kV/m (0.6 to 3.6 kV/ft), and animals were observed to avoid entering an area where the electric field was greater than 4 kV/m (1.2 kV/ft). *See* RADIATION INJURY (BIOLOGY).

[P.M.Ac.]

Radiation chemistry The study of chemical changes resulting from the absorption of high-energy, ionizing radiation, including alpha particles, electrons, gamma rays, fission fragments, protons, deuterons, helium nuclei, and heavier charged projectiles. In absorbing materials of low and intermediate atomic weight such as aqueous systems and most biological systems, such radiation deposits energy in a largely indiscriminate manner, leaving behind a complex mixture of short-lived ions, free radicals, and electronically excited molecules. Radiation-induced chemical changes result from reaction with these intermediates. *See* PHOTOCHEMISTRY.

Sources of high-energy radiation include radioactive nuclides [for example, cobalt-60 (^{60}Co), strontium-90 (^{90}Sr), and hydrogen-3 (^{3}H)] and instruments such as x-ray tubes, Van de Graaff generators, the betatron, the cyclotron, and the synchrotron. An electron accelerator known as the Linac (linear electron accelerator) has proved particularly valuable for the study of transient species that have lifetimes as short as 16 picoseconds; and another electron accelerator, known as the Febetron, has been used for the study of the effects of single pulses of electrons with widths of several nanoseconds at very high currents.

The primary absorption processes for high-energy radiation are ionization and molecular excitation. The distribution of the absorbed energy, however, depends significantly upon the nature of the radiation and absorbing medium.

Evaluation of the yields of radiation-induced reactions requires knowledge of the energy imparted to the reacting system. The energy deposited in the system is termed the dose, and the measurement process is called dosimetry. Absorbed energy from ionizing radiation is described in terms of grays (Gy; joule/kg), in rads (100 ergs/g), or in electronvolts per gram or per cubic centimeter.

Because of its importance in both chemical and biological systems, the radiation chemistry of water has been extensively studied and serves as an example of radiation-induced chemical change. A primary radiation interaction process may be represented by the reaction below, where H_2O^* represents an

$$H_2O \rightarrow H_2O^+,\ e^-,\ H_2O^*$$

electronically excited water molecule. The secondary electron (e^-), if formed with sufficient energy, will form its own trail of ionization and excitation. Within 10^{-10} to 10^{-8} s, reactions within spurs form hydrogen (H) atoms, hydroxyl (OH) radicals, hydrated electrons and molecular products, molecular hydrogen (H_2), and hydrogen peroxide (H_2O_2). In pure water, radicals escaping the spurs undergo further radical-radical reactions and reactions with molecular products. Upon continuous irradiation, steady-state concentrations of H_2, H_2O_2, and smaller amounts of dioxygen (O_2) result and no further decomposition occurs.

In addition to basic kinetics and mechanistic studies, the principles of radiation chemistry find application in any process in which ionizing radiation is used to study, treat, or modify a biological or chemical system.

In radiation therapy, tumors are destroyed by the application of ionizing radiation from external or internally administered sources. Gamma rays are used for treatment of internal tumors; electron or charged-particle beams are applied to external or invasively accessible lesions.

The physiological concentration of iodine in the thyroid is the basis for the treatment of hyperthyroidism with ^{131}I. The beta radiation from this isotope is effective in localized tissue destruction.

A goal of any radiation therapy is maximum tumor cell destruction with minimum damage to healthy cells. *See* Radiation therapy.

Radiation chemistry is used in food preservation by using ionizing radiation in doses that are lethal to microorganisms. The use of ionizing radiation for pathogen control has been approved by most governments for a wide range of foods. In general, limitations on dose have been specified for all products. Radiation is used to control pathogens in meat and meat products.

Processing of commercial quantities of food supplies requires a source of stable intensity and a radiation of sufficient penetrating power to deposit energy throughout the product in an economic, brief time period. [F.J.J.]

Radiation damage to materials Harmful changes in the properties of liquids, gases, and solids, caused by interaction with nuclear radiations. For a discussion of radiation damage in minerals *see* Metamict state. For a description of damage caused to biological systems by radiation. *See* Radiation biology.

Radiation damage is usually associated with materials of construction that must function in an environment of intense high-energy radiation from a nuclear reactor. Materials that are an integral part of the fuel element or cladding and nearby structural components are subject to such intense nuclear radiation that a decrease in the useful lifetime of these components can result. Radiation damage will also be a factor in thermonuclear reactors. *See* Nuclear fusion; Nuclear reactor.

Electronic components are extremely sensitive to even moderate radiation fields. Transistors malfunction because of defect trapping of charge carriers. Ferroelectrics such as $BaTiO_3$ fail because of induced isotropy; quartz oscillators change frequency and ultimately become amorphous. High-permeability magnetic materials deteriorate because of hardening. Plastics used for electrical insulation rapidly deteriorate.

There are several mechanisms that function on an atomic and nuclear scale to produce radiation damage in a material if the radiation is sufficiently energetic, whether it be electrons, protons, neutrons, x-rays, fission fragments, or other charged particles.

Electronic excitation and ionization is most severe in liquids and organic compounds and appears in a variety of forms such as gassing, decomposition, viscosity changes, and polymerization in liquids. Rapid deterioration of the mechanical properties of plastics takes place either by softening or by embrittlement, while rubber suffers severe elasticity changes at low fluxes. Cross-linking, scission, free-radical formation, and polymerization are the most important reactions. *See* Radiation chemistry.

In an environment of neutrons, transmutation effects may be important. Even materials that have a low cross section such as aluminum can show an appreciable accumulation of impurity atoms from transmutations. The elements boron and europium have very large cross sections and are used in control rods. Damage to the rods is severe in boron-containing materials. *See* Transmutation.

Displaced atoms are the most important source of radiation damage in nuclear reactors outside the fuel element. It is a consequence of the ability of the energetic neutrons born in the fission process to knock atoms from their equilibrium position in their crystal lattice, displacing them many atomic distances away into interstitial positions and leaving behind vacant lattice sites.

Nuclear irradiations performed at low temperatures (4 K) result in the maximum retention of radiation-produced defects. As the temperature of irradiation is raised, many of the defects are mobile and some annihilation may take place. The increased mobility, particularly of vacancies and vacancy agglomerates, may lead to acceleration of solid-state reactions, such as precipitation, short- and long-range ordering, and phase changes. These reactions may lead to undesirable property changes.

The presence of small amounts of impurities may profoundly affect the behavior of engineering alloys in a radiation field. It has been observed that helium concentrations as low as 10^{-9} seriously reduce the high-temperature ductility of a stainless steel. Small amounts of copper, phosphorus, and nitrogen have a strong influence on the increase in the ductile-brittle transition temperature of pressure vessel steels under irradiation. Heat treatment prior to irradiation determines the retention of both major alloying components and impurities in solid solution in metastable alloys. It also affects the number and disposition of dislocations. Thus heat treatment is an important variable in determining subsequent radiation behavior. [D.S.B.]

Radiation hardening The protection of semiconductor electronic devices and electronic systems from the effects of high-energy radiation. Applications for such devices are in three major areas: (1) satellites, which are exposed to natural space radiation from the Van Allen belts, solar flares, and cosmic rays; (2) electronics, especially sensor and control electronics for commercial nuclear power-generating plants; and (3) equipment designed to survive the radiation from nuclear explosions.

Although most radiation effects have been explained and are well understood, much remains to be done. Among the better-understood phenomena are displacement damage from neutrons and photocurrent transients produced by ionizing-radiation pulses. Basic electromagnetic-pulse interactions are also well understood, although their effects on complex electronic systems are extremely difficult to predict. *See* Electromagnetic pulse (EMP).

The quasipermanent effects of exposure to ionizing radiation are least understood, and understanding the response of semiconductor devices to this radiation is probably the single most important remaining radiation-hardening problem. Hardening of metal-oxide-semiconductor (MOS) devices has been accomplished by lower-temperature processing, which probably reduces physical or crystalline defects, and by developing extremely clean processes, which probably reduce chemical defects. The most important electrical manifestations of ionizing dose damage in MOS devices are an increase in leakage current; a shift in threshold voltage; and a decrease in speed, transconductance, and channel conductance. *See* Crystal.

Dose-rate effects are well understood. The generation of electron-hole pairs in semiconductors is proportional to the dose. Carriers generated in or near a *pn* junction result in a transient photocurrent proportional to dose rate and the effective volume of the junction. High dose rates can damage semiconductor devices through logic upset, latch-up, and burnout. *See* PHOTOVOLTAIC EFFECT.

Displacement damage effects are caused by neutrons, protons, electrons, and other high-energy particles. The production of lattice defects is proportional to the nonionizing energy absorbed by the lattice. The dominant effect in bipolar silicon devices is a reduction in common-emitter current gain.

Single-event upsets are caused at a very low rate in logic and memory circuits by cosmic rays. Rates are low enough (less than 10^{-3} upset per bit per day) that error-detection-and-correction (EDAC) software can be effectively used. Single-event phenomena have led to the development of fault-tolerant architectures to mitigate the effects of random digital upsets, and to the design modification of integrated circuits to prevent an upset even when the active volume is struck by a cosmic ray. *See* FAULT-TOLERANT SYSTEMS.

Hardening of electronic systems is accomplished by a combination of selecting hardened components, designing circuits more tolerant to radiation-induced degradations, and shielding. Shielding is effective against x-rays and electrons, which have short ranges in materials, and relatively ineffective against gamma radiation, neutrons, and cosmic rays, which have long ranges in materials. *See* INTEGRATED CIRCUITS; RADIATION DAMAGE TO MATERIALS; RADIATION SHIELDING; SEMICONDUCTOR. [G.C.M.]

Radiation pressure Pressure exerted by electromagnetic radiation on objects on which it impinges. This pressure is caused by the fact that electromagnetic radiation transmits energy and possesses momentum. These pressures are very small. The effect is conspicuous in the case of a comet near the Sun, where the radiation pressure from the Sun forces the lighter cometary constituents away from the Sun. *See* ELECTROMAGNETIC RADIATION. [W.R.Sm.]

Radiation shielding Physical barriers designed to provide protection from the effects of ionizing radiation; also, the technology of providing such protection. Major sources of radiation are nuclear reactors and associated facilities, medical and industrial x-ray and radioisotope facilities, charged-particle accelerators, and cosmic rays. Types of radiation are directly ionizing (charged particles) and indirectly ionizing (neutrons, gamma rays, and x-rays). In most instances, protection of human life is the goal of radiation shielding. In other instances, protection may be required for structural materials which would otherwise be exposed to high-intensity radiation, or for radiation-sensitive materials such as photographic film and certain electronic components.

Charged particles lose energy and are thus attenuated and stopped primarily as a result of coulombic interactions with electrons of the stopping medium. Gamma-ray and x-ray photons lose energy principally by three types of interactions: photoemission, Compton scattering, and pair production. Neutrons lose energy in shields by elastic or inelastic scattering. Elastic scattering is more effective with shield materials of low atomic mass, notably hydrogenous materials, but both processes are important, and an efficient neutron shield is made of materials of both high and low atomic mass. *See* COMPTON EFFECT; ELECTRON-POSITRON PAIR PRODUCTION; PHOTOEMISSION.

The most common criteria for selecting shielding materials are radiation attenuation, ease of heat removal, resistance to radiation damage, economy, and structural strength.

For neutron attenuation, the lightest shields are usually hydrogenous, and the thinnest shields contain a high proportion of iron or other dense material. For gamma-ray attenuation, the high-atomic-number elements are generally the best. For heat removal, particularly from the inner layers of a shield, there may be a requirement for external cooling with the attendant requirement for shielding the coolant to provide protection from induced radioactivity.

Metals are resistant to radiation damage, although there is some change in their mechanical properties. Concretes, frequently used because of their relatively low cost, hold up well; however, if heated they lose water of crystallization, becoming somewhat weaker and less effective in neutron attenuation.

If shielding cost is important, cost of materials must be balanced against the effect of shield size on other parts of the facility, for example, building size and support structure. If conditions warrant, concrete can be loaded with locally available material such as natural minerals (magnetite or barytes), scrap steel, water, or even earth.

Radiation shields vary with application. The overall thickness of material is chosen to reduce radiation intensities outside the shield to levels well within prescribed limits for occupational exposure or for exposure of the general public. The reactor shield is usually considered to consist of two regions, the biological shield and the thermal shield. The thermal shield, located next to the reactor core, is designed to absorb most of the energy of the escaping radiation and thus to protect the steel reactor vessel from radiation damage. It is often made of steel and is cooled by the primary coolant. The biological shield is added outside to reduce the external dose rate to a tolerable level. *See* RADIATION BIOLOGY; RADIATION DAMAGE TO MATERIALS. [R.E.F.]

Radiation therapy The use of ionizing radiation to treat disease; the method is also known as radiotherapy and therapeutic radiology. Radiotherapy was widely used in the past to treat diseases of the skin, lymph nodes, and other organs. However, because radiation can cause cancer and because alternative treatments for these diseases have been discovered, radiation therapy is now mainly limited to treating malignant tumors: the medical specialty is called radiation oncology. *See* ONCOLOGY.

The exact mechanisms by which radiation kills cells remain uncertain. Most likely, electrons dislodged from water or biological molecules disrupt the bonds between atoms of the nuclear deoxyribonucleic acid (DNA), resulting in double-strand breaks. Although usually not immediately fatal, such damage may cause the death of cells when they attempt to divide. Complex enzymatic mechanisms can repair some of the damage if given sufficient time.

The fraction of cells surviving after irradiation depends on many factors. Radiation affects both normal and cancerous cells in a similar manner qualitatively, but different cell lines vary greatly in their quantitative sensitivity. Rapidly dividing tissues—such as the skin, bone marrow, and gastrointestinal mucosa—usually display the greatest sensitivity experimentally and the most immediate side effects clinically.

The goal of radiation therapy is either to cure the disease permanently (radical treatment) or to reduce or eliminate symptons (palliative treatment) by destroying tumors without causing unacceptable injuries to normal tissues. For many cancers—such as cancers of the reproductive organs, lymphomas, and small head and neck tumors—a cure usually is possible, and the chance of functionally significant complications is small. Some tumors, however, contain too many cells to be entirely destroyed by tolerable doses. Also, some neoplasms, such as sarcomas and glioblastomas, are relatively resistant to irradiation and are difficult to eradicate even when only small numbers of cells are present. Such situations are best handled by using surgery to remove all visible tumor. *See* CANCER (MEDICINE); RADIATION BIOLOGY. [A.R.]

Radiative transfer The study of the propagation of energy by radiative processes; it is also called radiation transport. Radiation is one of the three mechanisms by which energy moves from one place to another, the other two being conduction and convection. *See* ELECTROMAGNETIC RADIATION; HEAT TRANSFER.

The kinds of problems requiring an understanding of radiative transfer can be characterized by looking at meteorology, astronomy, and nuclear reactor design. In meteorology, the energy budget of the atmosphere is determined in large part by energy gained and lost by radiation. In astronomy, almost all that is known about the abundance of elements in space and the structure of stars comes from modeling radiative transfer processes. Since neutrons moving in a reactor obey the same laws as radiation being scattered by atmospheric particles, radiative transfer plays an important part in nuclear reactor design.

Each of these three fields—meteorology, astronomy, and nuclear engineering—concentrates on a different aspect of radiative transfer. In meteorology, situations are studied in which scattering dominates the interaction between radiation and matter; in astronomy, there is more interest in the ways in which radiation and the distribution of electrons in atoms affect each other; and in nuclear engineering, problems relate to complicated, three-dimensional geometry.

Radiative transfer is a complicated process because matter interacts with the radiation. This interaction occurs when the photons that make up radiation exchange energy with matter. These processes can be understood by considering the transfer of visible light through a gas made up of atoms. Similar processes occur when radiation interacts with solid dust particles or when it is transmitted through solids or liquids. *See* PHOTON.

If a gas is hot, collisions between atoms can convert the kinetic energy of motion to potential energy by raising atoms to an excited state. Emission is the process which releases this energy in the form of photons and cools the gas by converting the kinetic energy of atoms to energy in the form of radiation. The reverse process, absorption, occurs when a photon raises an atom to an excited state, and the energy is converted to kinetic energy in a collision with another atom. Absorption heats the gas by converting energy from radiation to kinetic energy. Occasionally an atom will absorb a photon and reemit another photon of the same energy in a random direction. If the photon is reradiated before the atom undergoes a collision, the photon is said to be scattered. Scattering has no net effect on the temperature of the gas. *See* ABSORPTION; ATOMIC STRUCTURE AND SPECTRA; SCATTERING OF ELECTROMAGNETIC RADIATION. [A.H.K.]

Radiator Any of numerous devices, units, or surfaces that emit heat, mainly by radiation, to objects in the space in which they are installed. Because their heating is usually radiant, radiators are of necessity exposed to view. They often also heat by conduction to the adjacent thermally circulated air.

Radiators are usually classified as cast-iron (or steel) or nonferrous. They may be directly fired by wood, coal, charcoal, oil, or gas (such as stoves, ranges, and unit space heaters). The heating medium may be steam, derived from a steam boiler, or hot water, derived from a water heater, circulated through the heat-emitting units.

Electric heating elements may be substituted for fluid heating elements in all types of radiators, convectors, and unit ventilators. *See* HOT-WATER HEATING SYSTEM; RADIANT HEATING; STEAM HEATING. [E.L.W./R.Ko.]

Radio Communication between two or more points, employing electromagnetic waves as the transmission medium.

Radio waves transmitted continuously, with each cycle an exact duplicate of all others, indicate only that a carrier is present. The message must cause changes in the carrier which can be detected at a distant receiver. The method used for the transmission of the information is determined by the nature of the information which is to be transmitted as well as by the purpose of the communication system.

In code telegraphy the carrier is keyed on and off to form dots and dashes. The technique, often used in ship-to-shore and amateur communications, has been largely superseded in many other point-to-point services by more efficient methods.

In frequency-shift transmission the carrier frequency is shifted a fixed amount to correspond with telegraphic dots and dashes or with combinations of pulse signals identified with the characters on a typewriter. This technique is widely used in handling the large volume of public message traffic on long circuits, principally by the use of teletypewriters. *See* TELETYPEWRITER.

In amplitude modulation the amplitude of the earner is made to fluctuate, to conform to the fluctuations of a sound wave. This technique is used in AM broadcasting, television picture transmission, and many other services. *See* AMPLITUDE-MODULATION RADIO.

In frequency modulation the frequency of the carrier is made to fluctuate around an average axis, to correspond to the fluctuations of the modulating wave. This technique is used in FM broadcasting, television sound transmission, and microwave relaying. *See* FREQUENCY-MODULATION RADIO.

In pulse transmission the carrier is transmitted in short pulses, which change in repetition rate, width, or amplitude, or in complex groups of pulses which vary from group to succeeding group in accordance with the message information. These forms of pulse transmission are identified as pulse-code, pulse-time, pulse-position, pulse-amplitude, pulse-width, or pulse-frequency modulation. Such techniques are complex and are employed principally in microwave relay systems. *See* PULSE MODULATION.

In radar the carrier is normally transmitted as short pulses in a narrow beam, similar to that of a searchlight When a wave pulse strikes an object, such as an aircraft, energy is reflected back to the station, which measures the round-trip time and converts it to distance. A radar can display varying reflections in a maplike presentation on a cathode-ray tube. *See* RADAR.

Hundreds of thousands of radio transmitters exist, each requiring a carrier at some radio frequency. To prevent interference, different carrier frequencies are used for stations whose service areas overlap and receivers are built to select only the carrier signal of the desired station. Resonant electric circuits in the receiver are adjusted, or tuned, to accept one frequency and reject others.

All nations have a sovereign right to use freely any or all parts of the radio spectrum. But a growing list of international agreements and treaties divides the spectrum and specifies sharing among nations for their mutual benefit and protection. Each nation designates its own regulatory agency. In the United States all nongovernmental radio communications are regulated by the Federal Communications Commission (FCC). *See* AMATEUR RADIO; RADIO BROADCASTING; RADIO SPECTRUM ALLOCATIONS.

[J.D.Si.]

Radio astronomy The study of celestial objects by measurement and analysis of the electromagnetic radiation they emit in the wavelength range from 1 mm to 30 m (0.04 in. to 100 ft). Radio astronomers study an entire range of celestial objects, including the normal stars, planets, galaxies, and the exotic quasars, pulsars, and x-ray sources.

Radio universe. Since the late 1940s, radio telescopes have been used to map the skies and determine the positions and intensities, or fluxes, of individual sources of radio emission. Such maps have been made with increasing sensitivity and angular resolution; the latter property enables astronomers to determine the position of the radio sources accurately. Knowing the position, astronomers can refer to optical photographs of the sky and establish precisely which object is emitting radio waves. This procedure has led to the identification of radio sources with many bright galaxies and even with the most distant objects in the universe, the quasistellar objects (or quasars). However, nearly one-fifth of all radio sources are unidentified, that is, excellent photographs taken at the radio source positions show no object at all from which the radiation could arise. One concludes from this that these unidentified sources are “normal” galaxies and quasars at such great distances that they cannot be seen optically. *See* RADIO TELESCOPE.

It appears that there are more sources at great distances per unit volume of space than there are nearby, a result that means the universe is expanding, and that those distant sources are, in general, stronger than ones nearby. These two conclusions are fundamentally linked, and together they mean that further work on cosmological problems must await a clearer understanding of the nature and evolution of individual radio sources. *See* COSMOLOGY.

Galaxies and radio galaxies. Spiral galaxies, such as the Milky Way Galaxy, are often radio sources, although most are quite weak. Elliptical galaxies are usually not radio sources. However, the few elliptical galaxies that are radio sources are very spectacular ones, being among the most energetic radio objects in the sky. These are known as the radio galaxies.

The radio emission from spiral galaxies is typically confined to a small nuclear region supplemented by much weaker extended emission from the disk of the galaxy. In elliptical radio galaxies, on the other hand, the radio emission emanates from a small region at the center of the galaxy. Radio-emitting material is expelled from the nuclear region in two oppositely directed collimated streams, or jets, that extend out to distances many times the size of the visible galaxy. The enormous radio energy involved, 10^{10}–10^{12} times the solar luminosity, together with the very small size of the nuclear region from which this energy arises, less than 10^{14} km, leads to the conclusion that the source of energy is a black hole at the center of the radio galaxy. Such a black hole would be 10^7–10^9 times as massive as the Sun. *See* BLACK HOLE.

The radio emission from galaxies and radio galaxies is generated by the electron synchrotron process, in which relativistic electrons spiral around magnetic field lines and emit a continuous radiation spectrum throughout the band accessible to radio astronomers. *See* GALAXY, EXTERNAL.

Solar system astronomy. The Sun is an intense radio source, but only because it is so close to Earth. If it were at the distance of the nearest stars, its radio emission could not be detected. Solar radio emission tends to be intermittent: solar flares that produce cosmic rays and plasma streams that interact with Earth are visible as radio bursts; these are most frequent during the peak of the 11-year solar cycle. *See* COSMIC RAYS; SUN.

Jupiter is a much stronger radio source than had been expected from estimates of its surface temperature by optical astronomers. Most of its radio emission is caused by electron synchrotron emission in its very strong magnetic field. The very-long-wavelength emission of Jupiter is impulsive, and its strength depends upon the position of Io, one of Jupiter's moons. Similar impulsive long-wavelength bursts have also been discovered from Saturn. *See* JUPITER; SATURN.

Radio stars. Several nearby, apparently normal stars are detectable at radio wavelengths. Such stars as Algol, β Persei, and AR Lacerta are multiple star systems that have been found to be radio sources. The radio emission from these stars is dominated by radio bursts in which the radio fluxes may increase by a factor of 100 or more. It is clear that the radio bursts are initiated by or are a product of mass exchange processes going on between (at least) two closely bound stars.

An extreme example of radio emission from stars comes from stars that are also x-ray sources. Again, these objects are usually binary systems in which mass exchange plays a deciding role in their continuing evolution, but with x-ray sources one of the component stars appears to be a star that has exhausted its reservoir of nuclear fuel and is collapsing to its final state. *See* BINARY STAR; X-RAY ASTRONOMY.

Supernova remnants. During the formation of a supernova, the atmospheric envelope of a star is ejected and in this process becomes a rapidly expanding cloud of relativistic particles, magnetic field, and filaments of ionized gas. These conditions are precisely those necessary for the generation of radio emission through electron synchrotron radiation, and very intense radio sources indeed exist at the positions of old supernovae chronicled by ancient astronomers. One of the most interesting of the radio sources associated with a supernova remnant is the Crab Nebula. *See* CRAB NEBULA; SUPERNOVA.

HII regions. An HII region (a region of ionized hydrogen) is a large cloud of interstellar gas that has been ionized and heated by one or more bright, hot stars located within. These nebulae are sources of both continuum and line energy at radio and optical wavelengths. Since cosmic matter consists mostly of hydrogen, the ionized gas consists mainly of protons and electrons that emit continuum energy by bremsstrahlung. *See* NEBULA.

Hydrogen line. Study of the 21-cm line of neutral atomic hydrogen has been exceptionally rewarding in its contribution to the knowledge of galactic structure and of the physical characteristics of interstellar gas. Line intensity normally reflects the amount of gas in the line of sight; line wavelength and width indicate the line-of-sight velocity of the gas and the state of internal motion, just as with recombination lines in HII regions. If the gas overlies a strong radio source, the gas temperature can be inferred by observing the 21-cm line in absorption.

The structure of the Galaxy has been elucidated by the study of the amount and velocity of the hydrogen within it. A prime advantage of this method is that the very distant gas is just as visible as nearby gas, whereas optical studies of the whole Galaxy are impossible because the very distant stars are made invisible by intervening clouds of dust. The results of these radio studies indicate that the Milky Way Galaxy is a spiral. *See* MILKY WAY GALAXY.

Molecular lines. It has long been believed that simple molecules could not exist in the tenuous gas between stars, because the starlight radiation field would be sufficiently intense to break apart even the simplest molecular species. In spite of these arguments, by 1968 radio astronomers had found rotational transitions of three simple molecules, OH, H_2O, and NH_3. These molecules were found in dark clouds of gas and dust in the interstellar medium. Such dark clouds are believed to be the sites of recent and continuing star formation. Since 1968, more than 87 molecular species have been detected in interstellar space principally by observations of millimeter rotational lines or lines arising from the interaction of the rotation of the molecule's nuclei with the spin of its electrons. More complicated organic molecules containing as many as 12 atoms have been discovered. Observations of these molecular species may make it possible to establish the chemistry and thermodynamics in the interstellar clouds from which, ultimately, stars, planets, and life itself must form. *See* MOLECULAR STRUCTURE AND SPECTRA; RADIO TELESCOPE.

[R.L.Bro.]

Radio broadcasting The transmission, via radio-frequency electromagnetic waves, of audible program material for direct reception by the general public. Electromagnetic waves can be made to travel or propagate from a transmitting antenna to a receiving antenna. By modifying the amplitude, frequency, or relative phase of the wave in response to some message signal (a process known as modulation), it is possible to convey information from the transmitter to the receiver. In radio broadcasting, this information usually takes the form of voice or music. *See* ELECTRICAL COMMUNICATIONS; ELECTROMAGNETIC WAVE TRANSMISSION; MODULATION; RADIO.

Radio broadcasting occurs in seven frequency bands. Long-wave broadcasting is permitted by international agreement in a portion of the low-frequency band from 150 to 290 kHz in Europe. The most widely used broadcast band is in the medium-frequency (mf) range between 525 and 1700 kHz. It is commonly known as AM after amplitude modulation, the technique employed. Shortwave broadcasting is permitted worldwide in eight frequency bands between 5950 and 26,100 kHz. The very high frequency (VHF) band of 88 to 108 MHz is used for what is commonly called FM broadcasting, after frequency modulation that is used for transmissions. During the 1990s, a digital audio broadcasting (DAB) service in the 1452–1492- and 174–240-MHz frequency bands was put in place in Europe, Canada, and other countries. This band is unavailable in the United States for this service, so an alternate DAB system is being devised for use there. Radio broadcasting from satellites to listeners has been authorized in the 2310–2360-MHz frequency band. *See* AMPLITUDE MODULATION; AMPLITUDE-MODULATION RADIO; FREQUENCY MODULATION; FREQUENCY-MODULATION RADIO.

AM medium-frequency band. Broadcast stations in the medium-frequency band use amplitude modulation of a carrier wave to transmit information. The amplitude of the wave is modified in response to the changing amplitude of an audible voice or music signal. The AM receiver detects these amplitude changes and converts them back into audible signals, which can then be amplified and reproduced on acoustical transducers or speakers. *See* RADIO RECEIVER; RADIO TRANSMITTER.

The audible frequency range is generally considered to extend from 20 to 20,000 Hz. As a practical matter, AM broadcasting transmissions are limited to a range of 50 to 10,000 Hz. Because of transmission components and directional antennas, the fidelity of many stations is more severely restricted, resulting in voice transmission that is still acceptable but music transmission that is of relatively low fidelity.

An AM station may use a single tower for an antenna, resulting in an omnidirectional radiation pattern; or two or more transmitting towers to augment the radiation in certain directions while suppressing it in others, in order to comply with station allocation criteria. Since the allocation restrictions may be different during the daytime and nighttime hours, many stations employ two different directional antennas. The radiation from the antenna is expressed in millivolts per meter at 1 km (0.62 mi) from the antenna. *See* ANTENNA (ELECTROMAGNETISM).

AM broadcast signals propagate from the transmitter by three mechanisms: ground-wave, space-wave, and skywave. Ground waves travel along the ground surface (the boundary between the Earth and the atmosphere). Because they are surface waves, they penetrate into the ground, resulting in the energy being diminished because of losses in the ground. The current flowing in the antenna also produces space waves, which travel through the atmosphere from transmitter to receiver. Space-wave propagation is usually limited by intervening terrain obstacles or the curvature of the Earth. Sky-wave propagation occurs when space waves directed toward the ionosphere are reflected toward the Earth. This phenomenon can result in substantial signal strengths at distances of several hundred miles from the antenna. AM sky-wave propagation occurs primarily during nighttime hours by reflections from the E and F layers of the ionosphere at about 60 and 130 mi (100 and 220 km) altitude above the Earth's surface, respectively. *See* IONOSPHERE; RADIO-WAVE PROPAGATION.

The daytime ground-wave signal level protected by allocation criteria is usually 0.5 mV/m, although much higher signal strengths may be necessary to overcome noise from atmospheric and artificial sources, especially in highly urbanized areas. During nighttime hours, the service area for most AM stations (other than class A stations) is usually limited by interference from other cochannel stations. For low-power stations, this may be only 10 mi (16 km) or less from the transmitter. For the highest class of stations (class A), nighttime service is protected by the allocation criteria to the 0.5-mV/m, 50%-time sky-wave contour. Because such service is subject to the time variations and fading of sky-wave propagation, the 0.5-mV/m, 50%-time contour is considered to be a secondary service area.

FM VHF band. FM broadcasting has become the dominant broadcast service in the United States primarily because of its better fidelity and its superior reception, which is less subject to noise and interference than that of AM. Information is conveyed by frequency modulation or deviation of a carrier wave. In the United States, the carrier frequency may be deviated ±75 kHz around the assigned carrier frequency. The carrier frequencies, or channels, are spaced at 200-kHz intervals in the United States; a few other countries use slightly different channel spacings. Nearly all FM stations transmit in stereo.

The service area of an FM station depends on the propagation of space waves from the transmitter to the receiver. Space waves propagate through the atmosphere and are diffracted around, and reflected off, mountains, buildings, and other objects. Propagation within areas that have an unobstructed line-of-sight from transmitter to receiver is most reliable and predictable.

Shortwave broadcasting. For reaching audiences in foreign countries or other distant places, shortwave broadcasting is most often used. Nearly 600 million shortwave radio receivers are in use worldwide. Shortwave broadcasting is permitted worldwide in eight frequency bands from 5950 to 26,100 kHz. The assigned transmitting frequencies are spaced at 5-kHz intervals, resulting in a limited usable audio bandwidth. Voice transmissions are most effective, while music transmissions have limited fidelity.

Shortwave signals propagate via sky waves that are reflected one or more times from the E and F layers of the ionosphere. Multiple reflections are possible because a signal can also bounce off the Earth's surface after reflecting off the ionosphere in a "Ping-Pong" effect.

Digital audio broadcasting. To enhance audio quality, a digital audio broadcasting service has been put in place in Europe and elsewhere, operating primarily in the 1452–1492-MHz band. As in VHF FM broadcasting, DAB uses transmitters located at elevated locations (mountaintops, building roofs) that provide the best line-of-sight paths to the intended service area. Digital broadcasting differs from VHF FM broadcasting in that the audio signal (voice or music) is first converted to a stream of binary digits (data bits) that represent the audio signal. These data bits are then used to modulate the radio-frequency carrier signal using one of several techniques. After transmission via the radio waves, the radio-frequency carrier is demodulated at the receiver to recover the stream of data bits, and the bits are then converted back to the audio signal. DAB offers improved reception quality and fidelity because error-correcting codes in the digital signal can be used to eliminate many flaws that may occur during transmission. *See* INFORMATION THEORY; MODULATION.

Satellite broadcasting. Satellite broadcasting also uses digital modulation techniques. However, in this case the transmitters are located on satellites high above the Earth. From this position, satellite broadcasting can achieve essentially universal coverage of an entire nation or most of a continent from one or two transmitters. Both geostationary and low-Earth-orbit satellites are used for these systems. Specialized receiving antennas placed in locations visible to the sky are usually needed, along with a special radio receiver specifically designed for satellite service. To extend coverage into areas that are not visible to the sky, some satellite broadcasting networks employ a network of ground-based transmitters (repeaters) to supplement the coverage of the satellite signal. Satellite broadcasting is capable of providing 100 or more channels of audio programming, usually on a subscription or fee basis. *See* DIRECT BROADCASTING SATELLITE SYSTEMS. [H.R.A.]

Radio broadcasting network

A group of broadcast stations interconnected by leased channels on wire, microwave, or satellite to one or more central feed points for the purpose of receiving and rebroadcasting program material of a timely nature. Networks make it possible to broadcast live programs simultaneously to the public through affiliated radio stations; they make national and regional markets available to advertisers and offer stations quality entertainment and public service programs.

Radio networking is now carried out almost exclusively through Earth-orbiting satellites which are geosynchronous with the Earth's rotation; that is, they remain essentially stationary with respect to terrestrial locations, approximately 22,250 mi (35,800 km) above the surface of the Earth. Basically the transmit-receive technology is microwave, using uplink (ground station to satellite) frequencies in the 6-GHz frequency range, and 4-GHz downlink frequencies. Typically, each satellite contains 24 transponders. Each transponder is in effect a receiver-transmitter unit, which receives the uplink signal and then modulates a downlink transmitter, which returns the signal to Earth station receivers. *See* COMMUNICATIONS SATELLITE.

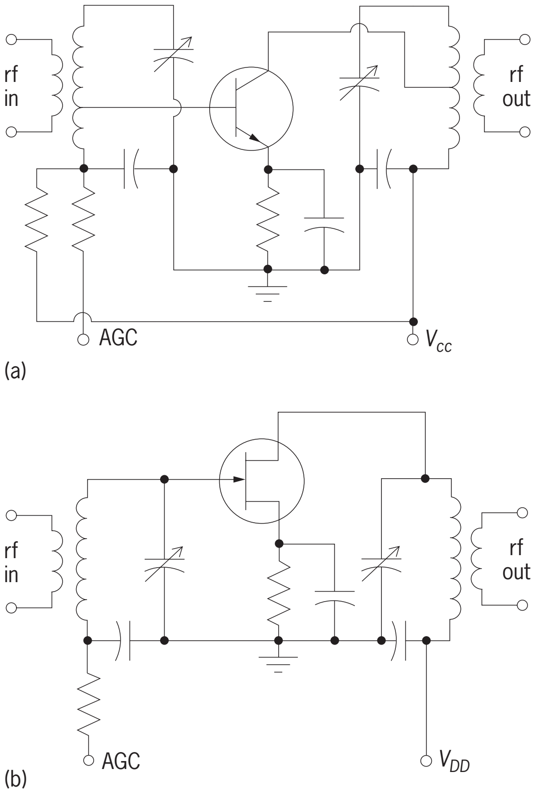
The "fixed-position" satellites, operated and maintained in their orbiting positions by the common carriers, repeat the signal on assigned transponder frequencies, beaming a broad pattern of signal which can cover an entire continent. The signal may be received in any location by the affiliated radio station utilizing low-noise receiving amplifiers centered in the focus of microwave receiving antennas aimed toward the satellite. *See* FREQUENCY-MODULATION RADIO; RADIO; RADIO BROADCASTING. [O.R.]

Radio compass A popular term for an automatic radio direction finder used for navigation purposes on ships and aircraft. It is not strictly a compass, because it indicates direction with respect to the radio station to which it is tuned, rather than to the north magnetic pole. The modern radio compass uses a nondirectional antenna in combination with a bidirectional loop antenna to provide a unidirectional bearing indication. Navigators thus know at all times whether they are traveling toward or away from the radio station used as a reference. The antennas are used with a special radio receiver that provides a visual indication of direction on a meter or cathode-ray indicator. *See* DIRECTION-FINDING EQUIPMENT. [J.Mar.]

Radio-frequency amplifier A tuned amplifier that amplifies the high-frequency signals commonly used in radio communications. The frequency at which maximum gain occurs in a radio-frequency (rf) amplifier is made variable by changing either the capacitance or the inductance of the tuned circuit. A typical application is the amplification of the signal received from an antenna before it is mixed with a local oscillator signal in the first detector of a radio receiver. The amplifier that follows the first detector is a special type of rf amplifier known as an intermediate-frequency (i-f) amplifier. *See* AMPLIFIER; INTERMEDIATE-FREQUENCY AMPLIFIER.

An rf amplifier is distinguished by its ability to tune over the desired range of input frequencies. The shunt capacitance, which adversely affects the gain of a resistance-capacitance coupled amplifier, becomes a part of the tuning capacitance in the rf amplifier, thus permitting high gain at radio frequencies. The power gain of an rf amplifier is always limited at high radio frequencies, however.

Two typical rf amplifier circuits are shown in the illustration. The conventional bipolar transistor amplifier of illus. *a* uses tapped coils in the tuned circuits to provide optimum gain-bandwidth characteristics consistent with the desirable value of tuning capacitance. Inductive coupling provides the desired impedance transformation in the input and output circuits. The tuning capacitors are usually ganged so as to rotate on a single shaft, providing tuning by a single knob. Sometimes varactor diodes are used to tune the circuits, in which case the tuning control is a potentiometer that controls the diode voltage. Automatic gain control (AGC) is frequently used on the rf amplifier, as shown. AGC voltage controls the bias and hence the transconductance of the amplifier. In the field-effect transistor (FET) circuit (illus. *b*), tapped coils are not required because of the very high input and output resistances of the FET. *See* AUTOMATIC GAIN CONTROL (AGC); SEMICONDUCTOR; TRANSISTOR. [C.L.A.]



Typical rf amplifiers. Circuits with (*a*) bipolar transistor and (*b*) field-effect transistor. V_{CC} = collector supply voltage; V_{DD} = drain supply voltage.

Radio-frequency impedance measurements Measurements of electrical impedance at frequencies ranging from a few tens of kilohertz to about 1 gigahertz. In the electrical context, impedance is defined as the ratio of voltage to current (or electrical field strength to magnetic field strength), and it is measured in units of ohms (Ω). *See* ELECTRICAL IMPEDANCE.

At zero frequency, that is, when the current involved is a direct current, both voltage and current are expressible as real numbers. Their ratio, the resistance, is a scalar (real) number. However, at nonzero frequencies, the voltage is not necessarily in phase with the current, and both are represented by vectors, and therefore are conveniently described by using complex numbers. To distinguish between the scalar quantity of resistance at zero frequency and the vectorial quantity at nonzero frequencies, the word impedance is used for the complex ratio of voltage to current. *See* ALTERNATING CURRENT; DIRECT CURRENT; ELECTRICAL RESISTANCE.

The measurement of impedance at radio frequencies cannot always be performed directly by measuring an rf voltage and dividing it by the corresponding rf current, for the following reasons: (1) it may be difficult to measure rf voltages and currents without loading the circuit by the sensing probes; (2) the distributed parasitic reactances (stray capacitances to neighboring objects, and lead inductances) may be altered by the sensing probes; and (3) the spatial voltage and current distributions may prevent unambiguous measurements (in waveguides, for instance).

At low frequencies, impedance measurements are often carried out by measuring separately the resistive and reactive parts, using either Q-meter instruments (for resonance methods), or reconfigurable bridges, which are sometimes called universal LCR (inductance-capacitance-resistance) bridges. In one such bridge the resistive part of the impedance is measured at dc with a Wheatstone bridge. Capacitive reactance is measured with a series-resistance-capacitance bridge, and inductive reactance is measured with a Maxwell bridge, using alternating-current (ac) excitation and a standard capacitance. *See* WHEATSTONE BRIDGE.

Transformer bridges are capable of operating up to 100 MHz. The use of transformers offers the following advantages: (1) only two bridge arms are needed, the standard, and the unknown arms, and (2) both the detector and the source may be grounded at one of their terminals, minimizing ground-loop problems and leakage. *See* TRANSFORMER.

A coaxial line admittance bridge is usable from 20 MHz to 1.5 GHz. The currents flowing in three coaxial branch lines are driven from a common junction, and are sampled by three independently rotatable, electrostatically shielded loops, whose outputs are connected in parallel.

A quantity related to impedance is the complex (voltage) reflection coefficient, defined as the ratio of the reflected voltage to the incident voltage, when waves propagate along a uniform transmission line in both directions. Usually, uppercase gamma (Γ) or lowercase rho (ρ) is used to represent the reflection coefficient. When a transmission line of characteristic impedance Z_0 is terminated in impedance Z_T, the reflection coefficient at the load is given by Eq. (1), and the voltage standing-wave ratio (VSWR) is related to the magnitude of Γ by Eq. (2).

$$\Gamma = \frac{Z_T - Z_0}{Z_T + Z_0} \tag{1}$$

$$\text{VSWR} = \frac{1 + |\Gamma|}{1 - |\Gamma|} \tag{2}$$

See TRANSMISSION LINES.

When it is sufficient to measure only the voltage standing-wave ratio, resistive bridges may be used. Resistive bridges employed as reflectometers use a matched source and detector, and therefore differ from the Wheatstone bridge, which aims to use a zero-impedance voltage source and an infinite-impedance detector.

Some specialized electronic instruments make use of the basic definition of impedance, and effectively measure voltage and current. One such instrument is called an rf vector impedance meter. Instead of measuring both the voltage and the current, it drives a constant current into the unknown impedance, and the resultant voltage is measured.

Vector voltmeters (VVM) are instruments with two (high-impedance) voltmeter probes, which display the voltages at either probe (relative to ground) as well as the phase difference between them. One type operates from 1 MHz to 1 GHz, and linearly converts to a 20-kHz intermediate frequency by sampling.

When the magnitude of the reactive part of the impedance is much greater than the resistive part at a given frequency, resonance methods may be employed to measure impedance. The most commonly used instrument for this purpose is the Q meter. *See* Q METER.

At the upper end of the rf range, microwave methods of impedance measurement may also be used, employing slotted lines and six-port junctions. *See* MICROWAVE MEASUREMENTS.

[P.I.S.]

Radio paging systems

Radio paging systems Systems, consisting of three basic elements—a personal paging receiver, radio transmitter, and an encoding device—whose primary purpose is to alert an individual, or group of individuals, and deliver a short message of a temporary or perishable nature. Characteristics that are used to define a specific paging system include distance covered, radio frequency, modulation type, paging code format, and message type.

On-site systems cover a single building or a small complex of buildings typically utilizing one low-power transmitter. Wide-area systems can cover an entire city or country and usually use multiple transmitters which simulcast the paging signals. Most paging systems now utilize the very high-frequency (VHF) or ultrahigh-frequency (UHF) radio spectrum using frequency modulation (FM). *See* FREQUENCY MODULATION; RADIO SPECTRUM ALLOCATIONS.

Paging receivers fall into four basic categories: tone alert, tone and voice, numeric, and alphanumeric. Tone pagers emit a "beep" when they are signaled. Some models silently alert the user with a vibration in place of a beep; other models use differing staccato beeps to provide the user with several alert messages. Tone and voice pagers allow the initiator of the page to transmit a simple voice message which will follow a pager's beep alert. Numeric pagers, sometimes called digital pagers, allow the initiator to convey numerical information. These messages are typically composed by using a tone telephone key pad. Alphanumeric pagers allow the initiator to send a complete textual message to the pager user. These messages are composed on word processors, personal computers, or dedicated terminals which can connect to a paging terminal. *See* MICROCOMPUTER; WORD PROCESSING.

[J.A.Wr.]

Radio receiver

Radio receiver The part of the radio communications system that extracts information from radio-frequency (rf) energy intercepted by the antenna. Radio receivers are the most common electronic equipment worldwide and a vital part of all radio, television, and radar systems. Since the 1960s, radio receiver performance has improved greatly, while size, weight, and cost have fallen dramatically. In the past, radio receivers were built from analog circuits, but increasingly they are realized by digital signal processing. *See* RADIO.

The antenna intercepts a band of energy in the radio frequencies containing many transmissions. These may have different modes of modulation; the two most common are amplitude modulation (AM) and frequency modulation (FM). Signals have a large size range, from a large fraction of a volt down to a small fraction of a microvolt. The receiver must be selective, responding to only one signal, must demodulate the signal, extracting the impressed information from the radio-frequency wave, and must raise it to an acceptable power level by amplification.

Single-sideband (SSB) transmissions are similar to amplitude modulation, but with one of the symmetrical pair of sidebands eliminated and the carrier suppressed. Single-sideband is significant because it conserves electromagnetic spectrum, introducing less spectrum pollution than any other modulation. Because of the growing prevalence of digital signals, digital modulation systems are increasingly important. *See* AMPLITUDE MODULATION; FREQUENCY MODULATION; MODULATION; SINGLE SIDEBAND.

Amplitude modulation. Figure 1 shows a simple receiver for amplitude-modulated signals. A band-pass filter selects the required signal, which, after optional amplification, is passed to the demodulator (obsolete term: detector), which in this version consists of a limiting amplifier and a multiplier. The high-gain limiting amplifier has an output of the same sign as the input but constant magnitude (a square wave). When multiplied by the amplitude-modulated waveform, this inverts negative half-cycles. After low-pass filtering to remove residual radio-frequency ripple, the modulating waveform is obtained, shown as an audio waveform, which passes to the loudspeaker. There are other amplitude demodulator circuits, all of which either suppress or invert alternate half-cycles of the amplitude-modulated waveform. *See* AMPLIFIER; AMPLITUDE-MODULATION DETECTOR; ELECTRIC FILTER.

Since the input signal may be on the order of microvolts whereas volts are required to operate a loudspeaker, the total receiver gain may range up to the order of a million or more. In this simple tuned-radio-frequency (TRF) receiver it is difficult to adjust the center frequency of a high-performance band-pass radio-frequency filter in order to receive other stations; also, the radio frequency may be too high for effective amplification. For this reason the superheterodyne (superhet) receiver (Fig. 2) superseded it.

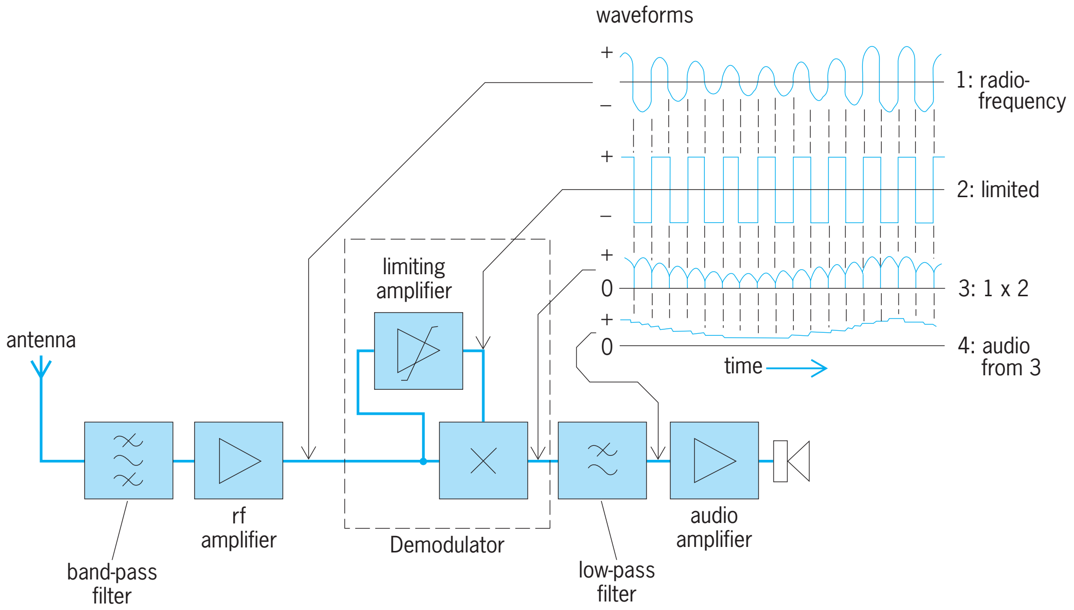


Fig. 1. Simple tuned-radio-frequency (TRF) receiver for amplitude-modulated (AM) signals.

In superheterodyne receivers, after a radio-frequency filter and amplifier, the signal passes to a mixer, from which the output is formed by the product of the signal and a locally generated wave. If the signal carrier is at f_c and the local oscillator is at f_o, the result is a wave at a frequency $\pm(f_o - f_c) = f_{\text{i-f}}$, known as the intermediate frequency (i-f), and this difference frequency can be kept constant, whatever the value of f_c, by a suitable choice of f_o. Subsequent to the mixer, the superheterodyne receiver becomes similar to the tuned-radio-frequency receiver except that it is now operating at a fixed frequency, so that, provided a low intermediate frequency is chosen, amplification is easy and high-performance filters can be used. Fixed-frequency intermediate-frequency filters, based on mechanical resonance in piezoelectric ceramics and crystals or on surface-acoustic waves, give extreme attenuation outside the passband. *See* Heterodyne principle; Mixer; Oscillator; Piezoelectricity; Surface-acoustic-wave devices.

In amplitude-modulation systems, the amplitude of the signal carries the information, and so to keep the audio output from wide level changes it is desirable to adjust the strength of the signal at the demodulator to be roughly constant, despite variations at the antenna due to transmitter power or range. Thus, automatic gain control (AGC) is used in most amplitude-modulation receivers. *See* Automatic gain control (AGC).

Frequency-modulation. For frequency modulation, the signal is of constant amplitude but varies in frequency, and so it is usual for the intermediate-frequency amplifier to be a limiter, giving a constant output. In other respects the receiver may be identical with one of those in Fig. 2. Automatic gain control is often omitted, but may be combined with limiting for the highest performance. The frequency demodulator is quite different, often utilizing a phase-sensitive detector. *See* Frequency-modulation detector; Limiter circuit. [W.Go.]

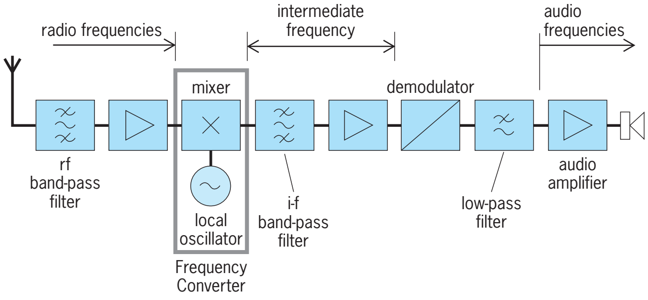

Fig. 2. Superheterodyne (superhet) receiver.

Radio spectrum allocations The specification of the frequency bands of the radio spectrum which are made available for use by the various radio services. The radio spectrum is the part of the natural spectrum of electromagnetic radiation lying between the frequency limits of 10^4 and 3×10^{11} hertz. Since the characteristics of the radiation do not change abruptly, these limits are not sharply defined and may change, depending upon the demands for changes in service and upon changes in technology.

For purposes of identification the radio spectrum is divided into bands differing from adjacent bands by frequency ratios of 10. These bands are identified by the metric wavelength of the shortest waves in each band (kilometric band, and so forth) or by adjective or numerical designators (for example, very-low-frequency band or band 4). The wavelength λ in meters is related to the frequency f in hertz by the relationship $c = f\lambda$, where c, the velocity of propagation of radio waves in space, is about 3×10^8 m/s.

The major classes of radio services are provided with international allocations within the various frequency bands. Within the United States there is a national allocation which conforms in general to the international allocation. The Radio Regulations divide the Earth into three regions and contain a detailed table of allocations, with some differences between regions, together with exceptions to the listed allocations and conditions for frequency use. Regional and national allocations can be made within the worldwide framework, but any departures by signatories of the Regulations must be accomplished on the basis of noninterference with services operating in accordance with the agreed allocations.

The characteristics of radio waves, due to natural phenomena such as atmospherics, vary greatly with frequency. Attempts are made to take advantage of propagation characteristics when making allocations, and normally the frequencies allocated have characteristics satisfying the operational requirements of the service with regard to distance, bandwidth, and other technique factors. Allocations are sometimes made for a new service which has already begun to use a particular band. Since many services have varied and continually growing requirements, allocations to them will be found in several frequency bands. In making specific frequency assignments to individual radio stations, the separation between assignable frequencies must be such as to avoid harmful interference in view of the bandwidth requirements, the frequency stability of the transmitters, the frequency selectivity of the receivers, the transmitter power and its distance separation from receivers operating on adjacent channels, and other factors. Thus the separation between adjacent assigned frequencies varies widely between services and between different locations in the frequency spectrum.

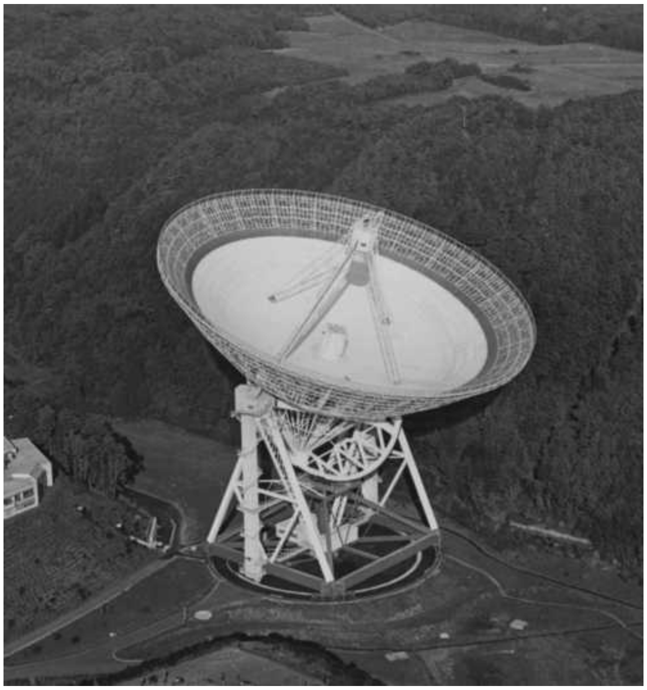
In most of the frequency bands it has been found practical to make block allocations of frequencies to given services in each region. Individual frequency assignments can then be made to radio stations operating in that service without the need for coordination with frequency assignments to stations in other services. Interference problems are more easily resolved, as they occur between compatible users. Some of these allocations are exclusive to a particular service, and some are shared between specified services to varying degrees. Similarly, in some services the stations have individual frequency assignments which are protected from interference from other stations, whereas the stations in other services may share time or geographic coverage on frequencies common to several stations. These arrangements are based upon the nature and the needs of the particular services being provided. [L.M.P.; J.M.L.]

Radio telescope An instrument used in astronomical research to detect and measure the radio-frequency power coming from various directions in the sky. It consists of three complementary parts: the large reflecting surface that collects and focuses the incident radiation; the electronic receiver that amplifies and detects cosmic radio signals; and a data display device. From the ground, observations with radio telescopes must be made at wavelengths shorter than 100 ft (30 m), because of ionospheric attenuation, and longer than 0.04 in. (1 mm), because the very-short-wavelength radio radiation is absorbed by atmospheric H_2O, CO_2, and O_3.

The fundamental principle of a radio telescope is identical to that of a reflecting telescope used at visual wavelengths. The incoming waves (radio or optical) are intercepted by a precise mirror and reflected to a common focal point. The shape of the reflecting surface or “dish” is important: the radio waves must arrive “in phase” at the focal point following their reflection from the dish; that is, the path length from the point of reflection to the focus must be exactly the same for all points on the dish. This restriction can be most simply satisfied if the shape of the reflecting surface is made paraboloidal; consequently, most modern radio telescopes have this shape (see illustration). *See* TELESCOPE.

Once the radio waves are collected and brought together at the focal point of the telescope, they are in general still extremely weak. The incoming radio-frequency (rf) signals are first amplified at the focus 10 to 1000 times and then converted to a lower frequency, the intermediate frequency (i-f), that can be easily transmitted by cables from the focal point to the telescope-control building. There the i-f is further amplified, and the signal is detected and displayed in the manner the astronomer finds most suited to the particular investigation.

The types of astronomical objects that emit radio-frequency radiation and hence can be studied by radio astronomers are of such a diverse nature that a variety of radio telescopes and receiving equipment are necessary for a modern radio observatory. Two general astronomical considerations dictate what instruments are needed: first, radio telescopes should have the highest possible angular resolution so that the small-scale details of radio sources can be studied; second, the radio receivers should be extremely sensitive to the very weak signals emitted by cosmic radio sources.



The 328-ft-diameter (100-m) radio telescope operated by the Max Planck Institut für Radioastronomie at Effelsberg, Germany. (*Max Planck Insititut für Radioastronomie*)

The ultimate in angular resolution is achieved by the technique of very-long-baseline interferometry (VLBI), in which one simultaneously utilizes radio telescopes separated by thousands of miles. Data are acquired independently at each telescope and recorded on video tape. Precise time markings are made on the tape using hydrogen maser clocks. After the data are recorded, the video tapes from the separate telescopes are brought together; the time markings on the individual tapes are aligned, and data taken at precisely the same times can be compared and analyzed. Such VLBI techniques have achieved angular resolutions of about 0.0003 second of arc. *See* ASTRONOMY. [R.L.Bro.]

Radio transmitter A generator of radio-frequency (rf) signals for wireless communication over some distance, which can vary from the short ranges within a building to intercontinental distances. Most applications utilize signals from very low frequencies (VLF) to extremely high frequencies (EHF); some applications require frequencies as low as 45 Hz or as high as 100 GHz. The radio-frequency output power varies from a fraction of a watt in emergency beacons and portable equipment to several megawatts in long-range, low-frequency transmitters. *See* RADIO SPECTRUM ALLOCATIONS.

The architecture (organization) of a radio transmitter is determined by the type of signal it is intended to produce. The four basic architectures are those used for continuous-wave, frequency-modulation, amplitude-modulation, and single-sideband signals. Transmitters for some applications (for example, television) use a combination of these architectures (for example, frequency modulation for sound and single sideband for video), while others (for example, Loran C) use unique architectures. Alternative architectures such as envelope elimination and restoration or outphasing can be used to improve efficiency. *See* ELECTRICAL COMMUNICATIONS; MODULATION.

Continuous-wave (CW) transmitter. The most basic type of radio transmitter produces only a continuous-wave signal. Such transmitters are often switched on and off (keyed) to produce telegraph signals. The block diagram of a simple continuous-wave transmitter is shown in Fig. 1. The oscillator *G*1 produces a low-power signal, which is boosted to the final

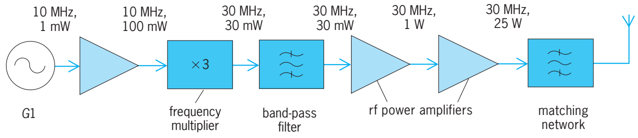


Fig. 1. Basic continuous-wave (CW) transmitter.

output power by a series of progressively larger power amplifiers. The optional inclusion of a frequency multiplier improves stability by allowing the frequencies of the oscillator and high-power amplifiers to be different. *See* Frequency multiplier; Oscillator; Power amplifier.

The architecture includes both frequency translation and power splitting, which makes it more suitable for generating high-power signals at various frequencies. While at a relatively low level, the signal is translated by a mixer to the desired output frequency. After amplification by a chain of power amplifiers, it is split into two parts to drive two final power amplifiers whose outputs are combined to produce the transmitter output. *See* Mixer; Telegraphy.

Frequency-modulation (FM) transmitter. Analog frequency modulation is widely used for voice communication, high-quality audio broadcasting, and television audio. Frequency-shift keying (FSK) and phase-shift keying (PSK) are widely used for transmission of digital data via radio-frequency signals. *See* Frequency modulation; Frequency-modulation radio; Mobile radio; Radio broadcasting; Television.

Frequency-modulated and phase-modulated (PM) signals have constant amplitudes and are therefore produced by transmitters with architectures similar to those of the continuous-wave transmitter (Fig. 1). The principal change is the replacement of oscillator *G*1 by a frequency or phase modulator. In frequency-modulation transmitters, the frequency multiplier increases the frequency deviation as well as the carrier frequency of the frequency-modulated signal. *See* Phase modulation.

In communication applications, the frequency modulator is typically a voltage-controlled crystal oscillator (VCXO) in which the capacitance of a varactor diode is used to vary slightly the frequency of a crystal oscillator. Other applications employ various types of modulators, including phase-shift, phase-locked-loop, comparator, and Armstrong. *See* Frequency modulator.

Amplitude-modulation transmitter. Full-carrier amplitude modulation is used in medium-frequency (MF) broadcasting, high-frequency (HF) international broadcasting, citizen-band communication, aircraft communication, and nondirectional navigation beacons. *See* Amplitude modulation; Electronic navigation systems.

Most modern full-carrier amplitude-modulation transmitters produce the output signal by amplitude modulation of the final radio-frequency power amplifier. Generally, the modulation is accomplished by varying the supply voltage of the radio-frequency power amplifier with a high-power radio-frequency amplifier. Since the radio-frequency carrier has constant amplitude until the final power amplifier, the architecture of the radio-frequency chain (Fig. 2) is similar to that of a continuous-wave or frequency-modulation transmitter. *See* Audio amplifier.

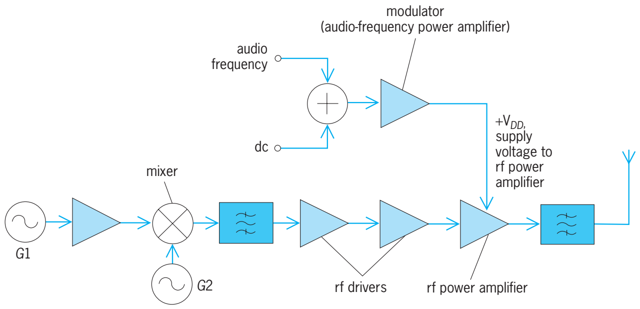

Fig. 2. Amplitude-modulation (AM) transmitter.

Single-sideband (SSB) transmitter. Single-sideband amplitude modulation is widely used for high-frequency voice communications, including military, marine, aeronautical, diplomatic, and amateur. It also finds use (as amplitude-compandored single-sideband, or ACSB) at very high frequencies (VHF) and ultrahigh frequencies (UHF).

Although single sideband is technically a form of amplitude modulation, the single-sideband signal itself has variations of both amplitude and phase. Signals such as multitone, independent sideband (ISB), and vestigial sideband (VSB), used for video, also possess such characteristics. Consequently, these signals are traditionally amplified by a chain of linear radio-frequency power amplifiers operating in class B. *See* Single sideband.

The low-level output of the single-sideband modulator is first shifted by the local oscillator *G*2 to an intermediate frequency (i-f) that is at least twice the highest output frequency. The intermediate-frequency signal is then shifted downward to the desired output frequency by the variable-frequency oscillator (VFO) *G*3. The mixer output is low-pass-filtered and then amplified to the desired power. *See* Electric filter. [F.H.Ra.]

Radio-wave propagation

The means by which radio signals are transported through space from a transmitting antenna to a receiving antenna. *See* Radio.

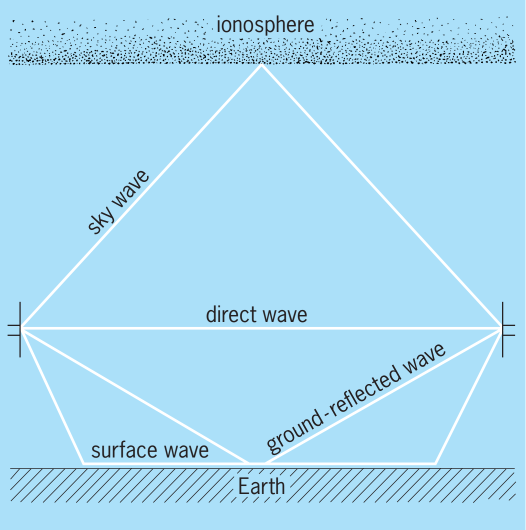
The frequencies around 20 kHz can be received reliably at distances of thousands of miles but are limited to telegraph-type signals and require very large transmitting antennas. Higher frequencies are needed for voice, and still higher frequencies for television transmission. As the frequency increases, the transmission range tends to decrease. Frequencies above 100 MHz can transmit wide-band signals, but they are limited to approximately line-of-sight distances with the usual type of equipment. However, distances of 200 mi (320 km) or more are possible by the use of high power and large antennas to provide narrow “searchlight” beams.

Reflections from the ionosphere (ionized layers 50–250 mi or 80–400 km above the Earth’s surface) provide a useful but variable long-distance service at frequencies less than about 30 MHz. These reflections account for the long-range broadcast coverage at night and for the shortwave intercontinental communication. *See* Radio broadcasting.

The principal components of the received radio signal are shown symbolically in the illustration. The vector sum of the direct, reflected, and surface waves has been called the space wave, ground wave, or tropospheric transmission to differentiate it from the ionospheric reflections. The ionospheric and surface waves are the principal components at frequencies below 10–30 MHz. The direct and reflected rays are the principal factors at frequencies above 30–50 MHz. Although the ionospheric, direct, and ground-reflected waves can be easily visualized as rays, the surface wave is more difficult to understand; it originates at the air-Earth boundary because the Earth is not a perfect reflector.

Variations in signal level with time are caused by changing atmospheric conditions. The severity of the fading usually increases as either the frequency or path length increases. Most fading is temporary diversion of energy to some direction other than the intended location, associated with refraction or interference, but absorption effects are important in the microwave region.

The dielectric constant of the atmosphere normally decreases gradually with increasing altitude. The result is that on the average the radio ray is bent or refracted toward the Earth so that the distance to the radio horizon is slightly greater than to the optical horizon. The amount of refraction is variable, and exceptionally long-range transmission may occur occasionally. Conversely, when the radio energy is bent away from the Earth (upward



Possible transmission paths between antennas.

bending), the transmission loss is increased. *See* REFRACTION OF WAVES. [K.B.]

Radioactive beams Beams of radioactive (unstable) nuclei. In several nuclear physics laboratories, a capability exists to produce such beams and, before these nuclei spontaneously decay, use them to gain insight into the reactions on and structure of nuclei never before accessible. Radioactive beams are particularly useful to study stellar explosions such as novae, supernovae, and x-ray bursts. These explosions are some of the most catastrophic events in the universe, generating enormous amounts of energy while synthesizing the elements that make up lifeforms and the world. These spectacular explosions involve, and in some cases are driven by, reactions where the atomic nuclei of hydrogen (protons) and helium (alpha particles) fuse with (are captured by) radioactive isotopes of heavier elements to form new elements. The capability to produce beams of radioactive nuclei allows direct measurements of these reactions, providing crucial information needed to theoretically model cataclysmic stellar events and to understand the origin of many chemical elements.

One approach to radioactive beam production is the isotope separator on-line (ISOL) technique. One accelerator bombards a target with a beam of stable nuclei, and a small number of the radioactive atoms of interest are produced through nuclear reactions. These atoms are transported, by various techniques, including thermal diffusion, to an ion source where they are ionized (removing or adding electrons to give atoms an electrical charge) and extracted. The radioactive ions are then mass-separated from other ions and accelerated to energies needed for nuclear physics experiments by a second accelerator. The ISOL technique can produce very high beam qualities, purities, and intensities; the disadvantages are that only a few radioactive beam species can be generated from each combination of production target and primary beam, and that beams with short lifetimes (less than 1 s) are difficult to produce. *See* ION SOURCES; MASS SPECTROSCOPE.

A complementary radioactive beam production technique is projectile fragmentation. When a high-energy beam of stable heavy ions passes through a thin target, the beam particles (projectiles) can break up into fragments—some of which are the radioactive isotope of interest. The desired fragments are then mass-separated from other ions and steered toward a target to undergo the reaction of interest. The projectile fragmentation technique can produce beams of very short lifetimes (10^{-6} s or less), and the same setup can be used to produce many different beam species; the disadvantages are that high beam quality, purity, and intensity are difficult to obtain. *See* NUCLEAR FUSION; NUCLEAR REACTION; PARTICLE ACCELERATOR. [M.S.S.]

Radioactive fallout Whenever radioactive materials become airborne, either from a nuclear device detonation or from a nuclear release accident, the resultant contaminated atmospheric plume will ultimately return radioactivity to the Earth's surface. Material settling from the radioactive plume and its subsequent surface deposition is known as radioactive fallout.

Radioactive materials consist of unstable atoms which emit gamma rays, beta particles, or alpha particles. These emissions—rays and particles—are unique in that they cause ionizations in neighboring atoms. The energy of the emitted radiation and subsequent ionizations can be a cause of concern if absorbed by living systems. *See* ALPHA PARTICLES; BETA PARTICLES; GAMMA RAYS; RADIOACTIVITY.

Fissioning of uranium and plutonium produces isotopes of about 70 different atoms; each atom may have several different isotopic forms. Examples of daughter products are the isotopes of elemental strontium, which are efficiently produced in nuclear fission. The isotope strontium-90 (^{90}Sr) has a 28-year half-life, while ^{89}Sr is produced in slightly higher concentrations but has a half-life of only 50 days. In addition to the differing half-lives, each isotope emits a unique radiation spectrum. The two strontium isotopes emit beta particles of different energies. Other isotopes such as cesium-137 (^{137}Cs, half-life 30 years) and iodine-131 (^{131}I, half-life 8 days) emit both beta particles and gamma rays. *See* CESIUM; IODINE; ISOTOPE; STRONTIUM.

Atmospheric fallout can be scavenged by rainfall. Wet deposition, involving washing out of atmospheric fallout, can increase local deposition patterns. This was the case following the Chernobyl accident, where local rainfall in Belarus, Ukraine, and Russia washed high concentrations of radioactive iodine and cesium out of the plume and onto the spring pasture. Radioactive iodine and cesium are relatively volatile and were more easily “boiled” out of Chernobyl's burning core. Cesium is a congener of potassium and therefore is fairly uniformly distributed throughout the body once inhaled or ingested. The result is a whole-body radiation dose. Furthermore, the energetic gamma-ray emission from ^{137}Cs adds a source of external radiation from surface deposits on the ground. These factors, in addition to its long half-life and relatively high concentration, make ^{137}Cs the major long-term contamination concern from fallout. For example, although the Chernobyl accident occurred in 1986, precautions must still be taken against potential intake doses of ^{137}Cs: inhalation doses can occur when burning wood from contaminated trees, and consuming mushrooms grown in contaminated forests delivers an ingestion dose.

Levels of ^{131}I in the plumes of radioactive fallout are of particular concern. With an 8 day half-life and a strong beta- and gamma-ray emission, this radionuclide concentrates almost exclusively in the thyroid gland. Recent dose reconstructions in the United States show that the 1950s and 1960s fallout radiation doses from ^{131}I were large enough to have increased the risk for thyroid cancer, especially in children. *See* THYROID GLAND.

In 1955, the United Nations established the Scientific Committee on the Effects of Atomic Radiation, due to concern over possible risks from fallout. It issues comprehensive reports about every 5 years and has collected and documented the world's literature on radioactive fallout and, more recently, on possible radiation consequences. *See* ATOMIC BOMB; NUCLEAR EXPLOSION; NUCLEAR FISSION; NUCLEAR FUELS; NUCLEAR REACTOR; RADIATION INJURY (BIOLOGY). [M.Gol.]

Radioactive minerals Minerals that contain uranium (U) or thorium (Th) as an essential component of their chemical composition. Examples are uraninite (UO_2) or thorite ($ThSiO_4$). There are radioactive minerals in which uranium and thorium substitute for ions of similar size and charge. There are approximately 200 minerals in which uranium or thorium are essential elements, although many of these phases are rare and poorly described. These minerals are important, as they are found in ores mined for uranium and thorium, most commonly uraninite and its fine-grained variety, pitchblende, for uranium. Thorite and thorogummite are the principal ore minerals of thorium. Minerals in which uranium and thorium occur in trace amounts, such as zircon ($ZrSiO_4$), are important because of their use in geologic age dating. The isotope uranium-238 (^{238}U) decays to lead-206 (^{206}Pb); ^{235}U decays to ^{207}Pb; ^{232}Th decays to ^{208}Pb; thus, the ratios of the isotopes of uranium, thorium, and lead can be used to determine the ages of minerals that contain these elements. *See* Dating methods; Geochronometry; Lead isotopes (geochemistry); Thorite; Thorium; Uraninite; Uranium. [R.Ew.]

Radioactive tracer A radioactive isotope which, when injected into a chemically similar substance or artificially attached to a biological or physical system, can be traced by radiation detection devices. Many problems in biology and medicine not amenable to other approaches can be solved by the use of these tracers. *See* Radioactivity; Radioactivity and radiation applications; Radioisotope; Radioisotope (biology).

The simplest radioactive tracer studies consist of the tagging of a biological entity with a radioactive isotope (radioisotope). The entity is then tracked by following the radiation from the isotope. The operation becomes more complex when a large number of biological particles are labeled, for example, in the tagging of red blood cells or bacteria. When the labeled substance is injected into an animal, it is impossible to follow the individual labeled particles, but their average movement can be tracked by observations of the radiation. Finally, a radioisotope of a particular element can be used to tag that element. Phosphorus-32 can be introduced into the soil where a plant is growing, and the amount of phosphorus absorbed and its distribution throughout the plant can be studied.

In most biological tracer experiments, the radio-isotope is introduced into the system and its radiation subsequently measured with Geiger-Müller counters or scintillation detectors. Extremely soft (low-intensity) radiations can be detected by the use of photographic film. *See* Geiger-Müller counter; Scintillation counter. [G.L.B.]

In medical applications, a radioactive atom can be attached to a molecule or more complex substance, which can then be used to examine a chemical reaction in a test tube, or it can be administered to a patient by ingestion or injection and subsequently be incorporated into a biochemical process. The radioactive emissions from the radioactive atom can be used to track (trace) the behavior of the labeled molecule or substance in biological processes by means of medical imaging, utilizing techniques such as positron emission tomography (PET) or single-photon-emission computed tomography (SPECT). *See* Medical imaging.

The branch of medicine that uses radioactive tracers in the care of patients is called nuclear medicine. Radiotracers of practically every element can be produced in nuclear reactors or cyclotrons. Radioactive tracers are used as part of the diagnostic process. Three radionuclides—carbon-14, tritium (hydrogen-3), and phosphorus-32—remain the backbone of modern biomedical sciences. *See* Nuclear medicine. [H.N.W.]

Radioactive waste management The treatment and containment of radioactive wastes. These wastes originate almost exclusively in the nuclear fuel cycle and in the nuclear weapons program. Their toxicity requires careful isolation from the biosphere. Their radioactivity is commonly measured in curies (Ci). Considering its toxicity, the curie is a rather large unit of activity. A more appropriate unit is the microcurie ($1\ \mu Ci = 10^{-6}$ Ci), but the nanocurie ($1\ nCi = 10^{-9}$ Ci) and picocurie ($1\ pCi = 10^{-12}$ Ci) are also frequently used. *See* Units of measurement.

Radioactive wastes are classified in four major categories: spent fuel elements and high-level waste (HLW), transuranic (TRU) waste, low-level waste (LLW), and uranium mill tailings. Examples of minor waste categories include radioactive gases produced during reactor operation, radioactive emissions resulting from the burning of uranium-containing coal, or contaminated uranium mine water.

Spent fuel elements arise when uranium is fissioned in a reactor to generate energy. Most of the existing radioactivity is contained in spent nuclear fuel and high-level waste. For the first 100 years, the toxicity is dominated by the beta- and gamma-emitting fission products [such as strontium-90 (^{90}Sr) and cesium-137 ($^{137}137$), with half-lives of approximately 30 years]; thereafter, the long-lived, alpha-emitting transuranium elements [for example, plutonium-239 (^{239}Pu), with a half-life of 24,000 years] and their radioactive decay daughters [for example, americium-241 (^{241}Am), with a half-life of 432 years, a daughter of plutonium-241 (^{241}Pu), with a half-life of 13 years] are important. Burial in geologic formations at a depth of 500–1000 m (1600–3200 ft) appears at present the most practical and attractive disposal method. *See* Nuclear fission; Nuclear fuel cycle; Nuclear fuels reprocessing; Transuranium elements.

However, geology as a predictive science is still in its infancy, and many of the parameters entering into model calculations of the long-term retention of the waste in geologic media are questionable. The major single problem is the heating of the waste and its surrounding rock by the radioactive decay heat. This heating can accelerate the penetration of groundwater into the repository, the dissolution of the waste, and its transport to the biosphere. Much effort has been devoted to the development of canisters to encapsulate the spent fuel elements or the glass blocks containing high-level waste, and of improved waste forms and overpacks that promise better resistance to attack by groundwater.

Although the radioactivity of the transuranic wastes is considerably smaller than that of high-level waste or spent fuel, the high radiotoxicity and long lifetime of these wastes also require disposal in a geologic repository. Waste with less than 100 nCi/g (3.78 Bq/kg) of transuranic elements will be treated as low-level waste.

Uranium is naturally radioactive, decaying in a series of steps to stable lead. It is currently a rare element, averaging between 0.1 and 0.2% in the mined ore. At the mill, the rock is crushed to fine sand, and the uranium is chemically extracted. The residues are discharged to the tailings pile. The tailings contain the radioactive daughters of the uranium. The long-lived isotope thorium-230 (^{230}Th, half-life 80,000 years) decays into radium-226 (^{226}Ra, half-life 1600 years), which in turn decays to radon-222 (^{222}Rn, half-life 3.8 days). Radium and radon are known to cause cancer, the former by ingestion, the latter by inhalation. Radon is an inert gas and thus can diffuse out of the mill tailings pile and into the air. Ground-water pollution by radium that has leached from the pile has also been observed around tailings piles, but its health effects are more difficult to estimate, since the migration in the ground water is difficult to assess and also highly site-specific. *See* Radioactivity; Radium; Radon; Uranium.

Although the radioactivity contained in the mill tailings is very small relative to that of the high-level waste and spent fuel, it is comparable to that of the transuranic waste. It is mainly the dilution of the thorium and its daughters in the large volume of the mill tailings that reduces the health risks to individuals relative to those posed by the transuranium elements in the transuranic wastes. However, this advantage is offset by the great mobility of the chemically inert radon gas, which emanates into the atmosphere from the unprotected tailings. New mill tailings piles will be built with liners to protect the ground water, and will be covered with earth and rock to reduce atmospheric release of the radon gas.

By definition, practically everything that does not belong to one of the three categories discussed above is considered low-level waste. This name is misleading because some wastes, though low in transuranic content, may contain very high beta and gamma activity. The current method of low-level waste disposal is shallow-land burial, which is relatively inexpensive but provides less protection than a geologic repository.

At the end of their lifetime, nuclear facilities have to be dismantled (decommissioned) and the accumulated radioactivity disposed of. Nuclear power plants represent the most important category of nuclear facilities, containing the largest amounts of radioactive wastes, which can be grouped in three classes: neutron-activated wastes, surface-contaminated wastes, and miscellaneous wastes. *See* Nuclear power; Nuclear reactor.

The neutron-activated wastes are mainly confined to the reactor pressure vessel and its internal components, which have been exposed to large neutron fluences during reactor operation. These components contain significant amounts of long-lived nontransuranic radioactive isotopes such as niobium-94 (^{94}Nb, an impurity in the stainless steel), which emits highly penetrating gamma rays and has a half-life of 20,000 years. These wastes are unacceptable for shallow-land disposal as low-level wastes. Disposal in a geologic repository is envisioned. *See* Decontamination of radioactive materials. [R.O.P.]

Radioactivity A phenomenon resulting from an instability of the atomic nucleus in certain atoms whereby the nucleus experiences a spontaneous but measurably delayed nuclear transition or transformation with the resulting emission of radiation. The discovery of radioactivity by H. Becquerel in 1896 marked the birth of nuclear physics.

All chemical elements may be rendered radioactive by adding or by subtracting (except for hydrogen and helium) neutrons from the nucleus of the stable ones. Studies of the radioactive decays of new isotopes far from the stable ones in nature continue as a major frontier in nuclear research. The availability of this wide variety of radioactive isotopes has stimulated their use in a wide variety of fields, including chemistry, biology, medicine, industry, artifact dating, agriculture, and space exploration. *See* Alpha particles; Beta particles; Gamma rays; Isotope; Radioactivity and radiation applications.

A particular radioactive transition may be delayed by less than a microsecond or by more than a billion years, but the existence of a measurable delay or lifetime distinguishes a radioactive nuclear transition from a so-called prompt nuclear transition, such as is involved in the emission of most gamma rays. The delay is expressed quantitatively by the radioactive decay constant, or by the mean life, or by the half-period for each type of radioactive atom, discussed below.

The most commonly found types of radioactivity are alpha, beta negatron, beta positron, electron capture, and isomeric transition. Each is characterized by the particular type of nuclear radiation which is emitted by the transforming parent nucleus. In addition, there are several other decay modes that are observed more rarely in specific regions of the periodic table.

Transition rates and decay laws. The rate of radioactive transformation, or the activity, of a source equals the number A of identical radioactive atoms present in the source, multiplied by their characteristic radioactive decay constant λ. Thus Eq. (1)

$$\text{Activity} = A\lambda \text{ disintegrations per second} \tag{1}$$

holds, where the decay constant λ has dimensions of s^{-1}. The numerical value of λ expresses the statistical probability of decay of each radioactive atom in a group of identical atoms, per unit time. For example, if $\lambda = 0.01\ \mathrm{s}^{-1}$ for a particular radioactive species, then each atom has a chance of 0.01 (1%) of decaying in 1 s, and a chance of 0.99 (99%) of not decaying in any given 1-s interval. The constant λ is one of the most important characteristics of each radioactive nuclide: λ is essentially independent of all physical and chemical conditions such as temperature, pressure, concentration, chemical combination, or age of the radioactive atoms.

Many radioactive nuclides have two or more independent and alternative modes of decay. For example, ^{238}U can decay either by alpha-particle emission or by spontaneous fission. When two or more independent modes of decay are possible, the nuclide is said to exhibit dual decay. The competing modes of decay of any nuclide have independent partial decay constants given by the probabilities $\lambda_1, \lambda_2, \lambda_3, \ldots$, per second, and the total probability of decay is represented by the total decay constant λ, defined by Eq. (2).

$$\lambda = \lambda_1 + \lambda_2 + \lambda_3 + \cdots \tag{2}$$

The actual life of any particular atom can have any value between zero and infinity. The average or mean life of a large number of identical radioactive atoms is, however, a definite and important quantity. The total L of the life-spans of all the A_0 atoms initially present is given by Eq. (3). Then the average lifetime L/A_0, which is called the mean life τ, is given by Eq. (4).

$$L = \frac{A_0}{\lambda} \tag{3}$$

$$\tau = 1/\lambda \tag{4}$$

The time interval over which the chance of survival of a particular radioactive atom is exactly one-half is called half-period T (also called the half-life, written $T_{1/2}$). The half-period T is related to the total radioactive decay constant λ, and to the mean life τ, by Eq. (5). For mnemonic reasons, the half-period T is much more frequently employed than the total decay constant λ or the mean life τ.

$$T = 0.693/\lambda = 0.693\tau \tag{5}$$

Radioactive series decay. In a number of cases a radioactive nuclide A decays into a nuclide B which is also radioactive; the nuclide B decays into C which is also radioactive, and so on. For example, $^{232}_{90}$Th decays into a series of 10 successive radioactive nuclides. Substantially all the primary products of nuclear fission are negatron beta-particle emitters which decay through a chain or series of two to six successive beta-particle emitters before a stable nuclide is reached as an end product.

Alpha-particle decay. Alpha-particle decay is that type of radioactivity in which the parent nucleus expels an alpha particle (a helium nucleus), which contains two protons and two neutrons. Thus, the atomic number, or nuclear charge, of the decay product is 2 units less than that of the parent, and the nuclear mass of the product is 4 atomic mass units less than that of the parent, because the emitted alpha particle carries away this amount of nuclear charge and mass. This decrease of 2 units of atomic number or nuclear charge between parent and product means that the decay product will be a different chemical element, displaced by 2 units to the left in a periodic table of the elements.

In the simplest case of alpha decay, every alpha particle would be emitted with exactly the same velocity and hence the same kinetic energy. However, in most cases there are two or more discrete energy groups called lines. For example, in the alpha decay of a large group of ^{238}U atoms, 77% of the alpha decays will be by emission of alpha particles whose kinetic energy is 4.20 MeV, while 23% will be by emission of 4.15-MeV alpha particles. When the 4.20-MeV alpha particle is emitted, the decay product nucleus is formed in its ground (lowest energy) level. When a 4.15-MeV alpha particle is emitted, the decay product is produced in an excited level, 0.05 MeV above the ground level. This nucleus promptly transforms to its ground level by the emission of a 0.05-MeV gamma ray or alternatively by the emission of the same amount of energy in the form of a conversion electron and the associated spectrum of characteristic x-rays. Thus in all alpha-particle spectra, the alpha particles are emitted in one or more discrete and homogeneous energy groups, and alpha-particle spectra are accompanied by gamma-ray and conversion electron spectra whenever there are two or more alpha-particle groups in the spectrum.

Among all the known alpha-particle emitters, most alpha-particle energy spectra lie in the domain of 4–6 MeV, although a few extend as low as 2 MeV and as high as 10 MeV. There is a systematic relationship between the kinetic energy of the emitted alpha particles and the half-period of the alpha emitter. The highest-energy alpha particles are emitted by short- lived nuclides, and the lowest-energy alpha particles are emitted by the very-long-lived alpha-particle emitters. H. Geiger and J. M. Nuttall showed that there is a linear relationship between log λ and the energy of the alpha particle.

The Geiger-Nuttall rule is inexplicable by classical physics, but emerges clearly from quantum, or wave, mechanics. In 1928 the hypothesis of transmission through nuclear potential barriers was shown to give a satisfactory account of the alpha-decay data, and it has been altered subsequently only in details.

Beta-particle decay. Beta-particle decay is a type of radioactivity in which the parent nucleus emits a beta particle. There are two types of beta decay established: in negatron beta decay (β^-) the emitted beta particle is a negatively charged electron (negatron); in positron beta decay (β^+) the emitted beta particle is a positively charged electron (positron). In beta decay the atomic number shifts by one unit of charge, while the mass number remains unchanged. In contrast to alpha decay, when beta decay takes place between two nuclei which have a definite energy difference, the beta particles from a large number of atoms will have a continuous distribution of energy.

For each beta-particle emitter, there is a definite maximum or upper limit to the energy spectrum of beta particles. This maximum energy, $E_{\max}$, corresponds to the change in nuclear energy in the beta decay. As in the case of alpha decay, most beta-particle spectra include additional continuous spectra which have less maximum energy and which leave the product nucleus in an excited level from which gamma rays are then emitted.

For nuclei very far from stability, the energies of these excited states populated in beta decay are so large that the excited states may decay by proton, two-proton, neutron, two-neutron, three-neutron, or alpha emission, or spontaneous fission.

The continuous spectrum of beta-particle energies implies the simultaneous emission of a second particle besides the beta particle, in order to conserve energy and angular momentum for each decaying nucleus. This particle is the neutrino. The neutrino has zero charge and extremely small rest mass, travels at nearly the same speed as light (3×10^{10} cm/s), and is emitted as a companion particle with each beta ray. By postulating the simultaneous emission of a beta particle and a neutrino, E. Fermi developed in 1934 a quantum-mechanical theory which satisfactorily gives the shape of beta-particle spectra, and the relative half-periods of beta-particle emitters for allowed beta decays. *See* NEUTRINO.

When the ground state of a nucleus differing by two units of charge from nucleus *A* has lower energy than *A*, then it is theoretically possible for *A* to emit two beta particles, either $\beta^+\beta^+$ or $\beta^-\beta^-$ as the case may be, and two neutrinos or antineutrinos, and go from Z to $Z \pm 2$. Here two protons decay into two neutrons, or vice versa. This is a second-order process and so should go much slower than beta decay. There are a number of cases where such decays should occur, but their half-lives are of the order of 10^{20} years or greater. Such decay processes are obviously very difficult to detect. The first direct evidence for two-neutrino double-beta-minus decay of selenium-82, was found only in 1987.

Whenever it is energetically allowed by the mass difference between neighboring isobars, a nucleus Z may capture one of its own atomic electrons and transform to the isobar of atomic number $Z - 1$. Usually the electron-capture (EC) transition involves an electron from the *K* shell of atomic electrons, because these innermost electrons have the greatest probability density of being in or near the nucleus. *See* ELECTRON CAPTURE.

Gamma-ray decay. Gamma-ray decay involves a transition between two excited levels of a nucleus, or between an excited level and the ground level. A nucleus in its ground level cannot emit any gamma radiation. Therefore gamma-ray decay occurs only as a sequel of another radioactive decay process or of some other process whereby the product nucleus is left in an excited state. Such additional processes include the fusion of two nuclei, Coulomb excitation, and induced nuclear fission. *See* COULOMB EXCITATION; NUCLEAR FISSION; NUCLEAR FUSION.

A gamma ray is high-frequency electromagnetic radiation (a photon) in the same family with radio waves, visible light, and x- rays. The energy of a gamma ray is given by $h\nu$, where h is Planck's constant and ν is the frequency of oscillation of the wave in hertz. The gamma-ray or photon energy $h\nu$ lies between 0.05 and 3 MeV for the majority of known nuclear transitions. Higher- energy gamma rays are seen in neutron capture and some reactions. *See* ELECTROMAGNETIC RADIATION.

Gamma rays carry away energy, linear momentum, and angular momentum, and account for changes of angular momentum, parity, and energy between excited levels in a given nucleus. This leads to a set of gamma-ray selection rules for nuclear decay and a classification of gamma-ray transitions as "electric" or as "magnetic" multipole radiation of multipole order 2^l, where $l = 1$ is called dipole radiation, $l = 2$ is quadrupole radiation, and $l = 3$ is octupole, l being the vector change in nuclear angular momentum. The most common type of gamma-ray transition in nuclei is the electric quadrupole (E2). There are cases where several hundred gamma rays with different energies are emitted in the decays of atoms of only one isotope. *See* MULTIPOLE RADIATION.

An alternative type of deexcitation which always competes with gamma-ray emission is known as internal conversion. Instead of the emission of a gamma ray, the nuclear excitation energy can be transferred directly to a bound electron of the same atom. Then the nuclear energy difference is converted to energy of an atomic electron, which is ejected from the atom.

When the energy between two states in the same nucleus exceeds 1.022 MeV, twice the rest mass energy of an electron, it is also possible for the nucleus to give up its excess energy to an electron-positron pair—a pair creation process. *See* ELECTRON-POSITRON PAIR PRODUCTION.

Spontaneous fission. This involves the spontaneous breakup of a nucleus into two heavy fragments and neutrons. Spontaneous fission can occur when the sum of the masses of the two heavy fragments and the neutrons is less than the mass of the parent undergoing decay. After the discovery of fission in 1939, it was subsequently discovered that isotopes like ^{238}U had very weak decay branches for spontaneous fission, with branching ratios on the order of 10^{-6}. Some isotopes with relatively long half-lives such as ^{252}Cf have large (3.1%) spontaneous fission branching. [J.H.H.]

Heavy cluster decays. Alpha-particle decay and spontaneous fission are two natural phenomena in which an atomic nucleus spontaneously breaks into two fragments, but the fragments are of very different size in one case and almost equal size in the other. On the basis of fragmentation theory and the two-center shell model, new kinds of radioactivities that are intermediate between alpha particle decay and fission were predicted in 1980. Subsequently, it was shown theoretically that the new processes should occur throughout a very broad region of the nuclear chart, including elements with atomic numbers higher than 40. However, experimentally observable emission rates could be expected only for nuclei heavier than lead, in a breakup leading to a very stable heavy fragment with proton and neutron numbers equal or very close to $Z = 82$, $N = 126$ ($^{208}_{82}$Pb or its neighborhood). The main competitor is always alpha-particle decay. In 1984, a series of experimental confirmations began with the discovery of $^{14}_{6}C$ radioactivity of $^{223}_{88}Ra$. A very promising technique uses solid-state track-recording detectors with special plastic films and glasses that are sensitive to heavier clusters but not to alpha particles. [W.Gr.; J.H.H.]

Proton radioactivity. Proton radioactivity is a mode of radioactive decay that is generally expected to arise in proton-rich nuclei far from the stable isotopes, in which the parent nucleus changes its chemical identity by emission of a proton in a single-step process. Its physical interpretation parallels almost exactly the quantum-mechanical treatment of alpha-particle decay. For many years only a few examples of this decay mode were observed, because of the narrow range of half-lives and decay energies where this mode can compete with other modes. However, in the late 1990s, experimental techniques using new recoil mass spectrometers, which can separate rare reaction products, and new double-sided silicon strip detectors became available and opened up the discovery of many new proton radioactivities. Two-proton radioactivity (the simultaneous emission of two protons) was first observed in 2001 in an excited state of neon-18 and in 2002 in the ground state of iron-45.

Delayed particle emissions. Twelve types of beta-delayed particle emissions have been observed. Beta-delayed deuteron (^2H) emission, which is not shown there, also can be expected. Over 100 beta-delayed particle radioactivities are now known. Theoretically, the number of isotopes which can undergo beta-delayed particle emission could exceed 1000. Thus, this mode, which was observed in only a few cases prior to 1965, is among the important ones in nuclei very far from the stable ones in nature. Studies of these decays can provide insights into the nucleus which can be gained in no other way. [J.H.H.]

Radioactivity and radiation applications

The field in which the subatomic fragments emitted in radioactive decay (alpha-, beta-, gamma-rays) or produced by high-voltage accelerators (electrons, protons, x-rays) are applied to the problems of science, engineering, industry, and medicine. The techniques are extraordinarily versatile and sensitive and are basically inexpensive. A disadvantage that limits the range and extent of these applications is the health hazard that may be involved. *See* RADIOACTIVITY; RADIOISOTOPE.

Tracer applications are based on two principles. First is the chemical similarity of radioactive atoms and other atoms of the same element. Periodically a few of the radioactive atoms decay, emitting some penetrating subatomic fragments that can be detected one by one, usually through their ability to cause ionization. Thus the movement of a particular element can be followed through various chemical, physical, and biological steps. The second principle involves the characteristic half-life and nature of the emitted fragments. This makes a radioactive species unique and thereby detectable above a background of radioactive emitters associated with elements. For discussions of radioisotope techniques relating to tracer methodology *see* ACTIVATION ANALYSIS; ISOTOPE DILUTION TECHNIQUES; RADIOACTIVE TRACER; RADIOECOLOGY.

Penetration and scattering applications arise from the fact that subatomic fragments can penetrate a thick section of a material, and yet a small fraction of the incident particles can be backscattered by a relatively thin section. The oldest application of the penetrating properties of energetic ionizing photons is radiography. An extension of this technique is autoradiography. Since World War II the penetration and scattering properties of beta- and gamma-rays have been applied in industry in the form of thickness gages. *See* AUTORADIOGRAPHY; RADIOGRAPHY.

The absorption of small amounts of energy from ionizing particles and ionizing photons has chemical effects that have been the basis of several practical applications. The oldest application of this principle is radiation therapy. For example, in cancer therapy the local affected areas are irradiated by external beams of gammas from cobalt-60 or of radiation from accelerators. Radioactive sources have also been administered internally to induce beneficial biochemical reactions in patients afflicted with various ailments. *See* ISOTOPIC IRRADIATION; RADIOLOGY.

A related area is the radiation sterilization of biomedical supplies. The advantages to this method of biochemical destruction of microscopic life are that (1) unlike steam sterilization, it can be performed at low temperatures on plastics and other thermally unstable materials, and (2) unlike germicidal gases, ionizing radiation can reach every point in the treated product. Radiation-sterilized objects are not radioactive.

The radiation preservation of food is an area of considerable promise. Small doses can inhibit sprouting in potatoes, kill insects in wheat, and sterilize pork products but practical applications have been sharply limited due to a cautious role by regulatory authorities in approving such procedures.

Kinetic energy of emissions in radioactive decay can be converted to useful forms of light, heat, and electricity. *See* LUMINOUS PAINT; NUCLEAR BATTERY. [J.Sil.]

Radioactivity standards

Calibrated standard sources of radioactive substances used to determine, by comparison, the strength or activity of samples of the same substances in terms of the number of radioactive atoms they contain or in terms of some figure proportional to this number. The calibration of the standard source in terms of the number of radioactive atoms is usually an elaborate procedure but need only be carried out once, and the calibration may be made at a standardizing laboratory, such as the National Institute of Standards and Technology, having special equipment for the work. Comparison between a sample and the standard is usually made by finding the ratio of the response of an ionization chamber, or other detector of radiation, to the radiation from a sample and from the standard. In each case the intensity of the radiation, and therefore the response of the detector under identical conditions, is proportional to the number of radioactive atoms in the source, because this number is also proportional to the activity or disintegration rate of a source. *See* HALF-LIFE; RADIOACTIVITY. [L.F.Cu.; K.Z.M.]

Radiocarbon dating

A method of obtaining age estimates on organic materials which has been used to date samples as old as 75,000 years. The method has provided age determinations in archeology, geology, geophysics, and other branches of science.

Radiocarbon (^{14}C) determinations can be obtained on wood; charcoal; marine and fresh-water shell; bone and antler; peat and organic-bearing sediments; carbonate deposits such as tufa, caliche, and marl; and dissolved carbon dioxide (CO_2) and carbonates in ocean, lake, and ground-water sources. Each sample type has specific problems associated with its use for dating purposes, including contamination and special environmental effects. While the impact of ^{14}C dating has been most profound in archeological research and particularly in prehistoric studies, extremely significant contributions have also been made in hydrology and oceanography. In addition, beginning in the 1950s the testing of thermonuclear weapons injected large amounts of artificial ^{14}C ("bomb ^{14}C") into the atmosphere, permitting it to be used as a geochemical tracer.

Carbon (C) has three naturally occurring isotopes. Both ^{12}C and ^{13}C are stable, but ^{14}C decays by very weak beta decay (electron emission) to nitrogen-14 (^{14}N) with a half-life of approximately 5700 years. Naturally occurring ^{14}C is produced as a secondary effect of cosmic-ray bombardment of the upper atmosphere. As $^{14}CO_2$, it is distributed on a worldwide basis into various atmospheric, biospheric, and hydrospheric reservoirs on a time scale much shorter than its half-life. Metabolic processes in living organisms and relatively rapid turnover of carbonates in surface ocean waters maintain ^{14}C levels at approximately constant levels in most of the biosphere. The natural ^{14}C activity in the geologically recent contemporary "prebomb" biosphere was approximately 13.5 disintegrations per minute per gram of carbon. *See* COSMOGENIC NUCLIDE; ISOTOPE.

To the degree that ^{14}C production has proceeded long enough without significant variation to produce an equilibrium or steady-state condition, ^{14}C levels observed in contemporary materials may be used to characterize the original ^{14}C activity in the corresponding carbon reservoirs. Once a sample has been removed from exchange with its reservoir, as at the death of an organism, the amount of ^{14}C begins to decrease as a function of its half-life. A ^{14}C age determination is based on a measurement of the residual ^{14}C activity in a sample compared to the activity of a sample of assumed zero age (a contemporary standard) from the same reservoir. The relationship between the ^{14}C age and the ^{14}C activity of a sample is given by the equation below, where t

$$t = \frac{1}{\lambda} \ln \frac{A_o}{A_s}$$

is radiocarbon years B.P. (before the present), λ is the decay constant of ^{14}C (related to the half-life $t_{1/2}$ by the expression $t_{1/2} = 0.693/\lambda$), A_o is the activity of the contemporary standards, and A_s is the activity of the unknown age samples. Conventional radiocarbon dates are calculated by using this formula, an internationally agreed half-life value of 5568 ± 30 years, and a specific contemporary standard.

The naturally occurring isotopes of carbon occur in the proportion of approximately 98.9% ^{12}C, 1.1% ^{13}C, and 10^{-10}% ^{14}C. The extremely small amount of radiocarbon in natural materials was one reason why ^{14}C was one of the isotopes which had been produced artificially in the laboratory before being detected in natural concentrations. A measurement of the ^{14}C content of an organic sample will provide an accurate determination of the sample's age if it is assumed that (1) the production of ^{14}C by cosmic rays has remained essentially constant long enough to establish a steady state in the $^{14}C/^{12}C$ ratio in the atmosphere, (2) there has been a complete and rapid mixing of ^{14}C throughout the various carbon reservoirs, (3) the carbon isotope ratio in the sample has not been altered except by ^{14}C decay, and (4) the total amount of carbon in any reservoir has not been altered. In addition, the half-life of ^{14}C must be known with sufficient accuracy, and it must be possible to measure natural levels of ^{14}C to appropriate levels of accuracy and precision. [R.E.T.]

Radiochemical laboratory A laboratory or facility used for investigation and handling of radioactive chemicals that provides a safe environment for the worker and the public. Features vary depending on the type of radioactive emissions to be handled, the quantity, the half-life, and the physical form (solid, liquid, gas, or powder). Special measures to minimize spread of contaminated material and to dispose of radioactive waste are required. Working surfaces should be smooth and easily washable to permit effective decontamination if necessary. Good ventilation and detectors for monitoring radiation and contamination on surfaces or people are also typical features. *See* VENTILATION.

Investigations utilizing only very small amounts (a few microcuries) of beta or gamma emitters which are not readily dispersed (no powders or volatile liquids) may sometimes be performed without special facilities on the bench top. In this case, precautions such as working on plastic-backed absorbent paper and wearing protective gloves and lab coat may be sufficient. A special bag or can for disposing of the paper and gloves as radioactive waste is required. If the radioactive isotopes are solely alpha-particle emitters, containment and isolation from direct contact are more serious concerns. Due to the limited penetration but high biological toxicity of alpha particles, it is essential to avoid ingestion or inhalation. For very small quantities, work may take place with double rubber gloves in a fume hood with appropriate filter. Generally, an enclosed glove box is used, situated inside a hood and maintained at negative pressure with respect to the face of the hood and the room. Sensors to monitor proper differential pressure and adequate airflow are usually used to assure containment and to generate an alarm if conditions degrade.

For work with pure beta-emitting isotopes, long-handled tongs or other tools are used for higher levels of radioactivity in order to shield the hands. Generally, since most beta emission is also accompanied by penetrating gamma emission, the entire work area must be enclosed in heavily shielded enclosures. *See* ALPHA PARTICLES; BETA PARTICLES; RADIATION CHEMISTRY; RADIOACTIVITY; RADIOCHEMISTRY; RADIOISOTOPE.

Hot laboratories contain walled enclosures for remotely handling larger quantities of gamma-emitting isotopes. A small enclosure is usually referred to as a cave, while large ones are called hot cells. Hot cells are usually equipped with remote manipulators and thick windows made from high-density lead glass. [L.F.M.]

Radiochemistry A subject which embraces all applications of radioactive isotopes to chemistry. It is not precisely defined and is closely linked to nuclear chemistry. The widespread use of isotopes in chemistry is based on two fundamental properties exhibited by all radioactive substances. The first property is that the disintegration rate of an isotopic sample is directly proportional to the number of radioactive atoms in the sample. Thus, measurement of its disintegration rate (with a Geiger counter, for example) serves to analyze a radioactive compound. With nearly all chemical elements (notable exceptions being nitrogen and oxygen, which have no suitable radioactive isotopes), an isotope may be incorporated in a chemical compound, and thereafter, masses of this compound as small as 10^{-6} to 10^{-10} g may be measured with a high precision. The second property is that the disintegration rate is completely unaffected by the chemical form of the isotope, and conversely, the property of radioactivity does not affect the chemical properties of the isotope. By substituting or labeling a particular atom within a molecule, isotopes can be used to trace the fate of that atom during a chemical reaction. Radiochemistry has been used to study the efficiency of chemical separations, rates of chemical reaction and diffusion, isotopic exchange reactions, and chemical reaction mechanisms. *See* NUCLEAR CHEMISTRY; RADIATION CHEMISTRY; RADIOACTIVITY; RADIOCHEMICAL LABORATORY. [D.R.S.]

Radioecology The study of the fate and effects of radioactive materials in the environment. It derives its principles from basic ecology and radiation biology.

Responses to radiation stress have consequences for both the individual organism and for the population, community, or ecosystem of which it is a part. When populations or individuals of different species differ in their sensitivities to radiation stress, for example, the species composition of the entire biotic community may be altered as the more radiation-sensitive species are removed or reduced in abundance and are replaced in turn by more resistant species. Such changes have been documented by studies in which natural ecological systems, including grasslands, deserts, and forests, were exposed to varying levels of controlled gamma radiation stress. *See* POPULATION ECOLOGY.

Techniques of laboratory toxicology are also available for assessing the responses of free-living animals to exposure to low levels of radioactive contamination in natural environments. This approach uses sentinel animals, which are either tamed, imprinted on the investigator, or equipped with miniature radio transmitters, to permit their periodic relocation and recapture as they forage freely in the food chains of contaminated habitats. When the animals are brought back to the laboratory, their level of radioisotope uptake can be determined and blood or tissue samples taken for analysis. In this way, even subtle changes in deoxyribonucleic acid (DNA) structure can be evaluated over time. These changes may be suggestive of genetic damage by radiation exposure. In some cases, damage caused by a radioactive contaminant may be worsened by the synergestic effects of other forms of environmental contaminants such as heavy metals.

Because of the ease with which they can be detected and quantified in living organisms and their tissues, radioactive materials are often used as tracers. Radioactive tracers can be used to trace food chain pathways or determine the rates at which various processes take place in natural ecological systems. Although most tracer experiments were performed in the past by deliberately introducing a small amount of radioactive tracer into the organism or ecological system to be studied, they now take advantage of naturally tagged environments where trace amounts of various radioactive contaminants were inadvertently released from operating nuclear facilities such as power or production reactors or waste burial grounds. *See* RADIOACTIVE TRACER.

An important component of radioecology, and one that is closely related to the study of radioactive tracers, is concerned with the assessment and prediction of the movement and concentration of radioactive contaminants in the environment in general, and particularly in food chains that may lead to humans. *See* ECOLOGY; ENVIRONMENTAL RADIOACTIVITY; ENVIRONMENTAL TOXICOLOGY; FOOD WEB; RADIATION BIOLOGY. [I.L.B.]

Radiography The technique of producing a photographic image of an opaque specimen by the penetration of radiation such as gamma rays, x-rays, neutrons, or charged particles. When a beam of radiation is transmitted through any heterogeneous object, it is differentially absorbed, depending upon the varying thickness, density, and chemical composition of this object. The image registered by the emergent rays on a photographic film adjacent to the specimen under examination constitutes a shadowgraph or radiograph of its interior. Radiography is the general term applied to this nondestructive film technique of testing the gross internal structure of any object, whether it be of the chest of a patient for evidence of tuberculosis, silicosis, heart pathology, or embedded foreign objects; of bones in case of fractures or of arthritis or other bone diseases; or of a weld in a pipe to observe cracks, inclusions, or voids. Radiography with x-rays is commonly used in both medical and industrial applications. Industrial work also involves gamma and neutron radiography. Radiography with charged particles is under development. Most of this discussion will be concerned with radiography with x-rays and gamma rays. *See* CHARGED PARTICLE BEAMS; GAMMA RAYS; NEUTRON; X-RAYS.

Industrial radiography enables detection of internal physical imperfections such as voids, cracks, flaws, segregations, porosities, and inclusions. It is frequently used for visualization of inaccessible internal parts in order to check their location or condition. It is extensively applied wherever internally sound metallic components are required such as (1) in the foundry industry to guarantee the soundness of castings; (2) in the welding of pressure vessels, pipelines, ships, and reactor components to guarantee the soundness of welds; (3) in the manufacture of fuel elements for reactors to guarantee their size and soundness; (4) in the solid-propellant and high-explosives industry to guarantee the soundness and physical purity of the material; and (5) in the automotive, aircraft, nuclear, space, oceanic, and guided-missile industries, whenever internal soundness is required.

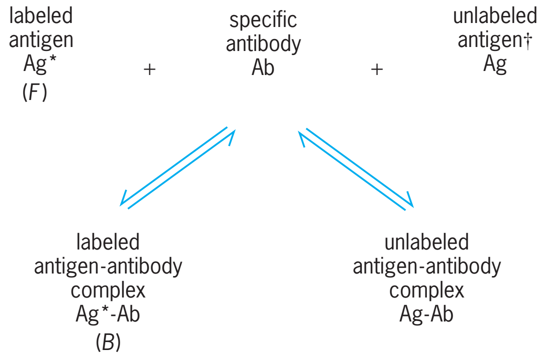
The general term applied to radiation imaging and inspection is radiology. This includes film and similar photographic image methods, such as radiographic paper, under the term radiography. In medical circles, the term roentgenography, derived from the name of the discoverer of x-rays, W. C. Roentgen, is used. The older technique of registering an image on a fluorescent screen is called fluoroscopy. The fluoroscopic prompt-response imaging of radiation has largely been replaced by electronic detection with image intensifiers or sensitive television cameras. This technique, called radioscopy, is now widely used in both medical and industrial applications. *See* RADIOLOGY.

Other variations of radiation imaging include xeroradiography, microradiography, flash radiography, and computerized tomography. Xeroradiography is a dry-plate, electrostatic image method similar to that used in photocopy machines. Microradiography involves a magnified image to improve spatial resolution and the detection of small detail. Flash radiography is the production of an x-ray image in a very short time, of the order of nanoseconds, in order to stop fast motion. The computerized tomography (CT) method recreates an image that is essentially a slice through the object. Computerized tomography has made a strong impact on medical diagnosis and industrial inspection. *See* COMPUTERIZED TOMOGRAPHY; MICRORADIOGRAPHY.

Neutron beams, obtained from nuclear reactors, accelerators, or radioactive sources, can penetrate matter with relative ease since they are not electrically charged. The attenuation of neutrons by most materials is relatively small because the neutron carries no electric charge and consequently is neither attracted nor repelled by the charged particles in the nucleus, nor by the electron clouds associated with the atoms of the material through which the neutron passes. On the other hand, the neutron absorption coefficients of some elements with low atomic numbers are high; hydrogen, lithium, and boron are particularly attenuating. This reversal of attenuation properties between neutrons and x-rays leads to complementary properties for the two radiographic methods. With neutrons, it is possible to visualize materials such as liquids, adhesives, rubber, plastic, or explosives even when they are in metal assemblies.

Proton radiography employs beams of protons. A rapidly moving, high-energy proton or other charged particle moves through material with little attenuation until it slows sufficiently for the charges on the particle and the material to interact. A monoenergetic charged particle travels a well-defined distance, called the range, in a given material before it is stopped. Since most of the attenuation of the charged particles occurs near the end of the range, a very small change in material thickness will result in a large change in radiation transmission. Therefore, the sensitivity of this method to small changes in object thickness is very great, if the total path for the radiation approximates the range. This is a major advantage of proton radiography. Changes in object thickness as small as 0.05% have been imaged with one-step film. [G.H.T.; G.L.Cl.; H.Be.]

Radioimmunoassay A general method employing the reaction of antigen with specific antibody, permitting measurement of the concentration of virtually any substance of biologic interest, often with unparalleled sensitivity. The basis of the method is summarized in the competing reactions shown in the illustration. The unknown concentration of the antigenic substance in a sample is obtained by comparing its inhibitory effect on the binding of radioactively labeled antigen to a limited



Competing reactions that form basis of radioimmunoassay; * indicates the labeled antigen, and † "in known standard solutions or unknown samples."

amount of specific antibody with the inhibitory effect of known standards.

A typical radioimmunoassay is performed by the simultaneous preparation of a series of standard and unknown mixtures in test tubes, each containing identical concentrations of labeled antigen and specific antibody. After an appropriate reaction time the antibody- bound (B) and free (F) fractions of the labeled antigen are separated by one of a variety of techniques. The B/F ratios in the standards are plotted as a function of the concentration of unlabeled antigen (standard curve), and the unknown concentration of antigen is determined by comparing the observed B/F ratio with the standard curve.

The radioimmunoassay principle has found wide application in the measurement of a large and diverse group of substances in a variety of problems of clinical and biological interest. It is therefore not unexpected that there are differences in the specific methods employed for the assay of a particular substance. The full potential of the method has yet to be exploited. It seems that virtually any substance of biologic interest can be measured, the method being modified according to the characteristics of the particular substance. *See* ANTIBODY; ANTIGEN; IMMUNOLOGY. [R.S.Y.]

Radioisotope A radioactive isotope (as distinguished from a stable isotope) of an element. Atomic nuclei are of two types, unstable and stable. Those in the former category are said to be radioactive and eventually are transformed, by radioactive decay, into the latter. One of the three types of particles or radiation (alpha particles, beta particles, and gamma rays) is emitted during each stage of the decay. *See* ISOTOPE; RADIOACTIVITY.

The term radioisotope is also loosely used to refer to any radioactive atomic species. Whereas approximately a dozen radioisotopes are found in nature in appreciable amounts, hundreds of different radioisotopes have been artificially produced by bombarding stable nuclei with various atomic projectiles.

A very wide variety of radioisotopes are produced in particle accelerators, such as the cyclotron. Charged particles, such as deuterons (D^+) and protons (H^+), are accelerated to great speeds by high-voltage electrical fields and allowed to strike targets in which nuclear reactions take place; for example, proton in, neutron out (p,n), increasing the target-atom atomic number by one without changing the atomic mass; and deuteron in, proton out (d,p), increasing the atomic mass by one without changing the atomic number. The target elements become radioactive because the nuclei of the atoms are unbalanced, having an excess or deficit of neutrons or protons. Although the particle-accelerating machines are most versatile in producing radioisotopes, the amount of radioactive material that can be produced is relatively smaller than that made in a nuclear reactor [less than curie amounts; a curie (abbreviated Ci) is that quantity of a radioisotope required to supply 3.7×10^{10} disintegrations per second or 3.7×10^{10} becquerels (Bq)]. For large-scale production, nuclear reactors with neutron fluxes of 1×10^{10} to 5×10^{15} neutrons per square centimeter per second are required. *See* NUCLEAR REACTION; NUCLEAR REACTOR; PARTICLE ACCELERATOR; REACTOR PHYSICS; UNITS OF MEASUREMENT. [A.F.Ru.]

Radioisotope (biology) A radioactive isotope used in studying living systems, such as in the investigation of metabolic processes. The usefulness of radioisotopes as tracers arises chiefly from three properties: (1) At the molecular level the physical and chemical behavior of a radioisotope is practically identical with that of the stable isotopes of the same element. (2) Radioisotopes are detectable in extremely minute concentrations. (3) Analysis for radioisotopic content often can be achieved without alteration of the sample or system. In some applications, principally those in which reaction rates and transfer rates are studied, isotopes, particularly radioisotopes, have unique advantages as tracers. *See* ISOTOPE; RADIOISOTOPE.

The amount of isotope to be used and the path by which it is introduced into the system are governed by many factors. Sufficient tracer to be detectable must be used, but the amounts of material which are introduced must be small enough not to disturb the system by their mass, pharmacological effects, or the effects of radiation. The mass of 1 curie, the unit of disintegration rate, depends inversely upon the half-life and directly upon the atomic weight of the particular radioisotope; it is 1 gram for ^{226}Ra (half-life 1620 years), but only 8 micrograms for ^{131}I (half-life 8.0 days). In tracer experiments with small animals, microcurie quantities are usually adequate.

There are many methods for detecting the presence of radioactive material. The Geiger counter has largely been displaced by thallium-activated sodium iodide scintillation crystals for counting gamma rays, but Geiger counters and proportional counters are still useful for counting alpha and beta particles. In histological and cytological studies the method of autoradiography, in which photographic film is exposed through contact with the specimen, is very useful. The autoradiographic method is also used extensively in conjunction with paper or column chromatography, particularly in studies of metabolic pathways. *See* AUTORADIOGRAPHY; CHROMATOGRAPHY; GEIGER-MÜLLER COUNTER; PARTICLE DETECTOR; SPECTROSCOPY.

One of the outstanding achievements in which radioisotopes have played a role has been the use of carbon-14 in the elucidation of the metabolic path of carbon in photosynthesis. The products produced in the first few seconds following exposure to light have been identified by combinations of paper chromatography and autoradiography. The extrathyroidal metabolism of iodine, the path of iodine in the thyroid gland, and other problems of intermediary metabolism have been studied intensively. The concept of the dynamic state of cell constituents is largely attributable to discoveries made with isotopic tracers. At one time it was thought that concentration gradients across cell membranes depended upon their being impermeable, but the use of isotopes has refuted this hypothesis by proving that in many such cases the substances involved are normally transported in both directions across the membrane. In physiology, radioisotopes have been used in a wide variety of permeability, absorption, and distribution studies. *See* ABSORPTION (BIOLOGY); CELL MEMBRANE; PHOTOSYNTHESIS.

The kinetics of cellular proliferation has provided a rich vein for application of radioisotopic methods. For example, the lifetime of human red blood cells (about 120 days) was established with the use of ^{59}Fe-labeled cells. Some applications, such as the intake of ^{131}I by the thyroid, the measurement of the red-cell mass with ^{51}Cr-labeled red cells, and the absorption of ^{60}Co-labeled vitamin B_{12}, are of practical clinical importance in the diagnosis and treatment of disease, and knowledge of the rates of distribution and disposal of a wide variety of radioactive substances is basic to the problem of evaluating the hazard from fallout radiation. [J.S.Ro.]

Radioisotope geochemistry A branch of environmental geochemistry and isotope geology concerned with the occurrence of radioactive nuclides in sediment, water, air, biological tissues, and rocks. The nuclides have relatively short half-lives ranging from a few days to about 10^6 years, and occur only because they are being produced by natural or anthropogenic nuclear reactions or because they are the intermediate unstable daughters of long-lived naturally occurring radioactive isotopes of uranium and thorium. The nuclear radiation, consisting of alpha particles, beta particles, and gamma rays, emitted by these nuclides constitutes a potential health hazard to humans. However, their presence also provides opportunities for measurements of the rates of natural processes in the atmosphere and on the surface of the Earth. *See* ALPHA PARTICLES; BETA PARTICLES; GAMMA RAYS.

The unstable daughters of uranium and thorium consist of a group of 43 radioactive isotopes of 13 chemical elements, including all of the naturally occurring isotopes of the chemical elements radium, radon, polonium, and several others. A second group of radionuclides is produced by the interaction of cosmic rays with the chemical elements of the Earth's surface and atmosphere. This group includes hydrogen-3 (tritium), beryllium-10, carbon-14, aluminum-26, silicon-32, chlorine-36, iron-55, and others. A third group of radionuclides is produced artificially by the explosion of nuclear devices, by the operation of nuclear reactors, and by various particle accelerators used for research in nuclear physics. Some of the radionuclides produced in nuclear reactors decay sufficiently slowly to be useful for geochemical research, including strontium-90, cesium-137, iodine-129, and isotopes of plutonium. The explosion of nuclear devices in the atmosphere has also contributed to the abundances of certain radionuclides that are produced by cosmic rays such as tritium and carbon-14. *See* Cosmogenic nuclide; Dating methods; Environmental radioactivity; Radioactive fallout; Radioisotope; Transuranium elements. [G.Fau.]

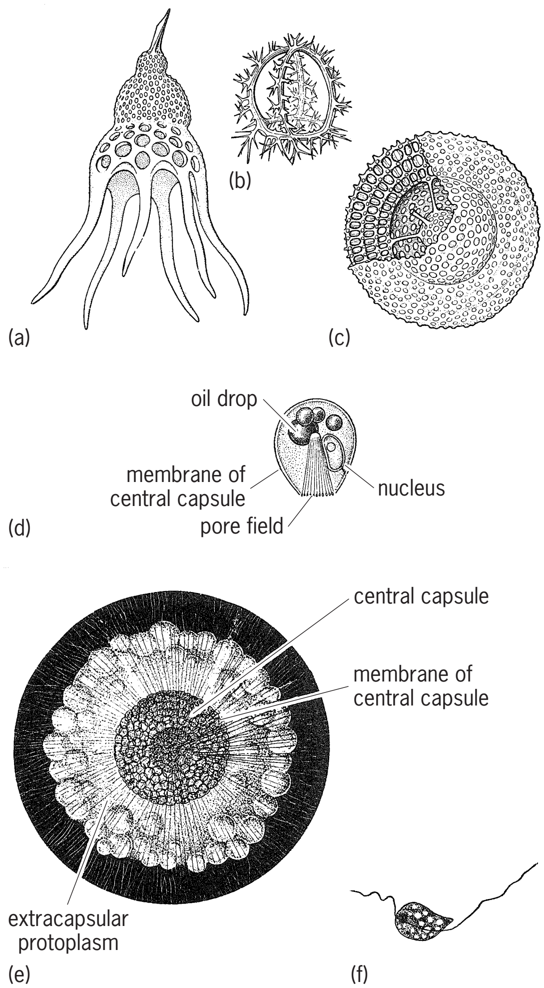
Radiolaria A group of marine protozoa, regarded as a subclass of Actinopodea in older classifications, but not recognized as a natural group in some modern systems owing to its heterogeneity. In certain modern systems, the Radiolaria are subdivided into two classes, Polycystinea and Phaeodarea. Radiolarians occur almost exclusively in the open ocean as part of the plankton community, and are widely recognized for their ornate siliceous skeletons produced by most of the groups (illus. *a–c*). Their skeletons occur abundantly in ocean sediments and are used in analyzing the layers of the sedimentary record (biostratigraphy).

A characteristic feature of the group is the capsule, a central mass of cytoplasm bearing one or more nuclei, food reserves, and metabolic organelles. This is surrounded by a perforated wall and a frothy layer of cytoplasm known as the extracapsulum, where food digestion generally occurs and where numerous axopodia (stiffened strands of cytoplasm) and rhizopodia radiate toward the surrounding environment. Algal symbionts including dinoflagellates, green algae, and golden-brown pigmented algae occur profusely in the extracapsulum. The algal symbionts living within the protection of the extracapsulum provide photosynthetically derived food for the radiolarian host.

In the order Spumellarida (class Polycystinea) the central capsule is perforated by numerous pores distributed evenly on the surface of the capsular wall. These pores, containing strands of cytoplasm, provide continuity between the cytoplasm in the central capsule and the surrounding extracapsulum. The skeletons of the Spumellarida are characteristically developed on a spherical organizational plan, but some are spiral-shaped (resembling snail shells) or produce elongate skeletons composed of numerous chambers built one upon another. In some genera, such as *Thalassicolla* (illus. *e*), there is no skeleton; in others there are rods or spicules, or often a single or multiple concentric latticework skeleton (illus. *c*).

Multicellular aggregates (colonies of spumellaridans), measuring several centimeters in diameter (or even several meters in some rare elongate forms), consist of numerous radiolarian central capsules enclosed within a gelatinous envelope and interconnected by a web of rhizopodia that bears abundant algal symbionts. A thin halo of feeding rhizopodia protrudes from the surface of the colony and is used to capture prey. Reproduction is poorly understood. In some colonial forms, daughter colonies are produced by asexual reproduction (fission). Flagellated swarmers (illus. *f*) released from mature central capsules of some species are possibly gametes and contain a large crystal inclusion of strontium sulfate.

In the Nasselarida (Polycystinea), the central capsule is often ovate and the pores are localized at one pole (illus. *d*). The axopodia and rhizopodia emerge from this pore field and are supplied by a conelike array of microtubules within the central capsule. The skeleton, when present, is often shaped like a dome or helmet.



Radiolaria. Skeletons representing (*a*, *b*) certain Nasselarida (or Monopylina) and (*c*) certain Spumellarida (or Peripylina). (*d*) Central capsule, one of the Nasselarida showing one group of pores. (*e*) *Thalassicolla*, one of the Spumellarida without skeletal elements. (*f*) Biflagellate gametes. (*After L. H. Hyman*, *The Invertebrates*, *vol. 1*, *McGraw-Hill*, *1940*)

Radiolarians in the class Phaeodarea possess a central capsule with two types of pore areas, a larger one (astropyle) that serves as a kind of cytopharynx where food is carried into the central capsule, and two accessory openings (parapylae) where smaller strands of cytoplasm emerge. The skeleton exhibits a wide range of shapes, including geodesic-like lattice spheres and small porous clam-shaped shells.

Radiolarians have a fossil record that extends back to early Paleozoic time, about a half billion years ago. Compared to other groups of shell-bearing marine microplankton, they are highly diverse, several hundred species having inhabited the oceans at any given time. Because they are planktonic and have undergone continuous evolutionary change, radiolarians are particularly useful for determining time equivalence (and geological ages) of marine sedimentary deposits at widely separated localities. The Cenozoic record of radiolarians in sediments, particularly on the deep-sea floor, is sufficiently complete to show the course of evolutionary change in considerable detail.

Assemblages of fossil radiolarians also provide clues to oceanic conditions during the geological past. Each of the major oceanic water masses has its characteristic radiolarian fauna, and so changes in the distribution or composition of these assemblages can be interpreted in terms of changes in the pattern of water masses, or in their oceanographic properties. *See* OCULOSIDA; PROTOZOA. [O.R.A.; W.R.R.]

Radiology The medical science concerned with x-rays, radioactive materials, and other ionizing radiations, and the application of the principles of this science to diagnosis and treatment of disease. Nonionizing radiations of infrared and ultrasound are also used for diagnosis.

Diagnostic radiology uses radiation, usually x-rays, to study the configuration of anatomical structures or the function of body organ systems. *See* RADIOGRAPHY.

Radioactive isotopes are used to obtain images of organ systems and functions. The accumulation of isotope in a tumor or an organ such as the thyroid is recorded by a suitable γ-ray detector attached to an electronic amplifier and recording equipment. The image of the radioactivity concentrated in an organ is viewed on a television-type screen and recorded on a photographic print. *See* RADIOACTIVE TRACER.

Sound waves of 1–10 MHz are transmitted from a crystal transducer, and after amplification are displayed on an oscilloscope and recorded on a photographic print. The ultrasound pulses demonstrate organ structures such as the heart, liver, and spleen. Although the resolution is less fine than that obtained with x-ray, there is an advantage in that the ultrasound is nonionizing radiation. Ultrasound is particularly useful, therefore, in determining the size and degree of development of the human fetus. *See* ULTRASONICS.

Infrared radiation from the human body is used to detect tumors such as breast tumors, which are near the body surface. The technique, thermography, is based on the idea that tumors are warmer than the surrounding normal tissue. This increase in temperature is detected by an infrared device, and the "hot spot" scan is displayed on a television-type screen, with permanent records kept on photographic prints.

Radiation therapy deals with the treatment of disease with ionizing radiation. The diseases most commonly treated are cancer and allied diseases. Radiation therapy has been found useful in the management of some diseases such as ringworm of the scalp and bursitis, but because of possible serious complications occurring many years later, the use of ionizing radiation is generally avoided if alternative methods of treatment are available.

In cancer therapy the objective is to destroy a tumor without causing irreparable radiation damage in normal body tissues that must of necessity be irradiated in the process of delivering a lethal dose to the tumor. This applies particularly to important normal structures in the vicinity of the tumor. The relative radiosensitivity of the tumor with respect to these normal structures is the chief factor determining the success of the treatment. [L.B.Lu.]

Radiometry A branch of science that deals with the measurement or detection of radiant electromagnetic energy. Radiometry is divided according to regions of the spectrum in which the same experimental techniques can be used. Thus, vacuum ultraviolet radiometry, intermediate-infrared radiometry, far-infrared radiometry, and microwave radiometry are considered separate fields, and all of these are to be distinguished from radiometry in the visible spectral region. Curiously, radiometry in the visible is called radiometry, optical radiation measurement science, or photometry, but it is not called visible radiometry. *See* ELECTROMAGNETIC RADIATION; INFRARED RADIATION; LIGHT; MICROWAVE; ULTRAVIOLET RADIATION.

Any radiation detector (such as a thermometer) that responds to an increase in temperature caused by the absorption of radiant energy is known as a thermal detector. Similarly, any detector (such as a photochemical reaction) that responds to the excitation of a bound electron is called a photon or quantum detector.

Liquid-in-glass thermometers are sluggish and relatively insensitive. The key to developing thermal detectors with better performance than liquid-in-glass thermometers has been to secure a large and rapid rise in temperature associated with a high sensitivity to temperature changes.

Thermal detectors have been based upon a number of different principles. Radiation thermocouples produce a voltage, bolometers undergo a change in resistance, pyroelectric detectors undergo a change in spontaneous electric polarization, and the gas in pneumatic detectors (Golay cells) and photoacoustic detectors expands in response to incident radiation. The periodic expansion and contraction of the gas in response to high-frequency modulated radiation is detected by a sensitive microphone in the case of the photoacoustic detector. The Golay cell, on the other hand, uses a sensitive photomultiplier and a reference beam of light to detect distortion of a flexible membrane mirror caused by the expansion and contraction of the gas. *See* BOLOMETER; PYROELECTRICITY; THERMOCOUPLE.

The main problem with thermal detectors is that they respond not only to electromagnetic radiation but to any source of heat. This makes their design, construction, and use rather difficult, because they must be made sensitive to the radiation of interest while remaining insensitive to all other sources of heat, such as conduction, convection, and background radiation, that are of no interest in the particular measurement.

Photon detectors respond only to photons of electromagnetic radiation that have energies greater than some minimum value determined by the quantum-mechanical properties of the detector material. Since heat radiation from the environment at room temperature consists of infrared photons, photon detectors for use in the visible can be built so that they do not respond to any source of heat except the radiation of interest.

Following the introduction of planar silicon technology for microelectronics, the same technology was quickly exploited to make planar photodiodes based on the internal photoelectric effect in silicon. In these devices, the separation of a photogenerated electron-hole pair by the built-in field surrounding the p^+n junction induces the flow of one electron in an external short circuit (such as the inputs to an operational amplifier) across the electrodes. The number of electrons flowing in an external short circuit per absorbed photon is called the quantum efficiency. The use of these diodes has grown to the point where they are the most widely used detector for the visible and nearby spectral regions. Their behavior as a radiation detector in the visible is so nearly ideal that they can be used as a standard, their cost is so low that they can be used for the most mundane of applications, and their sensitivity is so high that they can be used to measure all but the weakest radiation (which requires the most sensitive photomultipliers). *See* JUNCTION DIODE; PHOTODIODE; SEMICONDUCTOR DIODE.

Research efforts have been directed at producing photon detectors based on more exotic semiconductors, and more complicated structures to extend the sensitivity, time response, and spectral coverage. *See* OPTICAL DETECTORS. [J.Gei.]

Radish A cool-season annual or biennial crucifer, *Raphanus sativus*, of Chinese origin belonging to the plant order Capparales. The radish is grown for its thickened hypocotyl, which is eaten uncooked as a salad vegetable. Colors include red, yellow, white, black, pink, and red-white combinations. *See* CAPPARALES. [H.J.C.]

Radium A chemical element, Ra, with atomic number 88. The atomic weight of the most abundant naturally occurring isotope is 226. Radium is a rare radioactive element found in uranium minerals to the extent of 1 part for about every 3×10^6 parts of uranium. Chemically, radium is an alkaline-earth metal having properties quite similar to those of barium. Radium is important because of its radioactive properties and is used primarily in medicine for the treatment of cancer, in atomic energy technology for the preparation of standard sources of radiation, as a source for actinium and protactinium by neutron bombardment, and in certain metallurgical and mining industries for preparing gamma-ray radiographs. *See* PERIODIC TABLE.

Thirteen isotopes of radium are known; all are radioactive; four occur naturally; the rest are produced synthetically. Only ^{226}Ra is technologically important. It is distributed widely in nature, usually in exceedingly small quantities. The most concentrated source is pitchblende, a uranium mineral containing about 0.014 oz (0.4 g) of radium per ton of uranium.

Biologically, radium behaves as a typical alkaline-earth element, concentrates in bones by replacing calcium and, as a result of prolonged irradiation, causes anemia and cancerous growths. The tolerance dose for the average human being has been estimated at a total of 1 μg of radium fixed within the body. However, because radiations from radium and its decay products preferentially destroy malignant tissue, radium and radon, the gaseous decay product of radium, have been used to check the growth of cancer.

When first prepared, nearly all radium compounds are white, but they discolor on standing because of intense radiation. Radiation causes a purple or brown coloration in glass on long contact with radium compounds. Eventually the glass crystallizes and becomes crazed. Radium salts ionize the surrounding atmosphere, thereby appearing to emit a blue glow, the spectrum of which consists of the band spectrum of nitrogen. Radium compounds will discharge an electroscope, fog a light-shielded photographic plate, and produce phosphorescence and fluorescence in certain inorganic compounds such as zinc sulfide. The emission spectrum of radium compounds is similar to those of the other alkaline earths; radium halide imparts a carmine color to a flame.

Physical properties of radium

Property	Value
Atomic number	88
Atomic weight	226.05
Valence states	0, 2+
Specific gravity	6.0 at 20°C
Melting point	700°C (1290°F)
Boiling point	∼1140°C (2080°F)
Ionic radius, Ra^{2+}	0.245 nm (estimated)
Atomic parachor	∼140
Decomposition potential	1.718 volt
Heat of formation of oxide	130 kcal/mole
Magnetic susceptibility	Feebly paramagnetic

When freshly prepared, radium metal has a brilliant white metallic luster. Some of its physical properties are shown in the table. Chemically, the metal is highly reactive. It blackens rapidly on exposure to air because of the formation of a nitride. Radium reacts readily with water, evolving hydrogen and forming a soluble hydroxide. *See* ALKALINE-EARTH METALS; NUCLEAR REACTION; RADIOACTIVE MINERALS; RADIOACTIVITY; RADON. [M.L.S.]

Radius of gyration

A relation of the area or mass of a figure to its moment of inertia. If I is the moment of inertia about a line of a figure whose area is A, the figure's radius of gyration with respect to that line is $k = +\sqrt{I/A}$. Accordingly, $I = k^2A$. For a figure of mass M, $k = +\sqrt{I/M}$; $I = k^2M$. In these equations, k is measured in length units such as feet. Geometrically similar figures have equal radii of gyration about corresponding centroidal axes. *See* MOMENT OF INERTIA. [N.S.F.]

Radome

A strong, but electrically transparent, thin shell used to house a radar antenna, or a space-communications antenna of similar structure. The shell must be large enough not to interfere with the scanning motion of the antenna. In airborne radar the radome prevents the antenna from upsetting the aerodynamic characteristics of the airplane or missile and protects the antenna against aerodynamic forces. Shipboard radars frequently require radomes to protect them against wind and water damage and blast pressures from nearby guns. Large land-based radars are usually shielded by radomes, especially in severe climatic conditions. *See* ANTENNA (ELECTROMAGNETISM); RADAR. [R.I.B.]

Radon

A chemical element, Rn, atomic number 86. Radon is produced as a gaseous emanation from the radioactive decay of radium. The element is highly radioactive and decays by the emission of energetic alpha particles. Radon is the heaviest of the noble, or inert, gas group and thus is characterized by chemical inertness. More than 25 isotopes of radon have been identified. All isotopes are radioactive with short half-lives. *See* PERIODIC TABLE.

Radon is found in natural sources only because of its continuous replenishment from the radioactive decay of longer-lived precursors in minerals containing uranium, thorium, or actinium. ^{222}Rn (half-life 3.82 days), ^{220}Rn (thoron; half-life 55 s), and ^{219}Rn (actinon; half-life 4.0 s), occur in nature as members of the uranium (U), thorium (Th), and actinium (Ac) series, respectively. All three decay by the emission of energetic alpha particles. *See* ACTINIUM; ALPHA PARTICLES; RADIOACTIVITY; RADIUM; THORIUM; URANIUM.

Any surface exposed to ^{222}Rn becomes coated with an active deposit which consists of a group of short-lived daughter products. The radiations of this active deposit include energetic alpha particles, beta particles, and gamma rays. The ultimate decay products of radon following the rapid decay of the active deposit to lead-210 include bismuth-210, polonium-210, and finally, stable lead-206. Radon possesses a particularly stable electronic configuration, which gives it the chemical properties characteristic of noble gas elements. It has a boiling point of −62°C (−80°F) and a melting point of −71°C (−96°F). The spectrum of radon has been extensively studied, and resembles that of the other inert gases. Radon is readily adsorbed on charcoal, silica gel, and other adsorbents, and this property can be used to separate the element from gaseous impurities. [E.K.H.]

The rocks and soils of the Earth's crust contain approximately 3 parts per million of ^{238}U, the long-lived head of the uranium series; 11 ppm of ^{232}Th, the head of the thorium series; but only about 0.02 ppm of ^{235}U, the long-lived member of the actinium group. The radon isotopes ^{222}Rn and ^{220}Rn are produced in proportion to the amount of the parent present. Some of the newly formed radon atoms which originate in or on the surface of mineral grains escape into the soil gas, where they are free to diffuse within the soil capillaries. Some of the radon atoms eventually find their way to the surface, where they become a part of the atmosphere. Even though thorium (^{232}Th) is generally more abundant than uranium in the Earth's crust, the probability for decay is smaller; hence, the production rate of ^{222}Rn and ^{220}Rn in the soil is roughly the same. Much of the ^{220}Rn decays before reaching the Earth's surface due to its short half-life.

When radon (^{222}Rn or ^{220}Rn) passes from soil to air, it is mixed throughout the lower atmosphere by eddy diffusion and the prevailing winds. Mean radon levels are found to be higher during those times of year when atmospheric stability is the greatest such as may occur during the fall months. Radon and its daughters play an important role in atmospheric electricity. Near the Earth's surface almost half of the ionization of the air is due to ^{220}Rn and ^{222}Rn and their daughter products. The alpha emitters from these chains typically produce about 10^7 ion pairs per second per cubic meter. *See* ATMOSPHERIC CHEMISTRY; ATMOSPHERIC ELECTRICITY.

Radon is readily soluble in water. Since ground and surface waters are in close contact with soil and rocks containing small quantities of radium, it is not surprising to find radon in public water supplies.

The radon isotopes ^{220}Rn and ^{222}Rn are used widely in the study of gaseous transport processes both in the underground environment and in the atmosphere. Radon accumulates to high levels of the order of 4000 becquerels/m^3 or more in caves unless natural or artificial ventilation occurs. Changes in ^{222}Rn concentrations in spring and well water and in soil and rocks have been suggested as a means of predicting earthquakes.

The tendency of the decay products of radon to attach to aerosols means that these nuclides will be inhaled and deposited in the bronchial epithelium and lungs. The daughter products, therefore, make up the major part of the internal radiation dose from radon. Ways of reducing radon levels within homes or workplaces include increased ventilation and sealing of major sources of entry from soil and building materials. Workers in uranium mines may encounter radon and decay product levels of the order of 50,000 Bq/m^3 or more. Ventilation procedures and special filters for the miners must be used. *See* BIOSPHERE; RADIATION INJURY (BIOLOGY); RADIOECOLOGY; RADIOISOTOPE (GEOCHEMISTRY). [M.Wi.]

Raffinose The best-known trisaccharide (oligosaccharide), widely distributed in higher plants. The best-known sources are cottonseed meal and the manna of *Eucalyptus*. It is also known as melitose, melitriose, gossypose, and *O*-α-D-galactopyranosyl-(1→6)-*O*-α-D-glucopyranosyl-(1→2)-β-D-fructofuranoside. *See* OLIGOSACCHARIDE.

Complete acid hydrolysis gives 1 mole each of D-galactose, D-glucose, and D-fructose. In structure, it comprises melibiose and sucrose with the central D-glucose in common. *See* FRUCTOSE; GALACTOSE; GLUCOSE.

Raffinose can be hydrolyzed by enzymes in two ways. Invertase (β-D-fructofuranoside) hydrolyzes the sucrose part of the molecule to give melibiose and D-fructose. Almond emulsin, which contains an α-D-galactosidase, hydrolyzes the melibiose residue to yield D-galactose and sucrose.

Raffinose was found to be enzymically synthesized in plants from uridine diphosphate D-galactose and sucrose by an enzyme which transfers the D-galactose moiety of this sugar nucleotide to sucrose, resulting in the formation of raffinose. [W.Z.H.]

Rafflesiales An order of flowering plants, division Magnoliophyta (Angiospermae), in the subclass Rosidae of the class Magnoliopsida (dicotyledons). The order consists of three families and fewer than a hundred species, all tropical or subtropical. The plants are highly specialized, nongreen, rootless parasites which grow from the roots of the host. They have few or solitary, rather large to very large flowers with numerous ovules and a single set of tepals that are commonly united into a conspicuous, corolloid calyx. *See* MAGNOLIOPSIDA; ROSIDAE. [A.Cr.]

Railroad control systems Those devices and systems used to direct or restrain the movement of trains, cars, or locomotives on railroads, rapid-transit lines, and similar guided ground-transportation networks. Such control varies from the use of simple solenoid valves to fully automatic electronic-electromechanical systems.

A primary function of railroad control systems is to ensure the safe movement of trains. This is generally accomplished by providing train operators and track-side operators with visual indications of equipment status. The simplest form of control consists of track-switch-position indicators combined with track-side manually operated “stop” or “proceed” signals, which the train operator follows. Advanced systems incorporate fully automated train control, subject to human supervisory control and potential intervention when faults occur in automated systems. *See* CONTROL SYSTEMS; RAILROAD ENGINEERING; TRAFFIC-CONTROL SYSTEMS.

Block signaling significantly improves the safety of railroad operations. Automatic block signaling is accomplished by sectionalizing the track into electrical circuits to detect the presence of other trains, engines, or cars. Logic circuits in the control system detect the locations of the trains and the positions of switches, and then set the necessary signals to inform the train operators when to stop, run slowly, or proceed at posted speeds. The control system automatically detects the presence of a leading train, selects the signal to be given, and then sets the signal indications for the following train operators to read so that they may perform accordingly. In conjunction with automatic block signals, many subway rapid-transit lines incorporate automatic trip stops along the tracks to ensure that train operators obey the stop signals.

Automatic cab signaling systems display signaling information (traditionally, permitted speeds) on board the train. Coded information is transmitted to the train, generally via the running rails. Antennas and receivers aboard the train pick up, amplify, decode, and distribute the intelligence, which then causes the proper signal aspects to be displayed in the cab. Automatic cab signaling reduces or eliminates the need for wayside signals and improves the all-weather capability of trains and the train-handling capacity of the track.

Automatic train control (ATC) subsystems, located wholly on board the train, sense whether or not the train is operating within safe speed limits. If it is not, automatic train control sets the brake to bring the train to a stop or to a speed below the allowed speed. Automatic cab signaling with automatic train control is used on many railroads and several rapid-transit lines in the United Sates and on systems in Europe and Japan. Automatic train operation (ATO) subsystems perform nonvital operating functions such as starting, running at the prescribed speeds, slowing down, and stopping, and on some rapid-transit installations include passenger-door controls. Automatic train operation builds upon the information transmitted to the train as part of automatic cab signaling, and is a logical next step in automating train operations.

Station stopping presents a special set of requirements for rapid transit, commuter railroads, and mainline railroad passenger operations. Accurate positioning of car doors at the station platform and smooth deceleration at relatively high rates are desirable for passenger comfort and efficient operating performance. A special subsystem of control referred to as programmed train-stop systems (or station-stop systems) are a combination of on-board and wayside electronic and electromechanical equipment that can bring a train to rest within inches of its stopping-point target.

Car identification systems is an example of central line supervision. This system scans and decodes a series of colored and patterned lines placed on the side of each car to identify an individual car. This information is transmitted to the operations area, where a computer system is used to establish routing, determine maintenance schedules, and so on. Dispatchers and central operators can also use computer workstations to obtain information on system status.

Railroad terminals (points of origin and destination of trains) are critical to the efficient, cost-effective operation of railroads, so they represent a major focus for automation. A terminal generally contains three types of yards: a receiving yard, where incoming trains from the main line are temporarily stored; the hump yard, where cars are classified and resorted into new trains; and a departure yard, where trains are assembled and stored for dispatch onto the main line. [J.Cos.; D.C.N.]

Railroad engineering A branch of engineering concerned with the design, construction, maintenance, and operation of railways. Railway engineering includes elements of civil, mechanical, industrial, and electrical engineering. It is unique in being concerned with the interaction between moving vehicles (mechanical engineering) and infrastructure (civil engineering). The employment of both a load-supporting guideway and groups or strings of connected vehicles on flanged wheels for the transport of goods and people sets railways apart from other modes of transport. *See* CIVIL ENGINEERING; MECHANICAL ENGINEERING.

The plan view of a railroad track is known as the horizontal alignment. It is made up of a series of curves (arcs of simple circles), tangents (straight tracks), and spirals joining the curves and tangents. Deviations from any of the three are flaws. These imperfections are corrected periodically by a technique known as lining the track.

The side or elevation view of track, composed of a series of straight portions and the vertical curves joining them, is known as the vertical alignment. The vertical change in elevation, in feet, over a horizontal distance of 100 ft is the percent grade. Because the friction coefficient of steel wheels on steel rails is low, railroad grades must also be low, with values from zero to 1.5% fairly common. Two-percent grades are severe, usually requiring helper locomotives. Grades that are more severe, up to about 4%, can be surmounted only with considerable extra operating care and at significant additional expense.

Track gage is the distance between rails. The standard gage throughout the world is 4 ft 8.5 in. Narrow gages of 3 ft and broad gages of 5 and 6 ft have all been tried at various times and in different places.

The function of rail is to guide wheels and distribute their vertical and lateral loads over a wider area. Neither cast nor wrought iron was ideally suited to this task. The development of steel that was three times harder than wrought iron at reasonable cost made it possible for the weight of vehicles and therefore the productivity of railways to increase. Rails are joined end to end by butt welding, whereby continuous rails of over 1000 ft (300 m) in length can be produced. When laid in track, the rails are heavily anchored to restrain movement due to temperature changes. *See* CAST IRON; STEEL; STEEL MANUFACTURE; WROUGHT IRON.

Crossties play important roles in the distribution of wheel loads vertically, longitudinally, and laterally. Each tie must withstand loads up to one-half that imposed on the rail by a wheel. The crosstie must then distribute that load to the ballast surrounding it. Timber crossties vary in section from 6 in. × 6 in. (15 cm × 15 cm) for the lightest applications to 7 in. × 9 in. (18 cm × 23 cm) for heavy-duty track and in length from 8 ft 6 in. (2.6 m) to 9 ft (2.7 m) in length. Well-treated hardwood ties in well-maintained track may be expected to last 30 years or more. Timber crossties become unserviceable after time because of splitting, decay, insect attack, center cracking, mechanical wear, and crushing. Prestressed concrete monoblock crossties are standard in the United Kingdom and parts of continental Europe.

The granular material that supports crossties vertically and restrains them laterally is known as ballast. Ideal ballast is made up of hard, sharp, angular interlocking pieces that drain well and yet permit adjustments to vertical and horizontal alignment. Materials that crush and abrade, creating fines that block drainage or that cement, should not be used. Soft limestones and gravel, including rounded stones, are examples of poor ballast, while crushed granite, trap rock, and hard slags are superior.

The earliest diesel-electric switching locomotives developed about 600 horsepower and road freight units 1350 hp. Single locomotive units of 4000 hp are common. Common practice since dieselization began has been to employ a number of locomotive units coupled together to form a single, more powerful power source.

Locomotive development includes designs using liquefied natural gas as a fuel to reduce environmental pollutants. Locomotives equipped with the necessary power conditioning equipment and squirrel-cage asynchronous motors, made possible by the advent of high-capacity solid-state electronics, exhibit superior adhesion and have no troublesome commutators. They are adept at hauling heavy-tonnage mineral freight, fast passenger trains, or high-speed merchandise trains (freight trains that haul primarily high-value merchandise, as opposed to low-cost raw materials such as coal or grain). *See* LOCOMOTIVE.

Rail passenger systems such as the Shinkansen in Japan (1964); TGV (Très Grande Vitesse; 1981) in France; ICE (Inter City Eisenbahn; 1991) in Germany; X-2000 in Sweden (1990); or Britain's several High-Speed Intercity Trains are notable for speed and convenience. These systems have developed in context of an awareness of deteriorating highway infrastructures, serious concern with the air pollution generated by automobiles and trucks, increasing traffic congestion in urban areas, and worries over petroleum usage and supply. *See* AIR POLLUTION; MAGNETIC LEVITATION.

High-speed passenger trains require significantly different track configurations (for example, curve superelevation and turnout designs) than do slower freight trains, even those high-valued merchandise or intermodal highway trailers and containers, which frequently travel at speeds of 70 mi/h (110 km/h). These engineering differences are impractical on lines primarily moving heavy mineral freight, where axle loadings and speeds differ even more radically from high-speed passenger trains. [G.H.W.]

Rain shadow An area of diminished precipitation on the lee side of mountains. There are marked rain shadows, for example, east of the coastal ranges of Washington, Oregon, and California, and over a larger region, much of it arid, east of the Cascade Range and Sierra Nevadas. All mountains decrease precipitation on their lee; but rain shadows are sometimes not marked if moist air often comes from different directions, as in the Appalachian region.

The causes of rain shadow are (1) precipitation of much of the moisture when air is forced upward on the windward side of the mountains, (2) deflection or damming of moist air flow, and (3) downward flow on the lee slopes, which warms the air and lowers its relative humidity. [J.R.F.]

Rainbow An optical effect of the sky formed by sunlight falling on the spherical droplets of water associated with a rain shower. The circular arc of colors in the rainbow is seen on the side of the sky away from the Sun. The bright, primary rainbow shows the spectrum of colors running from red, on the outside of the bow, to blue on the inside. Sometimes a fainter, secondary bow is seen outside the primary bow with the colors reversed from their order in the primary bow. The shape of each bow is that of a circle, centered on the antisolar point, a point in the direction exactly opposite to that of the Sun, which is marked by the shadow of the observer's head.

As a light ray from the Sun strikes the surface of a water drop, some light is reflected and some passes through the surface into the drop. The primary bow results from light that enters the drop, reflects once inside the drop, and then leaves the drop headed toward the observer's eye. Light that is reflected twice inside the drop produces the secondary bow. The change of direction that occurs when a light ray enters or leaves the waterdrop (refraction) is different for the different colors that make up white sunlight. As a result, the size of the circle is different for each color, thereby separating the colors into the rainbow sequence. *See* METEOROLOGICAL OPTICS. [R.Gr.]

Rainforest Forests that occur in continually wet climates with no dry season. There are relatively small areas of temperate rainforests in the Americas and Australasia, but most occur in the tropics and subtropics.

The most extensive tropical rainforests are in the Americas. These were originally 1.54×10^6 mi^2 (4×10^6 km^2) in extent, about half the global total, and mainly in the Amazon basin. A narrow belt also occurs along the Atlantic coast of Brazil, and a third block lies on the Pacific coast of South America, extending from northern Peru to southern Mexico.

Tropical rainforests have a continuous canopy (commonly 100–120 ft or 30–36 m tall) above which stand huge emergent trees, reaching 200 ft (60 m) or taller. Within the rainforest canopy are trees of many different sizes, including pygmies, that reach only a few feet. Trees are the main life form and are often, for purposes of description and analysis, divided into strata or layers. Trees form the framework of the forest and support an abundance of climbers, orchids, and other epiphytes, adapted to the microclimatic conditions of the different zones of the canopy, from shade lovers in the gloomy, humid lower levels, to sun lovers in the brightly lit, hotter, and drier upper levels. Most trees have evergreen leaves, many of which are pinnate or palmate. These features of forest structure and appearance are found throughout the world's lowland tropical rainforests. There are other equally distinctive kinds of rainforest in the lower and upper parts of perhumid tropical mountains, and additional types on wetlands.

Rainforests occur where the monthly rainfall exceeds 4 in. (100 mm) for 9–12 months. They merge into other seasonal or monsoon forests where there is a stronger dry season (3 months or more with 2.5 in. or 60 mm of rainfall). The annual mean temperature in the lowlands is approximately 64°F (18°C). There is no season unfavorable for growth.

Primary rainforests are exceedingly rich in species of both plants and animals. There are usually over 100 species of trees 2.5 in. (10 cm) in diameter or bigger per 2.4 acres (1 ha). There are also numerous species of climbers and epiphytes. Flowering and fruiting occur year-round, but commonly there is a peak season; animal breeding may be linked to this. Secondary rainforests are much simpler. There are fewer tree species, less variety from location to location, and fewer epiphytes and climbers; the animals are also somewhat different. *See* ECOLOGICAL SUCCESSION.

Tropical rainforests are a source of resins, dyes, drugs, latex, wild meat, honey, rattan canes, and innumerable other products essential to rural life and trade. Modern technology for extraction and for processing has given timber of numerous species monetary value, and timber has come to eclipse other forest products in importance. The industrial nations use much tropical hardwood for furniture, construction, and plywood. Rainforest timbers, however, represent only 11% of world annual industrial wood usage, a proportion that has doubled since 1950. West Africa was the first main modern source, but by the 1960s was eclipsed by Asia, where Indonesia and Malaysia are the main producers of internationally traded tropical hardwoods. Substantial logging has also developed in the neotropics. *See* FOREST ECOSYSTEM; FOREST TIMBER RESOURCES. [T.C.Wh.]

Raman effect A phenomenon observed in the scattering of light as it passes through a material medium, whereby the light suffers a change in frequency and a random alteration in phase. Raman scattering differs in both these respects from Rayleigh and Tyndall scattering, in which the scattered light has the same frequency as the unscattered and bears a definite phase relation to it. The intensity of normal Raman scattering is roughly one-thousandth that of Rayleigh scattering in liquids and smaller still in gases. *See* SCATTERING OF ELECTROMAGNETIC RADIATION; TYNDALL EFFECT.

Because of its low intensity, the Raman effect was not discovered until 1928, although the scattering of light by transparent solids, liquids, and gases had been investigated for many years before. The development of the laser has led to a resurgence of interest in the Raman effect and to the discovery of a number of related phenomena. *See* LASER.

When the exciting radiation falls within the frequency range of a molecule's absorption band in the visible or ultraviolet spectrum, the radiation may be scattered by two different processes, resonance fluorescence or the resonance Raman effect. Both these processes give much more intense scattering than the normal nonresonant Raman effect. The absolute frequencies of the resonance Raman effect shift by exactly the amount of any shift in the exciting frequency, just as do those of the normal Raman effect. Thus the main characteristic of the resonance as compared to the normal Raman effect is its intensity, which may be greater by two or three orders of magnitude. *See* FLUORESCENCE.

Raman scattering is analyzed by spectroscopic means. The collection of new frequencies in the spectrum of monochromatic radiation scattered by a substance is characteristic of the substance and is called its Raman spectrum. Although the Raman effect can be made to occur in the scattering of radiation by atoms, it is of greatest interest in the spectroscopy of molecules and crystals. In a typical experiment monochromatic radiation from a laser impinges on the sample in an appropriate transparent cell. Raman scattering is approximately uniform in all directions and is usually studied at right angles. In this way the intense radiation of the laser beam interferes least with the observation of the weak scattered light.

Raman spectroscopy is of considerable value in determining molecular structure and in chemical analysis. Molecular rotational and vibrational frequencies can be determined directly, and from these frequencies it is sometimes possible to evaluate the molecular geometry, or at least to find the molecular symmetry. Even when a precise determination of structure is not possible, much can often be said about the arrangement of atoms in a molecule from empirical information about the characteristic Raman frequencies of groups of atoms. This kind of information is closely similar to that provided by infrared spectroscopy; in fact, Raman and infrared spectra often provide complementary data about molecular structure. Raman spectra also provide information for solid-state physicists, particularly with respect to lattice dynamics but also concerning the electronic structures of solids. *See* INFRARED SPECTROSCOPY; LATTICE VIBRATIONS; MOLECULAR STRUCTURE AND SPECTRA. [R.C.L.]

Ramie The plant *Boehmeria nivea*, a stingless member of the nettle family; the only member of the family used commercially for fiber. This herbaceous perennial is erect, usually nonbranching, and 3 to 9 ft (1 to 2 m) tall at maturity. The fiber, which comes from the inner bark, is exceptionally strong and has uses similar to those for fiber flax. Ramie is grown mostly in the tropics and subtropics of the Far East and Brazil. *See* NATURAL FIBER. [E.G.N.]

Ramjet A member of a class of high-speed air-breathing propulsion systems. These include subsonic combustion ramjets (RAM), supersonic combustion ramjets (SCRAM), dual-mode ram-scramjets (RAM-SCRAM), dual-combustor ramjets (DCR or DCRJ), and air-ducted rockets (ADR). In each case, air collected from the atmosphere is ducted into the engine to serve as the oxidizer for the burning of fuel that is stored on board. All the engines operate on a modified form of the basic Joule or Brayton cycle; that is, the air is compressed in the inlet, burned at near-constant pressure, and accelerated in an expansion nozzle. In accordance with Newton's second law, thrust is produced by the increase in momentum as the gas passes from the inlet to the nozzle exit. Compression is produced by one or a multiplicity of compression waves generated on the inlet surfaces. The level of pressure that can be reached in these waves is insufficient to produce net thrust unless the air speed is greater than about Mach 0.9 (that is, the velocity is 0.9 times the local speed of sound). Thus the ramjet must be launched from a high-speed aircraft or brought up to speed by a booster rocket or another adjunct engine. The latter type are known as combined-cycle engines. A classic example is the combination of a turbojet and a ramjet, which is called a turboramjet. *See* BRAYTON CYCLE; MACH NUMBER; NEWTON'S LAWS OF MOTION; ROCKET PROPULSION; TURBOJET; TURBORAMJET.

A subsonic combustion ramjet may be boosted to its operating speed by a solid-fueled rocket (see illustration). After the booster separates, the air entering the inlet is compressed through oblique shocks and a terminal normal shock. The flow aft of the normal shock and in the combustor is subsonic, but the velocity is high and flameholders are needed to anchor the flame and thereby produce high combustion efficiency. Passing from the combustor, the exhaust gases are reaccelerated in a

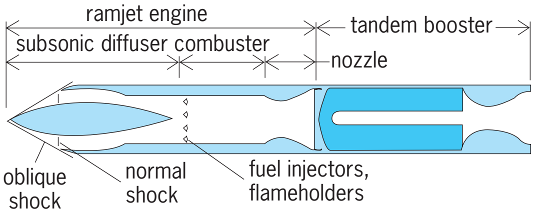


Diagram of a ramjet engine.

converging-diverging nozzle to supersonic speed at the engine exit. *See* DIFFUSER; NOZZLE.

There are several characteristics that lead to the choice of one of the ramjet cycles for a variety of missions. Foremost are the engine performance as measured by specific impulse, light weight, and low cost. For applications up to about Mach 3, the turbojet has the highest specific impulse among hydrocarbon-fueled engines, which leads to its choice as the power plant for subsonic and supersonic aircraft. Most missile applications demand higher thrust which requires afterburning. For flight speeds between Mach 3 and 5, the subsonic combustion ramjet is optimal, and above Mach 5 the choice is among the supersonic combustion ramjet, the dual-mode ram-scramjet, and the dual-combustor ramjet. The solid rocket has much lower engine performance and is used only when high specific impulse is not the governing factor. Rocket-powered vehicles are used for relatively short-range missions or for near-to-vertical flight. *See* AFTERBURNER; AIRCRAFT ENGINE PERFORMANCE; AIRCRAFT FUEL. [F.S.Bi.]

Random matrices

Random matrices Collections of large matrices, chosen at random from some ensemble. Random-matrix theory is a branch of mathematics which emerged from the study of complex physical problems, for which a statistical analysis is often more enlightening than a hopeless attempt to control every degree of freedom, or every detail of the dynamics. Although the connections to various parts of mathematics are very rich, the relevance of this approach to physics is also significant.

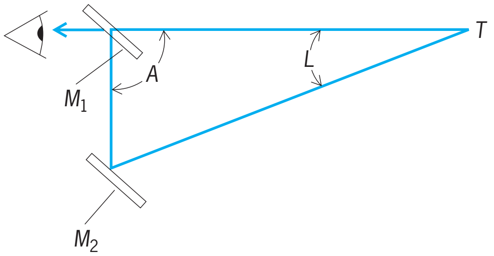
Random matrices were introduced by Eugene Wigner in nuclear physics in 1950. In quantum mechanics the discrete energy levels of a system of particles, bound together, are given by the eigenvalues of a hamiltonian operator, which embodies the interactions between the constituents. This leads to the Schrödinger equation which, in most cases of interest in the physics of nuclei, cannot be solved exactly, even with the most advanced computers. For a complex nucleus, instead of finding the location of the nuclear energy levels through untrustworthy approximate solutions, Wigner proposed to study the statistics of eigenvalues of large matrices, drawn at random from some ensemble. The only constraint is to choose an ensemble which respects the symmetries that are present in the forces between the nucleons in the original problem, and to select a sequence of levels corresponding to the quantum numbers that are conserved as a consequence of these symmetries, such as angular momentum and parity. The statistical theory does not attempt to predict the detailed sequence of energy levels of a given nucleus, but only the general properties of those sequences and, for instance, the presence of hidden symmetries. In many cases this is more important than knowing the exact location of a particular energy level. This program became the starting point of a new field, which is now widely used in mathematics and physics for the understanding of quantum chaos, disordered systems, fluctuations in mesoscopic systems, random surfaces, zeros of analytic functions, and so forth. *See* CONSERVATION LAWS (PHYSICS); EIGENVALUE (QUANTUM MECHANICS); MATRIX THEORY; NONRELATIVISTIC QUANTUM THEORY; QUANTUM MECHANICS.

The mathematical theory underlying the properties of random matrices overlaps with several active fields of contemporary mathematics, such as the asymptotic behavior of orthogonal polynomials at large-order, integrable hierachies, tau functions, semiclassical expansions, combinatorics, and group theory; and it is the subject of active research and collaboration between physics and mathematics. [E.B.]

Rangefinder (optics)

Rangefinder (optics) An optical instrument for measuring distance, usually from its position to a target point. Light from the target enters the optical system through two windows spaced apart, the distance between the windows being termed the base length of the rangefinder. The rangefinder operates as an angle-measuring device for solving the triangle comprising the rangefinder base length and the line from each window to the target point. Rangefinders can be classified in general as being of either the coincidence or the stereoscopic type.

In coincidence rangefinders, one-eyed viewing through a single eyepiece provides the basis for manipulation of the rangefinder adjustment to cause two images or parts of each to match or coincide. This type of device is used, in its simpler forms, in photographic cameras. The basic optical arrangement is shown in the illustration, where M_1 and M_2 are a semitransparent mirror and a reflecting mirror, respectively. When coincidence is obtained, that is, when the target T is seen in the same apparent position along either path, the rangefinder equation for the range D is satisfied:



Simple coincidence rangefinder. *A* is a right angle; *L* = convergence angle at target *T*.

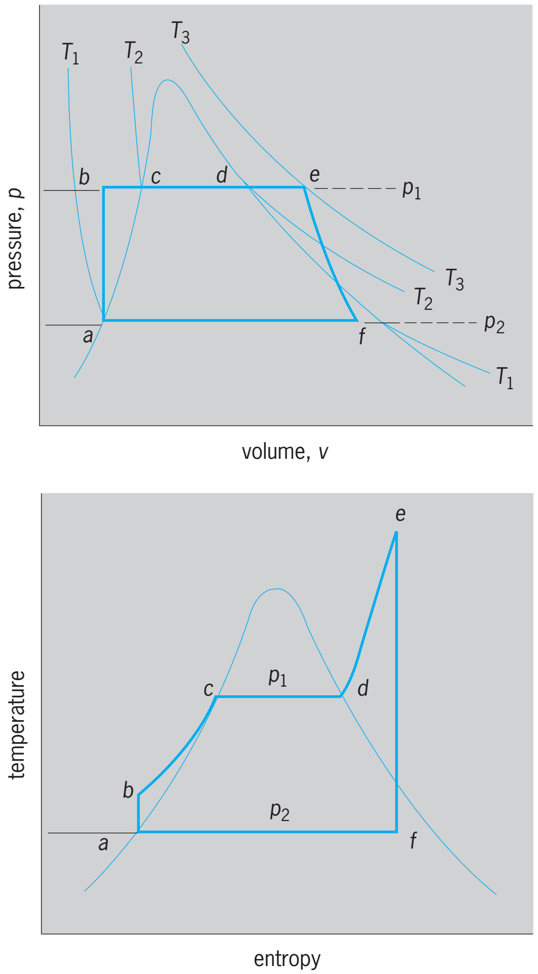
$$D = B \cot L$$

Stereoscopic rangefinders are entirely different, although externally they resemble coincidence rangefinders except for the fact that they possess two eyepieces. It is essentially a large stereobinocular fitted with special reticles which allow a skilled user to superimpose the stereo image formed by the pair of reticles over the images of the target seen in the eyepieces, so that the reticle marks appear to be suspended over the target and at the same apparent distance. [E.E.K.]

Rankine cycle

Rankine cycle A thermodynamic cycle used as an ideal standard for the comparative performance of heat-engine and heat-pump installations operating with a condensable vapor as the working fluid. Applied typically to a steam power plant, as shown in the illustration, the cycle has four phases: (1) heat addition *bcde* in a boiler at constant pressure p_1 changing water at *b* to superheated steam at *e*, (2) isentropic expansion *ef* in a prime mover from initial pressure P_1 to backpressure P_2, (3) heat rejection *fa* in a condenser at constant pressure p_2 with wet steam at *f* converted to saturated liquid at *a*, and (4) isentropic compression *ab* of water in a feed pump from pressure p_2 to pressure p_1.

This cycle more closely approximates the operations in a real steam power plant than does the Carnot cycle. Between given temperature limits it offers a lower ideal thermal efficiency for the conversion of heat into work than does the Carnot standard. Losses from irreversibility, in turn, make the conversion



Rankine-cycle diagrams (pressure-volume and temperature-entropy) for a steam power plant using superheated steam. Pressure-volume diagrams shows curves for constant temperatures T_1, T_2, and T_3 (isothermals).

efficiency in an actual plant less than the Rankine cycle standard. *See* CARNOT CYCLE; REFRIGERATION CYCLE; THERMODYNAMIC CYCLE; VAPOR CYCLE. [T.Ba.]

Ranunculales An order of flowering plants, division Magnoliophyta (Angiospermae), in the subclass Magnoliidae of the class Magnoliopsida (dicotyledons). The order consists of 8 families and about 3200 species. The vast majority of the species belong to only 3 families, the Ranunculaceae (2000), Berberidaceae (650), and Menispermaceae (425). Within its subclass, the order is characterized by its mostly separate carpels, triaperturate pollen, herbaceous or only secondarily woody habit, frequently numerous stamens, generally more than two sepals, and lack of ethereal oil cells. Many members of the order contain isoquinoline alkaloids, most notably berberin. The barberry (*Berberis*), in the family Berberidaceae, and the buttercup (*Ranunculus*), columbine (*Aquilegia*), larkspur (*Delphinium*), and wind flower (*Anemone*), in the family Ranunculaceae, are familiar genera of the Ranunculales. *See* MAGNOLIIDAE; MAGNOLIOPSIDA. [A.Cr.]

Rape Rape (*Brassica napus*) and turnip rape (*B. campestris*) plants are members of the Cruciferae family. The name is derived from the Latin *rapum*, meaning “turnip,” to which these plants are closely related. The aerial portions of rape plants have been bred to produce oilseeds, fodder, and vegetable crops. Rapeseed is small, round, and usually black, although varieties with yellow seed coats are also grown.

The seeds contain over 40% oil. Rapeseed contributes approximately 10–12% of the world’s total edible vegetable oil supply and is one of the few edible oilseed crops that can be produced in northern Canada, Europe, and Asia, or, as a cool season crop, in subtropical areas. Rapeseed meal, the by-product of oilseed extraction, is high-quality protein feed supplement for livestock and poultry. In some Asian countries it is also used as a fertilizer and soil conditioner for specialty crops such as tobacco and citrus fruits. Rape is widely used for forage. In some countries the whole plant is cut and fed to cattle. *See* CAPPARALES; TURNIP. [R.K.D.]

Raphidpophyceae A small class of poorly known biflagel-late unicellular algae (raphidomonads) in the chlorophyll *a-c* phyletic line (Chromophycota). It is sometimes called Chloromonadophyceae, and its members called chloromonads, but this nomenclature is confusing because it calls to mind *Chloromonas*, a totally unrelated genus of green algae (*Chlorophyceae*). The alternative nomenclature used here is derived from Raphidomonas, a generic name within the class. *See* CHROMOPHYCOTA.

Two families are recognized. All photosynthetic raphidomonads are placed in the Vacuolariaceae. The Thaumatomastigaceae comprises a few colorless forms that bear pseudopodia. They are osmotrophic or phagotrophic or both.

Most genera in both families occur in fresh water (acidic to neutral), but there are brackish-water and marine forms that produce conspicuous blooms. *Heterosigma*, for example, is a frequent cause of red tide in the inland seas of Japan. *See* ALGAE. [P.C.Si.; R.L.Moe]

Rare-earth elements The group of 17 chemical elements with atomic numbers 21, 39, and 57–71; the name lanthanides is reserved for the elements 58–71. The name rare earths is a misnomer, because they are neither rare nor earths. *See* ACTINIDE ELEMENTS; LANTHANIDE CONTRACTION; PERIODIC TABLE.

Most of the early uses of the rare earths took advantage of their common properties and were centered principally in the glass, ceramic, lighting, and metallurgical industries. Today these applications use a very substantial amount of the mixed rare earths just as they are obtained from the minerals, although sometimes these mixtures are supplemented by the addition of extra cerium or have some of their lanthanum and cerium fractions removed.

The elements exhibit very complex spectra, and the mixed oxides, when heated, give off an intense white light which resembles sunlight, a property finding application in cored carbon arcs, such as those employed in the movie industry.

The rare-earth metals have a great affinity for the nonmetallic elements, as, for example, hydrogen, carbon, nitrogen, oxygen, sulfur, phosphorus, and the halides. Considerable amounts of the mixed rare earths are reduced to metals, such as misch metal, and these alloys are used in the metallurgical industry. Alloys made of cerium and the mixed rare earths are used in the manufacture of lighter flints. Rare earths are also used in the petroleum industry as catalysts. Yttrium aluminum garnets (YAG) are used in the jewelry trade as artificial diamonds.

Although the rare earths are widely distributed in nature, they generally occur in low concentrations. They are found in high concentrations as mixtures in a number of minerals. The relative abundance of the different rare earths in various rocks, geological formations, and the stars is of great interest to the geophysicist, astrophysicist, and cosmologist.

The rare-earth elements are metals possessing distinct individual properties. Many of the properties of the rare-earth metals and alloys are quite sensitive to temperature and pressure. They are also different when measured along different crystal axes of the metal; for example, electrical conductivity, elastic constants, and so on. The rare earths form organic salts with certain organic chelate compounds. These chelates, which have replaced some of the water around the ions, enhance the differences in properties among the individual rare earths. Advantage is taken of this technique in the modern ion- exchange methods of separation. *See* CHELATION; ION EXCHANGE; TRANSITION ELEMENTS. [F.H.Sp.]

Rare-earth minerals Naturally occurring solids, formed by geological processes, that contain the rare-earth elements—the lanthanides (atomic numbers 57–71) and yttrium (atomic number 39)—as essential constituents. In a rare-earth mineral, at least one crystallographic site contains a total atomic ratio of lanthanides and yttrium that is greater than that of any other element. The mineral name generally has a suffix, called a Levinson modifier, indicating the dominant rare-earth element; for example, monazite-(La) [$LaPO_4$] contains predominantly lanthanum, and monazite-(Ce) [$CePO_4$] contains predominantly cerium. *See* MINERAL; MONAZITE; PERIODIC TABLE; RARE-EARTH ELEMENTS.

So far, about 170 distinct species of rare-earth minerals have been described. A large number of carbonates, phosphates, silicates, niobates, and fluorides are known as rare-earth minerals. It is necessary to obtain structural as well as chemical information about a mineral to judge the essentiality of its rare-earth elements (that is, whether the rare-earth element is part of the mineral's ideal formula or is an impurity). Sometimes, minerals with significant rare-earth content are treated as rare-earth minerals, even if the rare-earth element content appears unessential to the mineral. More than 60 mineral species, including the apatite group minerals, garnet group minerals, and fluorite, are in this category. *See* APATITE; FLUORITE; GARNET.

Rare-earth minerals can be observed as accessory minerals in igneous rocks, such as monazite-(Ce) in granite. Carbonatite is the typical host rock of rare-earth minerals such as bastnäsite-(Ce) [$CeCO_3F$] and monazite-(Ce). Rare-earth minerals also often occur in pegmatite. In both carbonatite and pegmatite, rare-earth elements are concentrated by primary crystallization from melt and by hydrothermal reactions. Carbonatite deposits containing rare-earth elements are found throughout the world. Chemically stable, rare-earth minerals are not weathered easily. As a result, they have been deposited as heavy minerals in beach sand. Such deposits are found in Southeast Asia and Western Australia. *See* CARBONATITE; PEGMATITE.

Among the rare-earth minerals, bastnäsite-(Ce) is the most important source of rare-earth elements. Monazite-(Ce), synchysite-(Ce) [$CaCe(CO_3)_2F$], xenotime-(Y), britholite-(Ce) [$(Ce_3Ca_2)(SiO_4)_3(OH)$], and allanite-(Ce) [$CaCeAl_2Fe(Si_2O_7)(SiO_4)O(OH)$] are also sources. Rare-earth elements have been leached with acid from the surface of clay minerals. Rare-earth minerals containing radioactive nuclear species, such as thorium and uranium, are not used as source materials. *See* CLAY MINERALS. [R.Miy.]

Rarefied gas flow Flow of gases below standard atmospheric pressure, sometimes called low-pressure gas flow. The flow may be confined to pipes between a chamber or vessel to be evacuated and a pump, or it may be the beam of molecules issuing from an orifice into a large evacuated chamber or the plume of exhaust gases from a rocket launched into the upper atmosphere, for example. The flow velocity is measured with respect to a fixed boundary such as the wall of a pipe, the surface of a rocket or jet plane, or a model in a wind tunnel. *See* FLUID FLOW; GAS; MOLECULAR BEAMS; PIPE FLOW; VACUUM PUMP; WIND TUNNEL.

For flow through ducts, the gases concerned are initially those of the original atmosphere inside a chamber that must be evacuated. However, even after the bulk of the original gas has been removed, the pumps must continue to remove gas evolved from surfaces and leaking in through imperfections in the walls. In some cases, gas is introduced through valves at a controlled rate as part of the process being carried out at a low pressure.

Since the flow through pipes involves an interaction or drag at the walls, a pressure drop is generated across the entrance and exit of the pipe. Also, gaseous impurities from the pump may flow toward the chamber when the pressure is very low. Proper design of the duct system therefore involves selecting pipes and valves of adequate internal diameter to ensure a minimal pressure drop and the insertion of baffles or traps to prevent impurities from the pumps from entering the process chamber.

The resistance due to the walls depends on the mass flow velocity, and may depend on the gas viscosity and the pressure or density of the gas. The mean free path of molecules is the distance between collisions with other molecules in the gas. *See* KINETIC THEORY OF MATTER; MEAN FREE PATH; VISCOSITY.

The analysis of low-pressure flow is divided into three or four flow regimes depending on the value of the Knudsen number Kn defined as the ratio of the mean free path to a characteristic length, and the dimensionless Reynolds number. The characteristic length may be chosen as the mean pipe diameter in the case of confined flow or as some length associated with a test model suspended in a wind tunnel, for example. *See* GAS DYNAMICS; KNUDSEN NUMBER; REYNOLDS NUMBER.

Another dimensionless number used in gas flow dynamics is the Mach number (Ma), defined as the ratio of the mass flow velocity to the local velocity of sound in the gas. *See* MACH NUMBER.

When the mean free path is much smaller than the pipe diameter ($Kn < 0.01$), the gas flows as a continuous viscous fluid with velocity near the axis of the pipe at locations well beyond the pipe entrance much higher than the velocity in gas layers near the wall. The velocity profile as a function of radial distance from the axis depends on the distance from the entrance and the viscosity of the gas. When the Reynolds number is less than 2000, the profile is a simple curved surface so that the flow is laminar (laminar flow regime). When the mean free path becomes greater than about 0.01 times the diameter, the profile is distorted by boundary-layer effects, and the velocity near the wall does not approach zero (sometimes referred to as slip flow). *See* LAMINAR FLOW.

For Reynolds numbers above the critical value (approximately 2100), the flow is subject to instabilities depending on the geometry of the boundary and at high Reynolds numbers becomes turbulent (turbulent flow regime). *See* TURBULENT FLOW.

When the mean free path is about equal to or greater than the pipe diameter ($Kn \geq 1$), the gas molecules seldom collide with each other, but can either pass through the pipe without striking the wall or scatter randomly back and forth between various points on the wall and eventually escape through the exit or pass back through the entrance. This type of gas flow is known as free-molecule flow (molecular flow regime). The transition region ($0.01 < Kn < 1$) between the laminar flow regime and the molecular flow regime is referred to as the Knudsen or transition flow regime.

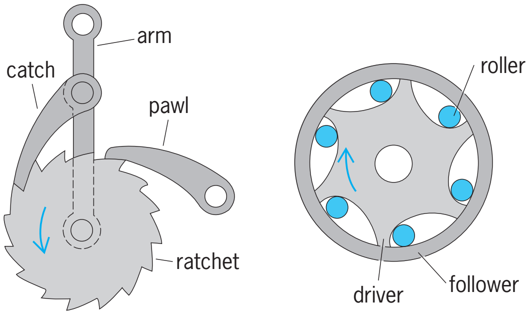
The flow may also be classified by the boundary conditions or by the Mach number. For example, Couette flow involves the flow of rarefied gas between two surfaces that are moving with respect to each other with different parallel tangential velocities. For hypersonic flow, $Ma \geq 5$. [B.B.Da.]

Raspberry The horticultural name for certain species of the genus *Rubus*, plant order Resales. In these species the fruit, when ripe (unlike the blackberry), separates thimblelike from the receptacle. Raspberry plants are upright shrubs with perennial roots and prickly, biennial canes (stems). There are several species, both American and European, from which the cultivated raspberries have been developed. Varieties are grouped as to color of fruit—black, red, and purple, the last being hybrids between the red and black types. Leading states in commercial production are Michigan, Oregon, New York, Washington, Ohio, Pennsylvania, New Jersey, and Minnesota. The fruit is sold fresh for dessert purposes, is canned, and is made into jelly or jam, but quick freezing is the most important processing method. *See* Fruit; Rosales. [J.H.Cl.]

Rat The name for over 650 species of mammals in a number of different families of the order Rodentia. These animals are of great economic importance to humans. In addition to harboring many diseases transmissible to humans, such as bubonic plague, endemic typhus, rat-bite fever, and infectious jaundice, ingested rats can transmit trichinosis to swine. *See* Plague.

Rats are usually active at night, feeding on nearly every type of food. The teeth are modified for gnawing, with sharp and chisellike incisors that grow continually and have heavily enameled fronts. There is a large space between the one pair of incisors and the molars into which the flesh of the cheeks is drawn during gnawing. This prevents the cheek teeth from meeting and wearing down and also prevents the swallowing of dirt and debris. *See* Rodentia. [C.B.C.]

Ratchet A wheel, usually toothed, operating with a catch or a paw] so as to rotate in a single direction (see illustration).



toothed ratchet roller rachet

Ratchets. Toothed ratchet is driven by catch when arm moves to left; pawl holds ratchet during return stroke of catch. In roller ratchet, rollers become wedged between driver and follower when driver turns faster than follower in direction of arrow.

A ratchet and pawl mechanism locks a machine such as a hoisting winch so that it does not slip. The locking action may serve to produce rotation in a desired direction and to disengage in the undesired direction as in a drill brace. The catch or pawl may be of various shapes such as an eccentrically mounted disk or ball bearing. Gravity, a spring, or centrifugal force (with the catch mounted internal to the ratchet) are commonly used to hold the pawl against the ratchet. A ratchet and pawl provides an arresting action. *See* Brake; Escapement; Pawl. [F.H.R.]

Rate-of-climb indicator An aircraft instrument that provides an indication of the vertical change of the aircraft position within the air mass. It is more commonly known as the vertical-velocity or vertical-speed indicator. Contained within a sealed case, it is connected to the aircraft static pressure source, the so-called at-rest air pressure outside the aircraft, through a calibrated leak. Although the instrument operates from a static pressure source, it is a differential pressure indicator. The differential pressure is established between the static pressure in the diaphragm or pressure capsule and the trapped static pressure within the case. When the aircraft changes vertical position, the static pressure in the diaphragm changes immediately but, because of the metering action of the calibrated leak, the case pressure will remain at its prior value and cause the needle to show a change in vertical speed. The needle is usually calibrated in feet per minute but may be calibrated in any appropriate unit of length over time.

In many modern aircraft with flight computers, the rate of climb or descent is electronically calculated by differentiating the altitude from the pitot-static source. *See* Aircraft instrumentation; Pitot tube. [G.W.W.]

Ratites A group of flightless (except for tinamous), mostly large, running birds formerly segregated as a superorder of birds, the Palaeognathae, but whose interrelationships have been a long-standing controversy. The ratites represent two or three phyletic lines (the emus, cassowaries, moos and kiwis, ostriches and elephant birds, and rheas and tinamous—the last two groups may be very closely related) which evolved from a common ancestral stock, possibly much like the still volant tinamous of Central and South America. *See* Aves; Neognathae; Struthioniformes. [W.J.B.]

Rauwolfia A genus of mostly poisonous, tropical trees and shrubs of the dogbane family (Apocynaceae). Certain species are the source of valuable emetics and cathartics. The species *Rauwolfia serpentina* has received special attention as the source of tranquilizing drugs. Among the purified alkaloids obtained from *R. serpentina*, reserpine is perhaps the one most used as a tranquilizing agent. *See* Gentianales; Tranquilizer. [P.D.St./E.L.C.]

Raw water Water obtained from natural sources such as streams, reservoirs, and wells. Natural water always contains impurities in the form of suspended or dissolved mineral or organic matter and as dissolved gases acquired from contact with earth and atmosphere. Industrial or municipal wastes may also contaminate raw water. *See* Water pollution.

If admitted to a steam-generating unit, such contaminations may corrode metals or form insulating deposits of sediments or scale on heat-transfer surfaces, with resultant overheating and possible failure of pressure parts.

Raw water can be treated to remove objectionable impurities or to convert them to forms that can be tolerated. For steam generation, suspended solids are removed by settling or filtration. Scale-forming hardness is diminished by chemical treatment to produce insoluble precipitates that are removable by filtration, or soluble compounds that do not form scale. Essentially complete purification is achieved by demineralizing treatment or evaporation. *See* Water softening; Water treatment. [F.G.E.]

Reactance The imaginary part of the impedance of an alternating-current circuit.

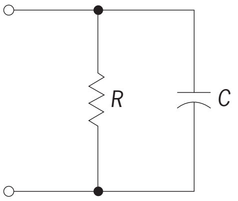
The impedance Z of an alternating current circuit is a complex number given by Eq. (1). The imaginary part X is the reactance.

$$Z = R + jX \tag{1}$$

$$Z = jL\omega = jX \tag{2}$$

$$Z = -\frac{j}{C\omega} = jX \tag{3}$$

The units of reactance, like those of impedance, are ohms. Reactance may be positive or negative. For example, the impedance of an inductor L at frequency ω is given by Eq. (2), so X is positive. The impedance of a capacitor C is given by Eq. (3), so X is negative.



Circuit with a resistor and capacitor in parallel.

The reactance of a circuit may depend on both the resistors and the inductors or capacitors in the circuit. For example, the circuit in the illustration has admittance [Eq. (4)] and impedance

$$Y = \frac{1}{R} + jC\omega \qquad (4)$$

[Eq. (5)], so that the reactance [Eq. (6)], depends on both the capacitor C and the resistor R.

$$Z = \frac{R}{1 + jRC\omega} \qquad (5)$$

$$X = -\frac{R^2C\omega}{1 + R^2C^2\omega^2} \qquad (6)$$

See Admittance; Alternating-current circuit theory; Electrical impedance. [J.O.S.]

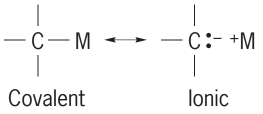
Reaction turbine A power-generation prime mover utilizing the steady-flow principle of fluid acceleration, where nozzles are mounted on the moving element. The rotor is turned by the reaction of the issuing fluid jet and is utilized in varying degrees in steam, gas, and hydraulic turbines. All turbines contain nozzles; the distinction between the impulse and reaction principles rests in the fact that impulse turbines use only stationary nozzles, while reaction turbines must incorporate moving nozzles. *See* Impulse turbine; Prime mover. [T.Ba.]

Reactive intermediates Unstable compounds which are formed as necessary intermediate stages during a chemical reaction. Thus, if a reaction in which A is converted to B requires that A first be converted to C, then C is an intermediate in the reaction ($A \rightarrow C \rightarrow B$). The term reactive further implies a certain degree of instability of the intermediate; reactive intermediates are typically isolable only under special conditions, and most of the information regarding the structure and properties of reactive intermediates comes from indirect experimental evidence.

In organic reactions the most common types of reactive intermediates are those arising from dissociative reactions, in which carbon has a decreased valence. Associative reactions can also give rise to some of the same intermediates, and to others in which carbon has an increased valence. *See* Valence.

Carbocations are compounds in which carbon bears a positive charge. Classical carbocations (also called carbenium ions) are trivalent, and have only six valence electrons. Nonclassical carbocations (also called carbonium ions) are tetra- or pentavalent, and have eight valence electrons. Examples are the methyl cation (classical) CH_3^+, and the methonium ion (nonclassical) CH_5^+.

Carbanions are compounds in which carbon bears a negative charge. A carbanion will always have a positive counterion in association with it; depending upon the particular cation and the stability of the carbanion, the association may be ionic, covalent, or some intermediate combination of ionic and covalent bonding, as shown below (M = metal). Carbanions are trivalent, with eight valence electrons.



$$-\overset{|}{\underset{|}{C}}-M \longleftrightarrow -\overset{|}{\underset{|}{C}}\!:^- \; {}^+M$$

Free radicals are neutral compounds having an odd number of electrons and therefore one unpaired electron. Carbon free radicals are trivalent, with seven valence electrons, and typically assume a planar structure. Free radicals are primarily electron-deficient species and are stabilized by structural features which donate electron density or delocalize the odd electron by resonance. *See* Free radical; Resonance (molecular structure).

Radical ions are charged compounds with an unpaired electron, and are either radical cations (positively charged) or radical anions (negatively charged). In many cases a radical ion is derived from a stable neutral molecule by addition of one electron (radical anion) or removal of one electron (radical cation).

Carbenes are compounds which have a divalent carbon. The divalent carbon also has two nonbonded electrons, for a total of six valence electrons. The two nonbonded electrons may have either the same spin quantum number, which is a triplet state, or an opposite spin quantum number, which is a singlet state. Generation of carbenes is most commonly by photolysis or thermolysis of diazo compounds or ketenes, or by alpha-elimination reactions.

There are many other kinds of reactive intermediates which do not fit into the previous classifications. Some are simply compounds which are unstable for a variety of possible reasons, such as structural strain or an unusual oxidation state. *See* Chemical dynamics; Electrophilic and nucleophilic reagents; Molecular orbital theory. [C.C.W.]

Reactor (electricity) A device for introducing an inductive reactance into a circuit. Inductive reactance x is a function of the product of frequency f and inductance L; thus, $x = 2\pi fL$. For this reason, a reactor is also called an inductor. Since a voltage drop across a reactor increases with frequency of applied currents, a reactor is sometimes called a choke. All three terms describe a coil of insulated wire. *See* Choke (electricity); Inductor.

According to their construction, reactors can be divided into those that employ iron cores and those where no magnetic material is used within the windings. The first type consists of a coil encircling a circuit of iron which usually contains an air gap or a series of air gaps. The air gaps are used to attenuate the effects of saturation of the iron core. The second type, called an air-core reactor, is a simple circular coil, wound around a cylinder constructed of nonmagnetic material for greater mechanical strength. This strength is necessary for the coil to withstand the electromagnetic forces acting on each conductor. These forces become very large with heavy current flow, and their direction tends to compress the coil into less space: radial forces tend to elongate internal conductors in the coil and to compress the external ones while the axial forces press the end sections toward the center of the coil.

Both iron-core and air-core reactors may be of the air-cooled dry type or immersed in oil or a similar cooling fluid. Both types of reactors are normally wound with stranded wire in order to reduce losses due to eddy currents and skin effect. In addition, it is important to avoid formation of short-circuited metal loops when building supporting structures for air-core reactors since these reactors usually produce large magnetic fields external to the coil. If these fields penetrate through closed-loop metal structures, induced currents will flow, causing both losses and heating of the structures. Which of these two reactor types should be used depends on the particular application. *See* Eddy current; Skin effect (electricity). [V.R.S.]

Reactor physics The science of the interaction of the elementary particles and radiations characteristic of nuclear reactors with matter in bulk. These particles and radiations include neutrons, beta rays, and gamma rays of energies between zero and about 10^7 electronvolts. *See* Beta particles; Gamma rays.

The study of the interaction beta and gamma radiations with matter is, within the field of reactor physics, undertaken primarily to understand the absorption and penetration of energy through reactor structures and shields. *See* Radiation shielding.

With this exception, reactor physics is the study of those processes pertinent to the chain reaction involving neutron-induced nuclear fission with consequent neutron generation. Reactor physics is differentiated from nuclear physics, which is concerned primarily with nuclear structure. Reactor physics makes direct use of the phenomenology of nuclear reactions. Neutron physics is concerned primarily with interactions between neutrons and individual nuclei or with the use of neutron beams as analytical devices, whereas reactor physics considers neutrons primarily as fission-producing agents. In the hierarchy of professional classification, neutron physics and reactor physics are both ranked as subfields of the more generalized area of nuclear physics. *See* Chain reaction (physics); Neutron; Nuclear fission; Nuclear physics.

Concepts. Reactor physics borrows most of its basic concepts from other fields. From nuclear physics comes the concept of the nuclear cross section for neutron interaction, defined as the effective target area of a nucleus for interaction with a neutron beam. The total interaction is the sum of interactions by a number of potential processes, and the probability of each of them multiplied by the total cross section is designated as a partial cross section. An outgrowth of this is the definition of macroscopic cross section, which is the product of cross section (termed microscopic, for specificity) with atomic density of the nuclear species involved.

Cross sections vary with energy according to the laws of nuclear structure. In reactor physics this variation is accepted as input data to be assimilated into a description of neutron behavior. Common aspects of cross section dependence, such as variation of absorption cross section inversely as the square root of neutron energy, or the approximate regularity of resonance structure, form the basis of most simplified descriptions of reactor processes in terms of mathematical or logical models.

The concept of neutron flux is related to that of macroscopic cross section. This may be defined as the product of neutron density and neutron speed, or as the rate at which neutrons will traverse the outer surface of a sphere embedded in the medium, per unit of spherical cross-sectional area. The product of flux and macroscopic cross section yields the reaction rate per unit volume and time.

Criticality. The critical condition is what occurs when the arrangement of materials in a reactor allows, on the average, exactly one neutron of those liberated in one nuclear fission to cause one additional nuclear fission. If a reactor is critical, it will have fissions occurring in it at a steady rate. This desirable condition is achieved by balancing the probability of occurrence of three competing events: fission, neutron capture which does not cause fission, and leakage of neutrons from the system. If ν is the average number of neutrons liberated per fission, then criticality is the condition under which the probability of a neutron causing fission is $1/\nu$. Generally, the degree of approach to criticality is evaluated by computing k_{eff}, the ratio of fissions in successive links of the chain, as a product of probabilities of successive processes.

Reactivity. Reactivity is a measure of the deviation of a reactor from the critical state at any frozen instant of time. The term reactivity is qualitative, because several sets of units are in current use to describe it.

Reflectors. Reflectors are bodies of material placed beyond the chain-reacting zone of a reactor, whose function is to return to the active zone (or core) neutrons which might otherwise leak. Reflector worth can be crudely measured in terms of the albedo, or probability that a neutron passing from core to reflector will return again to the core.

Good reflectors are materials with high scattering cross sections and low absorption cross sections. The first requirement ensures that neutrons will not easily diffuse through the reflector, and the second, that they will not easily be captured in diffusing back to the core.

Beryllium is the outstanding reflector material in terms of neutronic performance. Water, graphite, D_2O, iron, lead, and ^{283}U are also good reflectors.

Reactor dynamics. Reactor dynamics is concerned with the temporal sequence of events when neutron flux, power, or reactivity varies. The inclusive term takes into account sequential events, not necessarily concerned with nuclear processes, which may affect these parameters. There are basically three ways in which a reactor may be affected so as to change reactivity. A control element, absorbing rod, or piece of fuel may be externally actuated to start up, shut down, or change reactivity or power level; depletion of fuel and poison, buildup of neutron-absorbing fission fragments, and production of new fissionable material from the fertile isotopes ^{232}Th, ^{234}U, ^{238}U, and ^{240}Pu make reactivity depend upon the irradiation history of the system; and changes in power level may produce temperature changes in the system, leading to thermal expansion, changes in neutron cross sections, and mechanical changes with consequent change of reactivity.

Reactor control physics. Reactor control physics is the study of the effect of control devices on reactivity and power level. As such, it includes a number of problems in reactor statics, because the primary question is to determine the absorption of the control elements in competition with the other neutronic processes. It is, however, a problem in dynamics, given the above information, to determine what motions of the control devices will lead to stable changes in reactor output.

Reactivity changes. Long-term reactivity changes may represent a limiting factor in the burning of nuclear fuel without costly reprocessing and refabrication. As the chain reaction proceeds, the original fissionable material is depleted, and the system would become subcritical if some form of slow addition of reactivity were not available. This is the function of shim rods in a typical reactor. The reactor is originally loaded with enough fuel to be critical with the rods completely inserted. As the fuel burns out, the rods are withdrawn to compensate. *See* Nuclear fuels.

Reactor kinetics. This is the study of the short-term aspects of reactor dynamics with respect to stability, safety against power excursion, and design of the control system. Control is possible because increases in reactor power often reduce reactivity to zero (the critical value) and also because there is a time lapse between successive fissions in a chain resulting from the finite velocity of the neutrons and the number of scattering and moderating events intervening, and because a fraction of the neutrons is delayed. *See* Delayed neutron; Nuclear reactor. [B.I.S.]

Reagent chemicals High-purity chemicals used for analytical reactions, for the testing of new reactions where the effects of impurities are unknown, and in general for chemical work where impurities must either be absent or at known concentrations.

Chemicals are purified by a variety of methods, the most common being recrystallization from solution. If the desired chemical is volatile and the impurities are not volatile, sublimation is an effective method of purification. For liquid chemicals, distillation is an effective procedure. Finally, the simplest procedure may be to synthesize the desired reagent from pure materials. *See* Chemical separation techniques; Crystallization; Distillation.

Commercial chemicals are available at several levels of purity. Chemicals labeled “technical” or “commercial” are usually quite impure. The grade “USP” indicates only that the chemical meets the requirements of the United States Pharmacopeia. The term “CP” means only that the chemical is purer than “technical.” Chemicals designated “reagent grade” or “analyzed reagent” are specially purified materials which usually have been analyzed to establish the levels of impurities. The American Chemical Society has established specifications and tests for purity for some chemicals. Materials which meet these specifications are labeled “Meets ACS Specifications.” [K.G.S./C.Ru.]

Real-time systems Computer systems in which the computer is required to perform its tasks within the time restraints of some process or simultaneously with the system it is assisting. Usually the computer must operate faster than the system assisted in order to be ready to intervene appropriately.

Real-time computer systems and applications span a number of different types.

In real-time control and real-time process control the computer is required to process systems data (inputs) from sensors for the purpose of monitoring and computing system control parameters (outputs) required for the correct operation of a system or process. The type of monitoring and control functions provided by the computer for subsystem units ranges over a wide variety of tasks, such as turn-on and turn-off signals to switches; feedback signals to controllers (such as motors, servos, and potentiometers) to provide adjustments or corrections; steering signals; alarms; monitoring, evaluation, supervision, and management calculations; error detection, and out-of-tolerance and critical parameter detection operations; and processing of displays and outputs.

In real-time assistance the computer is required to do its work fast enough to keep up with a person interacting with it (usually at a computer terminal device of some sort, for example, a screen and keyboard). The computer supports the person or persons interacting with it and provides access, retrieval, and storage functions, usually through some sort of database management system, as well as data processing and computational power. System access allows the individual to intervene in the system's operation. The real-time computer also often provides monitoring or display information, or both. *See* Multiaccess computer.

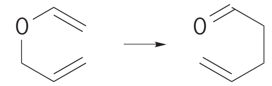
In real-time robotics the computer is a part of a robotic or self-contained machine. Often the computer is embedded in the machine, which then becomes a smart machine. If the smart machine also has access to, or has embedded within it, artificial intelligence functions (for example, a knowledge base and knowledge processing in an expert system fashion), it becomes an intelligent machine. *See* Computer; Digital computer; Embedded systems; Expert systems; Robotics. [E.C.J.]

Real variable A variable whose range is a subset of the real numbers. By extension the term is also used to refer to the theory of functions of one or more real variables. This theory has to do with properties of broad classes of functions, such as continuity, types of discontinuities, differentiability of functions, oscillation and variation of functions, and the various kinds of integrals. *See* Calculus; Integration.

Real numbers are those commonly used in the geometric theory of measurement. The integers and fractions, also called rational numbers, are included among the real numbers. In practice an irrational number x is specified by telling which rational numbers are less than x and which are greater than x. Such a division of the rational numbers into two classes was used by J. W. R. Dedekind as the formal definition of a real number and is called a Dedekind cut. [L.M.G.]

Realgar A mineral having composition AsS and crystallizing in the monoclinic system. Realgar can occur in short, vertically striated crystals, but more frequently is granular and in crusts. The hardness is 1.5–2 (Mohs scale) and the specific gravity is 3.48. The luster is resinous and the color red to orange. Realgar is found in ores of lead, silver, and gold associated with orpiment and stibnite. It occurs with the silver and lead ores in Hungary, Czechoslovakia, and Germany. Good crystals have come from Binnenthal, Switzerland, and Allchar, Macedonia. In the United States it is found at Manhattan, Nevada; Mercer, Utah; and as deposits from geyser waters in Yellowstone National Park. *See* Arsenic; Orpiment; Stibnite. [C.S.Hu.]

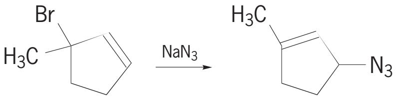
Rearrangement reaction A reaction in which an atom or bond moves or migrates, having been initially located at one site in a reactant molecule and ultimately located at a different site in a product molecule. A rearrangement reaction may involve several steps, but the key feature defining it as a rearrangement is that a bond shifts from one site of attachment to another. The simplest examples of rearrangement reactions are intramolecular, that is, reactions in which the product is simply a structural isomer of the reactant [reaction (1)].



(1)

See Molecular isomerism.

More complex rearrangement reactions occur when the rearrangement is accompanied by another reaction, for example, a substitution reaction (2).



(2)

Rearrangement reactions are classified and named on the basis of the group that migrates and the initial and final location of the migrating bond. The initial bond location is designated as position 1, and the final location as position i, where the number of atoms is simply counted along the connection from 1 to i. Such a migration is called a [1,i] rearrangement or [1,i] shift. If the migrating group also reattaches itself at a different site from the one to which it had originally been attached, then both shifts are indicated, as in [i,j] shift. Reaction (1) is an example of a [3,3] rearrangement, because the initial carbon-oxygen (C-O) bond that breaks designates the 1 position for each component, and both components then rearrange and form a new C-C bond by reattaching at position 3 for each component. Reaction (2) is an example of a [1,3] rearrangement with substitution, commonly called an S_N2' reaction.

In addition, classification can be based on how many electrons move with the migrating group. Of the two electrons in the initial bond that breaks, the migrating group may bring with it both electrons (nucleophilic or anionotropic), one electron (radical), or no electrons (electrophilic or cationotropic). If the rearrangement is a concerted reaction in which there is a cyclic delocalized transition state that results in shifts of pi bonds as well as sigma bonds, the reaction is called a sigmatropic rearrangement [for example, reaction (1)]. *See* Delocalization; Pericyclic reaction.

The great majority of rearrangement reactions occur when a molecule develops a severely electron-deficient site. Shift of a nearby atom or group, with its pair of electrons, can serve to satisfy the electron deficiency at the original site, although it typically leaves behind another site with electron deficiency. As long as the final site can bear the electron deficiency better than the original site, the rearrangement will be favorable. *See* Chemical bonding. [C.C.Wa.]

Reciprocating aircraft engine A fuel-burning internal combustion piston engine specially designed and built for minimum fuel consumption and light weight in proportion to developed shaft power. The rotating output shaft of the engine may be connected to a propeller, ducted fan, or helicopter rotor.

Reciprocating aircraft engines are used in about 86% of all powered aircraft flying in the United States. Most of the aircraft powered by these engines belong to the general aviation segment of the domestic aviation fleet. The reciprocating aircraft engine is used to power single-engine and multiengine airplanes, helicopters, and airships. It is the principal engine used in aircraft for air taxi, pilot training, business, personal, and sport flying as well as aerial application of seed, fertilizer, herbicides, and pesticides for farming. *See* Agricultural aircraft; General aviation.

Predominantly, reciprocating aircraft engines operate on a four-stroke cycle, where each piston travels from one end of its stroke to the other four times in two crankshaft revolutions to complete one cycle. The cycle is composed of four distinguishable events called intake, compression, expansion (or power), and exhaust, with ignition taking place late in the compression stroke and combustion of the fuel-air charge occurring early in the expansion stroke. These spark-ignition engines burn specially formulated aviation gasolines. *See* Internal combustion engine.

Most modern aircraft using engines with up to 336 kW (450 hp) output are powered by air-cooled, horizontally opposed, reciprocating engines. The trend in modern reciprocating engine development is toward lower engine weight and improved fuel economy rather than increased power. [K.J.S.]

Reciprocity principle In the scientific sense, a theory that expresses various reciprocal relations for the behavior of some physical systems. Reciprocity applies to a physical system whose input and output can be interchanged without altering the response of the system to a given excitation. Optical, acoustical, electrical, and mechanical devices that operate equally well in either direction are reciprocal systems, whereas unidirectional devices violate reciprocity. The theory of reciprocity facilitates the evaluation of the performance of a physical system. If a system must operate equally well in two directions, there is no need to consider any nonreciprocal components when designing it.

Some systems that obey the reciprocity principle are any electrical network composed of resistances, inductances, capacitances, and ideal transformers; systems of antennas, which obey certain restrictions; mechanical gear systems; and light sources, lenses, and reflectors.

Devices that violate the theory of reciprocity are transistors, vacuum tubes, gyrators, and gyroscopic couplers. Any system that contains the above devices as components must also violate the reciprocity theory. The gyrator differs from the transistor and vacuum tube in that it is linear and passive, as opposed to the active and nonlinear character of the other two devices. *See* Gyrator; Transistor. [H.S.La.]

Recombination (genetics) The formation of new genetic sequences by piecing together segments of previously existing ones. Recombination often follows deoxyribonucleic acid (DNA) transfer in bacteria and, in higher organisms, is a regular feature of sexual reproduction. *See* Deoxyribonucleic acid (DNA); Reproduction (animal); Reproduction (plant).

The fact that recombinants occur in sexual reproduction is due to reciprocal exchanges between chromosomes (crossing over) that take place in the first meiotic division. *See* Crossing-over (genetics).

Crossing-over between homologous chromosome pairs can also occur during the prophase of mitotic nuclear division. The frequency is very much lower than in meiosis, presumably because the mitotic cell does not form the synaptic apparatus for efficient pairing of homologs. *See* Mitosis.

Recombination was once thought to occur only between genes, never within them. Indeed, the supposed indivisibility of the gene was regarded as one of its defining features, the other being that it was a single unit of function. However, examination of very large progenies shows that, in all organisms studied, nearly all functionally allelic mutations of independent origin can recombine with each other to give nonmutant products, generally at frequencies ranging from a few percent (the exceptionally high frequency found in *Saccharomyces*) down to 0.001% or less. Recombination within genes is most frequently nonreciprocal.

Bacteria have no sexual reproduction in the true sense, but many or most of them are capable of transferring fragments of DNA from cell to cell by one of three mechanisms. (1) Fragments of the bacterial genome can become joined to plasmid DNA and transferred by cell conjugation. (2) Genomic fragments can be carried from cell to cell in the infective coats of bacterial viruses (phages), a process called transduction. (3) Many bacteria have the capacity to assimilate fragments of DNA from solution and so may acquire genes from disrupted cells. Fragments of DNA acquired by any of these methods can be integrated into the DNA of the genome in place of homologous sequences previously present. Homologous integration in bacteria is similar in its nonreciprocal nature to recombination within genes of eukaryotic organisms. *See* Bacterial genetics; Bacteriophage; Transduction (bacteria).

Bacteriophages, plasmids, bacteria, and unicellular eukaryotes provide many examples of differentiation through controlled and site-specific recombination of DNA segments. In vertebrates, a controlled series of deletions leads to the generation of the great diversity of gene sequences encoding the antibodies and T-cell receptors necessary for immune defense against pathogens. All these processes depend upon interaction and recombination between specific DNA sequences, catalyzed by site-specific recombinase enzymes. The molecular mechanisms may have some similarities with those responsible for general meiotic recombination, except that the latter does not depend on any specific sequence, only on similarity (homology) of the sequence recombined.

Techniques have been devised for the artificial transfer of DNA fragments from any source into cells of many different species, thus conferring new properties upon them (transformation). In bacteria and the yeast *S. cerevisiae*, integration of such DNA into the genome requires substantial sequence similarity between incoming DNA and the recipient site. However, cells of other fungi, higher plants, and animals are able to integrate foreign DNA into their chromosomes with little or no sequence similarity. These organisms appear to have some system that recombines the free ends of DNA fragments into chromosomes regardless of their sequences. It may have something in common with the mechanism, equally obscure, whereby broken ends of chromosomes can heal by nonspecific mutual joining. *See* Transformation (bacteria).

The science of genetics has been revolutionized by the development of techniques using isolated cells for specific cleaving and rejoining of DNA segments and the introduction of the reconstructed molecules into living cells. This artificial recombination depends on the use of site-specific endonucleases (restriction enzymes) and DNA ligase. *See* Gene; Gene action; Genetic engineering; Genetics; Restriction enzyme. [J.R.S.F.]

Rectifier A nonlinear circuit component that allows more current to flow in one direction than in the other. An ideal rectifier is one that allows current to flow in one (forward) direction unimpeded but allows no current to flow in the other (reverse) direction. Thus, ideal rectification might be thought of as a switching action, with the switch closed for current in one direction and open for current in the other direction. Rectifiers are used primarily for the conversion of alternating current (ac) to direct current (dc). *See* Electronic power supply.

A variety of rectifier elements are in use. The vacuum-tube rectifier can efficiently provide moderate power. Its resistance to current flow in the reverse direction is essentially infinite because the tube does not conduct when its plate is negative with respect to its cathode. In the forward direction, its resistance is small and almost constant. Gas tubes, used primarily for higher power requirements, also have a high resistance in the reverse direction. The semiconductor rectifier has the advantage of not requiring a filament or heater supply. This type of rectifier has approximately constant forward and reverse resistances, with the forward resistance being much smaller. Mechanical rectifiers can also be used. The most common is the vibrator, but other devices are also used. *See* Gas tube; Mechanical rectifier; Semiconductor rectifier.

If the average current is subtracted from the current flowing in the rectifier, an alternating current results. This ripple current flowing through a load produces a ripple voltage which is often undesirable. Filter and regulator circuits are used to reduce it to as low a value as is required. *See* Electric filter; Voltage regulator.

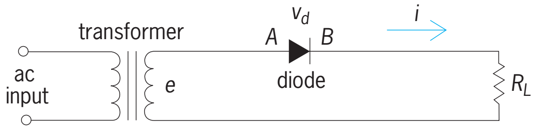


Fig. 1. **Half-wave diode rectifier. V_d = voltage across diode. Ideal diode allows current i to flow only in forward direction from A to B.**

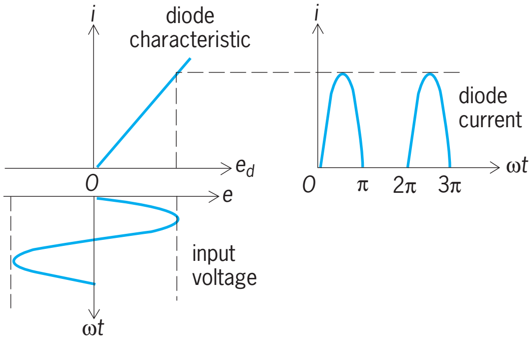

Fig. 2. **Rectifying action of half-wave diode rectifier. t = time; ω = angular frequency of input voltage.**

A half-wave rectifier circuit is shown in Fig. 1. The rectifier, a diode, is practically ideal. The ac input is applied to the primary of the transformer; secondary voltage e supplies the rectifier and load resistor R_L. The rectifying action of the diode is shown in Fig. 2, in which the current i of the rectifier is plotted against the voltage e_d across the diode. The applied sinusoidal voltage from the transformer secondary is shown under the voltage axis; the resulting current i flowing through the diode is shown at the right to be half-sine loops.

A full-wave rectifier circuit uses two separate diodes. The resulting current wave shape is shown in Fig. 3. A more continuous flow of direct current is produced because the first diode conducts for the positive half-cycle and the second diode conducts for the negative half-cycle.

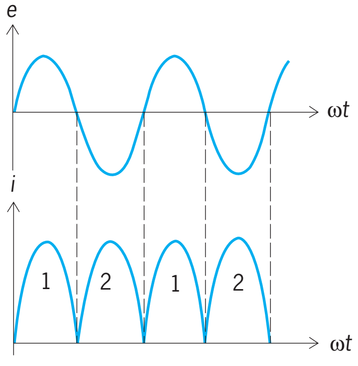

Fig. 3. **Applied voltage and output current of full-wave rectifier.**

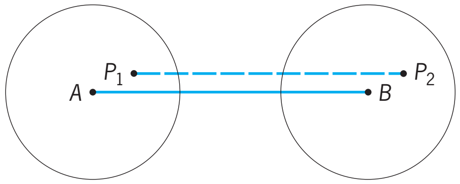
When high dc power is required by an electronic circuit, a polyphase rectifier circuit may be used. It is also desirable when expensive filters must be used. This is particularly true of power supplies for the final radio-frequency and audiofrequency stages of large radio and television transmitters. [D.L.W.]

Rectilinear motion Motion is defined as continuous change of position of a body. If the body moves so that every particle of the body follows a straight-line path, then the motion of the body is said to be rectilinear. *See* MOTION.



Rectilinear motion. All points move parallel to the center of mass.

When a body moves from one position to another, the effect may be described in terms of motion of the center of mass of the body from a point A to a point B (see illustration). If the center of mass of the body moves along a straight line connecting the points A and B, then the motion of the center of mass of the body is rectilinear. If the body as a whole does not rotate while it is moving, then the path of every particle of which the body is composed is a straight line parallel to or coinciding with the path of the center of mass, and the body as a whole executes rectilinear motion. This is shown by the straight line connecting points P_1 and P_2 in the illustration. *See* CENTER OF MASS.

Rectilinear motion is an idealized form of motion which rarely, if ever, occurs in actual experience, but it is the simplest imaginable type of motion and thus forms the basis for the analysis of more complicated motions. However, many actual motions are approximately rectilinear and may be treated as such without appreciable error. For example, a ball thrown directly upward may follow, for all practical purposes, a straight-line path. The motion of a high-speed rifle bullet fired horizontally may be essentially rectilinear for a short length of path, even though in its larger aspects the ideal path is a parabola. The motion of an automobile traveling over a straight section of roadway is essentially rectilinear if minor variations of path are neglected. The motion of a single wheel of the car is not rectilinear, although the motion of the center of mass of the wheel may be essentially so. *See* BALLISTICS. [R.D.Ru.]

Recursive function A function that maps natural numbers to natural numbers and is special in that it must be calculable by using a precisely specified algorithm. The mathematical definitions of partial recursive functions and recursive functions were developed to give a precise mathematical characterization of those functions or operations on the natural numbers which are computable by using effective procedures.

An effective procedure is a procedure or process determined by a finite list of precise instructions. There is no upper bound on the number of instructions in this list. These instructions can be carried out in a discrete one-step-at-a-time fashion. The only equipment needed is pencil and paper, and an unlimited supply is assumed to be available. No creativity is involved in applying these instructions, and no random devices such as flipping a coin are allowed in carrying them out.

An effective procedure may be used to calculate a function as follows: The calculator inputs to the effective procedure a natural number (0, 1, 2, 3, . . .) and allows the procedure to be carried out on this input. If an ouput is obtained, the function is said to be defined at this input and its value at this input is the output so obtained. Any function which can be computed in this way is called effectively computable. For example, addition and multiplication of natural numbers are effectively computable functions.

The notion of effective procedure is intuitive and vague. In the setting of an idealized computing device called a Turing machine, a more precise definition of certain effectively computable functions can be given. *See* AUTOMATA THEORY; GÖDEL'S THEOREM; LOGIC. [G.C.N.]

Recycling technology Methods for reducing solid waste by reusing discarded materials to make new products. The three integral phases of recycling are the collection of recyclable materials, manufacture or reprocessing of these materials into new products, and purchase of these products. Various techniques have been developed to recycle plastics, glass, metals, paper, and wood.

Plastics. Plastic discards represent an estimated 10% by weight and up to 26% by volume of the municipal solid waste in the United States discarded after materials recovery. About 2% by weight of discarded plastics is recovered. Approximately half of plastic waste consists of single-use convenience packaging and containers. Many manufacturers prefer plastic for packaging because it is lightweight, resists breakage and environmental deterioration, and can be processed to suit specific needs. Once plastics are discarded, these attractive physical properties become detriments.

The collected plastic waste is usually separated manually from the waste stream, and often it is cleaned to remove adhesives or other contaminants. It is sorted further, based on different resins. Mechanical separation techniques can be used to sort plastics based on unique physical or chemical properties.

A significant problem is the presence of contaminants such as dirt, glass, metals, chemicals from previous usage, toxicants from metallic-based pigments, and other materials that are part of or have adhered to the plastic products. Other constraints involve inconsistencies in the amount of different plastic resins in commingled plastic wastes used for recycling, and engineering aspects of recycled plastic products, such as lessened chemical and impact resistance, strength, and stiffness, and the need for additional chemicals to counteract other types of degradation for reprocessing. There may be limitations to the number of times that a particular plastic product can be effectively recycled as compared to steel, glass, or aluminum, which can be recycled many times with no loss of their properties and virtually no contamination. [R.L.Sw.; V.T.B.; M.L.Bo.]

Glass. Glass containers are a usual ingredient in community recycling programs; they are 100% recyclable and can be recycled indefinitely. In 1993 in the United States, glass containers, which constitute 6% of the solid-waste stream by weight, were recycled at a rate of 35%. Nearly one-third of the glass containers available for consumption in the United States were cycled back into glass containers and other useful items such as glasphalt, or were returned as refillable bottles.

The process of recycling glass is straightforward. Cullet (scrap glass) in the form of used glass bottles and jars is mixed with silica sand, soda ash, and limestone in a melting furnace at temperatures up to 2800°F (1540°C). The molten glass is poured into a forming machine, where it is blown or pressed into shape. The new containers are gradually cooled, inspected, and shipped to the customer. Before glass can be recycled, however, it must be furnace ready, that is, sorted by color and free of contaminants.

Cullet must meet a standard of quality similar to that of the raw material it replaces. Contamination from foreign material will result in the cullet being rejected by the plants, as it poses a serious threat to the integrity and purity of the glass packaging being produced. Contaminants include metal caps, lids, stones, dirt, and ceramics. Paper labels do not need to be removed for recycling, as they burn off at high furnace temperatures. [N.T.; N.U.R.]

Metals. Metals must be recycled to alleviate the need to mine more ore, to reduce energy consumption, to limit the dissemination of metals into the environment, and to reduce the cost of metals. In the United States a substantial portion of these needs are met by recycling metals.

The extensive recycling is important for three reasons. (1) The energy required to recycle a metal is considerably less in comparison to producing it from ore. (2) Extracting the metal from ore produces a tremendous amount of waste material. (3) Metals that are not recycled become dissipated throughout the environment; since many metals are toxic, this can result in the pollution of water and soil. *See* HAZARDOUS WASTE.

While it is beneficial to recycle, two important problems hinder recycling: collection and impurity buildup. When a metal becomes scrap and is a candidate for recycling, it must be collected at a cost that makes it attractive to recyclers. It is useful to divide scrap into three categories—home scrap, new or prompt scrap, and old or obsolete scrap—whose methods for collection differ significantly. Home scrap is waste produced during fabrication, and includes casting waste (for example, risers), shearings and trimmings, and rejected material. This scrap is usually recycled within the plant, and therefore it is not recognized as recycled material in recycling statistics. New or prompt scrap is waste generated by the user of semifinished material, that is, scrap from machining operations (such as turnings or borings), trimmings, and rejected material. This material is collected and sold to recyclers and, if properly labeled and segregated, it is easy to recycle and is valuable. Old or obsolete scrap is waste derived from products that have completed their life cycle, such as used beverage cans, old automobiles, and defunct batteries. The collection and the impurity buildup problems are most severe when considering old or obsolete scrap. [D.F.S.]

Paper. Paper and paperboard for recycling come from a variety of sources, including offices, retail businesses, coverters, printers, and households. Paper products that have been distributed, have been purchased, and have served their intended purposes are considered postconsumer waste. Other sources, such as scrap paper generated in the papermaking process (mill broke) or converting operations (such as trimmings from envelopes and boxes), are considered preconsumer waste.

Recycled paper fibers are used in the manufacture of many recycled-content paper products such as paperboard, corrugated containers, tissue products, newspapers, and printing and writing paper. They can also be used in other products such as insulation, packing materials, and molded egg cartons and flowerpots. *See* PRINTING.

Collection is the crucial first step in recycling. It occurs in curbside programs, in drop-off centers, in paper drives, and increasingly in commercial collection systems run side by side with waste collection for landfill or incineration.

Reprocessing begins by sorting waste papers by grade and level of cleanliness. Next, the waste paper (usually in bales) is mixed with water in a slusher or pulper to produce a fiber-and-water slurry. In this pulping stage the paper is agitated until broken down into fibers, and large-size contaminants (greater than about 5 mm or 0.2 in.) are removed when the pulper is emptied through the screen plate. Depending on the intended product, chemicals such as surfactants are added to the pulper to help remove undesirable materials from the fibers for separation in later operations.

The pulp is then pumped through several different-size slotted or perforated screens to separate medium-size contaminants (usually 5–0.2 mm or 0.2–0.05 in.) from the pulp. Screening is generally followed by centrifugal cleaning, where the pulp is subjected to a vortex in a tapered cone. Using specific designs, cleaners separate high-specific-gravity materials, such as dirt and sand, and low-specific-gravity materials, such as styrofoam and some plastics, from the pulp. *See* PAPER. [J.S.S.]

Wood. Waste is generated at every stage of the process by which a forest tree is turned into consumer and industrial products. Additional waste is generated in the disposal of those products. Wood waste is also produced by the homeowner and by large and small businesses and is generated from landscaping and agricultural operations such as pruning and tree removal. While these processes do not strictly return wood to the economy in its original form, they have the effect of diverting wood residues from the landfill, and thus they may be included under a broadly interpreted definition of recycling.

Wood recycling begins with wood separation from the waste stream. Recovered materials can be processed into various products, including fuel, raw material for particleboard or other wood-composite panel products, compost, landscaping mulch, animal bedding, landfill cover, amendments for municipal solid waste and sludge compost, artificial firewood, wood-plastic composite lumber and other composite products, charcoal, industrial oil absorbents, insulation, and specialty concrete.

Most of these products require that the wood be ground into small particles. A typical grinder is a hammermill, although a variety of grinders are used. The size of the particles is determined by the end use of the wood; sizes smaller than about 20 mesh are called wood flour (the particles passing the 20-mesh screen are usually less than 0.8 mm in size). Wood may then be passed over an electromagnet which removes items made of ferrous metals such as nails or staples. If additional processing is performed, it is typically to separate wood particles by size. This is accomplished in two ways: the particles can be passed through a series of screens of different mesh size and the various-sized particles can be collected from the screens; or the particles may be separated in a tower with air blown in the bottom and out the top; the particles distribute themselves in the tower, with the small, light particles on top and the large, dense ones at the bottom. *See* WOOD PRODUCTS. [J. Simo.]

Red dwarf star A low-mass main-sequence star of spectral classes M and L. Red dwarf stars range from about 0.6 solar mass at class M0 down to 0.08 solar mass in cool M and warm L, below which the proton-proton chain cannot run. Lower-mass bodies are termed brown dwarfs. Effective temperatures range from 3800 K (6400°F) at class M0 down to 2000 K (3100°F) at class L0, and absolute visual magnitudes from +9 to +20. Downward along the main sequence, red dwarfs produce progressively more radiation in the infrared. Luminosities range from about 0.05 down to 2×10^{-4} the solar luminosity. Radii range from about 0.5 to down 0.1 solar. Spectra become increasingly complex. *See* BROWN DWARF; MAGNITUDE (ASTRONOMY); PROTON-PROTON CHAIN.

Red dwarfs constitute over 70% of all stars, and as a result constitute about half the visible mass of the Milky Way Galaxy. Yet their intrinsic faintness renders them all invisible to the unaided eye. Their lifetimes are so long that none has ever evolved in the Milky Way Galaxy's lifetime. *See* DWARF STAR; MILKY WAY GALAXY; SPECTRAL TYPE; STAR; STELLAR EVOLUTION. [J.B.Ka.]

Red Sea A body of water that separates northeastern Africa from the Arabian Peninsula. The Red Sea forms part of the African Rift System, which also includes the Gulf of Aden and a complex series of continental rifts in East Africa extending as far south as Malawi. The Red Sea extends for 1920 km (1190 mi) from Ras (Cape) Muhammed at the southern tip of the Sinai Peninsula to the Straits of Bab el Mandab at the entrance to the Gulf of Aden. At Sinai the Red Sea splits into the Gulf of Suez, which extends for an additional 300 km (180 mi) along the northwest trend of the Red Sea and the nearly northward-trending Gulf of Aqaba. The 175-km-long (109-mi) Gulf of Aqaba forms the southern end of the Levant transform, a primarily strike-slip fault system extending north into southern Turkey. The Levant transform also includes the Dead Sea and Sea of Galilee and forms the northwestern boundary of the Arabian plate. *See* ESCARPMENT; FAULT AND FAULT STRUCTURES.

The Red Sea consists of narrow marginal shelves and coastal plains and a broad main trough with depths ranging from about 400 to 1200 m (1300 to 3900 ft). The main trough is bisected by a narrow (<60 km or 37 mi wide) axial trough with a very rough bottom morphology and depths of greater than 2000 m (6600 ft). The maximum recorded depth is 2920 m (9580 ft). *See* REEF.

Water circulation in the Red Sea is driven by monsoonal wind patterns and changes in water density due to evaporation. Evaporation in the Red Sea is sufficient to lower the sea level by over 2 m (6.6 ft) per year. No permanent rivers flow into the sea, and there is very little rainfall. As a result, there must be a net inflow of water from the Gulf of Aden to compensate for evaporative losses. During the winter monsoon, prevailing winds in the Red Sea are from the south, and there is a surface current from the Gulf of Aden into the Red Sea. During the summer monsoon, the wind in the Red Sea blows strongly from the north, causing a surface current out of the Red Sea. *See* MONSOON METEOROLOGY; SEAWATER. [J.R.Co.]

Redbeds Clastic sediments and sedimentary rocks that are pigmented by red ferric oxide which coats grains, fills pores as cement, or is dispersed as a muddy matrix. These conspicuously colored rocks commonly constitute thick sequences of nonmarine, paralic (marginal marine), and less commonly shallow marine deposits. Clastic redbeds accumulated in many parts of the globe during the past 10^9 years of Earth history. Ferric oxides also pigment marine chert, limestone, and cherty iron formations and ooidal ironstones, but these chemical deposits are not usually included among redbeds.

Some redbeds contain abundant grains of sedimentary and low-grade metamorphic rocks and relatively few grains of iron-bearing minerals. Most of them, however, contain feldspar and relatively abundant grains of opaque black oxides derived from igneous and high-grade metamorphic source rocks. Clay minerals in older redbeds, as in most other ancient clastic deposits, are predominantly illite and chlorite, thus providing no specific clue to the climate in the source area or at the place of deposition.

In many of the younger redbeds the pigmenting ferric oxide mineral cannot be identified specifically because of its poor crystallinity. In most of the older ones, however, hematite is the pigment. As seen under the scanning electron microscope, the hematite is in the form of hexagonal crystals scattered over the surface of grains and clay mineral platelets. In red mudstones most of the pigment is associated with the clay fraction.

Redbeds do not contain significantly more total iron than nonred sedimentary rocks. Normally, iron increases with decreasing grain size of redbeds. Moreover, the amount of iron in the grain-coating pigments is small compared with that in opaque oxides, dark silicates, and clay minerals.

On a global scale, paleomagnetic evidence of the distribution of redbeds relative to their pole position corroborates paleogeographic data, suggesting that most redbeds, evaporites, and eolian sandstones accumulated less than 30° north and south of a paleo equator where hot, dry climate generally prevailed. But diagenetic development of red hematite may be acquired long after deposition. Moreover, continental drift reconstructions reveal that the most widespread redbeds in the geologic record developed near the Equator in late Paleozoic and early Mesozoic time when the continents were assembled in a great landmass, Pangaea. *See* CONTINENTS, EVOLUTION OF; PALEOGEOGRAPHY; PALEOMAGNETISM. [F.B.V.H.]

Redshift A systematic displacement toward longer wavelengths of lines in the spectra of distant galaxies, and also of the continuous part of the spectrum. First studied systematically by E. Hubble, redshift is central to observational cosmology, in which it provides the basis for the modern picture of an expanding universe.

There are two fundamental properties of redshifts. First, the fractional redshift $\Delta\lambda/\lambda$ is independent of wavelength. This rule has been verified from 21 cm (radio radiation from neutral hydrogen atoms) to about 6×10^{-5} cm (the visible region of the electromagnetic spectrum) and leads to the interpretation of redshift as resulting from a recession of distant galaxies. Though this interpretation has been questioned, no other mechanism is known that would explain the observed effect.

Second, redshift is correlated with apparent magnitude in such a way that when redshift is translated into recession speed and apparent magnitude into distance, the recession speed is found to be nearly proportional to the distance. This rule was formulated by Hubble in 1929, and the constant of proportionality bears his name. *See* HUBBLE CONSTANT; MAGNITUDE (ASTRONOMY). [D.La.]

Redtop grass One of the bent grasses, *Agrostis alba* and its relatives, which occur in cooler, more humid regions of the United States on a wide variety of soils. Redtop tolerates both wet and dry lands and acid and infertile soils, and it is used where other species of grasses do not thrive. Redtop is a perennial and makes a coarse, loose turf. The inflorescence is a reddish open panicle. Redtop is used for pasture and hay and is fairly nutritious if harvested promptly when heading occurs. It is effective in preventing erosion by holding banks of drainage ditches, waterways, and terrace channels. *See* CYPERALES. [H.B.S.]

Redwood A member of the pine family, *Sequoia sempervirens*, is the tallest tree in the Americas, attaining a height of 350 ft (107 m) and a diameter of 27 ft (8.2 m). Its present range is limited to a strip along the Pacific Coast, extending from southwest Oregon to south of San Francisco. The leaves are evergreen, sharply pointed, small, disposed in two vertical rows on short branches, and scalelike on the main stem. The cones are egg-shaped. The bark is a dull red-brown, on old trees sometimes 1 ft (0.3 m) thick, densely fibrous, and highly resistant to fire. The tree gets its common name from the color of the bark as well as that of the heartwood.

The wood holds paint well and is used for bridge timbers, tanks, flumes, silos, posts, shingles, paneling, doors, caskets, furniture, siding, and many other building purposes. *See* PINALES; PINE. [A.H.G./K.P.D.]

Reef A mass or ridge of rock or rock-forming organisms in a water body, a rock trend on land or in a mine, or a rocky trend in soil. Usually the term reef means a rocky menace to navigation, within 6 fathoms (11 m) of the water surface. Various kinds of calcium carbonate–secreting animals and plants create biogenic, or organic, reefs throughout the warmer seas. Most biogenic reefs are made of corals and associated organisms, but some entire reefs and important parts of others consist mainly of lime-secreting algae, hydrozoans, annelids, oysters, or sponges. *See* ALGAE; SCLERACTINIA.

The term fringing reef refers to a coral or other biogenic reef that fringes the edge of the land. A barrier reef ordinarily made of corals or other organisms parallels the shore at the seaward side of a natural lagoon. An atoll is an annular coral reef that surrounds a lagoon. *See* ATOLL. [P.Cl.]

Reengineering The application of technology and management science to the modification of existing systems, organizations, processes, and products in order to make them more effective, efficient, and responsive. Responsiveness is a critical need for organizations in industry and elsewhere. It involves providing products and services of demonstrable value to customers, and thereby to those individuals who have a stake in the success of the organization. Reengineering can be carried out at the level of the organization, at the level of organizational processes, or at the level of the products and services that support an organization's activities. The entity to be reengineered can be systems management, process, product, or some combination. In each case, reengineering involves a basic three-phase systems-engineering life cycle comprising definition, development, and deployment of the entity to be reengineered.

Systems-management reengineering. At the level of systems management, reengineering is directed at potential change in all business or organizational processes, including the systems acquisition process life cycle itself. Systems-management reengineering may be defined as the examination, study, capture, and modification of the internal mechanisms or functionality of existing system-management processes and practices in an organization in order to reconstitute them in a new form and with new features, often to take advantage of newly emerged organizational competitiveness requirements, but without changing the inherent purpose of the organization itself.

Process reengineering. Reengineering can also be considered at the levels of an organizational process. Process reengineering is the examination, study, capture, and modification of the internal mechanisms or functionality of an existing process or systems-engineering life cycle, in order to reconstitute it in a new form and with new functional and nonfunctional features, often to take advantage of newly emerged or desired organizational or technological capabilities, but without changing the inherent purpose of the process that is being reengineered.

Product reengineering. The term "reengineering" could mean some sort of reworking or retrofit of an already engineered product, and could be interpreted as maintenance or refurbishment. Reengineering could also be interpreted as reverse engineering, in which the characteristics of an already engineered product are identified, such that the product can perhaps be modified or reused. Inherent in these notions are two major facets of reengineering: it improves the product or system delivered to the user for enhanced reliability or maintainability, or to meet a newly evolving need of the system users; and it increases understanding of the system or product itself. This interpretation of reengineering is almost totally product-focused.

Thus, product reengineering may be redefined as the examination, study, capture, and modification of the internal mechanisms or functionality of an existing system or product in order to reconstitute it in a new form and with new features, often to take advantage of newly emerged technologies, but without major change to the inherent functionality and purpose of the system. This definition indicates that product reengineering is basically structural reengineering with, at most, minor changes in purpose and functionality of the product. This reengineered product could be integrated with other products having rather different functionality than was the case in the initial deployment. Thus, reengineered products could be used, together with this augmentation, to provide new functionality and serve new purposes. There are a number of synonyms for product reengineering, including renewal, refurbishing, rework, repair, maintenance, modernization, reuse, redevelopment, and retrofit.

Much of product reengineering is very closely associated with reverse engineering to recover either design specifications or user requirements. Then follows refinement of these requirements or specifications and forward engineering to achieve an improved product. Forward engineering is the original process of defining, developing, and deploying a product, or realizing a system concept as a product; whereas reverse engineering, sometimes called inverse engineering, is the process though which a given system or product is examined in order to identify or specify the definition of the product either at the level of technological design specifications or at system- or user-level requirements. [A.P.S.]

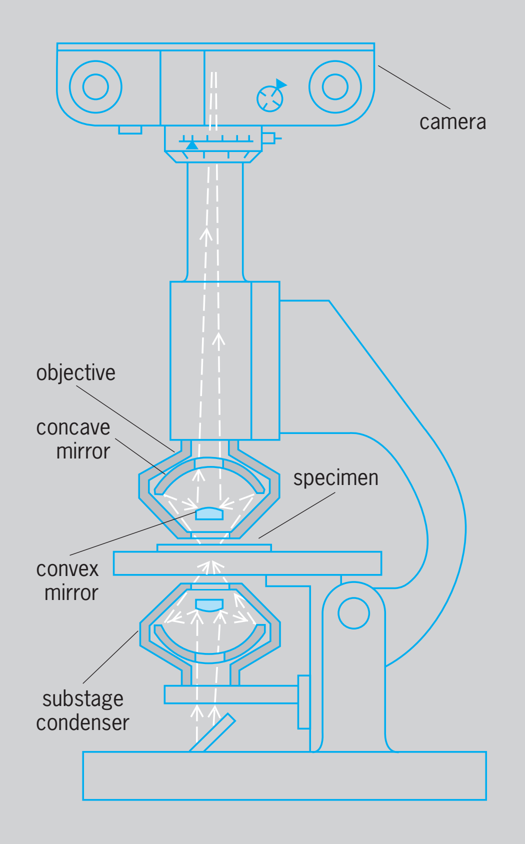
Reference electrode An electrode with an invariant potential. In electrochemical methods, where it is necessary to observe, measure, or control the potential of another electrode (denoted indicator, test, or working electrode), it is necessary to use a reference electrode, which maintains a potential that remains practically unchanged during the course of an electrochemical measurement. Potentials of indicator or working electrodes are measured or expressed relative to reference electrodes. *See* POTENTIALS.

One such electrode, the normal hydrogen electrode, has been chosen as a reference standard, relative to which potentials of other electrodes and those of oxidation-reduction couples are often expressed. By maintaining a constant pressure of hydrogen gas the potential of a hydrogen electrode can be used for determination of the activity of hydrogen ions in the tested solution. However, in practice the determination of the hydrogen-ion activity (pH) is performed by using a glass electrode. The hydrogen electrode itself is used only in fundamental studies and some nonaqueous solutions. The hydrogen electrode, however, remains important for providing a reference standard. *See* ACTIVITY (THERMODYNAMICS); PH.

In practice, potentials are measured against reference electrodes that are easier to work with than the normal hydrogen electrode. Such electrodes are known as secondary reference electrodes; the most common are the calomel and silver–silver chloride electrodes. *See* ELECTRODE; SOLVENT. [P.Z.]

Reflecting microscope

A microscope whose objective is composed of two mirrors, one convex and the other concave (see illustration). The imaging properties are independent of the wavelength of light, and this freedom from chromatic aberration allows the objective to be used even for infrared and ultraviolet radiation. Although the reflecting microscope is simple in appearance, the construction tolerances are so small and so difficult to achieve that the system is used only when refracting objectives are unsuitable. The distance from the objective to the specimen can be made very large; this large working distance is useful in special applications, such as examining objects situated within metallurgical furnaces. Reflecting microscopes have been mainly used for microspectrometry in the infrared and the ultraviolet, and for ultraviolet microphotography. *See* MICROSCOPE; OPTICAL MICROSCOPE. [D.S.G.]



Reflecting microscope arranged for photomicrography.

Reflection and transmission coefficients

When an electromagnetic wave passes from a medium of permeability μ_1 and dielectric constant ϵ_1 to one with values μ_2 and ϵ_2, part of the wave is reflected at the boundary and part transmitted. The ratios of the amplitudes in the reflected wave and the transmitted wave to that in the incident wave are called the reflection and transmission coefficients, respectively. For oblique incidence, the reflection and refraction formulas of optics are most convenient, but for normal incidence of plane waves on plane boundaries, such as occur with transmission lines, waveguides, and some free waves, the concept of wave impedance and characteristic impedance is useful. *See* ELECTROMAGNETIC RADIATION; TRANSMISSION LINES; WAVEGUIDE. [W.R.Sm.]

Reflection of electromagnetic radiation

The returning or throwing back of electromagnetic radiation such as light, ultraviolet rays, radio waves, or microwaves by a surface upon which the radiation is incident. In general, a reflecting surface is the boundary between two materials of different electromagnetic properties, such as the boundary between air and glass, air and water, or air and metal. Devices designed to reflect radiation are called reflectors or mirrors.

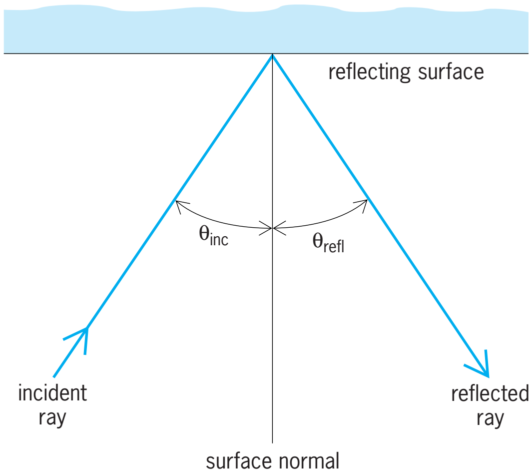
The simplest reflection laws are those that govern plane waves of radiation. The law of reflection concerns the incident and reflected rays (as in the case of a beam from a flashlight striking a mirror) or, more precisely, the wave normals of the incident and reflected waves. The law states that the incident and reflected rays and the normal to the reflecting surface all lie in one plane, called the plane of incidence, and that the reflection angle equals the angle of incidence as in Eq. (1) [see illustration]. The

$$\theta_{\mathrm{refl}} = \theta_{\mathrm{inc}} \qquad (1)$$

angles θ_{inc} and θ_{refl} are measured between the surface normal and the incident and reflected rays, respectively. The surface (in the above example, that of the mirror) is assumed to be smooth, with surface irregularities small compared to the wavelength of the radiation. This results in so-called specular reflection. In contrast, when the surface is rough, the reflection is diffuse. An example of this is the diffuse scattering of light from a screen or from a white wall where light is returned through a whole range of different angles.

The reflectivity of a surface is a measure of the amount of reflected radiation. It is defined as the ratio of the intensities of the reflected and incident radiation. The reflectivity depends on the angle of incidence, the polarization of the radiation, and the electromagnetic properties of the materials forming the boundary surface. These properties usually change with the wavelength of the radiation. Reflecting materials are divided into two groups: transparent materials also called dielectrics, and opaque conducting materials, usually metals.

The reflectivity of polished metal surfaces is usually quite high. Silver and aluminum, for example, reflect more than 90% of visible light. In ordinary mirrors the reflecting surface is the interface between metal and glass, which is thus protected from oxidation, dirt, and other forms of deterioration. When it is not



Reflection of electromagnetic radiation from smooth surface.

permissible to use this protection for technical reasons, one uses "front-surface" mirrors, which are usually coated with evaporated aluminum.

The material property that determines the amount of radiation reflected from an interface between two dielectric media is the phase velocity v of the electromagnetic radiation in the two materials. In optics one uses as a measure for this velocity the refractive index n of the material, which is defined by Eq. (2) as

$$n = c/v \tag{2}$$

the ratio of the velocity of light c in vacuum and the phase velocity in the material. For visible light, for example, the refractive index of air is about $n = 1$, the index of water is about $n = 1.33$, and the index of glass is about $n = 1.5$. *See* PHASE VELOCITY; REFRACTION OF WAVES.

For normal incidence ($\theta_{\text{inc}} = 0$) the reflectivity R of the interface is given by Eq. (3), in which the material constants are

$$R = \left(\frac{v_1 - v_2}{v_1 + v_2}\right)^2 = \left(\frac{n_2 - n_1}{n_2 + n_1}\right)^2 \tag{3}$$

labeled 1 and 2, where the radiation is incident in material 1. The reflectivity of an air-water interface is about 2% ($R = 0.02$) and that of an air-glass interface about 4% ($R = 0.04$); the other 98% or 96% are transmitted through the water or glass, respectively. *See* ALBEDO; GEOMETRICAL OPTICS; MIRROR OPTICS; REFLECTION OF SOUND. [H.K.]

Reflection of sound The return of sound waves from surfaces on which they are incident. The geometrical laws for reflection of sound waves are the same as those for light waves. The apparent differences involve only questions of scale, because the average wavelength of sound is about 100,000 times that of light. For example, a mirror or lens used to produce a beam of sound waves must be enormously large compared to mirrors and lenses used in optical systems. *See* REFLECTION OF ELECTROMAGNETIC RADIATION.

A concave surface tends to concentrate the reflected sound waves. Convex reflectors tend to spread the reflected waves. Therefore, when placed at the boundaries of a room, they tend to diffuse the sound throughout the room. For this reason, some radio-broadcasting studios employ cylindrical convex panels as part of their wall construction to promote diffusion. *See* ARCHITECTURAL ACOUSTICS; ECHO; SOUND. [C.M.H.]

Reflex A simple, unlearned, yet specific behavioral response to a specific stimulus. Reflexes are exhibited by virtually all animals from protozoa to primates. Along with other, more complex stimulus-bound responses such as fixed action patterns, they constitute much of the behavioral repertoire of invertebrates. In higher animals, such as primates, where learned behavior dominates, reflexes nevertheless persist as an important component of total behavior.

The simplest known reflexes require only one neuron or, in the strictest sense, none. For example, ciliated protozoa, which are single cells and have no neurons, nevertheless exhibit apparently reflexive behaviors. However, most reflexes require activity in a large sequence of neurons. The neurons involved in most reflexes are connected by specific synapses to form functional units in the nervous system. Such a sequence begins with sensory neurons and ends with effector cells such as skeletal muscles, smooth muscles, and glands, which are controlled by motor neurons. The central neurons which are often interposed between the sensory and motor neurons are called interneurons. The sensory side of the reflex arc conveys specificity as to which reflex will be activated. The remainder of the reflex response is governed by the specific synaptic connections that lead to the effector neurons. A familiar reflex is the knee-jerk or stretch reflex. It involves the patellar (kneecap) tendon and a group of upper leg muscles. Other muscle groups show similar reflexes. [J.L.La.]

Reforestation The reestablishment of forest cover either naturally or artificially. Given enough time, natural regeneration will usually occur in areas where temperatures and rainfall are adequate and when grazing and wildfires are not too frequent.

Reforestation occurs on land where trees have been recently removed due to harvesting or to natural disasters such as a fire, landslide, flooding, or volcanic eruption. When abandoned cropland, pastureland, or grasslands are converted to tree cover, the practice is termed afforestation (where no forest has existed in recent memory). Afforestation is common in countries such as Australia, South Africa, Brazil, India, and New Zealand. Although natural regeneration can occur on abandoned cropland, planting trees will decrease the length of time required until the first harvest of wood. Planting also has an advantage in that both tree spacing and tree species can be prescribed. The selection of tree species can be very important since it affects both wood quality and growth rates. Direct seeding is also used for both afforestation and reforestation, although it often is less successful and requires more seed than tree planting. Unprotected seed are often eaten by birds and rodents, and weeds can suppress growth of newly germinated seed. For these reasons, direct seeding accounts for only about 5% and 1% of artificial reforestation in Canada and the United States, respectively. [D.B.So.]

Reforming processes Those processes used to convert, with limited cracking, petroleum liquids into higher-octane gasoline. Due to the demand for higher-octane gasoline, thermal reforming was developed (from thermal cracking processes) to improve the octane number of fractions within the boiling range of gasoline. *See* CRACKING; GASOLINE; OCTANE NUMBER; PETROLEUM.

Upgrading by reforming may be accomplished, in part, by an increase in volatility (reduction of molecular size) or by the conversion of *n*-paraffins to isoparaffins, olefins, and aromatics, and of naphthenes (cycloalkanes) to aromatics. The nature of the final product is influenced by the structure and composition of the straight-run (virgin) naphtha (hydrocarbon mixture) feedstock. In thermal reforming, the reactions resemble those in the cracking of gas oils. The molecular size is reduced, while olefins and some aromatics are synthesized. For example, hydrocracking of high-molecular-weight paraffins yields lower-molecular-weight paraffins and an olefin; dehydrocyclization of paraffin compounds yields aromatic compounds; isomerization of *n*-paraffins yields isoparaffins; and isomerization of methylcyclopentane yields cyclohexane.

In the presence of catalysts and in the presence of the hydrogen available from dehydrogenation reactions, hydrocracking of paraffins to yield two lower-molecular-weight paraffins takes place, and olefins that do not undergo dehydrocyclization are dehydrogenated so that the end product contains only traces of olefins. *See* DEHYDROGENATION; HYDROCRACKING; ISOMERIZATION; PARAFFIN.

Thermal reforming was a natural development from thermal cracking, since reforming is also a thermal decomposition reaction. Cracking converts heavier oils into gasoline constituents, whereas reforming converts these gasoline constituents into higher-octane molecules. The equipment for thermal reforming is essentially the same as for thermal cracking, but higher temperatures are used. The higher octane number of the product (reformate) is due primarily to the cracking of longer-chain paraffins into higher-octane olefins. *See* DISTILLATION.

The products of thermal reforming are gases, gasoline, and residual oil. The amount and quality of the reformate are very dependent on the temperature. As a rule, the higher the reforming temperature, the higher the octane number of the product but the lower the reformate yield. Adding catalysts increases the yield for higher-octane gasolines at a given temperature.

Thermal reforming is less effective and less economical than catalytic processes and has been largely supplanted. The octane number was changed by the severity of the cracking, and the product had increased volatility, compared to the volatility of the feedstock.

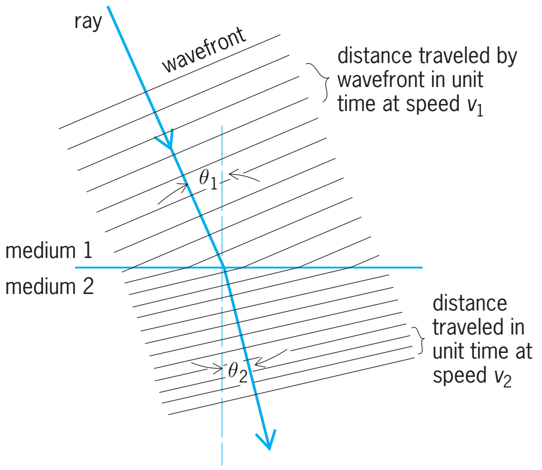
Modifications of the thermal reforming process due to the inclusion of hydrocarbon gases with the feedstock are known as gas reversion and polyforming. These are essentially the same but differ in the manner in which the gases and naphtha are passed through the heating furnace. In gas reversion, the naphtha and gases flow through separate lines in the furnace and are heated independently of one another. In naphtha reforming, the C_3 and C_4 gases are premixed with the naphtha and pass together through the furnace.

Like thermal reforming, catalytic reforming converts low-octane gasoline into high-octane gasoline (reformate). Although thermal reforming can produce reformate with a research octane number of 65–80 depending on the yield, catalytic reforming produces reformate with octane numbers on the order of 90–95. Catalytic reforming is conducted in the presence of hydrogen over hydrogenation-dehydrogenation catalysts. Depending on the catalyst, a definite sequence of reactions takes place, involving structural changes in the feedstock. *See* CATALYSIS; PETROLEUM PROCESSING AND REFINING. [J.G.S.]

Refraction of waves

Refraction of waves The change of direction of propagation of any wave phenomenon which occurs when the wave velocity changes. The term is most frequently applied to visible light, but it also applies to all other electromagnetic waves, as well as to sound and water waves.

The physical basis for refraction can be readily understood with the aid of the illustration. Consider a succession of equally spaced wavefronts approaching a boundary surface obliquely. The direction of propagation is in ordinary cases perpendicular to the wavefronts. In the case shown, the velocity of propagation is less in medium 2 than in medium 1, so that the waves are slowed down as they enter the second medium. Thus, the direction of travel is bent toward the perpendicular to the boundary surface (that is, $\theta_2 < \theta_1$). If the waves enter a medium in which the velocity of propagation is faster than in their original medium, they are refracted away from the normal.



Physical basis for Snell's law.

Snell's law. The simple mathematical relation governing refraction is known as Snell's law. If waves traveling through a medium at speed υ_1 are incident on a boundary surface at angle θ_1 (with respect to the normal), and after refraction enter the second medium at angle θ_2 (with the normal) while traveling at speed υ_2, then Eq. (1) holds. The index of refraction n of a

$$\frac{\upsilon_1}{\upsilon_2} = \frac{\sin\theta_1}{\sin\theta_2} \tag{1}$$

medium is defined as the ratio of the speed of waves in vacuum c to their speed in the medium. Thus $c = n_1\upsilon_1 = n_2\upsilon_2$, and therefore Eq. (2) holds. The refracted ray, the normal to the surface,

$$n_1 \sin\theta_1 = n_2 \sin\theta_2 \tag{2}$$

and the incident ray always lie in the same place.

The relative index of refraction of medium 2 with respect to that of medium 1 may be defined as $n = n_1/n_2$. Snell's law then becomes Eq. (3). For sound and other elastic waves which

$$\sin\theta_1 = n \sin\theta_2 \tag{3}$$

require a medium in which to propagate, only this last form has meaning. Equation (3) is frequently used for light when one medium is air, whose index of refraction is very nearly unity.

When the wave travels from a region of low velocity (high index) to one of high velocity (low index), refraction occurs only if $(n_1/n_2)\sin\theta_1 \leqq 1$. If θ_1 is too large for this relation to hold, then $\sin\theta_2 > 1$, which is meaningless. In this case the waves are totally reflected from the surface back into the first medium. The largest value that θ_1 can have without total internal reflection taking place is known as the critical angle θ_c. Thus $\sin\theta_c = n_2/n_1$.

Atmospheric refraction. The index of refraction of the Earth's atmosphere increases continuously from 1.000000 at the edge of space to 1.000293 (yellow light) at 0°C and 760 mmHg (101.3 kilopascals) pressure. Thus celestial bodies as seen in the sky are actually nearer to the horizon than they appear to be. The effect decreases from a maximum of about 35 minutes of arc for an object on the horizon to zero at the zenith, where the light enters the atmosphere at perpendicular incidence.

Other manifestations of atmospheric refraction are the mirages and "looming" of distant objects which occur over oceans or deserts, where the vertical density gradient of the air is quite uniform over a large area. *See* MIRAGE.

Sound waves. The velocity of sound in a gas is proportional to the square root of the absolute temperature. Because of the vertical temperature gradients in the atmosphere, refraction of sound can be quite pronounced. As in mirage formation, to allow large-scale refraction the temperature at a given height must be uniform over a rather large horizontal area. *See* ATMOSPHERIC ACOUSTICS; SOUND.

Seismic waves. The velocity of elastic waves in a solid depends upon the modulus of elasticity and upon the density of the material. Waves propagating through solid earth are refracted by changes of material or changes of density. Worldwide observations of earthquake waves enable scientists to draw conclusions on the distribution of density within the Earth. *See* SEISMOLOGY.

Water waves. As the waves enter shallower water they travel more slowly. As a train of waves approaches a coastline obliquely, its direction of travel becomes more nearly perpendicular to the shore because of refraction. *See* WAVE MOTION. [J.W.St.]

Refractometric analysis

Refractometric analysis A method of chemical analysis based on the measurement of the index of refraction of a substance. The most common type of refractometer is the Abbe refractometer. It is simple to use, requiring but a drop or two of sample and allowing a measurement of refractive index to be made in 1–2 min, with a precision of 0.0001. More precise measurements of refractive indices may be made by using a dipping or immersion refractometer, the prism of which is completely immersed in the sample. The most precise measurements of the refractive indices of gases or solutions containing small traces of impurities are made with an interferometer. For measurements in flowing systems, differential refractometers are used.

The measurement of refractive index is used to identify compounds whose other physical constants are quite similar. Because minute amounts of impurities often cause a measurable change in the refractive index of a pure material, refractive index is often used as a criterion for purity. A measurement of refractive index gives information as to the gross amount of impurity; it does not serve to identify the impurity. *See* REFRACTION OF WAVES. [R.F.G.; J.N.L.]

Refractory One of a number of ceramic materials for use in high-temperature structures or equipment. The term high temperatures is somewhat indefinite but usually means above about 1830°F (1000°C), or temperatures at which, because of melting or oxidation, the common metals cannot be used. In some special high-temperature applications, the so-called refractory metals such as tungsten, molybdenum, and tantalum are used. *See* CERAMICS.

The greatest use of refractories is in the steel industry, where they are used for construction of linings of equipment such as blast furnaces, hot stoves, and open-hearth furnaces. Other important uses of refractories are for cement kilns, glass tanks, nonferrous metallurgical furnaces, ceramic kilns, steam boilers, and paper plants. Special types of refractories are used in rockets, jets, and nuclear power plants. Many refractory materials, such as aluminum oxide and silicon carbide, are also very hard and are used as abrasives; some applications, for example, aircraft brake linings, make use of both characteristics.

Refractory materials are commonly grouped into (1) those containing mainly aluminosilicates; (2) those made predominantly of silica; (3) those made of magnesite, dolomite, or chrome ore, termed basic refractories (because of their chemical behavior); and (4) a miscellaneous category usually referred to as special refractories. [J.F.McM.]

Refrigeration The cooling of a space or substance below the environmental temperature. Mechanical refrigeration is primarily an application of thermodynamics wherein the cooling medium, or refrigerant, goes through a cycle so that it can be recovered for reuse. The commonly used basic cycles, in order of importance, are vapor-compression, absorption, steam-jet or steam-ejector, and air. Each cycle operates between two pressure levels, and all except the air cycle use a two-phase working medium which alternates cyclically between the liquid and vapor phases.

The term “refrigeration” is used to signify cooling below the environmental temperature to lower than about 150 K (−190°F; −123°C). The term “cryogenics” is used to signify cooling to temperatures lower than 150 K. *See* CRYOGENICS.

Vapor-compression cycle. The vapor-compression cycle consists of an evaporator in which the liquid refrigerant boils at low temperature to produce cooling, a compressor to raise the pressure and temperature of the gaseous refrigerant, a condenser in which the refrigerant discharges its heat to the environment, usually a receiver for storing the liquid condensed in the condenser, and an expansion valve through which the liquid expands from the high-pressure level in the condenser to the low-pressure level in the evaporator. This cycle may also be used for heating if the useful energy is taken off at the condenser level instead of at the evaporator level. *See* HEAT PUMP.

Absorption cycle. The absorption cycle accomplishes compression by using a secondary fluid to absorb the refrigerant gas, which leaves the evaporator at low temperature and pressure. Heat is applied, by means such as steam or gas flame, to distill the refrigerant at high temperature and pressure. The most-used refrigerant in the basic cycle is ammonia; the secondary fluid is then water. This system is used for the lower temperatures. Another system is lithium bromide-water, where the water is used as the refrigerant. This is used for higher temperatures. Due to corrosion, special inhibitors must be used in the lithium bromide-water system. The condenser, receiver, expansion valve, and evaporator are essentially the same as in any vapor-compression cycle. The compressor is replaced by an absorber, generator, pump, heat exchanger, and controlling-pressure reducing valve.

Steam-jet cycle. The steam-jet cycle uses water as the refrigerant. High-velocity steam jets provide a high vacuum in the evaporator, causing the water to boil at low temperature and at the same time compressing the flashed vapor up to the condenser pressure level. Its use is limited to air conditioning and other applications for temperatures above 32°F (0°C).

Air cycle. The air cycle, used primarily in airplane air conditioning, differs from the other cycles in that the working fluid, air, remains as a gas throughout the cycle. Air coolers replace the condenser, and the useful cooling effect is obtained by a refrigerator instead of by an evaporator. A compressor is used, but the expansion valve is replaced by an expansion engine or turbine which recovers the work of expansion. Systems may be open or closed. In the closed system, the refrigerant air is completely contained within the piping and components, and is continuously reused. In the open system, the refrigerator is replaced by the space to be cooled, the refrigerant air being expanded directly into the space rather than through a cooling coil.

Refrigerants. The working fluid in a two-phase refrigeration cycle is called a refrigerant. A useful way to classify refrigerants is to divide them into primary and secondary. Primary refrigerants are those fluids (pure substances, azeotropic mixtures which behave physically as a single pure compound, and zeotropes which have temperature glides in the condenser and evaporator) used to directly achieve the cooling effect in cycles where they alternately absorb and reject heat. Secondary refrigerants are heat transfer or heat carrier fluids. *See* AIR CONDITIONING; AIR COOLING; AUTOMOTIVE CLIMATE CONTROL; COLD STORAGE; COOLING TOWER; MARINE REFRIGERATION; REFRIGERATOR. [P.E.Li.; C.F.K.]

Refrigeration cycle A sequence of thermodynamic processes whereby heat is withdrawn from a cold body and expelled to a hot body. Theoretical thermodynamic cycles consist of nondissipative and frictionless processes. For this reason, a thermodynamic cycle can be operated in the forward direction to produce mechanical power from heat energy, or it can be operated in the reverse direction to produce heat energy from mechanical power. The reversed cycle is used primarily for the cooling effect that it produces during a portion of the cycle and so is called a refrigeration cycle. It may also be used for the heating effect, as in the comfort warming of space during the cold season of the year. *See* HEAT PUMP; THERMODYNAMIC PROCESSES.

In the refrigeration cycle a substance, called the refrigerant, is compressed, cooled, and then expanded. In expanding, the refrigerant absorbs heat from its surroundings to provide refrigeration. After the refrigerant absorbs heat from such a source, the cycle is repeated. Compression raises the temperature of the refrigerant above that of its natural surroundings so that it can give up its heat in a heat exchanger to a heat sink such as air or water. Expansion lowers the refrigerant temperature below the temperature that is to be produced inside the cold compartment or refrigerator. The sequence of processes performed by the refrigerant constitutes the refrigeration cycle. When the refrigerant is compressed mechanically, the refrigerative action is called mechanical refrigeration.

There are many methods by which cooling can be produced. The methods include the noncyclic melting of ice, or the evaporation of volatile liquids, as in local anesthetics; the Joule-Thomson effect, which is used to liquefy gases; the reverse Peltier effect, which produces heat flow from the cold to the hot junction of a bimetallic thermocouple when an external emf is imposed; and the paramagnetic effect, which is used to reach extremely low temperatures. However, large-scale refrigeration or cooling, in general, calls for mechanical refrigeration acting in a closed system. *See* PARAMAGNETISM; REFRIGERATION.

The purpose of a refrigerator is to extract as much heat from the cold body as possible with the expenditure of as little work as possible. The yardstick in measuring the performance of a refrigeration cycle is the coefficient of performance, defined as the ratio of the heat removed to the work expended. The coefficient of performance of the reverse Carnot cycle is the maximum obtainable for stated temperatures of source and sink. *See* CARNOT CYCLE.

The reverse Brayton cycle it was one of the first cycles used for mechanical refrigeration. Before Freon and other condensable fluids were developed for the vapor-compression cycle, refrigerators operated on the Brayton cycle, using air as their working substance. Air undergoes isentropic compression, followed by reversible constant-pressure cooling. The high-pressure air next expands reversibly in the engine and exhausts at low temperature. The cooled air passes through the cold storage chamber, picks up heat at constant pressure, and finally returns to the suction side of the compressor. *See* BRAYTON CYCLE. [T.Ba.; P.E.Li.]

Refrigerator An insulated, cooled compartment. If it is large enough for the entry of a person, it is termed a walk-in box; otherwise it is called a reach-in refrigerator. Cooling may be by mechanical or gas refrigeration, by water or dry ice, or by brine circulation. Temperatures maintained depend upon the requirements of the product stored, generally varying from 55°F (13°C) down to 0°F (−18°C), and sometimes lower.

A household or domestic refrigerator is a factory-built, self-contained cabinet. The range of storage capacities is wide and varies among manufacturers. Modem designs have a main compartment for holding food above freezing, a second compartment for storage below freezing, and trays for the freezing of ice cubes. Low-temperature household refrigerators, or home freezers, for the storage of frozen foods are manufactured in both the chest and the upright, or vertical, types.

A commercial refrigerator is any factory-built refrigerated fixture, cabinet, or room that can be assembled and disassembled readily. Commercial or built-in refrigerators are used in restaurants, markets, hospitals, hotels, and schools for the storage of food and other perishables. *See* REFRIGERATION. [C.F.K.]

Regeneration (biology) The process by which an animal restores a lost part of its body. Broadly defined, the term can include wound healing, tissue repair, and many kinds of restorative activities. Within the field of developmental biology, however, most research in regeneration involves systems in which removing a complex structure or major part of an organism initiates a chain of events that produces a structure that duplicates the missing part both functionally and anatomically.

The best-known and most widely studied examples of regeneration are those involving epimorphosis, in which the lost structure is reproduced directly by a combination of cell proliferation and redifferentiation of new tissue. Examples can be found throughout the animal kingdom. Research on regenerating systems yields information regarding basic mechanisms of animal development. Noteworthy has been the progress in understanding the factors that control pattern formation in the development of complex structures, such as vertebrate limbs.

Mammals, birds, and reptiles have a much more poorly developed ability than amphibians and fish to regenerate complete organs, but nevertheless can reform missing tissue and restore function after partial removal of certain organs. For example, if part of the liver is cut away, the remaining portions increase in size to compensate for the missing tissue and to restore the normal functional capacity of the organ. The process of liver regeneration involves the triggering of active growth in the remaining liver cells, in cells of bile ductules, and in unspecialized cells called stem cells, all of which are usually quiescent in the normal liver. Proliferation of these cells and their subsequent differentiation are key events in the process by which the missing liver mass is replaced and adequate hepatic function restored. In the musculoskeletal system, different populations of quiescent stem cells allow efficient replacement of damaged or partially removed bones and muscles. *See* BONE; LIVER; MUSCLE.

Of all vertebrates, amphibians have the most highly developed capacity for regeneration. Certain species have the ability to regenerate not only limbs and tails but also parts of the eye, lower jaw, intestine, and heart. Complete regeneration of amputated limbs can occur throughout the lifetime of most salamanders and newts. In frogs and toads, the ability to regenerate limbs is lost during metamorphosis to the adult form.

Protozoa and simple multicellular animals, including sponges, coelenterates, and flatworms, display remarkable capacities for regeneration following various experimental manipulations. Regenerative ability in such organisms correlates closely with their capacity to reproduce asexually, most commonly by fission or by budding, and the mechanisms of growth involved in regeneration are often very similar to those of asexual propagation. For example, just as complete ciliated protozoa will develop after fission, which divides the nucleus and organelles between daughter cells, intact individuals will also be reconstituted from fragments of a single organism if the fragment contains a complete set of the genetic material and a portion of the original cell's cortical cytoplasm. Similar rules regarding the importance of the nucleus apply to regenerative processes in all protozoa.

Most annelids, such as the earthworm, can readily regenerate segments after their removal: some species can regenerate whole organisms from any fragment. Like more primitive invertebrates, certain annelids can reproduce asexually by transverse fission. The capacities for fission and for reconstitution from fragments in annelids are remarkable, considering the anatomical complexity of animals in this phylum. When an earthworm is cut transversely into two parts, the anterior part can regenerate several posterior segments. The ability of the posterior half to regenerate anterior segments is, however, more limited and is absent altogether in some species. Experiments in which components of the nervous system are removed surgically have revealed the importance of a neural influence for segment regeneration, presumably mediated by a growth-stimulating hormone secreted from neural cells. *See* ANNELIDA.

The ability of certain echinoderms, such as starfish, to regenerate missing arms is well known. Cutting such an animal into several pieces results in each piece forming a new organism, a phenomenon that usually requires the presence of at least some of the central portion of the body. Equally remarkable is a regenerative response shown by another echinoderm, the sea cucumber. When this animal is strongly irritated, it eviscerates itself through its anus or through a rupture of its body wall. This phenomenon produces a nearly empty sack of skin and muscle, which then proceeds to regenerate all the internal organs, beginning with the digestive tract. *See* ECHINODERMATA.

The capacity for appendage regeneration is widespread among the many diverse members of the phylum *Arthropoda*. In these complex animals with well-developed exoskeletons and no asexual mode of reproduction, regeneration shows a close correlation with the molting process. *See* ARTHROPODA; DEVELOPMENTAL BIOLOGY. [A.Me.]

Regeneration (engineering) The process of feeding back a portion of the output signal of an amplifier to its input in such a way that the input signal is reinforced. The result is greatly increased amplification. The feedback must be positive; that is, the two signals must be in phase, and it must be limited in magnitude to prevent the circuit from going into oscillation. *See* FEEDBACK CIRCUIT. [J.Mar.]

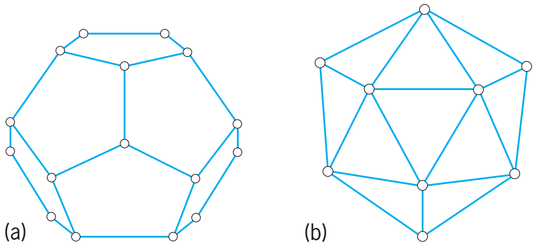
Regolith The mantle or blanket of unconsolidated or loose rock material that overlies the intact bedrock and nearly everywhere forms the land surface. The regolith may be residual (weathered in place), or it may have been transported to its present site. The undisturbed residual regolith may grade from agricultural soil at the surface, through fresher and coarser weathering products, to solid bedrock several feet or more beneath the surface. The transported regolith includes the alluvium of rivers, sand dunes, glacial deposits, volcanic ash, coastal deposits, and the various mass-wasting deposits that occur on hillslopes. The lunar surface also has a regolith. This layer of fragmental debris is believed to derive from prolonged meteoritic and secondary fragment impact. *See* Soil; Weathering processes. [V.R.B.]

Regular polytopes The *n*-dimensional analogs of the regular polygons ($n = 2$) and platonic solids ($n = 3$). They are conveniently denoted by their Schläfli symbols $\{p, q \ldots\}$; for instance, the pentagon, hexagon, octagon, tetrahedron, octahedron are denoted by $\{5\}$, (6), $\{8\}$, $\{3, 3\}$, $\{3, 4\}$. The cube is $\{4, 3\}$ because its faces are squares $\{4\}$ and there are three of them at each vertex. The five platonic solids $\{p, q\}$, are determined by the inequality below. The numbers of vertices, edges,

$$(p-2)(q-2) < 4$$

faces (V, E, F) can be deduced from the obvious relations $pF = 2E = qV$ with the help of Euler's formula $V - E + F = 2$.

The general polytope (sometimes loosely called a "polyhedron" [see illustration] regardless of the number of dimensions)



Two regular polyhedrons. (*a*) Dodecahedron $\{5, 3\}$. (*b*) Icosahedron $\{3, 5\}$.

is a finite region of *n*-dimensional space enclosed by a finite number of hyperplanes. When any redundant hyperplanes have been discarded, those that remain contain $(n-1)$-dimensional polytopes called cells or "facets." For instance, the cells of a polygon are its sides, those of a polyhedron are its faces, and those of a four-dimensional polytope are solids. *See* Analytic geometry; Euclidean geometry. [H.S.M.C.]

Regularia The name given by G. Cuvier in 1817 to an assemblage of echinoids in which the anus and periproct lie within the apical system. The test is globular and preponderantly radially symmetrical, and the ambulacral plates are commonly compound. The group included, in effect, all those echinoids which did not fall in the Irregularia. *See* Echinoidea; Irregularia. [H.B.F.]

Regulator A control device designed to maintain the value of some quantity substantially constant. The value to be maintained can usually be established at any value within the range of the regulator by making an appropriate setting. A regulated system is a feedback control system employing a regulator to maintain some quantity of the system at a constant value. *See* Control systems. [J.A.Hr.]

Reheating The addition of heat to steam of reduced pressure after the steam has given up some of its energy by expansion through the high-pressure stages of a turbine. The reheater tube banks are arranged within the setting of the steam-generating unit in such relation to the gas flow that the steam is restored to a high temperature. Under suitable conditions of initially high steam pressure and superheat, one or two stages of reheat can be advantageously employed to improve thermodynamic efficiency of the cycle. *See* Steam-generating unit; Steam turbine; Superheater; Vapor cycle. [R.A.M.]

Reindeer A ruminant, *Rangifer tarandus*, of the deer family, Cervidae. Reindeer inhabit the Arctic region and have a circumpolar distribution. They have been domesticated for centuries and are economically important to the Laplanders, who use them as draft animals as well as for their skins, flesh, and milk.

Both sexes have antlers, a characteristic peculiar to this deer species. Although their senses of sight and hearing are not sharp, their sense of smell is quite keen. The hooves are round and broad, giving the animal stable footing in snow and on ice. In the wild, they are the most migratory of all deer, traveling in large herds in search of food during the winter months. The rutting season begins during the autumn migrations; fawns are born during the spring. *See* Artiodactyla; Deer. [C.B.C.]

Reinforced concrete Portland cement concrete containing higher-strength, solid materials to improve its structural properties. Generally, steel wires or bars are used for such reinforcement, but for some purposes glass fibers or chopped wires have provided desired results.

Unreinforced concrete cracks under relatively small loads or temperature changes because of low tensile strength. The cracks are unsightly and can cause structural failures. To prevent cracking or to control the size of crack openings, reinforcement is incorporated in the concrete. Reinforcement may also be used to help resist compressive forces or to improve dynamic properties.

Steel usually is used in concrete. It is elastic, yet has considerable reserve strength beyond its elastic limit. Under a specific axial load, it changes in length only about one-tenth as much as concrete. In compression, steel is more than 10 times stronger than concrete, and in tension, more than 100 times stronger. *See* Steel.

During construction, the bars are placed in a form and then concrete from a mixer is cast to embed them. After the concrete has hardened, deformation is resisted and stresses are transferred from concrete to reinforcement by friction and adhesion along the surface of the reinforcement. Individual wires or bars resist stretching and tensile stress in the concrete only in the direction in which such reinforcement extends. Tensile stresses and deformations, however, may occur simultaneously in other directions. Therefore reinforcement must usually be placed in more than one direction. For this purpose, reinforcement sometimes is assembled as a rectangular grid. Bars, grids, and fabric have the disadvantage that the principal effect of reinforcement occurs primarily in the plane of the layer in which they are placed. Consequently, the reinforcement often must be set in several layers or formed into cages. Under some conditions, fiber-reinforced concrete is an alternative to such arrangements. *See* Composite beam; Concrete; Concrete beam; Concrete column; Concrete slab; Prestressed concrete. [F.S.M.]

Relapsing fever An acute infectious disease characterized by recurring fever. It is caused by spirochetes of the genus *Borrelia* and transmitted by the body louse (*Pediculus humanus humanus*) and by ticks of the genus *Ornithodoros*.

Louse-borne relapsing fever, caused by *Borrelia recurrentis*, is typically epidemic. Epidemics, once widespread on all continents, are rare but still occur in certain parts of South America, Africa, and Asia. Tick-borne relapsing fevers are endemic. They are more widely distributed throughout the Eastern and Western hemispheres. At least 15 species of *Borrelia* have been recognized as causative agents.

After incubation of 2–10 days, the initial attack begins abruptly with chills, high fever, headache, and pains in muscles and joints, and lasts 2–8 days, ending by crisis. A remission period of 3–10 days is followed by a relapse similar to the initial attack but milder. There may be 4–5 relapses, although occasionally 10 or more have been recorded. Mortality varies from 2 to 5% but may be considerably higher during epidemics.

Chlortetracycline is the most effective antibiotic drug, but penicillin, oxytetracycline, and streptomycin also have therapeutic value. *See* Antibiotic.

The best way to prevent relapsing fever is to control louse and tick populations with effective insecticides and acaricides. *See* MEDICAL BACTERIOLOGY; PEDICULOSIS. [W.Bu.]

Relative atomic mass The ratio of the average mass per atom of the natural nuclidic composition of an element to $^1/_{12}$ of the mass of an atom of nuclide ^{12}C. For example, $\mu(\mathrm{Cl}) = 35.453$. Relative atomic mass replaces the concept of atomic weight. It is also known as relative nuclidic mass. *See* NUCLIDE. [T.C.W.]

Relative molecular mass The ratio of the average mass per formula unit of the natural nuclidic composition of a substance to $^1/_{12}$ of the mass of an atom of nuclide ^{12}C. For example, $\mu(\mathrm{KCl}) = 74.555$. Relative molecular mass replaces the concept of molecular weight. *See* NUCLIDE. [T.C.W.]

Relative motion All motion is relative to some frame of reference. The simplest laboratory frame of reference is three mutually perpendicular axes at rest with respect to an observer. In terms of the frame of reference of an observer some distance from Earth, the laboratory frame of reference would be moving with Earth as it rotates on its axis and as it revolves about the Sun. What would be a simple form of motion in the laboratory frame of reference would appear to be a much more complicated motion in the frame of reference of the distant observer. *See* FRAME OF REFERENCE.

Motion means continuous change of position of an object with respect to an observer. To another observer in a different frame of reference the object may not be moving at all, or it may be moving in an entirely different manner. The motions of the planets were found in ancient times to appear quite complicated in the laboratory frame of reference of an observer on Earth. By transferring to the frame of reference of an imaginary observer on the Sun, Johannes Kepler showed that the relative motion of the planets could be simply described in terms of elliptical orbits. The validity of one description is no greater than the other, but the latter description is far more convenient. [R.D.Ru.]

Relativistic electrodynamics The study of the interaction between electrically charged particles and electromagnetic fields when the velocities involved are comparable to that of light.

A group of charged particles in motion can be represented by a distribution in charge and distribution in current. During the latter part of the eighteenth century and the early part of the nineteenth century, experiments by C. A. Coulomb, M. Faraday, A. M. Ampère, and others showed that electric and magnetic fields are produced by charge and current distributions. These fields, in turn, act on other charges and currents. The interaction between charges and currents on the one hand and electric and magnetic fields on the other is the topic of study of electrodynamics. This field of study was established as a quantitative and self-contained subject in 1864 when J. C. Maxwell formulated his equations for the electromagnetic field. Maxwell conjectured that a time-varying electric field is equivalent to an electric current in its effect of producing a magnetic field, and named it the displacement current. The inclusion of this displacement current enabled Maxwell to combine all the previously established laws of electromagnetism into a coherent whole in his equations. *See* CLASSICAL FIELD THEORY; DISPLACEMENT CURRENT; MAXWELL'S EQUATIONS.

With the inclusion of the displacement current, the Maxwell equations are relativistically covariant, meaning that they are valid for all velocities, even those approaching the velocity of light. However, the implications of the covariance of the equations were not fully appreciated until A. Einstein formulated the special theory of relativity in 1905. Relativistic electrodynamics was then rapidly developed into a powerful and precise field of physics. It describes and predicts all macroscopic electrodynamic phenomena to the minutest detail and with perfect accuracy, and now forms the foundation on which the entire electrical industry is based. However, its limitations soon became evident when attempts were made to apply it to atomic phenomena: Straightforwardly applied, relativistic electrodynamics failed to explain many of these phenomena, and its predictions frequently disagreed with experimental observations. For these microscopic phenomena, quantum electrodynamics (QED) was developed in the 1930s to replace classical relativistic electrodynamics. In 1967 quantum electrodynamics was further unified by S. Weinberg and A. Salam with the theory of weak interactions to form the electroweak theory. *See* QUANTUM ELECTRODYNAMICS; RELATIVISTIC MECHANICS; RELATIVITY; WEAK NUCLEAR INTERACTIONS.

Electrodynamic problems generally fall into one of two categories:

1. Finding the electromagnetic field produced by prescribed charge and current distributions. For example, one may want to determine the electromagnetic field produced or radiated by a given oscillatory electric current in a transmitting antenna, or the field radiated by an accelerating electron.
2. Finding the effect of a predetermined electromagnetic field on the motion of charges and currents. This is the inverse problem corresponding to that of the receiving antenna or of the motion of charged particles in an accelerator.

All other electrodynamic problems are combinations or iterations of these two basic types. For instance, the scattering of light (electromagnetic radiation) by a charged particle is composed of, first, the incident light shaking the charge and, second, the subsequent emission of the scattered light by the shaken charge. *See* SCATTERING OF ELECTROMAGNETIC RADIATION. [L.C.T.]

Relativistic heavy-ion collisions Collisions between heavy atomic nuclei at relative velocities close to the speed of light. These high-energy nuclear collisions are usually divided into two different domains, relativistic and ultrarelativistic collisions, depending on whether the kinetic energy per nucleon (the generic name for protons and neutrons) is either close to the rest mass of the nucleon (relativistic collisions) or much larger than the nucleon rest mass (ultrarelativistic collisions).

By utilizing high-energy nuclear collisions, it is possible to study nuclear matter under conditions of very high temperatures and densities. The most common form of nuclear matter, at least under terrestrial conditions, is found in the atomic nucleus, which consists of protons and neutrons bound together by the strong nuclear force. If nuclear matter is heated up to temperatures comparable to the rest mass of the pion, it becomes a mixture of nucleons, pions, and various other particles, collectively denoted hadrons. Under these circumstances, nuclear matter is referred to as hadronic matter. *See* HADRON; NEUTRON; NEUTRON STAR; NUCLEAR STRUCTURE; PROTON.

According to the quantum chromodynamics (QCD) theory, all hadrons are bound states of a set of more fundamental entities called quarks. The quarks are confined within the hadrons by the exchange of gluons. Quantum chromodynamics calculations using the most powerful computers available show that if hadronic matter is further heated or compressed to very high densities it will undergo a phase transition into a new phase of matter, called the quark-gluon plasma. In this phase the hadrons will lose their identity, and the quarks and gluons will be deconfined within volumes much larger than the typical hadron volume of 0.1–0.5 cubic femtometer. Quantum chromodynamics calculations indicate that the phase transition will occur at a critical density around 5–10 times the normal nuclear matter density of approximately 0.2 nucleon/fm^3, or at a critical temperature around 150 MeV. *See* GLUONS; QUANTUM CHROMODYNAMICS; QUARK-GLUON PLASMA; QUARKS.

When two nuclei collide at high energies, some of the nucleons in each nucleus, called spectators, will continue their motion unaffected, while other nucleons, called participants, will strike one or several nucleons in the other nucleus. In the overlap volume a hot and dense fireball will develop. If the temperature or density of the fireball becomes larger than the critical values, a quark-gluon plasma will be created with an estimated lifetime of 1–5 × 10^{-23} s. The fireball will start to expand and cool, and the quarks in the plasma will eventually be reconfined into a large number of hadrons (hadronization). After further expansion the hadrons will cease interacting with each other (freeze out) and leave the collision zone without further mutual interactions.

In the search for the quark-gluon plasma, a fundamental problem is that even if the plasma is created in the early phases of the collisions, the subsequent hadronization and scattering of the hadrons before freeze-out might mask any traces of the plasma. In order to circumvent this problem, many plasma signatures have been proposed. [S.P.S.]

Relativistic quantum theory The quantum theory of particles which is consistent with the special theory of relativity, and thus can describe particles moving arbitrarily close to the speed of light. It is now realized that the only satisfactory rela-tivistic quantum theory is quantum field theory; the attempt to relativize the Schrödinger equation for the wave function of a single particle fails [Eq. (1)]. However, with a change of interpretation, relativistic wave equations do correctly describe some aspects of the motions of particles in an electromagnetic field. *See* QUANTUM FIELD THEORY; QUANTUM MECHANICS; RELATIVITY.

The Schrödinger equation for the wave function $\psi(\mathbf{r},t)$ of a particle is Eq. (1), where E is the energy operator $i\hbar(\partial/\partial t)$, $\mathbf{p}$ is the

$$E\psi = H(\mathbf{p},\mathbf{r})\psi \tag{1}$$

momentum operator $-i\hbar\Delta$, $H(\mathbf{p},\mathbf{r})$ is the classical hamiltonian, and $\hbar$ is Planck's constant divided by 2π. For a nonrelativistic free particle, $H = \mathbf{p}^2/2m$. The naive way to relativize Eq. (1) would be to use the relativistic hamiltonian, Eq. (2). However, this equation is not relativistically invariant.

$$H = \sqrt{(mc^2)^2 + \mathbf{p}^2c^2} \tag{2}$$

The so-called Klein-Gordon equation, Eq. (3), is relativistically

$$E^2\varphi = [(mc^2)^2 + \mathbf{p}^2c^2]\varphi \tag{3}$$

invariant. However, the only possible density of a conserved quantity formed from [φ is of the form shown in (4). But this

$$\rho \propto \varphi^* E\varphi - \varphi E\varphi^* \tag{4}$$

cannot be a probability density, because it is not positive definite (it changes sign when φ is replaced by φ^*).

But ρ, in relation (4), can be interpreted as a charge density (when multiplied by a unit charge e); φ is then to be interpreted as a matrix element of a field operator Φ of a quantized field whose quanta are particles with mass m and charge e or $-e$ and zero spin.

P. A. M. Dirac found a relativized form of Eq. (1), Eq. (5), which is both linear in E and has a positive definite density form ρ, where β and α are constants which obey Eqs. (6). Obviously

$$E\psi = [\beta mc^2 + \alpha \cdot pc]\psi(\rho \propto \psi^*\psi) \tag{5}$$

$$\begin{gathered} \alpha_i\alpha_j + \alpha_j\alpha_i = 0, \quad i \neq j \\ \alpha\beta + \beta\alpha = 0 \quad \alpha_i^2 = 1 \quad \beta^2 = 1 \quad i, j = 1, 2, 3 \end{gathered} \tag{6}$$

the four constants β and α_i cannot be numbers; however, they can be 4 × 4 matrices, and Ψ is then a four-component object called a Dirac spinor.

If plane wave solutions of Dirac's equation (5) are considered, then $\mathbf{P}$ is now a number. Taking Eq. (5) as an eigenequation for E, four eigenstates are found (because H is a 4 × 4 matrix), two with

$$E = +\sqrt{(mc^2)^2 + p^2c^2}$$

and two with

$$E = -\sqrt{(mc^2)^2 + p^2c^2}$$

The interpretation of the two positive energy states is that they are the two spin states of a particle with spin $^1\!/_2[\hbar]$. But the two negative energy states are an embarrassment; even a particle that was initially in a positive energy state would quickly make radiative transitions down through the negative energy states. Dirac's solution was to observe that if the particle described by ψ obeyed the Pauli principle, then one can suppose that all the negative energy states are already filled with particles, thus excluding any more. There are still four single-particle states for a given momentum $\mathbf{p}$: the two spin states of a particle with positive energy, and the two states obtained by removing a negative energy particle (of momentum $-\mathbf{p}$). These last states ("hole states") have positive energy and a charge opposite the charge of the particle. The hole is in fact the antiparticle; if the particle is an electron, the hole is a positron. *See* ANTIMATTER; POSITRON.

With the filling up of the negative energy states, one no longer has a single-particle system, and ψ, just as in the Klein-Gordon case, no longer can be interpreted as a wave function but must be interpreted as a matrix element of a field operator Ψ. [C.J.G.]

Relativity A general theory of physics, primarily conceived by Albert Einstein, which involves a profound analysis of time and space, leading to a generalization of physical laws, with far-reaching implications in important branches of physics and in cosmology. Historically, the theory developed in two stages. Einstein's initial formulation in 1905 (now known as the special, or restricted, theory of relativity) does not treat gravitation; and one of the two principles on which it is based, the principle of relativity (the other being the principle of the constancy of the speed of light), stipulates the form invariance of physical laws only for inertial reference systems. Both restrictions were removed by Einstein in his general theory of relativity developed in 1915, which exploits a deep-seated equivalence between inertial and gravitational effects, and leads to a successful "relativistic" generalization of Isaac Newton's theory of gravitation.

Special theory. The key feature of the theory of special relativity is the elimination of an absolute notion of simultaneity in favor of the notion that all observers always measure light to have the same velocity, in vacuum, c, independently of their own motion. The impetus for the development of the theory arose from the theory of electricity and magnetism developed by J. C. Maxwell. This theory accounted for all observed phenomena involving electric and magnetic fields and also predicted that disturbances in these fields would propagate as waves with a definite speed, c, in vacuum. These electromagnetic waves predicted in Maxwell's theory successfully accounted for the existence of light and other forms of electromagnetic radiation. However, the presence of a definite speed, c, posed a difficulty, since if one inertial observer measures light to have velocity c, it would be expected that another inertial observer, moving toward the light ray with velocity v with respect to the first, would measure the light to have velocity $c + v$. Hence, it initially was taken for granted that there must be a preferred rest frame (often referred to as the ether) in which Maxwell's equations would be valid, and only in that frame would light be seen to travel with velocity c. However, this viewpoint was greatly shaken by the 1887 experiment of A. A. Michelson and E. W. Morley, which failed to detect any motion of the Earth through the ether. By radically altering some previously held beliefs concerning the structure of space and time, the theory of special relativity allows Maxwell's equations to hold, and light to propagate with velocity c, in all frames of reference, thereby making Maxwell's theory consistent with the null result of Michelson and Morley. *See* ELECTROMAGNETIC RADIATION; LIGHT; MAXWELL'S EQUATIONS.

Simultaneity in prerelativity physics. The most dramatic aspect of the theory of special relativity is its overthrowing of the notion that there is a well-defined, observer-independent meaning to the notion of simultaneity. The following terminology will be introduced: An event is a point of space at an instant of time. Since it takes four numbers to specify an event—one for the time at which the event occurred and three for its spatial

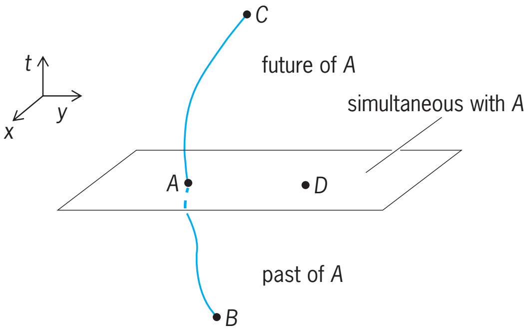


Fig. 1. Space-time diagram illustrating the causal relationships with respect to an event, *A*, in prerelativity physics. Event *B* lies to the past of *A*, event *C* lies to the future of *A*, and event *D* is simultaneous with *A*.

position—it follows that the set of all events constitutes a four-dimensional continuum, which is referred to as space-time.

A space-time diagram (Fig. 1) is a plot of events in space-time, with time, t, represented by the vertical axis and two spatial directions (x, y) represented by the horizontal axes. (The z direction is not shown.) For any event A shown in the diagram, there are many other events in this diagram—say, an event B—having the property that an observer or material body starting at event B can, in principle, be present at event A. The collection of all such events constitutes the past of event A. Similarly, there are many events—say, an event C—having the property that an observer or material body starting at event A can, in principle, be present at event C. These events constitute the future of A. Finally, there remain some events in space-time which lie neither to past nor future of A. In prerelativity physics, these events are assumed to make a three-dimensional set, and they are referred to as the events which are simultaneous with event A.

In both prerelativity physics and special relativity, an inertial observer is one who is not acted upon by any external forces. In both theories it is assumed that any inertial observer, $\mathcal{O}$ can build a rigid cartesian grid of meter sticks, all of which intersect each other at right angles. Observer $\mathcal{O}$ may then label the points on this cartesian grid by the coordinates (x, y, z) representing the distance of the point from $\mathcal{O}$ along the three orthogonal directions of the grid. A clock may then be placed at each grid point. In prerelativity physics, these clocks may be synchronized by requiring that they start simultaneously with each other. Any event in space-time may then be labeled by the four numbers t, x, y, z, where t is the time of the event as determined by the synchronized clock situated at that grid point. *See* FRAME OF REFERENCE.

It is of interest to compare the coordinate labelings given to events in space-time by two inertial observers, $\mathcal{O}$ and $\mathcal{O}'$, who are in relative motion. The relationship occurring in prerelativity physics is called a galilean transformation. In the simple case where $\mathcal{O}'$ moves with velocity v in the x direction with respect to $\mathcal{O}$, and these observers meet at the event A labeled by $(t, x, y, z) = (t', x', y', z') = (0, 0, 0, 0)$, with the axes of the grid of meter sticks carried by $\mathcal{O}'$ aligned (that is, not rotated) with respect to those of $\mathcal{O}$, the transformation is given by Eqs. (1). The galilean

$$t' = t \tag{1a}$$

$$x' = x - vt \tag{1b}$$

$$y' = y \tag{1c}$$

$$z' = z \tag{1d}$$

transformation displays in an explicit manner that the two inertial observers, $\mathcal{O}$ and $\mathcal{O}'$, agree upon the time labeling of events and, in particular, agree upon which events are simultaneous with a given event.

Causal structure in special relativity. In special relativity there is a different causal relationship between an arbitrary event A and other events in space-time (Fig. 2). As in prerelativity physics, there are many events, B, which lie to the past of A. There also are many events which lie to the future of A. However, there is now a much larger class of events which lie neither to the past nor to the future of A. These events are referred to as being spacelike-related to A.

The most striking feature of this causal structure (Fig. 2) is the absence of any three-dimensional surface of simultaneity. Indeed, the closest analog to the surface of simultaneity in prerelativity physics is the double-cone-shaped surface that marks the boundaries of the past and future of event A. This surface comprises the paths in space-time of all light rays which pass through event A, and for this reason it is referred to as the light cone of A. Thus, the statement that the events lying to the future of A are contained within the light cone of A is equivalent to the statement that a material body present at event A can never overtake a light ray emitted at event A. In special relativity, the light cone of an event A replaces the surface of simultaneity with event A as the absolute, observer-independent structure of space-time related to causality.

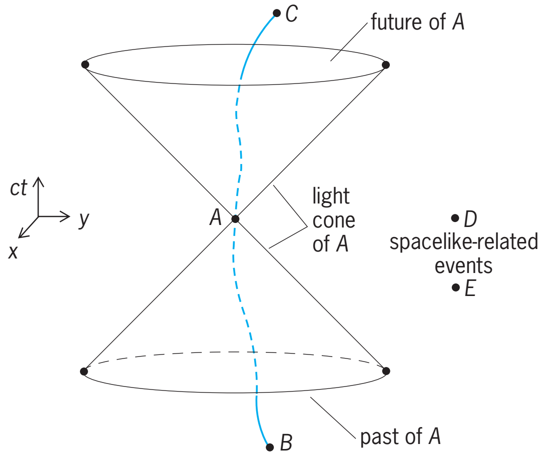

Fig. 2. Space-time diagram illustrating the causal relationships with respect to an event, *A*, in special relativity. Event *B* lies to the past of *A*, event *C* lies to the future of *A*, and events *D* and *E* are spacelike-related to *A*.

As in prerelativity physics, it is assumed in special relativity that an inertial observer, $\mathcal{O}$, can build a rigid grid of meter sticks, place clocks at the grid points, and label events in space-time by global inertial coordinates (t, x, y, z). The only difference from the procedure used for the construction of the similar coordinates in prerelativity physics is that the synchronization of clocks is now nontrivial, since the causal structure of space-time no longer defines an absolute notion of simultaneity. Nevertheless, any pair of clocks in $\mathcal{O}$'s system can be synchronized—and thereby all of $\mathcal{O}$'s clocks can be synchronized—by having an assistant stationed half-way between the clocks send a signal to the two clocks in a symmetrical manner. This synchronization of clocks allows $\mathcal{O}$ to define a notion of simultaneity; that is, $\mathcal{O}$ may declare events A_1 and A_2 to be simultaneous if time readings, t_1 and t_2, of the synchronized clocks at events A_1 and A_2 satisfy $t_1 = t_2$. However, events judged by $\mathcal{O}$ to be simultaneous will, in general, be judged by $\mathcal{O}'$ to be nonsimultaneous. *See* LORENTZ TRANSFORMATIONS.

The key assumptions of special relativity are encapsulated by the following two postulates.

Postulate 1: The laws of physics do not distinguish between inertial observers; in particular, no inertial observer can be said to be at rest in an absolute sense. Thus, if observer $\mathcal{O}$ writes down equations describing laws of physics obeyed by physically measurable quantities in her global inertial coordinate system

(t, x, y, z), then the form of these equations must be identical when written down by observer $\mathcal{O}'$ in his global inertial coordinates (t', x', y', z').

Postulate 2: All inertial observers (independent of their relative motion) must always obtain the same value, c, when they measure the velocity of light in vacuum. In particular, the path of a light ray in space-time must be independent of the motion of the emitter of the light ray. Furthermore, no material body can have a velocity greater than c.

The precise relationship between the labeling of events in space-time by the coordinate systems of two inertial observers, $\mathcal{O}$ and $\mathcal{O}'$, in special relativity is given by the Lorentz transformation formulas. In the simple case where $\mathcal{O}'$ moves with velocity v in the x direction with respect to $\mathcal{O}$ and crosses $\mathcal{O}$'s world line at the event labeled by $(t, x, y, z) = (t', x', y', z') = (0, 0, 0, 0)$ with spatial axes aligned, the Lorentz transformation is given by Eqs. (2*a*)–(2*d*). Equation (2*a*) shows explicitly that $\mathcal{O}$ and $\mathcal{O}'$ disagree over simultaneity.

$$t' = \frac{t - \dfrac{xv}{c^2}}{\sqrt{1 - \dfrac{v^2}{c^2}}} \qquad (2a)$$

$$x' = \frac{x - vt}{\sqrt{1 - \dfrac{v^2}{c^2}}} \qquad (2b)$$

$$y' = y \qquad (2c)$$

$$z' = z \qquad (2d)$$

Space-time geometry. A key question both in prerelativity physics and in special relativity is what quantities, describing the space-time relationships between events, are observer independent. Such quantities having observer-independent status may be viewed as describing the fundamental, intrinsic structure of space-time.

It has already been seen that in special relativity the time interval, Δt, between two events is no longer observer independent. Furthermore, since different inertial observers disagree over simultaneity, the spatial interval between two simultaneous events is not even a well-defined concept, and cannot be observer independent. Remarkably, however, in special relativity, all inertial observers agree upon the value of the space-time interval, I, between any two events, where I is defined by Eq. (3). What is most

$$I = (\Delta x)^2 + (\Delta y)^2 + (\Delta z)^2 - c^2(\Delta t)^2 \qquad (3)$$

remarkable about this formula for I is that it is very closely analogous to the formula for squared distance in euclidean geometry. The minus sign occurring in the last term in Eq. (3) is of considerable importance, since it distinguishes between the notions of time and space in special relativity. Nevertheless, this minus sign turns out not to be a serious obstacle to the mathematical development of the theory of lorentzian geometry based upon the space-time interval, I, in a manner which parallels closely the development of euclidean geometry. In particular, notions such as geodesics (straightest possible lines) can be introduced in lorentzian geometry in complete analogy with euclidean geometry. The Lorentz transformation between the two inertial observers is seen from this perspective to be the mathematical analog of a rotation between two cartesian frames in euclidean geometry.

The formulation of special relativity as a theory of the lorentzian geometry of space-time is of great importance for the further development of the theory, since it makes possible the generalization which describes gravitation. The lorentzian geometry defined by Eq. (3) is a flat geometry, wherein initially parallel geodesics remain parallel forever. The theory of general relativity accounts for the effects of gravitation by allowing the lorentzian geometry of space-time to be curved. *See* SPACE-TIME.

Consequences. The theory of special relativity makes many important predictions, the most striking of which concern properties of time. One such effect, known as time dilation, is predicted directly by the Lorentz transformation formula (2*a*). If observer $\mathcal{O}$ carries a clock, then the event at which $\mathcal{O}$'s clock reads time τ would be labeled by her as $(\tau, 0, 0, 0)$. According to Eq. (2*a*), the observer $\mathcal{O}'$ would label the event as $(t', x', 0, 0)$ where t' is given by Eq. (4). Thus, $\mathcal{O}'$ could say that a clock carried by $\mathcal{O}$

$$t' = \frac{\tau}{\sqrt{1 - \dfrac{v^2}{c^2}}} > \tau \qquad (4)$$

slows down on account of $\mathcal{O}$'s motion relative to $\mathcal{O}'$. Similarly, $\mathcal{O}$ would find that a clock carried by $\mathcal{O}'$ slows down with respect to hers. This apparent disagreement between $\mathcal{O}$ and $\mathcal{O}'$ as to whose clock runs slower is resolved by noting that $\mathcal{O}$ and $\mathcal{O}'$ use different notions is simultaneity in comparing the readings of their clocks.

The decay of unstable elementary particles provides an important direct application of the time dilation effect. If a particle is observed to have a decay lifetime T when it is at rest, special relativity predicts that its observed lifetime will increase according to Eq. (6) when it is moving. Exactly such an increase is routinely observed in experiments using particle accelerators, where particle velocities can be made to be extremely close to c. *See* PARTICLE ACCELERATOR.

An even more striking prediction of special relativity is the clock paradox: Two identical clocks which start together at an event A, undergo different motions, and then rejoin at event B will, in general, register different total elapsed time in going from A to B. This effect is the lorentzian geometry analog of the mundane fact in euclidean geometry that different paths between two points can have different total lengths. *See* CLOCK PARADOX. [R.H.Wa.]

General theory. One of the basic tenets of special relativity is that no physical effect can propagate with a velocity greater than the speed of light, c, which represents a universal speed limit. On the other hand, classical gravitational theory describes the gravitational field of a body throughout space as a function of its instantaneous position, which is equivalent to the assumption that gravitational effects propagate with an infinite velocity. Thus, special relativity and classical gravitational theory are inconsistent, and a modified theory of gravity is necessary.

Principle of equivalence. It had long been considered a fundamental question why bodies of different mass fall with the same acceleration in a gravitational field. This situation was explained by Newton with the statement that both the gravitational force on a body and its inertial resistance to acceleration are proportional to its mass.

Newton's explanation is more in the nature of an ad hoc description. A deeper and more natural explanation occurred to Einstein. There are numerous forces other than gravity which are mass-proportional. These generally arise due to the use of accelerated coordinate systems to describe the motion, for example, the centrifugal force encountered in a rotating coordinate system. If an observer in the gravitational field of the Earth and another in an accelerating elevator or rocket in free space both drop a test body, they will both observe it to accelerate relative to the floor. According to classical theory, the Earth-based observer would attribute this to a gravitational force and the elevator-based observer would attribute it to the accelerated floor overtaking the uniformly moving body. In both cases the motion is identical, and in particular the acceleration is independent of the mass of the test body. Einstein elevated this fact to a general principle, the principle of equivalence; the principle states that on a local scale all physical effects of a gravitational field are indistinguishable from the physical effects of an accelerated coordinate system. This profound principle is the physical cornerstone of the theory of general relativity. From the point of view of the principle of equivalence, it is obvious why the motion of a test body in a gravitational field is independent of its mass. But the principle applies not only to mechanics but to all physical phenomena and thereby has profound consequences for electromagnetic and other nonmechanical phenomena. *See* CENTRIFUGAL FORCE.

Tensor field equations. The close connection between gravity and accelerating coordinate systems convinced Einstein that gravity is fundamentally a geometric phenomenon. Because of this, it is naturally described by the mathematics of higher-dimensional abstract geometry. This geometry involves systems of equations, called tensor equations, that are manifestly independent of the coordinate system. Tensors are a simple generalization of vectors. *See* TENSOR ANALYSIS.

The space-time of relativity contains one covariant second-rank tensor of particularly great importance, called the metric tensor $g_{\mu\nu}$, which is a generalization of the Lorentz metric of special relativity, introduced in Eq. (3). Nearby points in space-time, called events, which are separated by coordinate distances dx^μ have an invariant physical separation whose square, called the line element, is defined by Eq. (5). This quantityis a generalization of the space-time interval, I, in special relativity.

$$ds^2 = g_{\mu\nu} dx^\mu dx^\nu \qquad (5)$$

Tensor equations are equations in which one tensor of a given type is set equal to another of the same type. The field equations of general relativity are tensor equations for the metric tensor, which completely describes the geometry of the space. The Riemann tensor (or curvature tensor), $R^\alpha_{\mu\beta\nu}$, plays a central role in the geometric structure of a space; if it is zero, the space is termed flat and has no gravitational field; if nonzero, the space is termed curved, and a gravitational field is present. In terms of the contracted Riemann tensor, that is, a Riemann tensor summed over $\alpha = \beta$, the Einstein field equations for empty space are given by Eq. (6).

$$\sum_\alpha R^\alpha_{\mu\alpha\nu} \equiv R_{\mu\nu} = 0 \qquad \text{(empty space)} \qquad (6)$$

The field equations are a set of 10 second-order partial differential equations since the four-by-four symmetric tensor $R^{\mu\nu}$ has 10 independent components; they are to be solved for the metric tensor. A solution in a given coordinate system defines an Einstein space-time. The curvature of this space corresponds to the intrinsic presence of a gravitational field. Thus the concept of a field of mechanical force in classical gravitational theory is replaced by the geometric concept of curved space in relativity theory. *See* DIFFERENTIAL EQUATION.

In a nonempty region of space the field equations (6) must be modified to include a tensor representing the matter or energy content of space, the energy-momentum tensor $T_{\mu\nu}$. The modified equations are Eq. (7), where G is the gravitational constant, equal to $6.67 \times 10^{-11}\ \mathrm{N \cdot m^2 \cdot kg^{-2}}$. On the left is the tensor $G_{\mu\nu}$ representing the geometry of space, and on the right is the tensor $T_{\mu\nu}$ representing the mass or energy content of space. The tensor $G_{\mu\nu}$ defined in Eq. (7) is called the Einstein tensor. These equations automatically imply the conservation of energy and momentum, which is an extremely important result. Moreover, in the limiting case when the mass densities of all the gravitating bodies are small and their velocities are small compared to c, the equations reduce to the classical newtonian equations of gravity.

$$\begin{aligned} G_{\mu\nu} &\equiv R_{\mu\nu} - {}^1\!/_2 g_{\mu\nu} \sum_\alpha R^\alpha_\alpha \\ &= -\frac{8\pi G}{c^4} T_{\mu\nu} \qquad \text{(nonempty space)} \qquad (7) \end{aligned}$$

Cosmological term. The field equations were given in the form of Eq. (7) by Einstein in 1916. However, they can be consistently generalized by the addition of another term on the left side, which he called the cosmological term, $\Lambda g_{\mu\nu}$. The more general equations are (8). The constant Λ is called the cosmological constant.

$$G_{\mu\nu} + \Lambda g_{\mu\nu} = -\frac{8\pi G}{c^4} T_{\mu\nu} \qquad (8)$$

Einstein introduced the cosmological term in 1917 in order to obtain mathematical models of the universe that were independent of time, since it was then believed that the universe was static. When it was discovered in 1929 that the universe is expanding, as evidenced by the Doppler shifts of distant galaxies, Einstein abandoned the cosmological term. However, interest in the cosmological constant has revived in connection with a serious inconsistency between relativity and quantum theory involving the quantum energy of the vacuum, and with observations since 1998 of type Ia supernovae which suggest that the expansion of the universe is accelerating.

Motion of test bodies. The path of a test body is a generalization of a straight line in euclidean space; it is the shortest "distance" (in terms of intervals ds) between points in space-time, known as a geodesic. General relativity theory possesses an extraordinary property: because the field equations are nonlinear, unlike those of newtonian theory, the motion of a test body in a gravitational field is not arbitrary since the body itself has mass and contributes to the field. Indeed, the field equations are so restrictive that the geodesic equation of motion is a necessary consequence and need not be treated as a separate postulate.

Schwarzschild solution. A very important solution of the field equations was obtained by K. Schwarzschild in 1916, surprisingly soon after the inception of general relativity. This solution represents the field in free space around a spherically symmetric body such as the Sun. It is the basis for a relativistic description of the solar system and most of the experimental tests of general relativity which have been carried out.

Gravitational redshift. Electromagnetic radiation of a given frequency emitted in a gravitational field will appear to an outside observer to have a lower frequency; that is, it will be redshifted. The redshift can be derived from the principle of equivalence. The most accurate test of the redshift to date was performed using a hydrogen maser on a rocket. Comparison of the maser frequency with Earth-based masers gave a measured redshift in agreement with theory to about 1 part in 10^4. *See* REDSHIFT.

Perihelion shift. The equations of motion can be solved for a planet considered as a test body in the Schwarzschild field of the Sun. As should be expected, the orbits obtained are very similar to the ellipses of classical theory. However, the ellipse rotates very slowly in the plane of the orbit so that the perihelion, the point of closest approach of the planet to the Sun, is at a slightly different angular position for each orbit. This shift is extremely small. It is greatest in the case of the planet Mercury, whose perihelion advance is predicted to be 43 seconds of arc in a century. This agrees with the discrepancy between classical theory and observation, which was well known for many years before the discovery of general relativity. *See* CELESTIAL MECHANICS.

Deflection of light. The principle of equivalence suggests an extraordinary phenomenon of gravity. Light or other electromagnetic radiation crossing the Einstein elevator horizontally will appear to be deflected downward in a parabolic arc because of the upward acceleration of the elevator. The same phenomenon must occur for light in the gravitational field of the Sun; it must be deflected toward the Sun. A calculation of this deflection gives 1.75 seconds for the net deflection of starlight grazing the edge of the Sun. Modern measurements, made by tracking quasars as they pass near or behind the Sun, find the deflection to be within 1% of the value predicted by general relativity.

In 1936 Einstein observed that if two stars were exactly lined up with the Earth, the more distant star would appear as a ring of light, distorted from its point appearance by the lens effect of the gravitational field of the nearer star. It was soon pointed out that a very similar phenomenon was much more likely to occur for entire galaxies instead of individual stars. Many candidates for such gravitational lens systems have been found. *See* GRAVITATIONAL LENS.

Radio time delay. In the curved space around the Sun the distance between points in space, for example between two planets, is not the same as it would be in flat space. In particular, the round-trip travel time of a radar signal sent between the Earth and the planet will be measurably increased by the curvature effect when the Earth, the Sun, and the planet are approximately lined up. Using a transponder on the Viking spacecraft, the time delay was found to agree with the predictions of general relativity to an accuracy of about one-half of 1%.

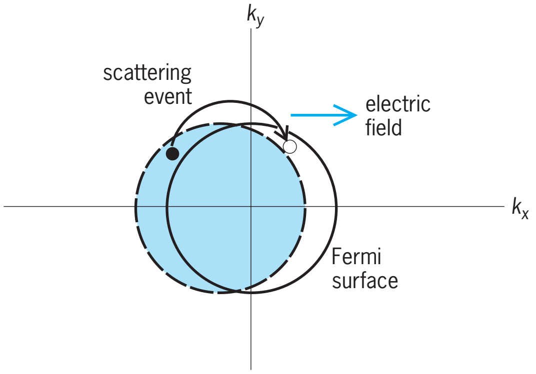
For applications of general relativity certain studies *see* BLACK HOLE; COSMOLOGY; GRAVITATIONAL RADIATION; PULSAR. [R.J.A.]

Relaxation time of electrons

The characteristic time for a distribution of electrons in a solid to approach or "relax" to equilibrium after a disturbance is removed. A familiar example is the property of electrical conductivity, in which an applied electric field generates an electron current which relaxes to an equilibrium zero current after the field is turned off. The conductivity of a material is directly proportional to this relaxation time; highly conductive materials have relatively long relaxation times. The closely related concept of a lifetime is the mean time that an electron will reside in a given quantum state before changing state as a result of collision with another particle or intrinsic excitation. This lifetime is related to equilibrium properties of the material, whereas the relaxation time relates to the thermal and electrical transport properties. The average distance that an electron travels before a collision is called the mean free path. Although typical collision times in metals are quite short (on the order of 10^{-14} s at room temperature), mean free paths range from about 100 atomic distances at room temperature to 10^6 atomic distances in pure metals near absolute zero temperature. Considering the very dense packing of atoms in a solid, these surprisingly long electron path lengths are analogous to the unlikely event that a rifle bullet might travel for miles through a dense forest without hitting a tree. The detailed explanation of the electron mean free path in metals is a major success of the modern theory of solids.

A relaxation time appears in the simplest expression for the transport property of electrical conductivity, which states that the electrical conductivity equals the product of the relaxation time, the density of conduction electrons, and the square of the electron charge, divided by the electron effective mass in the solid. *See* BAND THEORY OF SOLIDS; ELECTRICAL CONDUCTIVITY OF METALS.

The conduction process is a steady-state balance between the accelerating force of an electric field and the decelerating friction of electron collisions which occur on the time scale of the relaxation time. This process may be described in terms of the probability distribution function for the electrons, which depends on the electron momentum (proportional to the wave vector, **k**, which labels the quantum state of the electrons), the position, and the time. Viewed in **k**-space, the entire distribution will shift from an equilibrium state under the influence of a perturbation such as an electric field (see illustration). For example, in the ground state, the collection of occupied electron states in **k**-space is bounded by the Fermi surface centered at the origin, while in an electric field this region is shifted. Because of electron collisions with impurities, lattice imperfections, and vibrations (also called phonons), the displaced surface may be maintained in a steady state in an electric field. These collisions also restore the equilibrium distribution after the field is turned off, and the relaxation time is determined by the rate at which the shifted distribution returns to equilibrium. Specifically, the contribution of collisions to the rate of change of the shifted distribution after the field is turned off equals the difference between the shifted and equilibrium distributions divided by the relaxation time. This statement is referred to as the relaxation-time approximation, and is a simple way of expressing the role of collisions in the maintenance of thermodynamic equilibrium. The details of the various collision mechanisms are lumped into the parameter of the relaxation time. For example, in the case of mixed scattering by impurities and phonons, the inverse of the relaxation time can be determined from the sum of collision rates as the sum of the inverses of the electron-impurity and electron-phonon scattering times. *See* CRYSTAL DEFECTS; FERMI SURFACE; LATTICE VIBRATIONS; PHONON.



Effect of the electric field on electron distribution in a solid, viewed in k-space, where k is the electron wave vector. The shaded area indicates occupied states in distribution which result when the field is applied.

In pure metals at low temperatures, the long mean free path of conduction electrons results from their large velocity (on the order of 10^6 m/s near the Fermi surface) and relatively long relaxation time, on the order of 10^{-9} s. From a practical standpoint, this is what makes metals useful as electrical conductors even at room temperature, where a relaxation time on the order of 10^{-14} s and a mean free path (equal to the product of the velocity and the relaxation time) on the order of 10^{-8} m (or about 100 atomic distances) is typical.

As compared to poorly conducting solids or insulators, an excess of so-called free electrons in a metal contributes to the long mean free paths. From a quantum mechanical standpoint, the free-electron wave function readjusts in a perfectly periodic atomic lattice to avoid the atomic ion cores and spend most of the time in the spaces between. In the analogy of the rifle fired into a forest, the bullet will not travel far, but the sound of the gunshot can, because the sound waves bend around the trees in a constructive manner. In a perfectly periodic lattice, the electron waves scatter constructively from the atomic ion cores, resulting in screening of the cores and coherent transmission of the waves over large distances. Any disturbance to the lattice periodicity tends to destroy this wave phenomenon, resulting in lower transmission or energy loss. At room temperature, the conductivity is usually limited by scattering from lattice vibrations (phonons). At lower temperatures, vibrations are greatly reduced, but the conductivity is still limited by scattering from impurities and imperfections. *See* ELECTRICAL RESISTIVITY; FREE-ELECTRON THEORY OF METALS; QUANTUM MECHANICS.

In the superconductive state, observed in many metals and certain complex compounds at sufficiently low temperatures, impurities, imperfections, and lattice vibrations become completely ineffective in retarding current flow, leading to persistent electric currents even after the driving electric field is removed. This state of resistanceless conduction is described as an ordered quantum state of pairs of electrons resulting from lattice vibrations which deform the ion core potential in such a way as to provide an attractive electron-electron interaction. The relaxation time thus becomes infinite (as nearly as can be measured), a rare macroscopic manifestation of a quantum effect. *See* SUPERCONDUCTIVITY. [G.L.Ee.]

Relay

An electromechanical or solid-state device operated by variations in the input which, in turn, operate or control other devices connected to the output. They are used in a wide variety of applications throughout industry, such as in telephone exchanges, digital computers, motor and sequencing controls, and automation systems. Highly sophisticated relays are utilized to protect electric power systems against trouble and power blackouts as well as to regulate and control the generation and distribution of power. In the home, relays are used in refrigerators, automatic washers and dishwashers, and heat and air-conditioning controls. Although relays are generally associated with electrical circuitry, there are many other types, such as pneumatic and hydraulic. Input may be electrical and output directly mechanical, or vice-versa.

Relays using discrete solid-state components, operational amplifiers, or microprocessors can provide more sophisticated designs. Their use is increasing, particularly in applications where the relay and associated equipment are packaged together. *See* AMPLIFIER; MICROPROCESSOR. [J.L.Bl.]

Reliability, availability, and maintainability

Reliability is the probability that an engineering system will perform its intended function satisfactorily (from the viewpoint of the customer) for its intended life under specified environmental and operating conditions. Maintainability is the probability that maintenance of the system will retain the system in, or restore it to, a specified condition within a given time period. Availability is the probability that the system is operating satisfactorily at any time, and it depends on the reliability and the maintainability. Hence the study of probability theory is essential for understanding the reliability, maintainability, and availability of the system. *See* PROBABILITY.

Reliability is basically a design parameter and must be incorporated into the system at the design stage. It is an inherent characteristic of the system, just as is capacity, power rating, or performance. A great deal of emphasis is placed on quality of products and services, and reliability is a time-oriented quality characteristic. There is a relationship between quality or customer satisfaction and measures of system effectiveness, including reliability and maintainability. Customers are concerned with the performance of the product over time.

To analyze and measure the reliability and maintainability characteristics of a system, there must be a mathematical model of the system that shows the functional relationships among all the components, the subsystems, and the overall system. The reliability of the system is a function of the reliabilities of its components. A system reliability model consists of some combination of a reliability block diagram or a cause-consequence chart, a definition of all equipment failure and repair distributions, and a statement of spare and repair strategies. All reliability analyses and optimizations are made on these conceptual mathematical models of the system.

Maintainability is a measure of the ease and rapidity with which a system or equipment can be restored to operational status following a failure. It is a characteristic of equipment design and installation, personnel availability in the required skill levels, adequacy of maintenance procedures and test equipment, and the physical environment under which maintenance is performed. Maintainability is expressed as the probability that an item will be retained in or restored to a specific condition within a given period of time, when the maintenance is performed in accordance with prescribed procedures and resources. [K.C.K.]

Reluctance

A property of a magnetic circuit analogous to resistance in an electric circuit.

Every line of magnetic flux is a closed path. Whenever the flux is largely confined to a well-defined closed path, there is a magnetic circuit. That part of the flux that departs from the path is called flux leakage.

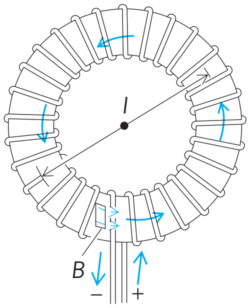
For any closed path of length l in a magnetic field H, the line integral of $H \cos\alpha \, dl$ around the path is the magnetomotive force (mmf) of the path, as in Eq. (1), where α is the angle between H and the path.

$$\text{mmf} = \oint H \cos\alpha \, dl \tag{1}$$

If the path encloses N conductors, each with current I, Eq. (2) holds.

$$\text{mmf} = \oint H \cos\alpha \, dl = NI \tag{2}$$

Consider the closely wound toroid shown in the illustration. For this arrangement of currents, the magnetic field is almost entirely within the toroidal coil, and there the flux density or magnetic induction B is given by Eq. (3), where l is the mean circumference of the toroid and μ is the permeability.



A toroidal coil.

$$B = \mu \frac{NI}{l} \tag{3}$$

The flux Φ within the toroid of cross-sectional area A is given by either form of Eqs. (4), which is similar in form to the equation for the electric circuit, although nothing actually flows in the magnetic circuit.

$$\begin{aligned} \Phi &= BA = \frac{\mu A}{l} NI \\ \Phi &= \frac{NI}{l/\mu A} = \frac{\text{mmf}}{l/\mu A} = \frac{\text{mmf}}{\mathcal{R}} \end{aligned} \tag{4}$$

The factor $l/\mu A$ is called the reluctance $\mathcal{R}$ of the magnetic circuit. The reluctance is not constant because the permeability μ varies with changing flux density. [K.V.M.]

Reluctance motor

An alternating current motor with a stator winding like that of an induction motor, and a rotor that has projecting or salient poles of ferromagnetic material. When connected to an alternating-current source, the stator winding produces a rotating magnetic field, with a speed of $4\pi f/p$ radians per second ($120f/p$ revolutions per minute), where f is the frequency of the source and p the number of magnetic poles produced by the winding. When the rotor is running at the same speed as the stator field, its iron poles tend to align themselves with the poles of that field, producing torque. If a mechanical load is applied to the shaft of the motor, the rotor poles lag farther behind the stator-field poles, and increased torque is developed to match that of the mechanical load. This torque is given by the equation below, where ϕ is the flux per pole, determined largely by the applied voltage.

$$\tau = \frac{p}{2} \phi^2 \frac{dR}{d\delta}$$

The quantity $dR/d\delta$ is the rate of change of magnetic reluctance per pole with respect to δ, the angle of lag in mechanical radians. This quantity typically varies as sin $p\delta$. Here, $p\delta = 2\delta_e$, where δ_e is the lag angle in electrical radians. Therefore, at constant torque load the rotor runs in synchronism with the stator field, with the rotor poles lagging the field poles by a constant angle. *See* ELECTRICAL DEGREE.

This phenomenon develops torque only at synchronous speed, and thus no starting torque is produced. For that reason, induction-motor rotor bars are usually built into the pole faces, and the motor starts as an induction motor. When the rotor speed approaches that of the magnetic field, the pole pieces lock in step with the magnetic poles of the field, and the rotor runs at synchronous speed.

Single-phase reluctance motors may be started by the methods used for single-phase induction motors, such as capacitor, split-phase, or shaded-pole starting. *See* ALTERNATING-CURRENT MOTOR; ELECTRIC ROTATING MACHINERY; INDUCTION MOTOR; MOTOR; SYNCHRONOUS MOTOR. [G.McP.]

Remipedia A unique class of the Crustacea whose members, at first glance, resemble polychaete worms in overall body form. This impression comes from their multiple serial segments and lack of obvious body divisions. The lack of body organization suggests that remipeds are the most primitive crustaceans yet recognized. When compared with the other presumably primitive crustacean class, the Cephalocarida, remipeds are relatively large, with mature individuals ranging from 0.6 to 1.7 in. (15 to 42 mm) in body length. Although the trunk appendages are biramous and paddle-shaped in both classes, endites and epipods that are present in cephalocarids are lacking in remipeds. *See* CEPHALOCARIDA; CRUSTACEA.

As now constituted, the Remipedia comprise two orders, three families, and four genera; however, as more marine caves are explored additional species will be discovered. [P.A.McL.]

Remote-control system A control system in which the issuing of the control command and its execution are separated by a relatively significant distance. The system normally includes a command device where the control command is entered, and an actuator that executes it. These are connected by a transmission medium that transmits the command, usually in a coded format.

The transmission medium may be a mechanical link, where the command is transmitted as force; a pneumatic or hydraulic line, where pressure represents the command; an electrical line with a voltage or current signal; or radio or infrared waves that are modulated according to the command. *See* MODULATION.

The simplest remote-control systems are limited to switching-type functions. These systems operate basically in an open loop, that is, without relying on feedback. Some typical examples are a ceiling lamp turned on and off by a light switch via an electrical wire; the on/off function of a television receiver with an infrared remote controller; and railway switches operated from a remote-control room.

The most characteristic remote-control systems involve feedback that is provided by the human operator. The person issuing the control command senses the result of the control action and guides the system accordingly. This kind of operation can be found, for example, in remote control of toy cars and airplanes by wire or radio, remote operation of large construction cranes, and cockpit control of an airplane's engines and control surfaces. *See* FLIGHT CONTROLS.

Teleoperation represents an important class within remote-control systems with human feedback. Teleoperators (or remote manipulators) act as extensions of the human hand. They are employed in situations where access is difficult or impossible or where the environment is hazardous for humans, such as in underwater and space operations, or in the presence of radiation, chemical, or biological contamination. *See* REMOTE MANIPULATORS.

Many automatic control systems may also be considered as remote controllers. This is the case whenever the sensing of the controlled variable and the automatic formation of the control command are removed from the actuator. A typical example is the heating and air-conditioning system of a building, where room thermostats operate remotely located furnaces, compressors, and fans. *See* CONTROL SYSTEMS. [J.Ger.]

Remote manipulators Mechanical, electromechanical, or hydromechanical devices which enable a person to perform manual operations while separated from the site of the work. Remote manipulators are designed for situations where direct contact would be dangerous to the human (working with radioactive material), where direct human contact is ill-advised or impossible (certain medical procedures), and where human force-producing capabilities are absent (the disabled) or need to be amplified to complete some task (industrial assembly or construction).
